The effects of levamfetamine were attenuated in a hyperactive child by a nasal decongestant containing chlorphenamine and phenylpropanolamine.

Clinical evidence, mechanism, importance and management

The use of **levamfetamine succinate** 42 mg daily was found to be ineffective in a 12-year-old hyperactive boy on two occasions when he took *Contac* cold capsules and *Allerest* tablets for colds. Both of these proprietary nasal decongestants contain **phenylpropanolamine** and **chlorphenamine**.[1] The reason for this interaction is not understood and there is too little information to make any statement about its general importance.

Methylphenidate + Carbamazepine

Carbamazepine may reduce methylphenidate levels.

Clinical evidence, mechanism, importance and management

A 7-year-old boy with attention deficit disorder taking carbamazepine 1 g daily for grand mal epilepsy was referred because of unmanageable behaviour. He failed to respond to methylphenidate in doses of up to 30 mg every 4 hours, and his blood levels of both methylphenidate and its metabolites were undetectable. The authors of the report attributed this to an interaction with the carbamazepine.[1] Similarly, symptoms of attention deficit hyperactivity disorder worsened in a 13-year-old girl taking methylphenidate after she also took carbamazepine. Methylphenidate serum levels decreased markedly and the dose of methylphenidate had to be increased from 20 mg three times daily to 60 mg three times daily to regain a benefit similar to that achieved before the addition of carbamazepine.[2] However, another report describes 4 out of 7 children taking methylphenidate and carbamazepine in whom the combination was successful. Blood levels of methylphenidate were apparently not measured.[3] Despite the scarcity of the information, and the cases of apparently successful use, it would seem wise to consider carbamazepine as a possible cause if patients do not respond adequately to methylphenidate. If this occurs, consider increasing the methylphenidate dose.

Note that the manufacturer says methylphenidate should be used with caution in patients with epilepsy, as clinical experience has shown that it can cause an increase in seizure frequency in a small number of such patients. If seizure frequency increases, methylphenidate should be discontinued.[4]

Methylphenidate + Clonidine

Much publicised fears about the serious consequences of using methylphenidate with clonidine appear to be unfounded. There is some evidence to suggest that concurrent use can be both safe and effective.

Clinical evidence, mechanism, importance and management

There have been fears about serious adverse events when methylphenidate is taken with clonidine,[1] due to reports of 3 deaths in children taking both drugs. One child died from ventricular fibrillation due to cardiac abnormalities, one from cardiac arrest attributed to an overdose of fluoxetine, and the third death was unexplained. Studies of these 3 cases and one other failed to establish any link between the use of methylphenidate with clonidine and these deaths, the final broad conclusion being that the event was largely a media-inspired scare story built on inconclusive evidence.[2,3] However, there are theoretical reasons to be concerned about combining clonidine and methylphenidate (which have opposing adrenergic effects), because missed doses, extra doses, or mistimed doses can lead to significant hypertension and/or tachycardia or hypotension and/or bradycardia.[2] These adverse responses have been reported in children given clonidine alone and in combination with methylphenidate.[4,5] Furthermore, one study suggested a potential pharmacokinetic interaction, with methylphenidate lowering clonidine plasma levels.[6]

However, over the 2 years following the initial adverse reports, there did not appear to be any more data to support an increase in deaths associated with the combination and the use of methylphenidate with clonidine appeared to be beneficial.[7] A small-scale pilot study in 24 patients suggested that the combination is both safe and effective for the treatment of attention deficit hyperactivity disorder (ADHD).[8] Similarly, a study in children with both ADHD and Tourette's syndrome found that clonidine used with methylphenidate was more effective than either drug alone, and only one child had evidence of adverse cardiac effects.[9] Furthermore, the manufacturers of one formulation of methylphenidate[1] said that, as of 2002, they were not aware of any reports describing adverse events when *Concerta XL* (methylphenidate) was used with clonidine.

Methylphenidate + Cocaine

Methylphenidate does not appear to alter the pharmacokinetics or physiological effects of cocaine to a clinically significant extent.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 7 otherwise healthy cocaine-dependent subjects found that methylphenidate 60 or 90 mg was well tolerated, did not significantly affect the pharmacokinetics of intravenous cocaine 20 or 40 mg, and did not have a clinically significant effect on the physiological effects of cocaine. However, some of the positive subjective effects (desire for cocaine and good drug effects) of cocaine were decreased. The results suggested that although both drugs can cause cardiovascular and CNS stimulation, in the doses studied, methylphenidate could be given to active cocaine users without any serious adverse reaction.[1]

Methylphenidate + Disulfiram

A psychotic episode occurred in a patient taking disulfiram when methylphenidate was also given.

Clinical evidence

A 33-year-old man who was taking disulfiram 400 mg daily, without any noticeable adverse effects, experienced a psychotic-like episode after receiving a single 36-mg dose of modified-release methylphenidate. He discontinued the methylphenidate, but continued to take the disulfiram, and when assessed 2 months later there was no clinical evidence of psychosis, anxiety or depression. After a further 3 months, the disulfiram was discontinued and he took methylphenidate without any adverse effect or recurrence of the psychotic experience.

Mechanism

It was suggested that an interaction might have occurred as disulfiram blocks dopamine-beta-hydroxylase. Low levels of this enzyme have been associated with psychotic symptoms.

Importance and management

Evidence of an interaction appears to be limited to this case report. As the effects of disulfiram persist for up to 2 weeks this interaction may occur even after the disulfiram is stopped. It has been suggested that a significant washout period should be observed before starting methylphenidate; alternatively, a non-dopaminergic drug might be preferred for the treatment of attention deficit hyperactivity disorder (ADHD) if disulfiram is being taken.[1] Note that one manufacturer of methylphenidate contraindicates its use in patients with alcoholism[2] and caution is advised in emotionally unstable patients, such as those with a history of alcoholism,[2-4] because such patients may increase the dosage on their own initiative.[3]

Methylphenidate + Risperidone

The use of methylphenidate with risperidone may possibly increase the risk of dyskinesias. Furthermore, there may be an increased risk of adverse effects if methylphenidate is started following risperidone withdrawal.

Clinical evidence

Although clinical studies have suggested that the use of risperidone with a psychostimulant (including methylphenidate) is safe, effective, and does not increase the incidence of adverse effects,[1] a limited case series suggested that children taking a psychostimulant and an atypical antipsychotic had a higher propensity for movement abnormalities.[2] A number of case reports support this suggestion. For example, a 7-year-old boy experienced acute dyskinesia, overactivity, distress, headache, fatigue and vomiting within 8 hours of starting to take modified-release methylphenidate 36 mg in place of risperidone, which was stopped abruptly 12 hours earlier. Similar but less severe symptoms were seen 5 months later when methylphenidate was started 6 days after the end of a course of risperidone which was reduced over 4 weeks.[3] Another report describes a patient taking methylphenidate 15 mg and risperidone 1.5 mg, both three times daily, who developed acute dystonia when the methylphenidate was withdrawn. He recovered when given benzatropine.[4] A further case of extrapyramidal symptoms occurred in a child taking methylphenidate, risperidone, sertraline and tropisetron.[5]

A case report describes 3 children who developed severe behavioural adverse reactions when switching from risperidone to methylphenidate. A 5 year-old boy who had been taking risperidone 1 mg daily for 8 months became agitated, irritable, vigilant and violent when risperidone was abruptly withdrawn and methylphenidate 15 mg daily started 2 days later. The methylphenidate was discontinued and the severe behavioural reactions disappeared. After a 6-week drug-free period, methylphenidate was restarted at the same dose with beneficial effects on attention and hyperactivity. A similar reaction occurred in a 6-year-old girl when risperidone was discontinued abruptly and methylphenidate was started. Similarly, a 15-year-old girl was given risperidone 1 mg daily to alleviate the symptoms of attention deficit hyperactivity disorder (ADHD). When risperidone was stopped for one week withdrawal symptoms were not seen, but irritability and agitation were reported when methylphenidate 18 mg daily was started.[6]

Mechanism

Antipsychotics and psychostimulants have conflicting mechanisms of action in the CNS; risperidone is a combined serotonin and dopamine antagonist whereas methylphenidate is a dopamine agonist.[1,2] It has been suggested that adverse effects develop because stopping risperidone removes the dopaminergic blockade, which results in supersensitive dopamine receptors. Over-stimulation then occurs when methylphenidate, which has dopamine agonist actions, is started.[3]

Importance and management

The combination of risperidone and methylphenidate carries the risk of drug-induced dyskinesias and particular care should be taken if one of the drugs is discontinued. Slow antipsychotic withdrawal, followed by a drug-free interval has been suggested when switching from risperidone to methylphenidate.[3,6] Methylphenidate should then be initiated at a low dose and withdrawn immediately if a dyskinesia appears.[3]

Methylphenidate + St John's wort (*Hypericum perforatum*)

St John's wort may decrease the efficacy of methylphenidate in the treatment of attention-deficit hyperactivity disorder.

Clinical evidence, mechanism, importance and management

A 22-year-old man who had been successfully treated with methylphenidate 20 mg daily for attention deficit hyperactivity disorder (ADHD) for 6 months started to take St John's wort 600 mg daily. Over the next 4 months the efficacy of the methylphenidate decreased, but 3 weeks after the St John's wort was stopped, the methylphenidate became more effective. No adverse effects were seen during the concurrent use of the herbal medicine and drug.[1]

This is an isolated case report and therefore no general recommendations can be made. However, if the efficacy of methylphenidate becomes reduced, it may be worth questioning the patient about St John's wort use, and giving consideration to stopping the herb.

1. Niederhofer H. St John's wort may diminish methylphenidate's efficacy in treating patients suffering from attention deficit hyperactivity disorder. *Med Hypotheses* (2007) 68, 1189.

Modafinil + Cocaine

Modafinil does not appear to alter haemodynamic effects of cocaine, but it may blunt cocaine-induced euphoria. Modafinil reduces the peak plasma levels of cocaine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 7 subjects, pretreatment with modafinil 200 or 400 mg daily for 4 days did not affect the increase in blood pressure, pulse or temperature; or changes in ECG, produced by a single 30-mg intravenous dose of cocaine. However, subjective cocaine-induced euphoria was blunted.[1] A similar lack of any significant haemodynamic interaction was found in 12 cocaine-dependent subjects who were given modafinil 400 or 800 mg daily and infusions of 20 or 40 mg of cocaine.[2] No serious adverse events were reported in a study of cocaine abstinence in 30 cocaine-dependent patients given modafinil 200 to 400 mg daily for 8 weeks, when compared with 32 patients given placebo. However, modafinil increased the incidence of minor adverse events including nausea, dizziness, anxiety and tachycardia, which required a dose reduction in 6 patients.[3]

In a placebo-controlled study in 12 cocaine-dependent subjects, modafinil 400 or 800 mg daily for 7 days reduced peak plasma levels of intravenous cocaine 40 mg given over one minute. The $AUC_{0\text{-}3}$ of cocaine was reduced by about 20% by modafinil, but there were no statistically significant changes in the total AUC, clearance, or elimination half-life of cocaine.[4]

Note that the manufacturer of modafinil advises caution if modafinil is given to patients with history of drug or illicit substance abuse.[5]

Modafinil + Dexamfetamine

No pharmacokinetic interaction appears to occur between modafinil and dexamfetamine.

Clinical evidence, mechanism, importance and management

In a steady-state study, 23 healthy subjects were given modafinil 200 mg daily for 7 days, then 400 mg daily for 3 weeks. During the last week, 10 of the subjects were also given dexamfetamine 20 mg daily, 7 hours after their modafinil dose. Dexamfetamine caused no significant change in the pharmacokinetics of modafinil and the combination was well tolerated. In addition, the pharmacokinetics of dexamfetamine did not appear to be affected by modafinil, when compared with values reported in the literature.[1] Similar results were found in a single-dose study.[2] No dosage adjustments appear to be necessary on concurrent use.

1. Hellriegel ET, Arora S, Nelson M, Robertson P. Steady-state pharmacokinetics and tolerability of modafinil administered alone or in combination with dextroamphetamine in healthy volunteers. *J Clin Pharmacol* (2002) 42, 448–58.

Modafinil + Methylphenidate

No pharmacokinetic interaction appears to occur between modafinil and methylphenidate.

Clinical evidence, mechanism, importance and management

In a single-dose study in healthy subjects, modafinil 200 mg and methylphenidate 40 mg were given together without any clinically relevant changes in the pharmacokinetics of either drug.[1] In a steady-state study, 30 healthy subjects were given modafinil 200 mg daily for 7 days, then 400 mg daily for 3 weeks. During the last week, 16 of the subjects were also given methylphenidate 20 mg daily, taken 8 hours after their modafinil dose. Methylphenidate caused no significant change in the pharmacokinetics of modafinil. In addition, the pharmacokinetics of methylphenidate did not appear to be affected by modafinil, when compared with values reported in the literature.[2] No dosage adjustments would appear to be necessary on concurrent use.

1. Wong YN, King SP, Laughton WB, McCormick GC, Grebow PE. Single-dose pharmacokinetics of modafinil and methylphenidate given alone or in combination in healthy male volunteers. *J Clin Pharmacol* (1998) 38, 276–82.
2. Hellriegel ET, Arora S, Nelson M, Robertson P. Steady-state pharmacokinetics and tolerability of modafinil given alone or in combination with methylphenidate in healthy volunteers. *J Clin Pharmacol* (2001) 41, 895–904.

Modafinil + Miscellaneous

The manufacturers advise caution if enzyme-inducing antiepileptics, particularly phenytoin, are given with modafinil. There is speculation, based on *in vitro* studies, about some possible interactions with other drugs, such as CYP2C19 substrates. Modafinil is a slight inducer of CYP3A4 and therefore may be expected to interact with substrates of this isoenzyme.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers and inhibitors

Animal studies suggest that **phenobarbital** reduces the serum levels of modafinil; both drugs are inducers of the cytochrome P450 isoenzyme

CYP3A4.[1] The manufacturers similarly suggest that this is a possibility.[2,3]

There is no clinical evidence of interactions with other potent enzyme inducers, but the manufacturers suggest that **carbamazepine**[2,3] and **rifampicin** (**rifampin**)[3] may reduce modafinil levels, see also *Phenytoin*, below. Also, inhibitors of CYP3A4 (**itraconazole** and **ketoconazole** are specifically named) are predicted to increase modafinil levels.[3] However, clinically relevant interactions with either CYP3A4 inducers or inhibitors seem unlikely because CYP3A4 is not the only cytochrome P450 isoenzyme that is involved in the metabolism of modafinil.

(b) CYP3A4 substrates

Modafinil is a minor inducer of the cytochrome P450 isoenzyme CYP3A4 *in vitro*. The manufacturers therefore predict that it may reduce the levels of drugs that are CYP3A4 substrates,[2,3] particularly those that undergo significant presystemic metabolism.[2] The UK manufacturer[2] specifically names **buspirone**, ciclosporin, midazolam, triazolam, **protease inhibitors**, and most of the **calcium-channel blockers** and **statins** [note that only some statins, namely atorvastatin, lovastatin and simvastatin, are CYP3A4 substrates]. For a list of substrates of CYP3A4, see 'Table 1.4', (p.6). Interactions have been seen with 'ciclosporin', (p.1244), and 'triazolam', (p.855).

(c) CYP2C19 substrates

In vitro, modafinil is a reversible inhibitor of CYP2C19 and it might therefore reduce the metabolism of drugs that are largely metabolised by CYP2C19. The manufacturers specifically name **propranolol**[2,3] and **omeprazole**[2] and suggest that a dose reduction may be necessary.[2,3] However, a clinically meaningful interaction with these two drugs seems unlikely, as propranolol is mainly metabolised by CYP2D6 and CYP1A2, and omeprazole has a very wide therapeutic margin. See also *Phenytoin*, below.

(d) Phenytoin

There is *in vitro* evidence to indicate that modafinil may possibly inhibit the metabolism of phenytoin by the cytochrome P450 isoenzymes CYP2C9 and CYP2C19, and so there is some reason for monitoring concurrent use for evidence of increased phenytoin effects and toxicity.[2,3] Nevertheless, modafinil did not have any clinically relevant inhibitory effect on CYP2C9 using warfarin as a substrate (see 'Coumarins + Modafinil', p.479). Note that phenytoin is also an inducer of CYP3A4, see under *CYP3A4 inducers and inhibitors*, above.

2. Provigil (Modafinil). Cephalon (UK) Ltd. UK Summary of product characteristics, November 2009.
3. Provigil (Modafinil). Cephalon, Inc. US Prescribing information, March 2008.

Orlistat + Anorectics

In two pharmacokinetic studies, healthy subjects were given phentermine 37.5 mg daily for 7 days or sibutramine 10 mg daily for 7 days with orlistat 120 mg three times daily for 6 or 7 days. Orlistat did not affect the bioavailability of phentermine or the active metabolites of sibutramine, and concurrent use did not appear to increase the incidence of adverse effects, or cause significant changes in vital signs (e.g. heart rate, blood pressure).[1]

1. Zhi J, Moore R, Kanitra L, Mulligan TE. Pharmacokinetic evaluation of the possible interaction between selected concomitant medications and orlistat at steady state in healthy subjects. *J Clin Pharmacol* (2002) 42, 1011–19.

Orlistat + Sucrose polyesters

A single case report suggests that the concurrent use of orlistat and sucrose polyesters (*Olestra* – used in some foods as a fat substitute) can result in additive gastrointestinal adverse effects (soft, fatty/oily stools, increased flatus and abdominal pain). In the case in question, symptoms resolved when the patient stopped eating *Olestra*-containing food while continuing to take orlistat.[1]

1. Heck AM, Calis KA, McDuffie JR, Carobene SE, Yanovski JA. Additive gastrointestinal effects with concomitant use of olestra and orlistat. *Ann Pharmacother* (2002) 36, 1003–5.

Phenmetrazine + Barbiturates

The CNS adverse effects and the weight-reducing effects of phenmetrazine are reduced by amobarbital. Psychotic episodes occurred in two patients taking barbiturates and phenmetrazine.

Clinical evidence, mechanism, importance and management

A comparative study in 50 overweight adults, of the effects of phenmetrazine 25 mg three times daily with or without **amobarbital** 30 mg three times daily, found that although the adverse CNS effects, particularly insomnia, headache and nervousness, were decreased by the presence of the barbiturate, the weight-reducing effects were also decreased (by 65%).[1]

A case report describes 2 cases of psychoses induced by the long-term use of barbiturates in combination with phenmetrazine, which resolved when the barbiturates or phenmetrazine were withdrawn.[2]

1. Hadler AJ. Phenmetrazine vs. phenmetrazine with amobarbital for weight reduction: a double-blind study. *Curr Ther Res* (1969) 11, 750–4.
2. Vinařová E, Vinař O. Psychotické epizody, vyvolané kombinací barbiturátů s fenmetrazinem. *Cesk Psychiatr* (1971) 67, 284–91.

Rimonabant + Miscellaneous

Ketoconazole doubles the AUC of rimonabant; other potent CYP3A4 inhibitors are expected to interact similarly, whereas potent CYP3A4 inducers are expected to lower rimonabant levels. Rimonabant does not appear to affect the levels of oral contraceptives, digoxin, midazolam, or warfarin, and alcohol, lorazepam, and orlistat do not appear to alter rimonabant levels.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inducers and inhibitors

Rimonabant is partly metabolised by the cytochrome P450 isoenzyme CYP3A4. **Ketoconazole**, a potent CYP3A4 inhibitor, doubles the AUC of rimonabant. The manufacturer therefore expects that other potent CYP3A4 inhibitors (they name **clarithromycin**, **itraconazole**, **nefazodone**, **ritonavir**, and **telithromycin**) will also raise rimonabant levels, and they therefore advise caution on concurrent use.[1] They similarly suggest that potent CYP3A4 inducers (such as **carbamazepine**, **phenobarbital**, **phenytoin**, **rifampicin** (**rifampin**) and **St John's wort**) may lower rimonabant plasma levels.[1] If concurrent use is necessary, monitor to ensure that rimonabant remains effective. See 'Table 1.4', (p.6), for a list of clinically relevant CYP3A4 inducers and inhibitors.

(b) Miscellaneous

Digoxin, **midazolam**, and **warfarin** were given with rimonabant in clinical studies to assess the effect of rimonabant on P-glycoprotein, CYP3A4 and CYP2C9, respectively. As rimonabant did not interact with these drugs, the manufacturer says this confirms *in vitro* evidence that it has no effect on these isoenzymes or transporter, and would not be expected to interact with other substrates of P-glycoprotein, CYP3A4 or CYP2C9. The manufacturer also notes that rimonabant had no effect on the pharmacokinetics of an oral contraceptive containing **ethinylestradiol** and **levonorgestrel**, and that **alcohol**, **lorazepam**, and **orlistat** did not affect the plasma levels of rimonabant.[1]

1. Acomplia (Rimonabant). Sanofi-Aventis. UK Summary of product characteristics, October 2007.

Sibutramine + Azoles

Ketoconazole modestly increases the steady-state levels of sibutramine and its active metabolites.

Clinical evidence, mechanism, importance and management

Twelve obese patients were given sibutramine 20 mg daily for 14 days, with **ketoconazole** 200 mg twice daily for the last 7 days. **Ketoconazole** caused moderate increases in the serum levels of sibutramine and its two metabolites (AUC and maximum serum level increases of 58% and 36%,

respectively, for metabolites M_1, and 20% and 19%, respectively, for M_2, probably by inhibition of the cytochrome P450 isoenzyme CYP3A4). Small increases in heart rates were seen (2.5 bpm at 4 hours and 1.4 bpm at 8 hours), while ECG parameters were unchanged.[1] Sibutramine alone can cause an increase in heart rate, and a rate increase of 10 bpm is an indication to withdraw the drug. Therefore, the manufacturer in the UK[2] suggests caution should be exercised when sibutramine is used with **ketoconazole**. They also suggest that, due to its ability to inhibit CYP3A4, **itraconazole** should also be used with caution.

2. Reductil (Sibutramine hydrochloride monohydrate). Abbott Laboratories Ltd. UK Summary of product characteristics, October 2007.

Sibutramine + Food

Food may delay the time to peak plasma levels of sibutramine and its metabolites. The bioavailability of sibutramine and possibly its M_1 metabolite may be increased by food.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that, compared with the fasted state, a **high-fat meal** increased the AUC and maximum plasma level of sibutramine 15 mg by about five- and threefold, respectively, and delayed the peak plasma level by 2 to 4 hours. The AUC and maximum plasma level of the M_1 metabolite was increased twofold, but the M_2 metabolite was not affected.[1] In contrast, another study found that giving a single 20-mg dose of sibutramine with a **standard breakfast** modestly reduced the peak levels of the active metabolites M_1 and M_2 by 27% and 32%, respectively, and delayed the peak levels by about 3 hours. However, the AUCs of M_1 and M_2 were not significantly altered.[2] Despite the large increases in sibutramine levels the manufacturers say that it may be given with or without food.[2,3] This is presumably because sibutramine is rapidly metabolised to its active metabolites, which are only modestly affected by food.

Sibutramine + Macrolides

Although no interaction appears to occur between sibutramine and erythromycin, the UK manufacturer still cautions the use of sibutramine with clarithromycin, erythromycin and troleandomycin.

Clinical evidence, mechanism, importance and management

Twelve obese patients were given sibutramine 20 mg daily for 14 days, with **erythromycin** 500 mg three times daily for the last 7 days. It was found that, apart from some slight and unimportant changes in the pharmacokinetics of the metabolites of sibutramine (probably caused by some inhibition of the cytochrome P450 isoenzyme CYP3A4), the pharmacokinetics of sibutramine were not significantly altered by **erythromycin**. No blood pressure changes were seen and only very small and clinically irrelevant increases in the QTc interval and heart rate occurred.[1] The extent of any interaction appears to be too small to matter,[1] and there would seem to be no reason for avoiding the concurrent use of these two drugs. Despite this, the UK manufacturer still says that caution should be exercised, probably because sibutramine is principally metabolised by CYP3A4.[2] They also extrapolate their caution to other potent CYP3A4 inhibiting macrolides, namely **clarithromycin** and **troleandomycin**.

2. Reductil (Sibutramine hydrochloride monohydrate). Abbott Laboratories Ltd. UK Summary of product characteristics, October 2007.

Sibutramine + Miscellaneous

The manufacturers of sibutramine contraindicate its use with MAOIs and centrally acting appetite suppressants, and suggest that it should not be given with serotonergic drugs or cold and influenza remedies containing sympathomimetic agents. The plasma levels of sibutramine are moderately increased by olanzapine and omeprazole, and are predicted to be increased by grapefruit juice. No clinically relevant pharmacokinetic interactions have been seen between sibutramine and cimetidine or simvastatin, and no interaction occurs with oral contraceptives.

Clinical evidence, mechanism, importance and management

(a) Centrally acting appetite suppressants, and drugs that raise blood pressure or heart rate

The manufacturers say that the concurrent use of sibutramine and other centrally acting appetite suppressants is contraindicated.[1,2] No work appears to have been done to see what happens if sibutramine is given with sympathomimetics including certain **decongestants**, **cough**, **cold** and **allergy medications**, but the manufacturers advise caution because of the risk of raised blood pressure or heart rate. The manufacturers in the UK and US both list **ephedrine** and **pseudoephedrine**,[1,2] while in the UK **xylometazoline** is also specifically named.[2]

(b) Cimetidine

When cimetidine 400 mg twice daily was given with sibutramine 15 mg once daily to 12 healthy subjects the maximum serum levels and AUCs of the combined sibutramine metabolites were increased by 3.4% and 7.3%, respectively.[1] These changes are too small to be of clinical significance, and there is no reason for avoiding the concurrent use of these two drugs.

(c) CYP3A4 inducers

The UK manufacturer states that **carbamazepine**, **dexamethasone**, **phenobarbital**, **phenytoin** and **rifampicin** (**rifampin**) are all inducers of CYP3A4, an isoenzyme involved in the metabolism of sibutramine.[2] These drugs might therefore increase the metabolism of sibutramine resulting in a fall in its serum levels. However, this has not been studied experimentally and, at the present time, the existence, the extent and the possible clinical relevance of any such interaction is unknown. Furthermore, clinically relevant interactions occurring as a result of **dexamethasone** inducing CYP3A4 appear rare.

(d) Grapefruit juice

Grapefruit juice is predicted to interact with sibutramine by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP3A4.[3] It has been suggested that, as the manufacturer of sibutramine advises caution if CYP3A4 inhibitors such as ketoconazole are given, it might also be appropriate to suggest avoidance of grapefruit juice especially as patients might consider the 'grapefruit diet' as an adjunct to weight reduction.[3] However, only modest increases in sibutramine levels were seen with the potent CYP3A4 inhibitor, 'ketoconazole', (p.230), and therefore a clinically relevant interaction with grapefruit juice would not generally be anticipated.

(e) MAOIs

There are no reports of adverse reactions between sibutramine and the MAOIs. However, sibutramine inhibits serotonin reuptake, and because the serious serotonin syndrome can occur when MAOIs and SSRIs are used together, the manufacturers contraindicate the concurrent use of sibutramine and MAOIs. They say that 14 days should elapse between stopping either drug and starting the other.[1,2] The US manufacturer includes **selegiline** in this warning.[1]

(f) Olanzapine

Olanzapine has been reported to moderately increase the AUC and maximum plasma levels of sibutramine by 63% and 47%, respectively, in healthy subjects; sibutramine had no significant effect on olanzapine pharmacokinetics.[1] However, the UK manufacturer of sibutramine contraindicates its use both with and for 2 weeks after the use of antipsychotics.[2]

(g) Omeprazole

In a study in 26 healthy subjects, omeprazole 20 mg daily for 7 days increased the maximum plasma level and AUC of sibutramine by 57% and 67%, respectively, and increased the levels of the active M_1 metabolite by 30% and 40%, respectively. The pharmacokinetics of the M_2 metabolite

were not significantly affected. Sibutramine had no significant effect on omeprazole pharmacokinetics.[1] These changes are modest, and no dosage adjustment would be expected to be necessary on concurrent use.

(h) Oral contraceptives

A crossover study in 12 subjects found that sibutramine 15 mg daily, given for 8 weeks, had no clinically significant effect on the inhibition of ovulation caused by an oral contraceptive, and it was concluded that there is no need to use alternative contraceptive methods while taking sibutramine.[1]

(i) Serotonergic drugs

Because sibutramine inhibits serotonin uptake, and because the serious serotonin syndrome has been seen when serotonergic drugs were taken with SSRIs, the manufacturers say that sibutramine should not be taken with any serotonergic drugs.[1,2] They name **dextromethorphan**, **dihydroergotamine**, **fentanyl**, **pentazocine**, **pethidine** (**meperidine**), SSRIs, **sumatriptan**, and **tryptophan**. Possible cases have been reported for sibutramine and 'SSRIs', (p.1492). The US manufacturer also includes **lithium** in their list.[1] Note that this list is not exhaustive (see MAOIs under (e) above) and a case of the serotonin syndrome has been seen when 'venlafaxine', (p.1480), was given with sibutramine. The extent of the risk with these serotonergic drugs is not known, but because of the potential severity of the reaction this warning would seem to be a prudent precaution. For more information on the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

(j) Simvastatin

In a study in 27 healthy subjects, giving simvastatin 20 mg daily in the evening and sibutramine 15 mg daily in the morning for 7 days resulted in a slight decrease in sibutramine maximum plasma levels and AUC of 14% and 21%, respectively. The plasma levels of the active M_1 and M_2 metabolites combined were not significantly affected, although the plasma levels of the M_1 metabolite were slightly reduced. Sibutramine decreased the maximum levels and AUC of simvastatin by 25% and 15%, respectively, but the AUC of the active metabolite, simvastatin acid, was increased by 7%.[1] These changes are not expected to be clinically significant.

Anthelmintics, Antifungals and Antiprotozoals

'Table 8.1', (p.234) lists the drugs covered in this section by therapeutic group and drug class. If the anti-infective is the drug causing the interaction, the interaction is generally dealt with under the affected drug. Also note that drugs such as the 5-nitroimidazoles (e.g. metronidazole), which have actions against more than one type of organism (e.g. bacteria and protozoa) are covered under Antibacterials.

(a) Amphotericin B

Intravenous amphotericin B causes important pharmacodynamic interactions via additive nephrotoxicity and myelotoxicity, and may increase the cardiotoxicity of other drugs because of amphotericin-induced hypokalaemia. No important pharmacokinetic interactions are known. Lipid formulations such as liposomal amphotericin B are less nephrotoxic than conventional amphotericin, and would therefore be expected to interact less frequently. Orally administered amphotericin B is not absorbed systemically, and no interactions are established.

(b) Azole antifungals

The most important interactions affecting and caused by the azole antifungals are those resulting from inhibition and induction of cytochrome P450 isoenzymes.

- **Fluconazole** is principally (80%) excreted unchanged in the urine, so is less affected by enzyme inducers and inhibitors than some other azoles. Fluconazole is a potent inhibitor of CYP2C9 and CYP2C19, and generally only inhibits CYP3A4 at high doses (greater than 200 mg daily). Interactions are less likely with single doses used for genital candidiasis than with longer term use.
- **Itraconazole** is extensively metabolised by CYP3A4, and its metabolism may become saturated with multiple dosing. Itraconazole and its major metabolite, hydroxy-itraconazole are potent inhibitors of CYP3A4.
- **Ketoconazole** is extensively metabolised, particularly by CYP3A4. It is also a potent inhibitor of CYP3A4.
- **Miconazole** is a potent inhibitor of CYP2C9. Because this azole is generally used topically as pessaries, cream, or an oral gel, it is less likely to cause interactions, although it should be noted that at maximum doses of the oral gel, sufficient may be absorbed to cause systemic effects, see 'warfarin', (p.438).
- **Posaconazole** is metabolised via UDP-glucuronidation, and may also be a substrate for P-glycoprotein. Posaconazole is an inhibitor of CYP3A4.
- **Voriconazole** is metabolised by CYP2C19, CYP2C9, and to a lesser extent by CYP3A4. Voriconazole is an inhibitor of CYP2C9, CYP2C19 and CYP3A4.

An number of other azole antifungals are only used topically in the form of creams or intravaginal preparations, and have not been associated with drug interactions, presumably since their systemic absorption is so low, see 'Azoles; Topical + Miscellaneous', p.251.

Fluconazole, ketoconazole and voriconazole have been associated with prolongation of the QT interval, although generally not to a clinically relevant extent. However, they may also raise the levels of other drugs that prolong the QT interval, and these combinations are often contraindicated, see 'Antihistamines + Azoles', p.665.

Table 8.1 Anthelmintics, antifungals and antimalarials and other antiprotozoals

Group	*Drugs*
Anthelmintics	
Benzimidazole derivatives	Albendazole, Flubendazole, Mebendazole, Tiabendazole (Thiabendazole)
Organophosphorous compounds	Metrifonate (Metriphonate)
Other	Diethylcarbamazine, Ivermectin, Levamisole, Niclosamide, Oxamniquine, Piperazine, Praziquantel, Pyrantel
Antifungals	
Allylamines	Naftifine, Terbinafine
Azoles:	
Imidazoles	Bifonazole,* Butoconazole,* Chlormidazole,* Clotrimazole,* Econazole,* Fenticonazole,* Isoconazole,* Ketoconazole, Miconazole, Oxiconazole,* Sertaconazole,* Sulconazole,* Tioconazole*
Triazoles	Fluconazole, Itraconazole, Posaconazole, Terconazole,* Voriconazole
Echinocandins	Anidulafungin, Caspofungin, Micafungin
Polyene antibiotics	Amphotericin B, Natamycin,* Nystatin*
Other	Amorolfine,* Butenafine,* Ciclopirox,* Flucytosine, Griseofulvin, Tolnaftate*
Antimalarials	
4-aminoquinolines	Amodiaquine, Chloroquine, Hydroxychloroquine
8-aminoquinolines	Primaquine
4-methanolquinolines	Mefloquine, Quinine
Artemisinin derivatives	Artemether, Artemotil, Artesunate, Co-artemether (Artemether/Lumefantrine)
Other	Atovaquone, Doxycycline,† Halofantrine, Lumefantrine, Proguanil, Pyrimethamine/Sulfadoxine, Tetracycline†
Antiprotozoals	
Antimony compounds	Sodium stibogluconate
Arsenicals	Melarsoprol
5-nitroimidazoles†	Metronidazole, Ornidazole, Tinidazole
Nitrofuran	Furazolidone, Nifurtimox
Other	Atovaquone, Diiodohydroxyquinoline, Diloxanide furoate, Eflornithine, Mepacrine, Pentamidine, Pyrimethamine/Sulfadiazine, Suramin

*Mainly used by topical application
†Covered under Antibacterials

Albendazole with Ivermectin + Azithromycin

The combination of albendazole and ivermectin with azithromycin causes moderate changes in the pharmacokinetics of all three drugs.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects investigated the interaction between the combination of single doses of ivermectin 200 micrograms/kg (to the nearest 3 mg) and albendazole 400 mg, with and without a single 500-mg dose of azithromycin. The combination of all three drugs increased the AUC and maximum concentration of azithromycin by 13% and 20%, respectively, and of ivermectin by 31% and 27%, respectively. In addition, the AUC and maximum concentration of albendazole sulfoxide (active metabolite of albendazole) were reduced by 16% and 14%, respectively. No serious adverse effects were reported.[1] These changes are unlikely to be of clinical significance, although the authors note that large inter-individual variability was seen in the pharmacokinetics of these drugs, suggesting that some patients may experience greater effects. Further study is needed to establish the safety and efficacy of concurrent use.

Note that a study has found no pharmacokinetic interaction between albendazole and ivermectin, see 'Albendazole + Ivermectin', p.236.

Albendazole or Mebendazole + Antiepileptics; Enzyme-inducing

Carbamazepine, phenytoin and phenobarbital lower the plasma levels of albendazole and mebendazole.

Clinical evidence

(a) Albendazole

In one study, 32 patients with intraparenchymatous neurocysticercosis were given albendazole 7.5 mg/kg every 12 hours for 8 days. These patients were also taking either **phenytoin** 200 to 300 mg daily (9 patients), **carbamazepine** 600 to 1200 mg daily (9 patients), or **phenobarbital** 100 to 300 mg daily (5 patients) all for at least 3 months, and a control group (9 patients) who did not receive any antiepileptics. The AUCs for (+)-albendazole sulfoxide were 49%, 66%, and 61% lower than the control group for the **carbamazepine**, **phenytoin**, and **phenobarbital** groups, respectively. The maximum plasma levels of (+)-albendazole sulfoxide were 50 to 63% lower and the half-lives about 3 to 4 hours shorter. The AUCs, peak plasma levels and half-life of (–)-albendazole sulfoxide (present in much lower levels than the (+)-isomer) were similarly reduced by the antiepileptics.[1]

(b) Mebendazole

A retrospective analysis found that patients with echinococcosis taking mebendazole and **phenytoin** or **carbamazepine** tended to have lower plasma mebendazole levels than patients not taking these antiepileptics.[2] Some patients had a clinically important rise in mebendazole levels when they were switched from **phenytoin** or **carbamazepine** to valproic acid,[2] although this increase would be expected when the enzyme-inducing drug is stopped.

Mechanism

Carbamazepine, phenytoin and phenobarbital appear to induce the oxidative metabolism of albendazole by the cytochrome P450 subfamily CYP3A to roughly the same extent, resulting in significantly reduced levels of albendazole sulfoxide, the active metabolite of albendazole. Mebendazole is similarly affected.

Importance and management

The pharmacokinetic interactions between albendazole or mebendazole and enzyme-inducing antiepileptics are established, and are likely to be clinically important when these anthelmintics are used to treat systemic worm infections. It may be necessary to increase the albendazole or mebendazole dosage in patients treated for systemic worm infections and also taking phenytoin (and therefore probably **fosphenytoin**), carbamazepine or phenobarbital (and therefore **primidone**). Monitor the outcome of concurrent use.

The interactions are of no importance when these anthelmintics are used for intestinal worm infections (where their action is a local effect on the worms in the gut), which is the most common use of mebendazole in particular.

Albendazole or Mebendazole + Cimetidine

Cimetidine raises serum mebendazole levels, and prolongs the half-life of albendazole sulfoxide, the active metabolite of albendazole. In some cases cimetidine appeared to increase the effectiveness of these anthelmintics against systemic infection.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects given albendazole 20 mg/kg and cimetidine 10 mg/kg twice daily found that cimetidine significantly inhibited the metabolism of the active metabolite sulfoxide metabolite of albendazole, as indicated by an increase in its elimination half-life from 7.4 to 19 hours. Cimetidine reduced inter-individual variability in plasma albendazole sulfoxide levels but tended to decrease the maximum levels of albendazole by around 50%, although this was not statistically significant. However, the AUC of albendazole sulfoxide was not significantly altered.[1] A similar study by the same authors[2] also found that cimetidine reduced the increase in albendazole sulfoxide levels produced by 'grapefruit juice', (p.236). Another study in patients with cystic echinococcosis given albendazole 20 mg/kg daily, for three 4-week courses separated by intervals of 10 days, found that levels of the active metabolite albendazole sulfoxide were higher in bile and hydatid cyst fluid in 7 patients who also received cimetidine 10 mg/kg daily. The therapeutic benefit of the combined treatment was reported to be greater than that with albendazole alone.[3]

(b) Mebendazole

A study in 8 patients (5 with peptic ulcers and 3 with hydatid cysts) taking mebendazole 1.5 g three times daily found that cimetidine 400 mg three times daily for 30 days raised the maximum plasma mebendazole levels by 48%. The previously unresponsive hepatic hydatid cysts resolved totally.[4] However, a previous study had found smaller increases in serum mebendazole levels with cimetidine 1 g daily in divided doses, which were considered too small to be clinically useful.[5]

Mechanism

It is suggested that the interaction is caused by the enzyme inhibitory actions of cimetidine, which result in a reduction in the metabolism of mebendazole.[4] Further, cimetidine inhibits the metabolism of albendazole to its active metabolite albendazole sulfoxide.[1] However, as cimetidine may also inhibit the metabolism of albendazole sulfoxide to its inactive sulfone metabolite, any reduction in levels of albendazole sulfoxide are compensated for by its prolonged elimination half-life.[1] Cimetidine may also reduce albendazole absorption and minimise inter-patient variability by reducing gastric acidity,[1,2] but the reduction in absorption appears to be outweighed by the enzyme-inhibitory effects.

Importance and management

These pharmacokinetic interactions would appear to be established, but their clinical relevance is uncertain. Increased efficacy has been shown in some studies for systemic worm infections. There would seem to be no

reason for avoiding concurrent use, but increased monitoring for efficacy and toxicity might be prudent.

Albendazole + Corticosteroids

Dexamethasone can raise levels of the active metabolite of albendazole, albendazole sulfoxide, by 50%, which might increase its efficacy in systemic worm infections.

Clinical evidence

In one study albendazole 15 mg/kg daily in three divided doses was given to 8 patients with cysticercosis. The plasma levels of the active metabolite of albendazole (albendazole sulfoxide) were found to be increased by about 50% by the use of **dexamethasone** 8 mg every 8 hours.[1] Another study did not detect significantly increased maximum plasma levels of albendazole sulfoxide when **dexamethasone** was given, but the AUC of albendazole sulfoxide was increased twofold, and there was a decrease in its clearance.[2]

Mechanism

Uncertain. Dexamethasone is a moderate inducer of the cytochrome P450 isoenzyme CYP3A4, and might therefore be expected to reduce levels of albendazole by increasing its metabolism to albendazole sulfoxide. Dexamethasone appears not to alter the rate of formation of albendazole sulfoxide, but decreases its elimination.[2]

Importance and management

Information about albendazole seems to be limited but the interaction would appear to be established. It would appear that albendazole can be given concurrently with dexamethasone without compromising treatment, and combined use may actually be beneficial.[3]

3. Sotelo J, Jung H. Pharmacokinetic optimisation of the treatment of neurocysticercosis. *Clin Pharmacokinet* (1998) 34, 503–15.

Albendazole + Diethylcarbamazine

There appears to be no pharmacokinetic interaction between albendazole and diethylcarbamazine.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of single doses of diethylcarbamazine 6 mg/kg and albendazole 400 mg were not significantly different when groups of 14 amicrofilaraemic subjects given either drug alone were compared with another group of 14 subjects given both drugs.[1] This study suggests there is no pharmacokinetic interaction between these two anthelmintic drugs, and the lack of adverse events[1] suggests that concurrent use is safe.

Albendazole + Food

Giving albendazole with a fatty meal markedly increases the levels of its active metabolite.

Clinical evidence, mechanism, importance and management

A study in Sudanese men found that giving a single 400-mg dose of albendazole with a meal resulted in a 7.9-fold higher level of the active metabolite, albendazole sulfoxide, than when albendazole was given in the fasted state.[1] Similarly, a further study in healthy subjects found that when albendazole 10 mg/kg was given with a fatty meal, rather than with water, the peak plasma levels of albendazole sulfoxide were increased by more than sixfold and the half-life decreased from 8.8 to 8.2 hours.[2] A study in 16 healthy subjects given a single 800-mg dose of albendazole after a fatty meal (representative of various foods in a Mexican diet) found that the maximum concentration and AUC of albendazole sulfoxide was increased sevenfold and eightfold, respectively.[3]

Albendazole absorption is poor, and if it is being used for systemic infections, it is advisable to take it with a meal.

3. Mares SS, Jung CH, López AT, González-Esquivel DF. Influence of a Mexican diet on the bioavailability of albendazole. *Basic Clin Pharmacol Toxicol* (2005) 97, 122–4.

Albendazole + Grapefruit juice

Grapefruit juice increases the plasma levels of albendazole sulfoxide, the active metabolite of albendazole.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, 250 mL of double-strength grapefruit juice increased albendazole sulfoxide peak levels by 3.2-fold and shortened its half-life by 46%. When cimetidine 10 mg/kg was also given, the effect of the grapefruit juice was diminished: the peak plasma level of albendazole sulfoxide was almost 50% lower than when albendazole was given with grapefruit juice alone. However, the peak level of albendazole sulfoxide was still 2.7-fold greater in the presence of cimetidine and grapefruit juice than that achieved when albendazole was given with water.[1]

It was suggested that grapefruit juice inhibits the metabolism of albendazole in the intestinal mucosa by the cytochrome P450 isoenzyme CYP3A4, resulting in raised albendazole levels. The addition of 'cimetidine', (p.235), may decrease this effect as cimetidine inhibits the metabolism of albendazole to its active metabolite, and the changes in gastric pH caused by cimetidine may also reduce albendazole absorption.[1]

The clinical outcome of the change in albendazole sulfoxide levels with grapefruit juice is uncertain. For systemic infections, increased absorption might be beneficial (although adverse effects may be increased), but the decrease in half-life might be detrimental. Further study is required.

1. Nagy J, Schipper HG, Koopmans RP, Butter JJ, Van Boxtel CJ, Kager PA. Effect of grapefruit juice or cimetidine coadministration on albendazole bioavailability. *Am J Trop Med Hyg* (2002) 66, 260–3.

Albendazole + Ivermectin

No pharmacokinetic interaction occurs between albendazole and ivermectin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 42 patients with onchocerciasis were given single doses of either ivermectin 200 micrograms/kg, albendazole 400 mg or both drugs together. The pharmacokinetics of both drugs were not significantly changed by concurrent use, and although the combination seemed to offer no advantage over ivermectin alone for the treatment on

onchocerciasis, the combination appeared safe. No dosage adjustments would be required during concurrent use.[1]

1. Awadzi K, Edwards G, Duke BOL, Opoku NO, Attah SK, Addy ET, Ardrey AE, Quarty BT. The co-administration of ivermectin and albendazole— safety, pharmacokinetics and efficacy against *Onchocerca volvulus*. *Ann Trop Med Parasitol* (2003) 97, 165–78.

Albendazole + Levamisole

Levamisole may markedly decrease the bioavailability of the active metabolite of albendazole, but albendazole has no clinically significant effects on levamisole pharmacokinetics.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg, alone or with albendazole 400 mg, found that albendazole produced a modest reduction in the AUC of levamisole but no other pharmacokinetic parameters were affected. However, the AUC of the active sulfoxide metabolite of albendazole was 75% in the presence of levamisole, when compared with historical values in subjects who had received albendazole alone.[1] An associated study in 44 patients found that levamisole with or without albendazole was not effective against *Onchocerca volvulus* infections. Both treatments caused a similar number of adverse effects.[1] The clinical relevance of these findings is unclear, but they suggest that caution is needed if a patient is given albendazole and levamisole for systemic worm infections as there may be a risk of treatment failure.

1. Awadzi K, Edwards G, Opoku NO, Ardrey AE, Favager S, Addy ET, Attah SK, Yamuah LK, Quartey BT. The safety, tolerability and pharmacokinetics of levamisole alone, levamisole plus ivermectin, and levamisole plus albendazole, and their efficacy against *Onchocerca volvulus*. *Ann Trop Med Parasitol* (2004) 98, 595–614.

Albendazole + Praziquantel

Albendazole does not alter the bioavailability of praziquantel. Praziquantel markedly increases the bioavailability of albendazole sulfoxide in fasted subjects, but has a much smaller effect when albendazole is given with a meal.

Clinical evidence, mechanism, importance and management

In a study, Sudanese men were given a single 400-mg dose of albendazole with praziquantel 40 mg/kg while fasting. The pharmacokinetics of praziquantel were not affected by albendazole, whereas the AUC of albendazole sulfoxide, the active metabolite of albendazole, was increased 4.5-fold by praziquantel. However, this difference was much less marked (only a 1.5-fold increase) when the drugs were given with food.[1] The reasons for these changes and their practical consequences are not known, but the increases in albendazole sulfoxide levels did not cause any adverse effects.[1]

In a randomised study, 23 healthy subjects were given albendazole 400 mg and ivermectin 200 micrograms/kg, with or without praziquantel 40 mg/kg. The addition of praziquantel increased the AUC and maximum plasma concentration of albendazole sulfoxide by 31% and 8%, respectively, although there was wide inter-individual variability in these results. No serious adverse effects were reported.[2]

In another randomised study, 21 children treated for giardiasis were given a single 400-mg dose of albendazole, either alone, or with a single 20-mg/kg dose of praziquantel. It was found that the pharmacokinetics of albendazole were not significantly affected by praziquantel when the drugs were given with 200 mL of milk, one hour after breakfast. There were wide inter-individual variations in the plasma levels and AUC of the active metabolite, albendazole sulfoxide, but these were similar whether albendazole was given alone or with praziquantel.[3]

If both drugs are given with food, as is advisable (see 'Albendazole + Food', p.236), any interaction is modest. On the basis of these studies, there do not seem to be any reasons why the concurrent use of these two drugs should be avoided.

Amodiaquine + Antihistamines

Chlorphenamine may improve the efficacy of amodiaquine, but concurrent use causes drowsiness.

Clinical evidence and mechanism

A small study in 5 children, treated unsuccessfully for acute uncomplicated falciparum malaria with amodiaquine, found that the addition of **chlorphenamine** (6 or 8 mg loading dose followed by 4 or 6 mg every 8 hours if less than 5-years-old or 5-years-old and above, respectively) improved the antimalarial efficacy and cure rate of amodiaquine. Drowsiness, after the first dose of the combination, was the only reported common adverse effect. However, no pharmacokinetic data for either drug were reported.[1]

Importance and management

The use of chlorphenamine with amodiaquine may improve the efficacy of amodiaquine; however, the mechanism of this is unclear, particularly as no pharmacokinetic data were collected. Therefore, it is unclear if this combination may increase the risk of amodiaquine adverse effects. It would seem prudent that if combination therapy with amodiaquine and chlorphenamine is indicated, patients should be advised of the increased risk of drowsiness, which would be expected with chlorphenamine alone. It seems likely that all sedating antihistamines may increase drowsiness with amodiaquine, but this does not appear to have been studied.

Amphotericin B + Azoles

The effects of amphotericin B and azole antifungals would be expected to be antagonistic, and there is some clinical evidence that supports this suggestion and describes increased adverse effects. An isolated study found that amphotericin B reduced the levels of itraconazole, and the combination may increase the incidence of hepatotoxicity.

Clinical evidence

There are numerous *in vitro* and *animal* studies of the potential interaction of azoles with amphotericin B, which show conflicting results from antagonism to additive or synergistic effects, some of which have been the subject of a review.[1] Many of the studies into the use of azoles with amphotericin B are investigating potential therapeutic uses and are therefore outside the scope of this monograph; however, there are some clinical reports of reduced efficacy and adverse effects, and these are discussed below.

In one study, 4 out of 6 patients did not respond to amphotericin B while also taking **ketoconazole**, whereas treatment was successful in 6 others, 5 of whom had stopped taking prophylactic **miconazole** or **ketoconazole**. The authors suggested that the numbers are too small to draw any definite conclusions, but antagonism is certainly a possibility.[2] Similarly, the antifungal effects of **miconazole** and amphotericin B were found to be antagonistic in one small study.[3] In contrast, two randomised studies, in patients with candidaemia, or HIV-positive subjects with cryptococcal meningitis, found that the use of amphotericin B with **fluconazole** may be slightly more effective than the use of **fluconazole** or amphotericin B alone.[4,5]

A comparative study found that patients given **itraconazole** and amphotericin B had serum **itraconazole** levels of less than 1 microgram/mL, whereas those given **itraconazole** alone had serum **itraconazole** levels of 3.75 micrograms/mL, which suggests that amphotericin B may reduce **itraconazole** levels.[6]

A retrospective study of **itraconazole** use found that 11 of 12 leukaemic

patients given amphotericin B and **itraconazole** had raised liver enzymes. These abnormalities resolved in 7 patients when the amphotericin B was discontinued. **Itraconazole** alone, given to another 8 patients did not cause liver enzyme abnormalities, even though it was used in high doses.[7]

Mechanism

Uncertain. In theory, the combination of an antifungal that binds to ergosterol in fungal cell membranes (amphotericin B) with one that inhibits the synthesis of ergosterol (azoles) would be expected to exert antagonistic effects.[1,8,9] *In vitro* studies with *Candida albicans* found that azole exposure may allow the generation of cells that are unaffected by subsequent exposure to amphotericin B. The degree of resistance appears to depend on concentration and the azole involved, with itraconazole causing more resistance than fluconazole.[10] Resistance of *Candida* species to amphotericin B appears to depend on the duration of pre-exposure to fluconazole and is also greater when amphotericin B is subsequently used in combination with fluconazole rather than alone.[9,11] Resistance may also depend on the organism involved and its sensitivity to azoles.[12,13]

Importance and management

Despite extensive *in vitro* and *animal* data, it is not entirely clear whether or not azoles inhibit the efficacy of amphotericin B.[8,14,15] The emergence of resistant strains of fungi and the fact that antifungal therapy for invasive fungal infections remains suboptimal, has meant that combinations of antifungals have continued to be tried. Critically ill patients are often given empirical treatment with amphotericin B, with a subsequent change to fluconazole if the organism is sensitive. The Infectious Disease Society of America advises that a combination of amphotericin B and fluconazole may be an option in selected patients.[16] However, combinations of azoles and amphotericin B should not be considered as routine practice, and until more is known it may be better to limit concurrent use to specific cases. The outcome of combined use should be well monitored for both a reduced antifungal response and an increase in adverse effects. There are a number of reviews that have usefully discussed the topic of antifungal combinations.[17-19]

The evidence for a pharmacokinetic interaction between amphotericin B and azole antifungals is poor and appears to be limited to the single study with itraconazole reported above. Similarly evidence for an adverse hepatic interaction is sparse. Amphotericin B has only rarely been associated with adverse effects on the liver, although increases in liver enzymes may occur in patients given itraconazole. Given these findings, it may be prudent to closely monitor the outcome of combined use of amphotericin and itraconazole for both a reduced antifungal response to the itraconazole, as well as an increase in adverse effects, such as a worsening of liver function tests.[7] Further study is needed to substantiate these results.

Amphotericin B + Drugs that lower potassium levels

The concurrent use of amphotericin B with drugs that can lower potassium levels (such as loop diuretics, thiazide diuretics and corticosteroids) can lead to hypokalaemia.

Clinical evidence

(a) Corticosteroids

Four patients given amphotericin B and **hydrocortisone** 25 to 40 mg daily developed cardiac enlargement and congestive heart failure secondary to hypokalaemia. In these cases the potassium levels decreased from about 5 mmol/L pre-treatment to between 2.3 and 3 mmol/L during amphotericin therapy. The cardiac size decreased and the heart failure disappeared within 2 weeks of stopping the **hydrocortisone**. The amphotericin B was continued successfully with the addition of potassium supplements in some cases.[1] A retrospective study reported an incidence of hypokalaemia of about 18% in patients prescribed amphotericin B and **hydrocortisone**.[2]

(b) Potassium-depleting diuretics

Amphotericin B and loop diuretics or thiazides and related diuretics can lower potassium levels, and their concurrent use may increase the risk of hypokalaemia.[3] One retrospective study reported an incidence of hypokalaemia of about 36% in patients prescribed both amphotericin B and **furosemide**.[2] Conversely, potassium-sparing diuretics such as **amiloride** might reduce the incidence of hypokalaemia with amphotericin B.[4]

Mechanism

Amphotericin B causes potassium to be lost in the urine: the incidence of hypokalaemia with amphotericin B alone has been reported to be as high as 75 to 90%.[4] Potassium-depleting diuretics (such as the loop diuretics, thiazides and related diuretics) and corticosteroids can also increase potassium excretion. Corticosteroids may also cause salt and water to be retained, and occasional instances of hypernatraemia with amphotericin B have also been seen. Working in concert these could account for the hypokalaemic cardiopathy and the circulatory overload that was seen.

Importance and management

Information is limited but the interaction would seem to be established. The manufacturer of conventional amphotericin B advises that corticosteroids should not be used concurrently unless necessary to control drug reactions.[5] However, in clinical practice, it is sometimes deemed necessary to use amphotericin B with corticosteroids or diuretics or all three together. In this situation, close monitoring of the patient's fluid balance, electrolytes (especially potassium, which should be closely monitored in patients receiving amphotericin B in any case) and renal and cardiovascular parameters is required. The elderly would seem to be particularly at risk of this interaction. One small study found that giving spironolactone 100 mg twice daily with amphotericin B reduced the need for potassium supplementation, and did not result in clinically significant adverse effects.[6] Note that hypokalaemia increases the risk of adverse interactions with 'digitalis glycosides', (p.1099), and 'QT-interval prolonging drugs', (p.289).

Amphotericin B + Pentamidine

Acute renal failure and electrolyte disturbances may develop in patients taking amphotericin B if they are also given pentamidine.

Clinical evidence, mechanism, importance and management

A retrospective study between 1985 and 1988 identified 101 patients with AIDS who had been given amphotericin B for various systemic mycoses. The patients were given amphotericin B 600 to 800 micrograms/kg daily for 7 to 10 days, then a dose three times each week for about 9 weeks. Nine patients were concurrently treated for pneumocystis pneumonia, and of these the 4 who had been given pentamidine parenterally developed acute and rapid reversible renal impairment. In all 4 cases, renal function returned to normal when the drugs were withdrawn. No renal impairment was seen in 2 others given pentamidine by inhalation or 3 given intravenous co-trimoxazole and the renal impairment was attributed to the additive nephrotoxicity of intravenous pentamidine with amphotericin.[1]

Both amphotericin B and intravenous pentamidine are known to be nephrotoxic. Reversible renal adverse effects may occur in up to 20% of patients given intravenous pentamidine alone, and, rarely, renal impairment may also occur in patients given inhaled pentamidine.[2] However, it seems likely that no toxicity occurred in the patients mentioned above when the pentamidine was given by inhalation because the serum levels achieved were low.

Close monitoring of renal function should be routine when either drug is used (daily monitoring is recommended in the case of parenteral pentamidine[2]), and it is essential that this recommendation is adhered to if both drugs are given. It may be prudent to use liposomal amphotericin B rather than conventional amphotericin B to reduce the risk of renal impairment. Anticipate the likelihood of renal impairment and consider the need to withdraw the drugs.

Note also that both drugs can cause significant electrolyte disturbances, such as hypomagnesaemia[2,3], and serum electrolytes should also be closely monitored on concurrent use.

Amphotericin B; Oral + Miscellaneous

The manufacturer of amphotericin B[1] notes that its absorption from the gastrointestinal tract is negligible, and that no interactions have been noted with amphotericin B lozenges, or other oral formulations. For a theoretical interaction with sucralfate, see 'sucralfate', (below).

1. Fungilin Lozenge, Oral Suspension, Oral Tablets (Amphotericin B). E. R. Squibb & Sons Ltd. UK Summary of product characteristics, May 2006.

Amphotericin B; Oral + Sucralfate

An *in vitro* study with amphotericin B found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that efficacy for intestinal candidiasis or gut decontamination might be decreased, but no study appears to have been conducted to establish this.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, amphotericin B 25 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution found that the amphotericin B concentration fell rapidly and progressively over 90 minutes to about 20%. When the pH of the mixture was then raised to about 6.5 to 7 for 90 minutes, there was no change in the concentration of amphotericin B, suggesting that the interaction was irreversible.[1] The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with amphotericin B.[1]

It is not known how important this interaction is likely to be in practice, but the efficacy of amphotericin B for intestinal candidiasis or gut decontamination may be decreased. Separating the dosages might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.[1] This study was conducted more than a decade ago, and nobody appears to have conducted a clinical study to establish its hypothesis. If both sucralfate and oral amphotericin B are required, it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

Artemether + Grapefruit juice

Grapefruit juice doubles the AUC of artemether.

Clinical evidence, mechanism, importance and management

In a crossover study, 6 healthy subjects were given a single 100-mg dose of artemether with water, after breakfast, then after a 7-day washout period the study was repeated, replacing water with 350 mL of double-strength grapefruit juice. Grapefruit juice increased the AUC of artemether by almost twofold, and increased its maximum level by more than twofold. The pharmacokinetics of the active metabolite of artemether, dihydroartemisinin, were unaffected. No ECG changes were reported on concurrent use.[1] In a further multiple-dose study, artemether 100 mg was taken with water or 350 mL of double-strength grapefruit juice, daily for 5 days. Grapefruit juice increased the AUC and maximum level of artemether twofold on both day one and day 5, but the AUC of artemether was markedly lower on day 5, due to auto-induction of its metabolism.[2] This suggests that grapefruit juice might increase the levels of artemether by inhibiting the cytochrome P450 isoenzyme CYP3A4 in the intestine, but that auto-induction does not affect this process.

The clinical relevance of the twofold increase in artemether levels seen in this study was not reported. However, based on the evidence for 'ketoconazole', (p.239), a potent inhibitor of CYP3A4, it seems unlikely to result in adverse effects or ECG changes, and the manufacturers advise that no dosage adjustments are needed when artemether/lumefantrine is used with potent CYP3A4 inhibitors.[3] The authors[2] suggest that the use of grapefruit juice might improve clinical efficacy of artemether in malaria, and might theoretically reduce recrudescence (the reappearance of a disease after a period of inactivity); however, artemether is used with lumefantrine to limit recrudescence.

3. Riamet (Artemether/Lumefantrine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2007.

Artemether/Lumefantrine + CYP3A4 inhibitors

Ketoconazole modestly increases the AUC of both artemether and lumefantrine, and other potent inhibitors of CYP3A4 are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

In a study, 16 healthy subjects were given a single dose of artemether/lumefantrine 80/480 mg with a high-fat breakfast, followed by **ketoconazole** 400 mg on day one and then 200 mg daily for 4 days.

Ketoconazole increased the AUC of artemether 2.4-fold, its metabolite dihydroartemisinin 1.7-fold, and lumefantrine 1.7-fold.[1] The maximum levels of the drugs were also increased to a similar extent. **Ketoconazole** probably increases the levels of artemether and lumefantrine by inhibiting intestinal and/or hepatic cytochrome P450 isoenzyme CYP3A4. Although a pharmacokinetic interaction with ketoconazole appears to be established, the clinical relevance of a modest, twofold increase in artemether and lumefantrine levels appears to be minimal, as no changes in ECG parameters or increases in adverse events were reported,[1] and the pharmacokinetic changes seen are within the expected intersubject variability for these drugs.[1] The manufacturer[2] therefore advises that no dosage adjustment is necessary when artemether/lumefantrine is given with **ketoconazole** or other potent inhibitors of CYP3A4, see 'Table 1.4', (p.6).

2. Riamet (Artemether/Lumefantrine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2007.

Artemether/Lumefantrine + Food

High-fat food and soya milk markedly increase the absorption of lumefantrine, and high-fat food moderately increases the absorption of artemether. As soon as patients can tolerate food they should be encouraged to take artemether/lumefantrine with meals.

Clinical evidence, mechanism, importance and management

In a study in healthy Chinese subjects, a single dose of artemether/lumefantrine 80/480 mg was taken after a **high-fat meal** and in the fasted state. The relative bioavailabilities of artemether and its active metabolite dihydroartemisinin were increased by more than twofold, and the bioavailability of lumefantrine was increased 16-fold by the meal.[1] Based on these data, the manufacturer notes that if 100% absorption is assumed for lumefantrine taken with a **high-fat meal**, then absorption in the fasted state is less than 10% of the dose.[2] In a clinical study in patients with malaria, intake of a **light meal** within one hour of lumefantrine increased the bioavailability by 48%, and intake of a **normal meal** increased absorption twofold, when compared with liquids alone. After 24 to 48 hours in this study, most patients were eating normally.[3]

A study in 11 healthy subjects to investigate the amount of fat required to maximise lumefantrine bioavailability found that giving increasing quantities of **soya milk** up to 500 mL) significantly increased the AUC of lumefantrine by more than fivefold. The optimum quantity of fat to obtain 90% bioavailability of lumefantrine was 1.2 g (equivalent to 36 mL of **soya milk**).[4] Artemether/lumefantrine should be taken with food. However, patients with acute uncomplicated malaria are unlikely to tolerate food. The manufacturer notes that patients should be encouraged to take artemether/lumefantrine with food as soon as this can be tolerated. Patients who remain averse to food during treatment should be closely monitored as they may be at greater risk of recrudescence (reappearance of the disease after a period of inactivity).[2] The study above[4] suggests that **soya milk** may also be an option to improve lumefantrine bioavailability in those patients unable to tolerate a full meal.

Atovaquone + Antiemetics

Preliminary evidence suggests that metoclopramide causes a marked decrease in atovaquone serum levels.

Clinical evidence, mechanism, importance and management

An analysis of 191 patients with AIDS, given atovaquone as part of efficacy studies, found that when normalised for plasma albumin, bodyweight, and the absence of other drugs, the expected steady-state plasma levels of atovaquone were 14.8 micrograms/mL. Steady-state atovaquone plasma levels achieved in the presence of other drugs were examined in an attempt to identify possible interactions. **Metoclopramide** was associated with a decrease in atovaquone levels of 7.2 micrograms/mL. Antiemetics other than **metoclopramide** (individual drugs not named) were not associated with any change in steady-state atovaquone serum levels.[1,2] This kind of analysis provides only the very broadest indication that a marked interaction might occur between atovaquone and **metoclopramide**, and there appears to be no further published studies to confirm this report of an interaction. However, it does highlight the need to be vigilant if **metoclopramide** is used concurrently, and the manufacturers of atovaquone[2] and atovaquone/proguanil[3] recommend caution in its use with **metoclopramide**. If an antiemetic is required in patients taking atovaquone/proguanil, they suggest that **metoclopramide** should be given only if other antiemetics are unavailable,[3] and that parasitaemia should be closely monitored.[4] In the UK, the manufacturers also say that **metoclopramide** should be given with caution to patients taking atovaquone suspension for pneumocystis pneumonia, until the interaction has been further studied.[2] The US manufacturers of atovaquone suspension do not mention **metoclopramide**.[5]

Atovaquone/Proguanil + Artesunate

Artesunate does not appear to affect the pharmacokinetics of atovaquone/proguanil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, a single dose of atovaquone/proguanil 1 g/400 mg was given to 12 healthy subjects with and without artesunate 250 mg. No change was noted in the pharmacokinetics of either atovaquone or proguanil and no unexpected adverse events were seen.[1] Although artesunate does not therefore appear to alter the pharmacokinetics of atovaquone/proguanil, this needs confirmation in a multiple-dose study.

A study to investigate whether the addition of artesunate to atovaquone/proguanil increased the risk of cardiotoxicity found that the QT_c interval was not significantly different in those receiving all three drugs, when compared with those receiving atovaquone/proguanil alone.[2]

Atovaquone + Co-trimoxazole

In one small study co-trimoxazole did not alter atovaquone levels, and atovaquone caused a minor decrease in co-trimoxazole levels, which was not considered clinically relevant.

Clinical evidence, mechanism, importance and management

As part of a larger study, 6 HIV-positive subjects received atovaquone 500 mg once daily, co-trimoxazole 960 mg (trimethoprim/sulfamethoxazole 160/800 mg) twice daily, or the combination, with food. There was no change in steady-state atovaquone levels but there was a minor 17% decrease in steady-state trimethoprim levels and a minor 8% decrease in sulfamethoxazole levels when both drugs were given together.[1]

This study shows there is no important pharmacokinetic interaction between atovaquone and co-trimoxazole. No dosage adjustments of either drug would be required on concurrent use.

Atovaquone + Food

Fatty foods markedly increase the AUC of atovaquone tablets and suspension by two to threefold.

Clinical evidence

(a) Suspension

A pharmacokinetic study in 12 HIV-positive subjects, designed to determine the dose of atovaquone suspension that would achieve specific steady-state plasma levels, found that **high-fat** food increased the bioavailability of atovaquone by 40%, when compared with the fasted state.[1] In another similar study, giving atovaquone suspension with food (23 g of fat) increased the average steady-state levels by 30 to 70% with different dosage regimens (using 500 mg to 1.5 g of atovaquone).[2]

In a single-dose study in healthy subjects, a **high-fat breakfast** (21 g of fat) increased the AUC of atovaquone suspension by 2.4-fold, and an **enteral nutrition supplement** (*Sustacal Plus*, containing 28 g of fat) increased the AUC by 2.7-fold, when compared with the fasted state.[3]

(b) Tablets

In a crossover study in 18 healthy subjects a single 500-mg dose of atovaquone given after a **high-fat standard breakfast** (23 g of fat) increased the AUC by 3.3-fold, when compared with the fasted state.[4] In a further study of similar design, 2 slices of **toast** alone had no effect on the AUC of atovaquone, 2 slices of **toast with 23 g of butter** increased the AUC by threefold, and 2 slices of **toast with 56 g of butter** increased the AUC by 3.9-fold.[4]

Mechanism

Atovaquone is a highly lipophilic compound, which shows considerable inter-individual variability in absorption. Dietary fat increases the rate and extent of atovaquone absorption from both the suspension and the tablets, probably by increasing its solubility in the gut. The suspension has about a twofold higher oral bioavailability than the tablets when given with food or when fasting.

Importance and management

Established interactions of clinical importance. Atovaquone suspension used for the treatment or prevention of pneumocystis pneumonia must be taken with food, since this is likely to increase the likelihood of successful treatment and survival.[5,6] Alternatively, an enteral nutritional supplement with a high-fat content appears to be suitable.[3] In the US, the manufacturer says that, for patients with pneumocystis pneumonia, who have difficulty taking atovaquone suspension with food, parenteral treatment (with other drugs) should be considered.[6]

Similarly, atovaquone/proguanil tablets used for the treatment or prophylaxis of malaria should be taken with a milky drink or with food to maximise absorption.[7,8] Be aware that if patients are unable to tolerate food, the systemic exposure to atovaquone will be reduced.[7] In this situation, monitoring of parasitaemia to ensure efficacy would seem advisable.

Atovaquone + Macrolides

Azithromycin and erythromycin do not appear to interact with atovaquone to a clinically significant extent, and the concurrent use of azithromycin and atovaquone may be beneficial in some diseases.

Clinical evidence, mechanism, importance and management

(a) Azithromycin

In a small study in 8 HIV-positive children given azithromycin suspension 5 mg/kg daily alone, or with atovaquone suspension 30 mg/kg daily for pneumocystis pneumonia, the maximum serum concentration and $AUC_{0\text{-}24}$ of azithromycin were reduced by about 30% by atovaquone. However, due to the large inter-subject variability in azithromycin pharmacokinetics, there were insufficient patients for this reduction to be statistically significant.[1]

A study in 58 patients compared the efficacy of atovaquone 750 mg twice daily and azithromycin (500 mg on day 1 followed by 250 mg daily) with the standard treatment of clindamycin and quinine in patients with non-life threatening babesiosis (a tick-borne, malaria-like illness). The two combinations were of similar efficacy, and the frequency of adverse effects in the 40 patients taking azithromycin with atovaquone was significantly less than that in the 18 patients taking quinine and clindamycin (15% compared with 72%). However, no pharmacokinetic data was recorded.[2] There are also reports of the successful treatment of babesiosis with azithromycin and atovaquone in a further 2 patients.[3,4] Another efficacy study in HIV-positive children found that the combination of azithromycin with atovaquone was as effective as co-trimoxazole for the prophylaxis of bacterial infections, and that the adverse effect profiles were similar. However, the patients taking co-trimoxazole were known to have taken it without problem previously and this may explain differences between this study and an earlier one which reported a higher rate of adverse effects with co-trimoxazole than with atovaquone alone.[5]

Information on a possible pharmacokinetic interaction appears to be limited to one report.[1] However, the clinical studies[2-5] appear to indicate that the efficacy of either drug is not affected when used in combination. Therefore, no particular precautions appear to be necessary if both drugs are given.

(b) Erythromycin

A preliminary analysis of 191 patients with AIDS given atovaquone as part of efficacy studies, found that erythromycin was not associated with any change in steady-state atovaquone serum levels. Erythromycin was represented by fewer than 5 subjects.[6] However, note that this kind of analysis provides only the very broadest indication that interactions might or might not occur.

Atovaquone + Miscellaneous

Preliminary evidence suggests that a number of drugs given in clinical studies do not interact with atovaquone.

Clinical evidence, mechanism, importance and management

An analysis of 191 patients with AIDS, given atovaquone as part of efficacy studies, found that when normalised for plasma albumin, bodyweight, and the absence of other drugs, the expected steady-state plasma levels of atovaquone were 14.8 micrograms/mL. Steady-state atovaquone plasma levels achieved in the presence of other drugs were examined in an attempt to identify possible interactions. **Fluconazole** and **prednisone** were associated with increases of 2.5 and 2.3 micrograms/mL, respectively, whereas **paracetamol** (**acetaminophen**), **aciclovir**, **opioids**, **antidiarrhoeals**, **cephalosporins**, **benzodiazepines** and **laxatives** were associated with decreases of greater than 3.4 micrograms/mL. **U plasma protein binders** [not defined], **clofazimine**, **antacids**, **clotrimazole**, **NSAIDs**, **ketoconazole**, **hydroxyzine**, **megestrol**, **antiemetics** (other than 'metoclopramide', (p.240)), **other systemic steroids**, and **H_2-receptor antagonists** were not associated with any change in steady-state atovaquone serum levels. **U plasma protein binders** and **clofazimine** were represented by fewer than 5 subjects.[1]

The kind of analysis described above[1] provides only the very broadest indication that interactions might or might not occur between atovaquone and these drugs; however, it would appear that no dosage adjustments are necessary when these drugs are used with atovaquone.

1. Sadler BM, Blum MR. Relationship between steady-state plasma concentrations of atovaquone (C_{ss}) and the use of various concomitant medications in AIDS patients with *Pneumocystis Carinii* (sic) pneumonia. IXth Int Conf AIDS & IVth STD World Congr, Berlin, 1993. 504.

Atovaquone + Proguanil

There appears to be no clinically relevant pharmacokinetic interaction between atovaquone and proguanil.

Clinical evidence, mechanism, importance and management

Atovaquone did not affect the pharmacokinetics of proguanil in a comparative study of 4 patients taking proguanil 200 mg twice daily for 3 days and 12 patients taking proguanil 200 mg twice daily with atovaquone 500 mg twice daily for 3 days.[1] A similar lack of interaction was seen in 18 healthy subjects given proguanil 400 mg daily with atovaquone 1 g daily for 3 days.[2]

In contrast, in a longer study, 13 healthy subjects were given a single 250/100-mg dose of atovaquone/proguanil, then, after an interval of one week, they were given daily doses for 13 days. There was no change in the AUC of atovaquone from single dose to steady state, indicating that accumulation did not occur. However, in the 9 subjects who had normal levels of the cytochrome P450 isoenzyme CYP2C19, the AUC of proguanil was modestly increased at steady state and the AUC of the active metabolite, cycloguanil, was modestly decreased. It was suggested that atovaquone may have inhibited the production of cycloguanil by CYP3A4. However, since this study had no arm with each drug alone, it is impossible to determine whether these changes in pharmacokinetics were due to an interaction or not.[3]

A pharmacokinetic interaction is not established. However, any interaction would be of little clinical relevance, since the efficacy of the combination product for malaria prophylaxis is established (up to 12 weeks). The enhanced activity of the combination may, in part, be due to proguanil lowering the effective concentration at which atovaquone collapses the mitochondrial potential in malaria parasites.[4]

Atovaquone + Rifamycins

Rifampicin reduces serum atovaquone levels by about 50%, whereas atovaquone modestly raises serum rifampicin levels. Rifabutin may interact similarly, although to a lesser extent.

Clinical evidence

(a) Rifabutin

In a study in 24 healthy subjects, when atovaquone 750 mg twice daily was given with rifabutin 300 mg daily for 14 days, there was a modest 34% decrease in the AUC of atovaquone and a small 19% decrease in rifabutin levels.[1]

(b) Rifampicin (Rifampin)

A steady-state study in 13 HIV-positive subjects found that the use of atovaquone 750 mg twice daily with rifampicin 600 mg four times daily for 14 days resulted in a more than 50% reduction in the atovaquone AUC and serum levels, but a more than 30% rise in the rifampicin AUC and serum levels.[2,3]

Mechanism

Uncertain. Atovaquone is predominantly excreted (greater than 90%) as unchanged drug in the faeces,[3,4] and would not therefore be expected to be affected by cytochrome P450 enzyme induction.

Importance and management

Although information is limited these pharmacokinetic interactions appear to be established. It seems highly likely that the efficacy of atovaquone will be reduced in the presence of rifampicin, and the combination should therefore be avoided. The effect of rifabutin is smaller than that of rifampicin, and the authors of the above report suggested that no atovaquone dosage adjustment is needed.[1] The manufacturers of atovaquone still consider that rifabutin use could result in subtherapeutic atovaquone levels in some patients,[3,4] and the UK manufacturers also advise against the concurrent use of this combination.[4]

4. Wellvone Oral Suspension (Atovaquone). GlaxoSmithKline UK. UK Summary of product characteristics, March 2008.

Atovaquone + Tetracyclines

Tetracycline reduces the plasma levels of atovaquone by about 40%. Doxycycline may increase the antimalarial efficacy of atovaquone.

Clinical evidence, mechanism, importance and management

A study looking at the population pharmacokinetics of atovaquone in 24 Thai patients found that neither the oral clearance nor the volume of distribution of atovaquone were significantly affected by the concurrent use of **tetracycline**.[1] This sort of data gives only the broadest indication of whether or not an interaction occurs, and the US manufacturer of atovaquone/proguanil[2] notes that **tetracycline** may reduce plasma levels of atovaquone by about 40%. They therefore suggest that parasitaemia should be closely monitored in patients taking atovaquone/proguanil with **tetracycline**.[2,3] In the UK, the manufacturer also says that **tetracycline** should be given with caution to patients taking atovaquone suspension for pneumocystis pneumonia, until the interaction has been further studied,[4] whereas the US manufacturers of atovaquone suspension do not mention **tetracycline**.[5]

Information about other tetracyclines is largely lacking. An *in vitro* study found that **doxycycline** potentiated the antimalarial activity of atovaquone,[6] but there appears to be no information on the effect of **doxycycline** on the absorption of atovaquone.

Azoles + Antacids

The gastrointestinal absorption of itraconazole capsules and ketoconazole are markedly reduced by antacids. Itraconazole solution, fluconazole and posaconazole appear not to be affected. Similarly, voriconazole is not expected to be affected by antacids.

Clinical evidence

(a) Fluconazole

Maalox forte (**aluminium**/**magnesium hydroxide**) 20 mL did not affect the absorption of a single 100-mg dose of fluconazole in 14 healthy subjects.[1]

(b) Itraconazole

In a randomised study, 12 healthy subjects were given 30 mL of an **aluminium**/**magnesium hydroxide** antacid suspension three times daily and before bedtime for 2 days before taking a single 200-mg dose of itraconazole capsules. The antacid reduced the peak serum level and AUC of itraconazole by 70% and 66%, respectively, and delayed absorption (time to peak level increased from 3 hours to 5.1 hours).[2] In contrast, a study in 204 liver transplant patients comparing the antifungal efficacy of itraconazole oral solution with fluconazole reported that itraconazole trough levels were not affected in 16 patients also taking 'proton pump inhibitors', (p.246), 'H_2-receptor antagonists', (p.245), or antacids.[3]

For mention of a study in which some patients needed an increase in their itraconazole dose when they took ranitidine and an antacid [not named], see 'Azoles + H_2-receptor antagonists', p.245.

(c) Ketoconazole

A haemodialysis patient did not respond to treatment with ketoconazole 200 mg daily while taking **cimetidine**, **sodium bicarbonate** 2 g daily and **aluminium [hydr]oxide** 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after **cimetidine** 400 mg, its absorption was considerably reduced (AUC reduced by about 60%). When this was repeated with the addition of **sodium bicarbonate** 500 mg, the absorption of ketoconazole was reduced by about 95%. In contrast, when this was again repeated, but with the ketoconazole in an acidic solution, the absorption was increased by about 50%.[4]

A study in 4 patients found that the concurrent use of *Maalox* reduced the absorption of ketoconazole, but this was not statistically significant.[5] An anecdotal report suggested that giving ketoconazole 2 hours before a stomatitis cocktail containing *Maalox* seemed to prevent the cocktail reducing ketoconazole effectiveness.[6]

(d) Posaconazole

A study in 12 healthy subjects found that *Mylanta* (**aluminium**/**magnesium hydroxide**) 20 mL did not significantly affect the bioavailability of a single 200-mg dose of posaconazole, either when taken with food or when fasting.[7]

Mechanism

Ketoconazole is a poorly soluble base, which must be converted by the acid in the stomach into the soluble hydrochloride salt before it can be absorbed. Drugs that reduce gastric acidity, such as antacids, 'H_2-receptor antagonists', (p.245), and 'proton pump inhibitors', (p.246), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. The absorption of itraconazole, and possibly posaconazole,[8] is also affected by changes in gastric pH. Fluconazole absorption is minimally affected by changes in gastric acidity.

Importance and management

The interaction of antacids with **ketoconazole** is clinically important, but not extensively documented. Advise patients to take antacids not less than 2 to 3 hours before or after ketoconazole so that absorption can take place with minimal changes in the pH of the gastric contents. Monitor to confirm that ketoconazole is effective.

Itraconazole *capsules* appear to be similarly affected, and it would therefore be prudent to separate administration. The manufacturer of itraconazole *capsules* recommend taking antacids at least two hours after itraconazole.[9] Although the manufacturers of itraconazole *solution*[10,11] do not give any specific advice regarding concurrent use of antacids, the solution is already in a soluble form and is therefore less likely to be affected.[12]

Antacids do not appear to significantly affect **posaconazole** or **fluconazole** levels. However, the manufacturers of posaconazole still consider that its absorption may be affected by drugs that affect gastric acidity, including antacids.[13] Note, they recommend avoiding concurrent administration with other acid reducing drugs[8] such as 'H_2-receptor antagonists', (p.245), and 'proton pump inhibitors', (p.246). Based on the data with 'H_2-receptor antagonists', (p.245), antacids would not be expected to affect **voriconazole** levels.

Azoles + Cola drinks

Some cola drinks can temporarily lower the stomach pH of patients with achlorhydria or hypochlorhydria due to disease or acid-suppressing drugs. This improves the bioavailability of itraconazole and ketoconazole.

Clinical evidence

(a) Itraconazole

A study in 8 healthy subjects given itraconazole 100 mg with either 325 mL of water or *Coca-Cola* (pH 2.5) found that the peak serum itraconazole levels were more than doubled by *Coca-Cola* and the AUC of itraconazole was increased by 80%, although two of the subjects did not show this effect.[1] Another study in 30 healthy subjects compared the bioavailability of itraconazole alone or after ranitidine, both with and without a cola drink. Ranitidine reduced the absorption of itraconazole but this effect was countered by the cola drink.[2] A study in 18 fasted patients with AIDS, who absorbed itraconazole poorly, found that the absorption was restored to that of fasted healthy subjects when itraconazole was given with a cola drink.[3]

(b) Ketoconazole

In a study in 9 healthy subjects, a single 200-mg dose of ketoconazole was given after pre-treatment with omeprazole 60 mg the night before (to simulate achlorhydria), with 240 mL of water or with 240 mL of *Coca-Cola Classic*. Pre-treatment with omeprazole reduced the absorption of ketoconazole by 83%, whereas when the cola drink was also given, the absorption of ketoconazole was only reduced by 35%. However, in 2 subjects the cola drink had only minor effects on ketoconazole absorption.[4]

Mechanism

Itraconazole and ketoconazole are poorly soluble bases, which must be transformed by the acid in the stomach into a soluble hydrochloride salt. Therefore any drug or condition that reduces gastric acidity can reduce the dissolution and absorption of these antifungals. Acidic drinks, which lower the pH, can increase the absorption.

Importance and management

The interactions of itraconazole and ketoconazole with cola drinks that lower the gastric pH are established. The interaction can be exploited to

improve the absorption of these antifungals in patients with achlorhydria or hypochlorhydria, and those taking gastric acid suppressants such as 'H_2-receptor antagonists', (p.245), and 'proton pump inhibitors', (p.246), and this is recommended by some manufacturers of ketoconazole[5] and itraconazole.[6,7] For a brief mention of the use of cola to increase itraconazole levels and thereby increase ciclosporin levels, see 'Ciclosporin + Azoles', p.1226. ***Coca-Cola Classic, Pepsi*** and ***Canada Dry Ginger Ale*** can be used because they can achieve stomach pH values of less than 3, but none of the other beverages examined in one study produced such a low pH. The authors suggest that these would be less effective, although they were not actually studied. They included ***Diet Coca-Cola***, ***Diet Pepsi***, ***Diet 7-Up***, ***Diet Canada Dry Ginger Ale***, ***Diet Canada Dry Orange Juice***, ***7-Up*** and ***Canada Dry Orange Juice***.[4] The acidic drug **glutamic acid** does not appear to increase the absorption of itraconazole in fasted or fed subjects, or increase the absorption of ketoconazole in subjects pre-treated with cimetidine. See 'Azoles + Food', below, and 'Azoles + H_2-receptor antagonists', p.245, respectively.

Azoles + Food

Some foods increase the absorption of itraconazole from capsules or tablets, however food decreases the absorption of itraconazole from solution. Food increases the absorption of posaconazole from suspension. Studies with ketoconazole have shown little effect of food on absorption although one found a decrease. The bioavailability of voriconazole is modestly reduced by food. Food does not appear to affect the bioavailability of fluconazole.

Clinical evidence

(a) Fluconazole

A study in 12 healthy subjects found that food had no therapeutically relevant effect on the pharmacokinetics of a single 100-mg dose of fluconazole in capsule form.[1]

(b) Itraconazole

A study in 24 patients with superficial dermatophyte, *Candida albicans* and pityriasis versicolor infections, given itraconazole 50 or 100 mg daily, found that taking the drug with or after breakfast produced higher serum levels and gave much better treatment results than taking the drug before breakfast.[2] A later study found that the relative bioavailability of itraconazole (given as a capsule) was 54% on an empty stomach, 86% after a light meal and 100% after a full meal.[1] Similar results were found in other studies using itraconazole.[3,4] Another study investigated the absorption of itraconazole in 144 healthy subjects given itraconazole 100 mg (tablets or capsules) either in the fasting state, or immediately after a bread or a rice-based meal. This study found that while a bread-based meal more than doubled the bioavailability of itraconazole, when compared with the fasting state, in contrast a rice-based meal *reduced* the bioavailability of itraconazole by 43 to 80%.[5]

Studies with itraconazole oral solution give different results. A study in 30 healthy males given itraconazole solution 200 mg daily, either on an empty stomach or with a standard breakfast, found that the bioavailability was 29% higher when itraconazole was taken in the *fasted* state.[6]

(c) Ketoconazole

A study in 10 healthy subjects found that the AUC and peak serum concentrations of a single 200-mg dose of ketoconazole tablets were *reduced* by about 40% (levels reduced from 4.1 to 2.3 micrograms/mL) when ketoconazole was given after a standardised meal.[7]

In contrast, one study found that high-carbohydrate and high-fat diets tended to reduce the rate, but not the overall amount of ketoconazole absorbed from tablets.[8] Further, a study in 8 healthy subjects found that the absorption of single 200- or 800-mg doses of ketoconazole was not altered when the ketoconazole was taken after a standardised breakfast, although the peak serum levels were delayed. The absorption of single 400- and 600-mg doses of ketoconazole were increased by about up to 50% with food, but this was not statistically significant.[9]

(d) Posaconazole

A study in 23 healthy subjects found that the maximum plasma levels and AUC of a single 400-mg dose of posaconazole oral suspension were increased 3.4- and 2.6-fold, respectively, when given with about 230 mL of a **nutritional supplement** (*Boost Plus*) rather than in the fasting state.[10] In a further study in 20 healthy subjects, single 200-mg doses of posaconazole oral suspension were given with either a high-fat meal, a non-fat breakfast, or after a 10-hour fast. The AUC of the suspension was increased fourfold by the high-fat meal, and 2.7-fold by the non-fat breakfast, when compared with fasting.[11]

(e) Voriconazole

In a study, 12 healthy subjects were given voriconazole capsules 200 mg twice daily either with food or in the fasted state (2 hours before or after food). Food delayed the oral absorption of voriconazole by about one hour and reduced the AUC by 22%.[12]

Mechanism

Not understood.

Importance and management

Itraconazole absorption from the *capsule* formulation is best when it is taken with or after food and patients should still be advised this. However, as one study[5] found a *reduction* in the bioavailability with a rice-based meal, further study may be needed to clarify if other foods may have the opposite effects to those expected. It would be prudent to be aware that the choice of food taken with the itraconazole may not always have a positive effect on its absorption and bear this in mind in case of an unexpected response to treatment. The absorption from the acidic *liquid* formulation appears to be better when it is taken at least one hour before food, and this is recommended by the manufacturers.[13]

Posaconazole absorption from the oral suspension is improved by food, and the manufacturer recommends that posaconazole should be taken with food, or with a nutritional supplement for those who cannot tolerate food.[14]

A confusing and conflicting picture is presented by the studies with **ketoconazole**, two showing no significant change in absorption with food, and one showing a decrease. However, one manufacturer of ketoconazole says that the absorption of ketoconazole is maximal when it is taken during a meal, as it depends on stomach acidity, and it should therefore always be taken with meals.[15]

The manufacturers of **voriconazole** tablets and the US manufacturers of voriconazole suspension recommend that it should be taken at least 1 hour before or at least 1 hour after a meal.[16,17] The UK manufacturer of voriconazole suspension suggests that it should be taken at least 1 hour before or at least *2* hours after a meal.[16]

There appears to be no relevant interaction between food and **fluconazole**.

Azoles + H_2-receptor antagonists

H_2-receptor antagonists markedly reduce the gastrointestinal absorption of ketoconazole; and modestly reduce that of itraconazole (possibly halved) and posaconazole (about 40%); whereas the absorption of fluconazole and voriconazole is not significantly affected. Not all H_2-receptor antagonists have been studied, but all are expected to interact similarly.
Ketoconazole may increase the levels of ranitidine.

Clinical evidence

A. Effects of H_2-receptor antagonists on the absorption of azoles

(a) Fluconazole

In a study in 6 healthy subjects, the AUC_{0-48} of fluconazole 100 mg was reduced by only 13% by a single 400-mg dose of **cimetidine**.[1] Two other studies found that **cimetidine**[2] and **famotidine**[3] did not affect fluconazole absorption.

(b) Itraconazole

In one study, 12 healthy subjects were given **cimetidine** 400 mg twice daily or **ranitidine** 150 mg twice daily for 3 days before and after a single 200-mg dose of itraconazole. The AUC and maximum serum levels of the itraconazole were reduced, but not significantly. The largest changes were 20% reductions in the AUC and maximum serum levels with **ranitidine**.[4] A study in 204 liver transplant patients,[5] comparing the antifungal efficacy of itraconazole with fluconazole, reported that itraconazole trough levels were not affected in the 16 patients also taking H_2-receptor antagonists, 'proton pump inhibitors', (p.246), or 'antacids', (p.243).

In contrast, another study in 30 healthy subjects found that **ranitidine** 150 mg twice daily for 3 days reduced the AUC of a single 200-mg dose of itraconazole by 44%, and reduced its maximum serum levels by 52%.[6] A study of the bioavailability of itraconazole, in 12 lung transplant patients also given **ranitidine** 150 mg twice daily and an antacid four times daily, found that the serum levels of itraconazole were highly variable. Half of the patients required the dose of itraconazole to be increased from 200 to 400 mg daily to achieve satisfactory serum levels.[7]

In 12 healthy subjects, the serum levels of a single 200-mg dose of itraconazole were reduced by about 50% when they were given two doses of **famotidine** 40 mg, one dose the night before and the second dose taken one hour before itraconazole.[3] In a further study **famotidine** 20 mg twice daily was given with itraconazole 200 mg daily for 10 days to 16 patients undergoing chemotherapy for haematological malignancies. The minimum plasma levels of itraconazole were reduced by about 39%, and 8 patients did not achieve the levels considered necessary to protect neutropenic patients from fungal infections.[8]

In another study in 20 HIV-positive patients, **glutamic acid** 1360 mg, given to acidify the stomach, either with or without food did not enhance itraconazole absorption.[9]

(c) Ketoconazole

A case report describes a haemodialysis patient, who did not respond to treatment with ketoconazole 200 mg daily while taking **cimetidine**, sodium bicarbonate 2 g daily and aluminium oxide 2.5 g daily. Only when the ketoconazole dosage was increased to 200 mg four times daily did her serum levels rise. A later study in 3 healthy subjects found that when ketoconazole 200 mg was taken 2 hours after **cimetidine** 400 mg, the absorption was considerably reduced (AUC reduced by about 60%). When these two drugs were given with the addition of sodium bicarbonate 500 mg, the absorption of ketoconazole was reduced by about 95%. In contrast, when cimetidine was given with ketoconazole in an acidic solution, the absorption of ketoconazole was *increased* by about 50%.[10]

The AUC of a single 200-mg oral dose of ketoconazole was reduced by 91% in 12 fasting subjects who received **cimetidine** 300 mg two hours before ketoconazole, and then sodium bicarbonate 2 g one hour before ketoconazole. This effect was only slightly reversed by the use of **glutamic acid**.[11] Another study[2] in 24 healthy subjects found that intravenous **cimetidine** titrated to give a gastric pH of 6 or more reduced the absorption of ketoconazole by 95%. Similarly, a study[12] in 6 healthy subjects found that **ranitidine** 150 mg given 2 hours before ketoconazole 400 mg reduced its AUC by about 95%.

(d) Posaconazole

A placebo-controlled study in 12 healthy subjects found that **cimetidine** 400 mg every 12 hours, given with posaconazole 200 mg once daily for 10 days, reduced the AUC and maximum plasma levels of posaconazole by about 40%.[13]

(e) Voriconazole

A study in 12 healthy subjects found that **cimetidine** 400 mg twice daily given with voriconazole 200 mg twice daily increased the maximum plasma levels and AUC of voriconazole by about 20%, but this is not considered sufficient to warrant a dosage adjustment.[14] **Ranitidine** 150 mg twice daily had no significant effect on the AUC and maximum plasma levels of voriconazole.[14]

B. Effects of azoles on H_2-receptor antagonists

A study in 8 healthy subjects found that **itraconazole** 200 mg twice daily for 3 days increased the AUC of intravenous **cimetidine** (loading dose 0.2 mg/kg followed by an infusion of 36 mg/hour for 4 hours) by 25%.[15] A study in 12 healthy subjects found that pre-treatment with **ketoconazole** 200 mg daily for 5 days had significant effects on the pharmacokinetics of a single 150-mg dose of **ranitidine**, taken 30 minutes before ketoconazole on day 5. Ketoconazole pre-treatment increased the AUC, peak serum level and half-life of ranitidine by 74%, 78% and 56%, respectively. The effects of ranitidine on ketoconazole were not reported in this study.[16]

Mechanism

Ketoconazole is a poorly soluble base, which must be converted by the acid in the stomach into the soluble hydrochloride salt. Drugs that reduce gastric acidity, such as H_2-receptor antagonists, 'proton pump inhibitors', (p.246) or 'antacids', (p.243), raise the pH in the stomach so that the dissolution of the ketoconazole and its absorption are reduced. Conversely, anything that increases the gastric acidity increases the dissolution and the absorption (e.g. 'cola drinks', (p.243)). The absorption of itraconazole capsules, and possibly posaconazole, is similarly affected by changes in gastric pH. The absorption of fluconazole and voriconazole[17] are not affected by reductions in gastric acidity.

The slight increase in cimetidine levels in the presence of itraconazole may be due to inhibition of P-glycoprotein mediated renal tubular secretion of cimetidine,[15] and the increase in the bioavailability of ranitidine is thought to be due to inhibition of intestinal P-glycoprotein by ketoconazole.[16]

Importance and management

The interactions of the H_2-receptor antagonists with **ketoconazole** are clinically important but not extensively documented. The situation with **itraconazole** is not entirely clear, but some reduction in its absorption apparently occurs which may be of clinical significance. It would therefore be prudent to confirm that both itraconazole and ketoconazole remain effective in the presence of H_2-receptor antagonists. It has been suggested[6] that the reduction in bioavailability due to H_2-receptor antagonists can be minimised by giving itraconazole and ketoconazole with an acidic drink such as 'cola', (p.243), and this is recommended by some manufacturers.[18-20] Although there appear to be no specific studies with itraconazole *solution*, the concurrent use of drugs that affect gastric acidity, such as H_2-receptor antagonists, would *not* be expected to have a similar effect. Studies with 'omeprazole', (p.246), have found no significant reduction in the absorption of itraconazole solution. The UK manufacturer of itraconazole oral solution[21] does not give any specific advice on concurrent use of these drugs; however, the US manufacturer advises caution with concurrent use, although they expect the effect to be significantly less than that seen with itraconazole capsules.[22]

The bioavailability of **posaconazole** also appears to be reduced by cimetidine. There appear to be no data on the effects of other H_2-receptor antagonists such as ranitidine, famotidine and nizatidine. If this reduction in absorption is due to the reduction in gastric acid, then it could minimised by taking posaconazole with a cola drink, as for ketoconazole and itraconazole. However, the manufacturer currently recommends that the use of posaconazole with cimetidine or other H_2-receptor antagonists (as there are no data) be avoided if possible, unless the benefit to the patient outweighs the risk.[23] Further study is needed.

Fluconazole only interacts to a small and clinically irrelevant extent with H_2-receptor antagonists and is therefore a possible alternative to ketoconazole and itraconazole. Similarly, **voriconazole** is not significantly affected by drugs that increase gastric pH such as the H_2-receptor antagonists,[17] and no dose adjustments are necessary with concurrent use.[24]

The clinical significance of the increases in **ranitidine** bioavailability produced by ketoconazole in one isolated study[16] are unclear: however, as ranitidine has a wide therapeutic margin, dose-related toxicity arising from this interaction seems unlikely.

Azoles + Proton pump inhibitors

The bioavailability of ketoconazole, itraconazole capsules (but not oral solution) and posaconazole is reduced by omeprazole and/or esomeprazole. Other proton pump inhibitors are expected to behave similarly. The bioavailability of fluconazole and voriconazole do not appear to affected by the proton pump inhibitors. Esomeprazole levels may be increased by voriconazole, omeprazole levels are increased by ketoconazole, and omeprazole levels are markedly increased by fluconazole and voriconazole.

Clinical evidence

(a) Esomeprazole

Esomeprazole 40 mg daily reduced the maximum plasma levels and AUC of **posaconazole** 400 mg by 46% and 32%, respectively.[1] Based on data for omeprazole, and the known acid-lowering effect of esomeprazole,[2] the manufacturers predict that esomeprazole might also reduce the absorption of **itraconazole**[2] and **ketoconazole**,[2,3] which depend on a low pH for optimal dissolution and absorption.

Voriconazole may more than double the levels of esomeprazole.[3]

(b) Omeprazole

1. Fluconazole. A study in 12 healthy subjects found that omeprazole 20 mg daily for 7 days did not affect the pharmacokinetics of a single 100-mg dose of fluconazole, given after a standard breakfast.[4]

In another study in 18 healthy subjects, fluconazole 100 mg daily for 5 days markedly increased the peak plasma levels and AUC of a single 20-mg dose of omeprazole by 2.4- and 6.3-fold, respectively.[5]

2. Itraconazole. In a study, 11 healthy subjects were given omeprazole 40 mg daily for 14 days, with a single 200-mg dose of itraconazole [capsule] given after a standard breakfast on day 14. The AUC and maximum serum level of itraconazole were both reduced by about 65% by omeprazole.[6] In contrast, another study in 15 healthy subjects found that omeprazole 40 mg daily did not significantly affect the pharmacokinetics of single 400-mg doses of itraconazole or its metabolite hydroxy-itraconazole, but in this study itraconazole was given as an oral solution, and there was a large interpatient variation in mean serum levels.[7] Another study similarly reported that omeprazole had little effect on the pharmacokinetics of itraconazole oral solution.[8] A study in 204 liver transplant patients,[9] comparing the antifungal efficacy of itraconazole solution with fluconazole, reported that itraconazole trough levels were not affected in 16 patients also taking proton pump inhibitors, 'H_2-receptor antagonists', (p.245), or 'antacids', (p.243).

3. Ketoconazole. A three-way crossover study in 9 healthy fasting subjects found that omeprazole 60 mg reduced the AUC of ketoconazole 200 mg by about 80%.[10]

Another study was carried out in 10 healthy subjects to find the extent to which the cytochrome P450 isoenzyme CYP3A4 is involved in the metabolism (sulfoxidation) of omeprazole. This revealed that ketoconazole 100 to 200 mg, a known inhibitor of CYP3A4, reduced the formation of the omeprazole sulfone in both subjects with normal amounts of CYP2C19, and those deficient or totally lacking CYP2C19. However, the serum omeprazole levels were doubled in the subjects totally lacking or deficient in CYP2C19.[11]

4. Posaconazole. Esomeprazole reduces posaconazole levels (see under *Esomeprazole*, above). The manufacturers of posaconazole therefore consider that proton pump inhibitors such as omeprazole might interact similarly.[1]

5. Voriconazole. A study in 18 healthy subjects found that omeprazole 40 mg daily for 7 days increased the maximum plasma levels and AUC of voriconazole by 15% and 41%, respectively. Food was prohibited within one hour before and after each dose.[12] In another study, voriconazole 200 mg twice daily increased the maximum plasma levels and AUC of omeprazole 40 mg once daily by about twofold and fourfold, respectively.[13]

An isolated case report suggests that the use of omeprazole with voriconazole may have contributed to the 'unmasking' of an inherited long QT syndrome in a young female patient. In this case, the patient developed torsade de pointes and cardiac arrest (successfully resuscitated). However, voriconazole had been stopped 12 hours previously and this particular patient had many other contributing risk factors to the development of torsade de pointes, such as hypomagnesaemia and the use of other drugs that have been reported to increase the QT interval.[14]

(c) Rabeprazole

In a randomised, placebo-controlled study, 18 healthy subjects were given **ketoconazole** 400 mg before and after taking rabeprazole 20 mg daily for 7 days. Rabeprazole significantly decreased the **ketoconazole** AUC and maximum serum levels,[15] representing about a 30% reduction in its bioavailability.[16] There was no evidence that **ketoconazole** affected rabeprazole metabolism.[15]

Mechanism

Ketoconazole and itraconazole are poorly soluble bases, which must be converted by the acid in the stomach into the soluble hydrochloride salt. Drugs that reduce gastric secretions, such as proton pump inhibitors, 'H_2-receptor antagonists', (p.245), or 'antacids', (p.243), raise the pH in the stomach so that the dissolution and absorption of drugs such as itraconazole (in capsule form), ketoconazole and posaconazole are reduced. Conversely, anything that increases the gastric acidity increases their dissolution and absorption.[10]

Fluconazole and voriconazole almost certainly cause a rise in omeprazole and esomeprazole levels by inhibiting their metabolism by the cytochrome P450 isoenzymes CYP2C19 and CYP3A4. Ketoconazole only inhibits CYP3A4 and therefore causes a less marked rise in omeprazole levels, although in subjects deficient in CYP2C19, where the metabolism of omeprazole is more dependent on CYP3A4, ketoconazole has greater effects. Itraconazole would be expected to interact similarly to ketoconazole.

Importance and management

(a) Fluconazole

Fluconazole pharmacokinetics are not affected by **omeprazole**, and are unlikely to be affected by other proton pump inhibitors. However, fluconazole markedly increases omeprazole levels. The clinical relevance of these changes is uncertain, but not likely to be important for single-dose fluconazole regimens. More study is needed to establish whether it is advisable to reduce the omeprazole dose in those given both drugs longer-term. Note that these increases in omeprazole levels are of a similar magnitude to those seen with voriconazole, and some manufacturers recommend dose adjustments with hepatic impairment or long term use.

(b) Itraconazole

The interaction between itraconazole and **omeprazole** appears to be established, but it appears that this can be minimised by using an oral itraconazole solution. As with ketoconazole, giving itraconazole capsules with an acidic drink such as 'cola', (p.243), would minimise the interaction, and this is recommended by one manufacturer of itraconazole.[17] Monitor patients taking itraconazole for antifungal efficacy if proton pump inhibitors are also given. The UK manufacturer of itraconazole oral *solution*[18] does not give any specific advice on concurrent use of drugs that reduce gastric acidity, such as the proton pump inhibitors. However the US manufacturers advise caution on concurrent use, although they expect the effect to be significantly less than that seen with itraconazole capsules.[19] The effect of itraconazole on omeprazole is unknown, but it might be expected to increase omeprazole levels similarly to ketoconazole: any effect seems unlikely to be significant in the majority of patients.

(c) Ketoconazole

The interaction between ketoconazole and **omeprazole** appears to be established and of clinical importance. Direct evidence seems to be limited to this study, but other drugs that raise the gastric pH have a similar effect (see 'Azoles + Antacids', p.243 or 'H_2-receptor antagonists', (p.245)). Such a large reduction in the absorption of ketoconazole would be expected to result in the failure of treatment. Separating the dosages of the two drugs is unlikely to be the answer because the effect of omeprazole is so prolonged. An alternative would simply be to monitor for any inadequate response to ketoconazole if omeprazole or **esomeprazole** is also given and to raise the dosage if necessary. Giving ketoconazole with an acidic drink[10] such as 'cola', (p.243), appears to minimise the interaction, and is recommended by some manufacturers.[20] However, bear in mind that ketoconazole can also double omeprazole levels, although the clinical relevance of this is likely to be small for the majority of patients.

The interaction between ketoconazole and **rabeprazole** is also established, but the reduction in ketoconazole bioavailability is only moderate (30%) and it may be possible to accommodate this by raising the antifungal dosage. There seem to be no reports about ketoconazole and other proton pump inhibitors but they are expected to interact similarly. It would therefore be prudent to monitor for a reduced effect if other proton pump inhibitors are used with ketoconazole.

(d) Posaconazole

Posaconazole levels are reduced by esomeprazole, the manufacturer therefore currently recommends that concurrent use of proton pump inhibitors be avoided if possible.[1] Further study is needed.

(e) Voriconazole

The small increase in the bioavailability of voriconazole seen with **omeprazole** is not expected to be of general clinical significance, and no adjustment to the dose of voriconazole is required.[13,21] The isolated report[14] of torsade de pointes in a patient taking voriconazole with omeprazole is complicated by multiple factors that may have contributed to the development of QT prolongation. As voriconazole alone has been reported to cause QT prolongation, its general significance is unclear. The clinical importance of the marked rise in serum omeprazole levels caused by voriconazole is not established, but the manufacturers of voriconazole recommend that the omeprazole dose be halved,[13,21] although the US manufacturers restrict this to patients taking omeprazole 40 mg or more.[13] The manufacturers of omeprazole do not recommend routine omeprazole dose adjustments with the concurrent use of voriconazole, but suggest that consideration is given to reducing the dose in patients with hepatic impairment or if long-term treatment is required.[22] The increase in the levels of **esomeprazole** by voriconazole does not routinely require a dose adjustment of esomeprazole. However, patients taking esomeprazole in doses of more than 240 mg daily (e.g. for Zollinger-Ellison syndrome) may require a dose adjustment.[3]

Azoles + Rifabutin

Rifabutin levels are increased by fluconazole, posaconazole, voriconazole, possibly itraconazole (and therefore possibly also ketoconazole). Patients taking this combination are at increased risk of rifabutin toxicity, specifically uveitis.

Rifabutin markedly reduces the plasma levels of itraconazole (and therefore possibly also ketoconazole), posaconazole, and voriconazole. Rifabutin does not affect the metabolism of fluconazole.

Clinical evidence

(a) Fluconazole

Twelve HIV-positive patients were given zidovudine 500 mg daily from day 1 to 44, fluconazole 200 mg daily from days 3 to 30 and rifabutin 300 mg daily from days 17 to 44. Rifabutin did not significantly affect the pharmacokinetics of fluconazole,[1] but fluconazole increased the AUC of rifabutin by 82%, and increased the AUC of the rifabutin metabolite LM565 by 216%.[1] In another study in 10 patients with HIV infection, fluconazole 200 mg daily increased the AUC of rifabutin 300 mg daily by 76% and increased its maximum level by 91%. When the patients were also given clarithromycin 500 mg daily, the AUC of rifabutin was further increased to 152%.[2] There is some evidence that fluconazole increases the prophylactic efficacy of rifabutin against *Mycobacterium avium* complex disease, although there was also an increase in incidence of leucopenia.[3] Uveitis developed in 6 HIV-positive patients taking rifabutin 450 to 600 mg daily and fluconazole, 5 of whom were also taking clarithromycin,[4] which is also known to increase rifabutin levels, see 'Macrolides + Rifamycins', p.357. Uveitis has been attributed to the concurrent use of rifabutin and fluconazole in other reports.[5,6]

Rifabutin does not appear to significantly affect the metabolism of fluconazole.[7,8]

(b) Itraconazole

1. Itraconazole levels. In a three-period study, 6 HIV-positive patients were given itraconazole 200 mg daily for 14 days, rifabutin 300 mg daily for 10 days, and then both drugs for 14 days. It was found that the rifabutin reduced the peak plasma levels of itraconazole by 71% and reduced its AUC by 74%.[9]

2. Rifabutin levels. A 49-year-old HIV-positive man taking rifabutin 300 mg daily was also given itraconazole 600 mg daily. Because of low plasma levels after 3 weeks the itraconazole dose was increased to 900 mg daily. One week later the patient developed anterior uveitis. It was found that the itraconazole trough serum levels were normal but rifabutin trough serum levels were 153 nanograms/mL (expected to be less than 50 nanograms/mL after 24 hours). Rifabutin was stopped and the uveitis was treated. Symptoms resolved after 5 days.[10]

(c) Posaconazole

In a study in healthy subjects the concurrent use of posaconazole 200 mg daily and rifabutin 300 mg daily for 10 days increased the AUC of rifabutin by 72% and decreased the AUC of posaconazole by 51%, when compared with either drug alone.[11] Another study in 24 healthy subjects given posaconazole 200 mg daily for 10 days alone or starting on day 8 of a 17-day course of rifabutin 300 mg daily found that rifabutin reduced the maximum plasma concentration and AUC of posaconazole by 43% and 49%, respectively. Posaconazole increased the AUC and maximum concentration of rifabutin by 72% and 31%, respectively. Adverse effects (headache, back pain, leucopenia, eye abnormalities) were more common with the concurrent use of posaconazole and rifabutin, leading to 4 subjects given both drugs being withdrawn from the study.[12]

(d) Voriconazole

The manufacturers describe a study in which rifabutin 300 mg daily decreased the AUC and maximum plasma levels of voriconazole 200 mg twice daily by 79% and 67%, respectively. Increasing the dose of voriconazole to 350 mg twice daily in the presence of rifabutin gave an AUC of 68% and maximum plasma levels more or less the same as that achieved with voriconazole 200 mg twice daily alone.[13,14] At a dose of 400 mg twice daily, voriconazole increased the maximum plasma level and AUC of rifabutin 300 mg twice daily by about threefold and fourfold, respectively.[13,14]

Mechanism

Rifabutin increases the metabolism of itraconazole and voriconazole, probably, at least in part, by inducing their metabolism by the cytochrome P450 CYP3A subfamily. Ketoconazole would be expected to be similarly affected. Rifabutin is also an inducer of P-glycoprotein and so would be expected to reduce the levels of posaconazole, which is a substrate for P-glycoprotein.[15] Fluconazole is largely excreted unchanged in the urine and so it is not affected by rifabutin.

The azoles apparently increase rifabutin levels by inhibiting its metabolism, probably by CYP3A4. Raised rifabutin levels can cause uveitis.

Importance and management

The interaction between rifabutin and **fluconazole** is established, the general picture being that concurrent use can be advantageous. However, because of the increased risk of uveitis, the CSM in the UK says that full consideration should be given to reducing the dosage of rifabutin to 300 mg daily. The rifabutin should be stopped if uveitis develops and the patient referred to an ophthalmologist.[16] A later review suggests this 300 mg dose is associated with a reduced risk of uveitis and maintains efficacy.[17] The combination should be well monitored. Note that the effects of 'clarithromycin', (p.357), are additive with those of fluconazole.

Information on the interaction between **itraconazole** and rifabutin is very limited, but if both drugs are given, monitor for reduced antifungal activity, raising the itraconazole dosage as necessary, and watch for increased rifabutin levels and toxicity (in particular uveitis). Note that the manufacturers do not recommend concurrent use.[18,19]

The manufacturer of **ketoconazole** does not recommend concurrent use with enzyme inducers, such as rifabutin.[20] However, if concurrent use is necessary, it may be prudent to follow the same precautions suggested for itraconazole.

On the basis of the interaction between rifabutin and **posaconazole**, the manufacturer suggests that the combination be avoided unless the benefit to the patient outweighs the risk.[15] If the combination is used, monitor the efficacy of posaconazole and the toxicity of rifabutin, particularly full blood counts and uveitis.

The manufacturer in the US contraindicates the combination of **voriconazole** and rifabutin.[14] However, the UK manufacturer permits concurrent use if the benefits outweigh the risks.[13] If used together, the oral dose of voriconazole should be increased from 200 mg twice daily to 350 mg twice daily (and from 100 to 200 mg twice daily in patients under 40 kg). The intravenous dose should also be increased from 4 to 5 mg/kg twice daily. Importantly, the manufacturer advises careful monitoring for rifabutin adverse effects (e.g. check full blood counts, monitor for uveitis).[13]

Azoles + Rifampicin (Rifampin) and/or Isoniazid

Rifampicin causes only a modest increase in fluconazole clearance; however, cases of reduced fluconazole efficacy have been reported. Rifampicin very markedly reduces itraconazole, ketoconazole, and voriconazole levels, and is predicted to have similar effects on posaconazole levels.

Fluconazole does not appear to affect rifampicin pharmacokinetics, but rifampicin levels are halved by ketoconazole.

Clinical evidence

(a) Fluconazole

1. Fluconazole levels. In a study in healthy subjects rifampicin 600 mg daily for 19 days reduced the AUC of a single 200-mg dose of oral fluconazole by 23% and decreased its half-life by 19%.[1] Similarly, a study in patients with AIDS, taking fluconazole 400 mg daily for cryptococcal meningitis found that the AUC and peak plasma level of fluconazole were reduced by 22% and 17%, respectively, in 12 patients also taking rifampicin 600 mg daily, when compared with 12 similar patients not given rifampicin. There were no significant changes in clinical outcome, although the subsequent use of a lower prophylactic dose of fluconazole 200 mg with rifampicin was found to result in levels of fluconazole below the MIC of the infecting organism.[2] Another 3 patients with AIDS, taking fluconazole 400 mg daily for cryptococcal meningitis relapsed when rifampicin was added.[3] Another report briefly states that one of 5 patients taking fluconazole needed an increased dosage or a replacement antifungal when given rifampicin,[4] and a small study found that the AUC of *intravenous* fluconazole was 52% lower in 2 patients taking rifampicin, when compared with 3 patients not taking rifampicin.[5]

2. Rifampicin (Rifampin) levels. A study in 11 patients with AIDS and cryptococcal meningitis found that fluconazole 200 mg twice daily for 14 days had no effect on the pharmacokinetics of rifampicin 300 mg daily.[6] Five patients with AIDS and tuberculosis, taking rifampicin and fluconazole, had normal rifampicin levels, when compared with 14 similar patients taking rifampicin alone, but in both groups rifampicin levels were only about 28% of those predicted.[7]

3. Hypercalcaemia. There is an isolated report of severe hypercalcaemia attributed to the use of rifampicin and fluconazole in a patient with tuberculosis and pneumocystosis.[8] The clinical relevance of this case is uncertain.

(b) Itraconazole

A patient receiving antitubercular treatment including rifampicin 600 mg and isoniazid 300 mg daily was also given itraconazole 200 mg daily. After 2 weeks of treatment his serum itraconazole levels were negligible (0.011 mg/L). Even when the itraconazole dosage was doubled the levels only reached a maximum of 0.056 mg/L. When the antitubercular drugs were stopped his serum itraconazole level increased to 3.23 mg/L with a 300 mg daily dose, and were 2.35 to 2.6 mg/L with a 200 mg daily dose.[9]

A later study in 8 other patients confirmed that itraconazole levels were reduced by rifampicin but the clinical outcome depended on the mycosis being treated. Four out of 5 patients responded to treatment for a *Cryptococcus neoformans* infection, despite undetectable itraconazole levels, apparently because of synergy between the two drugs (demonstrated *in vitro*). In contrast, 2 patients with coccidioidomycosis failed to respond, and 2 others with cryptococcosis suffered a relapse or persistence of seborrhoeic dermatitis (possibly due to *M. furfur*) while taking both drugs.[10] A further study in 6 healthy subjects found that the AUC of a single 100-mg dose of itraconazole was reduced by 80% by rifampicin 600 mg daily for 3 days.[11] Very markedly reduced serum itraconazole levels (undetectable in some instances) have been seen in other healthy subjects and patients with AIDS when they were given rifampicin.[12-14]

Retrospective review of the medical records of 2 patients given itraconazole and rifampicin indicated that itraconazole was not effective until rifampicin was stopped, based on the finding of continued weight loss while on the combination, and a clear weight gain after rifampicin was stopped.[15]

(c) Ketoconazole

1. Ketoconazole levels. A study[16] in 6 healthy subjects found that rifampicin 600 mg daily reduced the AUC of ketoconazole 200 mg by 80%. Similarly, in another patient, the serum levels of ketoconazole 200 mg daily were roughly halved by rifampicin 600 mg. After 5 months of concurrent use with rifampicin and isoniazid 300 mg daily, there was a ninefold decrease in peak serum levels and the AUC was reduced by nearly 90%.[17]

A study in a 3-year-old child who had responded poorly to treatment, found that the peak serum levels and AUC of ketoconazole were both reduced by about 65% to 80% by rifampicin and/or **isoniazid**. The interaction also occurred when the dosages were separated by 12 hours. When all three drugs were given together the ketoconazole serum levels were undetectable.[18] Other reports confirm these reports of decreased ketoconazole levels with rifampicin.[19-23]

2. Rifampicin (Rifampin) levels. A study in 6 healthy subjects found that the addition of ketoconazole 200 mg twice daily for one day then 200 mg daily for 2 days to rifampicin 600 mg daily had little effect on the peak level and AUC of rifampicin.[16] In contrast, the serum rifampicin levels of a child were roughly halved by ketoconazole, but when the rifampicin was given 12 hours after the ketoconazole, the serum levels of rifampicin were unaffected.[18] Other studies also show a reduction in rifampicin levels caused by ketoconazole,[21-23] one confirming that separation of the drugs by 12 hours minimised the interaction.[21]

(d) Voriconazole

A study investigating the steady-state pharmacokinetics of voriconazole reported a case where rifampicin was inadvertently started in a patient taking voriconazole 200 mg twice daily. The peak plasma level of voriconazole was reduced from 3.92 to 0.038 micrograms/L and the AUC of voriconazole was reduced by 99% after voriconazole was given with rifampicin (dose not stated) for 30 days.[24] The manufacturer[25] notes that rifampicin 600 mg once daily decreased the maximum plasma levels and AUC of voriconazole 200 mg twice daily by about 95%. Even doubling the dose of voriconazole to 400 mg twice daily did not give adequate exposure.[25]

Mechanism

Rifampicin is an inducer of many cytochrome P450 isoenzymes, including CYP3A4, and therefore increases the metabolism of the azole antifungals by these liver isoenzymes. However, as fluconazole (unlike ketoconazole, itraconazole and voriconazole) is mainly excreted unchanged in the urine, changes to its metabolism would not be expected to have as marked an effect as on these other azoles. Furthermore, posaconazole is a substrate for P-glycoprotein. Therefore, inducers of this transport system such as rifampicin are predicted to reduce its levels.[26]

The absorption of antitubercular drugs may be reduced in patients with AIDS and an increase in rifampicin levels may be due to increased absorption in the presence of fluconazole.[7] In contrast, it is suggested that ketoconazole impairs the absorption of rifampicin from the gut. Just how isoniazid interacts is uncertain.

Importance and management

The interaction between rifampicin and **fluconazole** appears to be established and of clinical importance. Although rifampicin has only a modest effect on fluconazole levels, the cases of relapse cited above[3] and the need for an increased dosage[4] indicate that this interaction can be clinically important. Monitor concurrent use and increase the fluconazole dosage if necessary. One study suggests that a 30% increase in the fluconazole dose may be considered for serious infections if rifampicin is also given. This may be especially important during prophylaxis of cryptococcal meningitis with lower doses of fluconazole, such as 200 mg daily.[2]

The interaction between **itraconazole** and rifampicin is established and clinically important. The effect on serum itraconazole levels can be very marked indeed. The clinical importance of this interaction can apparently depend on the mycosis being treated, and therefore if the decision is taken to use both drugs monitor the outcome closely, being alert for the need to increase the itraconazole dosage. However, note that the manufacturers do not recommend the concurrent use of itraconazole and rifampicin, as its levels are so markedly reduced.[27,28]

The interactions between **ketoconazole** and rifampicin appear to be established and of clinical importance, but there is very much less information about the interaction with isoniazid. The effects on rifampicin can apparently be avoided by giving the ketoconazole at a different time (12 hours apart seems to be effective) but this does not solve the problem of the effects on ketoconazole: because of this the manufacturer suggests that concurrent use is not recommended.[29]

The manufacturer of **posaconazole** predicts that its levels may be significantly lowered when used with rifampicin. They suggest that the combination be avoided unless the benefit to the patient outweighs the risk.[26]

Voriconazole levels are very markedly reduced by rifampicin and concurrent use is contraindicated.[25,30]

Azoles + Sucralfate

The gastrointestinal absorption of ketoconazole is modestly reduced by sucralfate, whereas the absorption of fluconazole does not appear to be significantly affected.

Clinical evidence

(a) Fluconazole

Sucralfate 2 g was found to have no significant effect on the pharmacokinetics of a single 200-mg dose of fluconazole in 10 healthy subjects, confirming the results of an *in vitro* study.[1]

(b) Ketoconazole

A study[2] in 6 fasting healthy subjects found that sucralfate 1 g given 2 hours before ketoconazole 400 mg reduced its AUC by about 20%. Another study in fasting healthy subjects found that sucralfate 1 g given with glutamic acid hydrochloride reduced the AUC and maximum serum levels of a single 100-mg dose of ketoconazole by about 25%, but no significant changes were seen when the ketoconazole was given 2 hours after the sucralfate.[3]

Mechanism

There is *in vitro* evidence that an electrostatic interaction occurs between ketoconazole and sucralfate to form an ion pair that cannot pass through the gut wall.[4]

Importance and management

The interaction of sucralfate with ketoconazole is modest and of uncertain clinical importance. Any interaction may be minimised by taking sucralfate not less than 2 to 3 hours before or after the ketoconazole. No adjustments would be expected to be necessary of fluconazole is given with sucralfate.

Azoles; Fluconazole + Hydrochlorothiazide

Hydrochlorothiazide modestly increases the levels of fluconazole, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

The manufacturer notes that, in 13 healthy subjects, hydrochlorothiazide 50 mg daily increased the AUC and plasma levels of fluconazole 100 mg daily for 10 days by about 40%.[1,2] They attribute these changes to a reduction in the renal clearance of fluconazole.[2] However they say it is unlikely that a change in the fluconazole dosage will be needed in patients taking diuretics, but that the interaction should be borne in mind.[1] Any interaction is almost certainly of no relevance in a patient taking a single dose of fluconazole (e.g. for genital candidiasis).

Azoles; Itraconazole + Grapefruit and other fruit juices

Grapefruit juice impaired the absorption of itraconazole capsules in one study, but not in another. Grapefruit juice had no effect on the absorption of itraconazole oral solution. Orange juice impaired the absorption of itraconazole capsules in one study.

Clinical evidence

(a) Capsules

In one study in 11 healthy subjects, either 240 mL of double-strength grapefruit juice or water were given with and 2 hours after a single 200-mg dose of itraconazole (*Sporanox capsules, Janssen*) immediately after a standard breakfast. Grapefruit juice unexpectedly decreased the AUC of itraconazole by 43% (range 81% reduction to 105% increase), with a similar decrease in hydroxy-itraconazole levels.[1] However, another similar study found that grapefruit juice had no effect on the pharmacokinetics of itraconazole capsules (*Itrizole, Janssen*). The only apparent differences in this study were that itraconazole was given at the lower dose of 100 mg, and that 350 mL of single-strength grapefruit juice was used.[2] Furthermore, in this study,[2] **orange juice** reduced the AUC of itraconazole by an average of 41%.

(b) Oral solution

In a study in 20 healthy subjects grapefruit juice caused a small 17% increase in the AUC of itraconazole. In this study, regular strength grapefruit juice 240 mL was given three times daily for 2 days, then together with itraconazole oral solution 200 mg on the morning of the third day in the fasted state, then again 2 hours later.[3]

Mechanism

Grapefruit juice is an inhibitor of intestinal cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in itraconazole metabolism. It was therefore predicted that it would enhance itraconazole absorption, a prediction confirmed with itraconazole oral solution. However, studies with itraconazole capsules have found decreased levels and no change. The

mechanism is not known, but it has been suggested that grapefruit juice may impair the absorption of itraconazole capsules either by affecting P-glycoprotein or lowering the duodenal pH.[1]

Importance and management

Evidence is limited and somewhat conflicting. The 40% reduction in itraconazole levels from itraconazole capsules seen with grapefruit juice would be anticipated to be clinically relevant in some situations, but it was seen in only one of two single-dose studies. Similarly, the reduction in levels with orange juice might be clinically relevant. However, at present, there is insufficient evidence to recommend avoiding concurrent use. Until more is known, in the event of unexpected inefficacy or low levels of itraconazole, consider grapefruit juice or orange juice intake as a possible factor.

Itraconazole oral solution, which is better absorbed than the capsules, did not appear to be affected by grapefruit juice.

Azoles; Topical + Miscellaneous

Butoconazole, clotrimazole, econazole and fenticonazole are absorbed very poorly from the vagina so that the risk of an interaction with other drugs given systemically is small. Similarly, econazole, oxiconazole and sertaconazole are minimally absorbed through the skin, and would not be expected to cause drug interactions. However, note that there have been a few cases of miconazole cream or pessaries and one case with econazole cream interacting with oral anticoagulants.

Clinical evidence, mechanism, importance and management

(a) Intravaginal application

The manufacturer notes that 1.3 to 2.2% of the dose of intravaginal **butoconazole** cream 2% was absorbed in a study in three women.[1]

Early studies with intravaginal **clotrimazole** revealed that only a small fraction (3 to 10% of the dose) was absorbed systemically, and that this was rapidly metabolised.[2]

A study in 14 women (5 of them healthy, 4 with relapsing vulvovaginal candidiasis, and 5 with cervical carcinoma) found that the systemic absorption of **fenticonazole** nitrate from a single 1-g pessary was very small indeed. The amount absorbed, based on the amount recovered from the urine and faeces over 5 days, ranged from 0.58 to 1.81% of the original dose.[3] **Econazole** is also poorly absorbed when given intravaginally.[4]

The risk of a clinically relevant interaction with other drugs that may be present in the body would therefore seem to be very small with these antifungals used vaginally. However, for a few reports of raised INRs in women taking oral anticoagulants while using intravaginal miconazole, see 'Coumarins and related drugs + Azoles; Miconazole', p.438.

(b) Topical application

Systemic **econazole** is known to inhibit cytochrome P450 isoenzymes, but because of the very low systemic availability after topical application the manufacturer notes that clinically relevant interactions are rare.[5] However, for a case report of raised INR in a man taking warfarin while using econazole cream see 'Coumarins + Azoles; Econazole', p.436.

The manufacturer of **oxiconazole** notes that systemic absorption is low, and in healthy subjects less than 0.3% of the applied dose was recovered in the urine after topical application of the cream.[6]

Plasma levels of **sertaconazole** were below the limit of detection (2.5 nanograms/mL) when 5 patients with interdigital tinea pedis applied sertaconazole cream 2% every 2 hours for a total of 13 doses.[7]

Based on this information the risk of a clinically relevant drug interaction with systemically administered drugs and these topical azoles would seem to be very small. However, for a case report of raised INR in a man taking warfarin while using miconazole cream for a groin infection, see 'Coumarins and related drugs + Azoles; Miconazole', p.438.

Azoles; Voriconazole + St John's wort (*Hypericum perforatum*)

St John's wort, taken for two weeks, more than halved the AUC of a single dose of voriconazole.

Clinical evidence, mechanism, importance and management

In a study in 17 healthy subjects, a single 400-mg dose of oral voriconazole was given alone and on the first and last day of St John's wort (*Jarsin, Lichtwer Pharma*) given at a dose of 300 mg three times daily for 15 days. One day of St John's wort had no effect on the voriconazole $AUC_{0-\infty}$, but slightly increased the maximum serum level and AUC_{0-10} by 22%. However, when voriconazole was given on day 15, the AUC of voriconazole was decreased by 59% and there was a 2.4-fold increase in oral clearance.[1]

These results suggest that the short-term effect of St John's wort is to slightly enhance the absorption of voriconazole, whereas the longer-term effect is to induce absorption-limiting transport proteins and intestinal metabolism by cytochrome P450 isoenzymes.[1]

The slight increase in voriconazole absorption with a single dose of St John's wort is not clinically relevant. However, the reduction in voriconazole levels after 15 days of St John's wort could have a significant impact on clinical efficacy. For this reason, the manufacturers contraindicate concurrent use of St John's wort with voriconazole.[2,3] Patients taking voriconazole should be advised not to take St John's wort. Patients requiring voriconazole should be asked about current or recent use of St John's wort, since this may indicate the need to use an increased voriconazole dose, at least initially, while the metabolic effects of the herb decline.

Chloroquine + Antihistamines

Chlorphenamine appears to increase the levels and therapeutic efficacy of chloroquine. Promethazine appears to increase the levels of intramuscular chloroquine and its metabolites, although no increase was seen with oral chloroquine.

Clinical evidence and mechanism

(a) Chlorphenamine

A study in 8 children given chloroquine 25 mg/kg over 3 days found that the addition of chlorphenamine (8 mg as a loading dose then 4 mg three times daily for 7 days) significantly increased the AUC and peak concentration of chloroquine, when compared with 9 children given chloroquine alone. A shorter parasite clearance rate (reduced from 3.5 days to 2 days) and higher cure rate (increased from 67% to 88%) were reported with the combination.[1]

A study in 10 healthy subjects given chloroquine 10 mg/kg on days 1 and 2 and 5 mg/kg on day 3, alone or with chlorphenamine (8 mg as a single dose followed by 4 mg every 8 hours for 7 days), found that the combination of chloroquine with chlorphenamine significantly increased the peak level of chloroquine in erythrocytes by about 25% and doubled the erythrocyte AUC and half-life,when compared with chloroquine alone. Increased erythrocyte bioavailability is thought to reduce resistance to chloroquine. However, the clinical efficacy of this increase was not studied.[2]

A study in 41 children found that the adverse cardiac effects (QT prolongation, PR interval prolongation) of chloroquine with chlorphenamine were similar to that of chloroquine alone and these effects were less severe and occurred in fewer children when compared with halofantrine alone.[3]

(b) Promethazine

A study in 20 healthy subjects found that intramuscular promethazine hydrochloride 25 mg increased the AUC of intramuscular chloroquine phosphate 200 mg and its metabolites by 85%. This may be due to promethazine enhancing the absorption of chloroquine from the injection site or displacing it and its metabolites from binding sites in the blood. The initial rate of excretion of chloroquine and the total drug excreted within 3 hours was unaffected by promethazine.[4] The increased bioavailability of chloroquine may improve its therapeutic effects but could also increase toxicity. A study in 10 healthy subjects given chloroquine 10 mg/kg on days 1 and 2, and 5 mg/kg on day 3, alone or with promethazine (25 mg followed by 12.5 mg every 8 hours for 5 days), found that promethazine had no statistically significant effect on the plasma or erythrocyte bioavailability of chloroquine.[2]

See also 'Metronidazole + Chloroquine', p.359, for details of an isolated case of acute dystonia in a patient given chloroquine, promethazine and metronidazole.

Importance and management

Evidence is limited and many of the available studies were primarily designed to assess efficacy. Nevertheless, it would appear that the concurrent use of chloroquine and chlorphenamine, or possibly promethazine, may result in a significant increase in chloroquine levels. This appears to improve the efficacy of chloroquine in malaria treatment without increasing serious adverse effects, particularly cardiac toxicity, although minor adverse effects, such as sedation, may be increased by promethazine.

If the concurrent use of chloroquine and chlorphenamine or promethazine is considered desirable, it would seem prudent to advise patients of the increased risk of drowsiness.

Chloroquine or Hydroxychloroquine + Antacids or Kaolin

The absorption of chloroquine is moderately reduced by magnesium trisilicate and kaolin. Calcium carbonate and gerdiga may have a similar effect.
Hydroxychloroquine absorption is predicted to be similarly reduced.

Clinical evidence

Six healthy subjects were given chloroquine phosphate 1 g (equivalent to 620 mg of chloroquine base) with either **magnesium trisilicate** 1 g or **kaolin** 1 g after an overnight fast. The **magnesium trisilicate** reduced the AUC of the chloroquine by about 18% and the **kaolin** reduced it by about 29%.[1]

Related *in vitro* studies by the same authors using segments of *rat* intestine found that the absorption of chloroquine was decreased as follows: **magnesium trisilicate** 31%, **kaolin** 47%, **calcium carbonate** 52%, and **gerdiga** 36%. **Gerdiga** is a clay containing hydrated silicates with sodium and potassium carbonates and bicarbonates. It is used as an antacid and is similar to **attapulgite**.[2]

Mechanism

These antacid and antidiarrhoeal compounds adsorb chloroquine thereby reducing the amount available for absorption by the gut. Dissolution of chloroquine from tablets may also be delayed by adsorbent antacids such as **aluminium hydroxide**, **magnesium oxide** and magnesium trisilicate.[3]

Importance and management

The modest pharmacokinetic interactions between chloroquine and magnesium trisilicate or kaolin are established, but their clinical importance does not seem to have been assessed. One way to minimise any interaction is to separate the doses of the antimalarials and magnesium trisilicate or kaolin as much as possible (at least 2 to 3 hours has been effective with similar adsorption interactions) to reduce admixture in the gut. Note that one manufacturer of chloroquine[4] suggests that the concurrent use of antacids should be separated by 4 hours. There do not appear to be any clinical studies to see if other antacids behave similarly, but it may be prudent to separate the administration of any type of antacid.

The manufacturer of **hydroxychloroquine**[5] predicts that, as with chloroquine, antacids might decrease hydroxychloroquine absorption, and they recommend separating administration by 4 hours.

Chloroquine + Colestyramine

Colestyramine can modestly reduce the absorption of chloroquine, but the clinical importance of this is uncertain.

Clinical evidence, mechanism, importance and management

In a study in 5 children aged 6 to 13 years, colestyramine 4 g reduced the absorption of chloroquine 10 mg/kg by about 30%. Considerable inter-individual differences were seen.[1] This reduced absorption is consistent with the way colestyramine interacts with other drugs by binding to them in the gut. The clinical importance of this isolated report is uncertain but separating the dosages is effective in minimising the interaction of colestyramine with other drugs. It is generally advised that other drugs are given 1 hour before or 4 to 6 hours after colestyramine.

1. Gendrel D, Verdier F, Richard-Lenoble D, Nardou M. Interaction entre cholestyramine et chloroquine. *Arch Fr Pediatr* (1990) 47, 387–8.

Chloroquine or Hydroxychloroquine + H_2-receptor antagonists

Cimetidine reduces the metabolism and clearance of chloroquine, but the clinical importance of this is uncertain. Hydroxychloroquine is predicted to interact with cimetidine in the same way as chloroquine. Ranitidine does not appear to interact with chloroquine.

Clinical evidence, mechanism, importance and management

Cimetidine 400 mg daily for 4 days approximately halved the clearance of a single 600-mg dose of chloroquine base in 10 healthy subjects. The elimination half-life was also prolonged from 3.11 to 4.62 days.[1] It was suggested that these effects occurred because **cimetidine** inhibits the metabolism of chloroquine by the liver. A similar study by the same authors found that **ranitidine** does not interact with chloroquine.[2] On the basis of these data for chloroquine and cimetidine, the manufacturer of **hydroxychloroquine** states that, even though specific reports have not appeared, **cimetidine** might inhibit **hydroxychloroquine** metabolism.[3]

The clinical importance of this interaction is uncertain, but it would seem prudent to be alert for any signs of chloroquine or hydroxychloroquine toxicity during concurrent use. Ranitidine would appear to be a non-interacting alternative to cimetidine.

3. Plaquenil (Hydroxychloroquine sulfate). Sanofi-Aventis. UK Summary of product characteristics, May 2007.

Chloroquine + Imipramine

No pharmacokinetic interaction was seen in 6 healthy subjects given single doses of chloroquine 300 mg and imipramine 50 mg.[1]

1. Onyeji CO, Toriola TA, Ogunbona FA. Lack of pharmacokinetic interaction between chloroquine and imipramine. *Ther Drug Monit* (1993) 15, 43–6.

Chloroquine + Methylthioninium chloride (Methylene blue)

Methylthioninium chloride possibly reduces the exposure to chloroquine.

Clinical evidence, mechanism, importance and management

Methylthioninium chloride 130 mg twice daily given orally to 12 healthy subjects taking a 3-day course of chloroquine tended to decrease the AUC of chloroquine by about 20% without affecting renal clearance, when compared with a control group of 12 subjects receiving chloroquine with placebo. This small reduction would not be expected to be clinically relevant.[1]

1. Rengelshausen J, Burhenne J, Fröhlich M, Tayrouz Y, Kumar Singh S, Riedel K-D, Müller O, Hoppe-Tichy T, Haefeli WE, Mikus G, Walter-Sack I. Pharmacokinetic interaction of chloroquine and methylene blue combination against malaria. *Eur J Clin Pharmacol* (2004) 60, 709–15.

Chloroquine or Hydroxychloroquine + Rifampicin (Rifampin)

A woman with discoid lupus, controlled by hydroxychloroquine, rapidly relapsed when rifampicin was started. Disease control was regained when the hydroxychloroquine dosage was doubled. Data in *mice* suggests that chloroquine may interact similarly.

Clinical evidence, mechanism, importance and management

A woman with discoid lupus, which was controlled by hydroxychloroquine 200 mg daily, was also given rifampicin, isoniazid and pyrazinamide for tuberculosis. Within 1 to 2 weeks the discoid lupus flared-up again but it rapidly responded when the hydroxychloroquine dosage was doubled. The reason for this reaction is not established but the authors of the report suggest that the rifampicin (a recognised and potent cytochrome P450 enzyme inducer) increased the metabolism and clearance of the hydroxychloroquine so that it was no longer effective.[1] It also seems possible that transport by P-glycoprotein may have a part to play. It is already known that discoid lupus flare-ups can occur within 2 weeks of stopping hydroxychloroquine,[2] which gives support to the suggested mechanisms. Neither isoniazid nor pyrazinamide is likely to have been responsible for the relapse.

This seems to be the first and only report of this interaction, but what happened is consistent with the way rifampicin interacts with many other drugs. If rifampicin is added to hydroxychloroquine, the outcome should be well monitored. Be alert for the need to increase the hydroxychloroquine dosage. Data from *mice* suggests that chloroquine may interact similarly,[3] and therefore similar precautions would seem prudent.

Diethylcarbamazine + Urinary acidifiers or alkalinisers

Urinary alkalinisers can reduce the loss of diethylcarbamazine in the urine, whereas urinary acidifiers can increase the loss of diethylcarbamazine in the urine.

Clinical evidence

Two studies, one in healthy subjects[1] and the other in patients with onchocerciasis,[2] found that making the urine alkaline with **sodium bicarbonate** markedly increased the retention of diethylcarbamazine. The urinary excretion of a 50-mg dose of diethylcarbamazine was about 62% and its elimination half-life 4 hours when the urine was made acidic (pH less than 5.5) by giving **ammonium chloride**, compared with about 5% and 9.6 hours, respectively, when the urine was made alkaline (pH more than 7.5) using **sodium bicarbonate**.[1]

Mechanism

In alkaline urine most of the diethylcarbamazine is non-ionised and is therefore easily reabsorbed in the kidney by simple diffusion through the lipid membrane. The opposing effect occurs with acidic urine.

Importance and management

The clinical importance of any unsought for changes in the urinary pH brought about by the use of other drugs during diethylcarbamazine treatment has not been assessed, but be aware that its pharmacokinetics and possibly the severity of its adverse effects can be changed.

One study concluded that in practice there is no advantage in making the urine alkaline in order to be able to use smaller doses of diethylcarbamazine because the severity of the adverse reactions (the Mazzotti reaction) is not reduced, and the microfilarial counts at the end of a month are not significantly different.[2]

Echinocandins + Amphotericin B

Amphotericin B does not appear to alter the pharmacokinetics of anidulafungin, caspofungin or micafungin. The pharmacokinetics of amphotericin B are not altered by caspofungin.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

The manufacturer notes that population pharmacokinetic analysis showed no difference in the pharmacokinetics of anidulafungin in 27 patients who were also given liposomal amphotericin B, when compared with data from patients receiving anidulafungin alone. This suggests that no dose adjustment of anidulafungin is required if it is given with amphotericin B.[1,2]

(b) Caspofungin

The manufacturers of caspofungin say there were no pharmacokinetic interactions between caspofungin and amphotericin B in a study in healthy subjects.[3,4] Therefore no dose adjustments are likely to be needed on concurrent use.

(c) Micafungin

The manufacturers of micafungin state that, in drug interaction studies in healthy subjects, no change in the pharmacokinetics of micafungin occurred with concurrent use of amphotericin B.[5] Therefore no dose adjustments are likely to be needed with concurrent use.

Echinocandins + Azoles

No significant pharmacokinetic interaction appears to occur between anidulafungin and voriconazole, between caspofungin and itraconazole, or between micafungin and fluconazole or voriconazole. Micafungin may slightly increase itraconazole levels.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

In a crossover study in 17 healthy subjects the steady state maximum level and AUC of both anidulafungin and **voriconazole** were not significantly altered by concurrent use, when compared with either drug given with placebo. Intravenous anidulafungin was given at a dose of 200 mg on the first day, then 100 mg daily for 3 days. **Voriconazole** was given orally, at a dose of 400 mg every 12 hours on the first day, then 200 mg every 12 hours for 3 days.[1] No dosage adjustment of either drug appears to be necessary when they are used together.

(b) Caspofungin

Caspofungin 70 mg on day 1 and 50 mg for the next 13 days did not alter the pharmacokinetics of **itraconazole** 200 mg daily.[2] The pharmacokinetics of caspofungin were also unaltered. No dosage adjustment of either drug appears to be necessary when they are used together.

(c) Micafungin

A study in 35 healthy subjects found no evidence of a clinically relevant pharmacokinetic interaction when intravenous micafungin 150 mg was given daily for 14 days with oral **voriconazole** 400 mg twice daily on day 11 then 200 mg twice daily on days 12 to 14.[3]

A study in 62 patients undergoing a bone marrow or stem cell transplant found that the pharmacokinetics of both **fluconazole** 400 mg daily and micafungin 12.5 mg to 200 mg daily for 7 days were unaffected by concurrent use. No increase in adverse effects was seen with combined use, when compared with the use of fluconazole alone. An unpublished study in 30 healthy subjects also found similar results.[4]

The manufacturer states that in studies in healthy subjects, **fluconazole**, **itraconazole**, and **voriconazole** did not alter the pharmacokinetics of micafungin. Micafungin was found to increase the AUC and maximum concentration of **itraconazole** by 22% and 11%, respectively. Although this small change is unlikely to be of clinical significance, the manufacturers of micafungin recommend that patients taking both drugs should be monitored and the dose of **itraconazole** reduced as necessary.[5] No dose adjustments appear to be necessary with the concurrent use of **fluconazole** or **voriconazole** and micafungin.

Echinocandins + Ciclosporin

Ciclosporin appears to modestly increase caspofungin levels, and concurrent use may result in raised liver enzymes. Ciclosporin slightly raised anidulafungin levels in one study, without any serious adverse events. Micafungin may slightly decrease ciclosporin oral clearance in some subjects.

Clinical evidence, mechanism, importance and management

(a) Anidulafungin

Intravenous anidulafungin 200 mg on day one, then 100 mg daily for 7 days was given to 12 healthy subjects with oral ciclosporin solution (*Neoral*) 1.25 mg/kg twice daily on the last 4 days. Ciclosporin caused a small 22% increase in the steady-state AUC of anidulafungin, which was not considered to be clinically relevant. No dose-limiting toxicities or serious adverse events were noted. One subject had a mild increase in liver enzymes on day 6 (after 2 days of concurrent use), and the study drugs were withdrawn at this point.[1]

Anidulafungin is not expected to alter ciclosporin levels based on an *in vitro* study where anidulafungin had no effect on the metabolism of ciclosporin.[1]

The manufacturer states that no dosage adjustment of either drug is needed on concurrent use.[2]

(b) Caspofungin

The manufacturers report that in two studies in healthy subjects, ciclosporin (a single 4-mg/kg dose, or two 3-mg/kg doses 12 hours apart) increased the AUC of caspofungin by 35%. Moreover, 5 of 12 subjects (43%) had increases in AST and ALT of up to threefold. The liver enzymes returned to normal on discontinuation of both drugs, and during concurrent use the levels of ciclosporin were not affected.[3-5] These findings led to the exclusion of patients receiving ciclosporin from phase II/III studies of caspofungin.[5] Note that elevated liver enzymes (typically mild and rarely leading to discontinuation) are a common adverse effect of caspofungin alone.[3] More recently, four studies have reported retrospective analyses of the clinical use of caspofungin in a total of 75 patients taking ciclosporin.[6-9] No serious hepatic adverse events were found, and three reported no clinically significant elevations of liver enzymes;[6,8,9] however, one found 2 of 40 patients had discontinued treatment because of abnormalities in hepatic enzymes, possibly related to caspofungin and/or ciclosporin.[7] Another retrospective review of 54 patients with invasive aspergillosis also found that the concurrent use of caspofungin with ciclosporin for more than 7 days was an independent risk factor for elevated liver enzymes.[10]

The manufacturers say that ciclosporin and caspofungin can be used together if the potential benefit outweighs the risk. If they are used together, close monitoring of liver enzymes is recommended.[3,4]

(c) Micafungin

In a study in 27 healthy subjects, a single 5-mg/kg dose of oral ciclosporin (*Neoral*) was given alone, with a single 100-mg dose of intravenous micafungin, and on the last day of a 5-day course of intravenous micafungin 100 mg daily. Micafungin (at steady state) very slightly increased the AUC and half-life of ciclosporin and decreased the mean oral clearance by about 10%. However in five subjects, oral ciclosporin clearance was decreased by about 25% (up to about 60% in two patients with steady-state micafungin) The data suggest that in general micafungin does not have a clinically significant effect on ciclosporin clearance, although note that the potential effects on steady-state ciclosporin were not investigated. However, given the wide variability seen, until further data are available, it would appear to be prudent to monitor ciclosporin levels if micafungin is also given.[11]

Echinocandins + Mycophenolate

The manufacturers of caspofungin say that the pharmacokinetics of caspofungin and mycophenolate are not altered by concurrent use.[1,2] Similarly the manufacturers of micafungin found no pharmacokinetic interaction between micafungin and mycophenolate in studies in healthy subjects.[3,4] No additional precautions therefore appear to be needed with concurrent use of either caspofungin or micafungin with mycophenolate.

Echinocandins + Rifampicin (Rifampin) or other enzyme inducers

Rifampicin modestly reduces the trough levels of caspofungin. One case of caspofungin treatment failure has been reported in a patient taking rifampicin. Other potent enzyme inducers are predicted to interact similarly.
Rifampicin does not appear to alter anidulafungin clearance or affect the pharmacokinetics of micafungin.

Clinical evidence

(a) Anidulafungin

A population pharmacokinetic analysis of anidulafungin in patients with serious fungal infections found that the clearance of anidulafungin did not differ between 27 patients also taking rifampicin (rifampin) and 77 patients taking no known interacting drugs.[1]

(b) Caspofungin

A parallel-group study in healthy subjects looked at the effects of rifampicin on the pharmacokinetics of caspofungin. In the first group, rifampicin 600 mg daily was given with intravenous caspofungin 50 mg daily, started on the same day. It was found that the trough levels and AUC of caspofungin were increased by 170% and 61%, respectively, on day one. However, after 2 weeks the AUC had returned to normal, and, when compared with subjects not taking rifampicin, there was a trend to *lower* trough levels of caspofungin. In the second group of healthy subjects in this study, rifampicin 600 mg daily was given for 14 days alone and then for a further 14 days combined with caspofungin. No significant increase in the caspofungin AUC was seen on day one of concurrent use. On both day one and day 14, the trough levels of caspofungin were reduced by about 30%, without any change in the AUC, similar to the findings on day 14 in the first group. In this second group, caspofungin did not alter the pharmacokinetics of rifampicin.[2]

A case report describes a neutropenic patient with fungaemia who did not respond to intravenous caspofungin (70 mg on the first day then 50 mg daily) while taking rifampicin 600 mg daily. Although this patient was given a standard dose of caspofungin, the authors note she weighed just 47 kg and did not show even an initial response. Susceptibility testing found that the isolate was not resistant to caspofungin. The patient was subsequently successfully treated with amphotericin B. The authors suggest that caspofungin doses of more than 70 mg daily would have been required for efficacy in their patient.[3]

(c) Micafungin

The manufacturers of micafungin state that, in drug interaction studies in healthy subjects, rifampicin did not affect the pharmacokinetics of micafungin.[4]

Mechanism

Caspofungin is a poor substrate for cytochrome P450 and is not a substrate for P-glycoprotein,[5] therefore these mechanisms are not thought to be involved in the interaction with rifampicin. It is possible that the modest effect of rifampicin on caspofungin is due to induction of tissue uptake transport proteins at steady-state.[2]

Importance and management

The UK manufacturer of caspofungin recommends that consideration should be given to increasing the dose from 50 to 70 mg daily in patients taking rifampicin,[5] whereas the US manufacturer specifically states that this dose should be used.[6] A 70-mg dose has been generally well tolerated in clinical studies.[2] However, bear in mind the case report of possible caspofungin failure, even at this dose. The manufacturers also say that a population pharmacokinetic analysis suggested that the concurrent use of other metabolic inducers (**carbamazepine**, **dexamethasone**, **efavirenz**, **nevirapine** or **phenytoin**) may result in clinically meaningful reductions in the AUC of caspofungin.[5,6] They suggest considering increasing the dose of caspofungin from 50 to 70 mg daily if it is used with these enzyme inducers. Further study is needed.

No dose adjustments anidulafungin or micafungin appear to be necessary with the concurrent use of rifampicin.

Echinocandins; Caspofungin + Nelfinavir

Nelfinavir does not have a clinically relevant effect on the pharmacokinetics of multiple doses of caspofungin.

Clinical evidence, mechanism, importance and management

In a parallel-group study, healthy subjects were given nelfinavir 1.25 g every 12 hours and intravenous caspofungin 50 mg daily, started on the same day. The AUC and trough level of caspofungin were increased by 16% and 58%, respectively, on the first day, when compared with subjects receiving caspofungin alone. However, after 2 weeks of combined use, the AUC and trough level of caspofungin were similar in both groups of patients.[1] The authors note that their previous population pharmacokinetic analysis had shown that nelfinavir might decrease the AUC and trough level of caspofungin, which in the light of the controlled study, they consider to be a spurious finding.

It appears that nelfinavir does not have a clinically significant effect on the pharmacokinetics of caspofungin, when both drugs are given in multiple doses, and therefore no dosage adjustment of caspofungin is required on concurrent use.

1. Stone JA, Migoya EM, Hickey L, Winchell GA, Deutsch PJ, Ghosh K, Freeman A, Bi S, Desai R, Dilzer SC, Lasseter KC, Kraft WK, Greenberg H, Waldman SA. Potential for interactions between caspofungin and nelfinavir or rifampin. *Antimicrob Agents Chemother* (2004) 48, 4306–14.

Echinocandins; Micafungin + Miscellaneous

Micafungin may increase the AUCs of nifedipine and sirolimus. Micafungin has no effect on the pharmacokinetics of prednisolone. Nifedipine, prednisolone, ritonavir and sirolimus do not affect the pharmacokinetics of micafungin.

Clinical evidence and mechanism

(a) Nifedipine

The manufacturers state that micafungin (at steady-state) increased the AUC and maximum concentration of nifedipine by 18% and 42%, respectively, when compared with nifedipine alone. Nifedipine did not affect the pharmacokinetics of micafungin in healthy subjects.[1]

(b) Prednisolone

Prednisolone did not affect the pharmacokinetics of micafungin in a study in healthy subjects. Similarly, both single dose and multiple dose micafungin had no effect on the pharmacokinetics of prednisolone.[1]

(c) Ritonavir

Ritonavir did not affect the pharmacokinetics of micafungin in a study in healthy subjects.[1]

(d) Sirolimus

The manufacturers report that micafungin (at steady-state) increased the AUC of sirolimus by 21%, however the maximum concentration was not affected. Sirolimus did not affect the pharmacokinetics of micafungin in healthy subjects.[1]

Importance and management

Evidence is limited to these studies reported by the manufacturer. The increase in nifedipine levels is modest and would not be expected to be clinically significant in most patients. Nevertheless, the manufacturer advises increased monitoring for adverse effects and toxicity, and as the occasional patient may be affected it would seem prudent to check that blood pressure is not excessively reduced when micafungin is started.

Similarly, and increase in the AUC of sirolimus would not generally be expected to be clinically relevant. Nevertheless, the manufacturer advises increased monitoring for adverse effects and toxicity. As a greater effect in patients cannot be excluded, consider monitoring sirolimus levels when micafungin is started.

No dosage adjustments appear to be needed in patients taking prednisolone or ritonavir with micafungin, although note that ritonavir is usually prescribed as part of a regimen with other antiretrovirals, which do not appear to have been studied with micafungin.

1. Mycamine (Micafungin sodium). Astellas Pharma US, Inc. US Prescribing information, January 2008.

Flucytosine + Amphotericin B

For some fungal infections the combination of flucytosine with amphotericin B may be more effective than flucytosine alone, but amphotericin B increases the toxicity of flucytosine.

Clinical evidence, mechanism, importance and management

The combined use of flucytosine and amphotericin B is more effective than the use of flucytosine alone in the treatment of cryptococcal meningitis, as demonstrated in an early study.[1] However, amphotericin B can cause deterioration in renal function, which reduces flucytosine elimination, and may result in raised flucytosine blood levels. In addition, amphotericin B may increase the cellular uptake of flucytosine.[2] Whatever the exact mechanism, combined use increases flucytosine bone marrow toxicity. A study of 194 patients randomised to either a 4 or 6-week course of low-dose amphotericin B (initially 0.3 mg/kg daily) and maximal dose flucytosine (150 mg/kg daily, adjusted for renal function) found that severe adverse effects were common. These included azotaemia (51 patients), blood dyscrasias (52 patients), and hepatitis (13 patients).[3]

Combined therapy is the recommended treatment for some systemic fungal infections.[4] Nevertheless, flucytosine levels and renal function should be very closely monitored when the drugs are used concurrently.

Flucytosine + Antacids

Aluminium/magnesium hydroxide delays the absorption of flucytosine from the gut, but the total amount absorbed remains unaffected.[1] No additional precautions therefore appear to be needed if this antacid is given with oral flucytosine.

1. Cutler RE, Blair AD, Kelly MR. Flucytosine kinetics in subjects with normal and impaired renal function. *Clin Pharmacol Ther* (1978) 24, 333–42.

Flucytosine + Cytarabine

Some very limited evidence suggests that cytarabine may oppose the antifungal effects of flucytosine, or reduce flucytosine levels. Theoretically, their bone marrow suppressant effects might be additive.

Clinical evidence, mechanism, importance and management

A man with Hodgkin's disease treated for cryptococcal meningitis with flucytosine 100 mg/kg daily had reduced flucytosine serum and CSF levels, from a range of 30 to 40 mg/L down to undetectable levels, when he was given cytarabine intravenously. When the cytarabine was replaced by procarbazine, the flucytosine levels returned to their former values. *In vitro* tests found that cytarabine 1 mg/L completely abolished the activity of up to 50 mg/L of flucytosine against the patient's strain of *Cryptococcus*, whereas procarbazine did not.[1] In another study in a patient with acute myeloid leukaemia, the predose flucytosine level fell from 65 to 42 mg/L and the post-dose flucytosine level fell from 80 to 53 mg/L when cytarabine and daunorubicin were given. However, these levels were still within the therapeutic range. The drop in levels was attributed to an improvement in renal function rather than antagonism between the two drugs.[2]

In an *in vitro* study the antifungal effects of flucytosine against 14 out of 16 wild isolates of *Cryptococcus* were not changed in the presence of cytarabine. In the remaining two isolates, an increase in effect was seen in one and a decrease was seen the other.[2]

The evidence for any interaction is therefore very limited indeed and its general clinical importance remains uncertain. The manufacturer of flucytosine advises that strict monitoring of flucytosine levels is required if both drugs are given,[3] whereas, despite the very limited evidence, the manufacturer of cytarabine recommends avoiding concurrent use.[4] It would seem prudent to closely monitor the efficacy and clinical response to flucytosine if both drugs are needed.

Of equal concern is the fact that both drugs are bone marrow suppressants, and this effect might be additive; however, it should be standard practice to closely monitor full blood counts if either of these drugs is given, and therefore additional monitoring seems unnecessary.

Furazolidone + Miscellaneous

After 5 to 10 days of use furazolidone has MAO-inhibitory activity about equivalent to that of the non-selective MAOIs. The concurrent use of furazolidone with amfetamines or nasal decongestants (indirectly-acting sympathomimetic amines), or with tyramine-rich foods and drinks may be expected to result in a potentially serious rise in blood pressure. However, direct evidence of accidental adverse reactions of this kind does not seem to have been reported. The pressor effects of noradrenaline (norepinephrine) (a directly-acting sympathomimetic) are unchanged by furazolidone.

Clinical evidence

A study in 4 hypertensive patients found that after 6 days of treatment with furazolidone 400 mg daily, the pressor responses to **tyramine** or **dexam-**

fetamine had increased two to threefold, and after 13 days had increased by about tenfold. These responses to furazolidone were about the same as those found in 2 other patients taking the MAOI pargyline.[1] The MAO-inhibitory activity of furazolidone was confirmed by measurements taken on jejunal mucosal samples.[2]

The pressor effects of **noradrenaline** (**norepinephrine**) were unchanged by furazolidone.[1]

Mechanism

The MAO-inhibitory activity of furazolidone is not immediate and may in fact be due to a metabolite of furazolidone.[3] It develops gradually so that after 5 to 10 days of use, amfetamines and tyramine (indirectly-acting sympathomimetics) will interact with furazolidone in the same way as they do with other non-selective MAOIs.[2,4] More details of the mechanisms of this interaction are to be found elsewhere, see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395 and 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388.

Importance and management

The MAO-inhibitory activity of furazolidone after 5 to 10 days of use is established, but reports of hypertensive crises either with sympathomimetics or tyramine-containing foods or drinks appear to be lacking. This may be, in part, a reflection of the fact that furazolidone may be given for just 2 to 5 days. Notwithstanding, it would seem prudent to warn patients given furazolidone not to take any of the drugs, foods or drinks that are prohibited with non-selective MAOIs. See the appropriate monographs on 'MAOIs', (p.1370) for more detailed lists of these drugs, 'foods', (p.1395), and 'drinks', (p.1393).

No adverse interaction would be expected with many of the inotropes and vasopressors that are 'directly-acting sympathomimetics', (p.1388), such as noradrenaline (norepinephrine).

Furazolidone + Proton pump inhibitors

Omeprazole modestly reduces the serum levels of furazolidone. Other proton pump inhibitors could interact similarly.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that omeprazole 20 mg twice daily for 5 days reduced the peak serum level of a single 200-mg dose of furazolidone by about 30%. Omeprazole may alter the bioavailability of furazolidone by reducing its dissolution or increasing its degradation before it reaches the intestine and/or inducing its first-pass metabolism.[1] The clinical relevance of this modest change is uncertain, as there are a large number of clinical studies describing the successful combination of furazolidone with omeprazole in regimens to eradicate *H. pylori*. However, there is some evidence that success rates are unacceptable if low-dose furazolidone (100 mg twice daily) rather than standard dose (200 mg twice daily) is used.[2] It is possible that a pharmacokinetic interaction could play a part in this finding. It may be prudent to be alert for a decrease in the effects of low doses of furazolidone if it is given with omeprazole outside of an established regimen. Other proton pump inhibitors do not appear to have been studied, but if the proposed mechanism is correct, it seems likely that they would interact similarly.

Griseofulvin + Food

The rate and probably extent of griseofulvin absorption is markedly increased if it is taken with a high-fat meal.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects found that the absorption of micronised griseofulvin 125 mg (*Fulcin*) was enhanced if it was given with a fatty meal rather than in the fasting state, as assessed by a 37% increase in griseofulvin urinary excretion.[1] Other studies similarly found that the absorption of griseofulvin at 4 and 8 hours was approximately doubled when it was taken with a high-fat meal.[2,3] A further study in 12 healthy subjects found that the higher the fat content of the meal the higher the bioavailability of griseofulvin (70% increase in bioavailability with a low-fat meal and 120% increase with a high-fat meal, when compared with fasting state absorption).[4] However, another study found that although food increased the rate of absorption of micronised and PEG-ultramicronised griseofulvin, the extent of absorption was not changed.[5] Another report suggested that giving griseofulvin with food tended to reduce the differences in the bioavailability of griseofulvin from micronised and ultramicronised tablets.[6] Enhanced absorption was also found with a formulation of griseofulvin in a **corn oil** emulsion, when compared with tablets or an aqueous suspension.[7]

This interaction is established and of clinical importance. Some manufacturers have advised that griseofulvin should be given after meals, otherwise absorption is likely to be inadequate.[8]

Griseofulvin + Phenobarbital

The antifungal effects of griseofulvin can be reduced or even abolished by phenobarbital.

Clinical evidence

Two epileptic children taking phenobarbital 40 mg daily did not respond to long-term treatment for tinea capitis with griseofulvin 125 mg three times daily until the barbiturate was withdrawn.[1] Five other patients similarly did not respond to griseofulvin while taking phenobarbital (3 patients were also taking phenytoin).[2-4]

Two studies, in a total of 14 healthy subjects, found that phenobarbital 30 mg three times daily reduced the serum levels of oral griseofulvin by about one-third,[5] and the absorption of griseofulvin was reduced from about 58% without phenobarbital to 41% in the presence of phenobarbital.[6]

Mechanism

Not fully understood. Initially it was thought that phenobarbital increased the metabolism and clearance of griseofulvin,[7] but it has also been suggested that phenobarbital reduces the absorption of griseofulvin from the gut.[6] It has variously been suggested that this is due to an increase in peristalsis reducing the opportunity for absorption,[6] the formation of a complex, which makes an already poorly soluble drug even less soluble and therefore less readily absorbed,[8] and a reduction in the level of intestinal bile salts leading to reduced griseofulvin solubility.[9]

Importance and management

An established interaction of clinical importance, although the evidence seems to be limited to the reports cited. If phenobarbital must be given, it has been suggested that the griseofulvin should be given in divided doses three times a day to give it a better chance of being absorbed;[6] however, griseofulvin was given in divided doses in one of the reports describing an interaction.[1] The effect of increasing the dosage of griseofulvin appears not to have been studied. An alternative, where possible, is to use a

non-interacting antiepileptic, such as sodium valproate. This proved to be successful in one of the cases cited.[1]

Halofantrine + Antacids

Magnesium carbonate halves the maximum plasma levels of halofantrine. Aluminium hydroxide and magnesium trisilicate seem less likely to interact.

Clinical evidence

A single-dose study in healthy subjects found that **magnesium carbonate** 1 g reduced the maximum plasma levels of halofantrine 500 mg by almost 50%. The AUC was also reduced by 28%, but this was not statistically significant. The active metabolite of halofantrine, which is equally potent, was similarly affected.[1]

Mechanism

Magnesium carbonate might decrease the absorption of halofantrine. An *in vitro* study showed that the halofantrine adsorptive capacity of various antacids was highest for magnesium carbonate, intermediate for **aluminium hydroxide**, and least for **magnesium trisilicate**.[1]

Importance and management

The pharmacokinetic interaction between halofantrine and magnesium carbonate appears to be established. Its clinical importance does not seem to have been assessed, but the authors note that the clinical efficacy of halofantrine is related to peak levels, and therefore they consider that magnesium carbonate might affect antimalarial efficacy.[1] One way to minimise the interaction is to separate the dosages of halofantrine and magnesium carbonate as much as possible (at least 2 to 3 hours has worked with other drugs that interact with antacids in this way) to reduce admixture in the gut. There do not appear to be any studies to see if other antacids behave similarly, but the *in vitro* data with aluminium hydroxide and magnesium trisilicate (see Mechanism, above) suggest that they are less likely to interact.[1]

Halofantrine + Miscellaneous

Halofantrine prolongs the QT interval and therefore should not be used with other drugs that can prolong the QT interval because of the increased risk of cardiac arrhythmias. The concurrent and sequential use of halofantrine and mefloquine markedly increased the risk of clinically important increases in the QT interval.

Pyrimethamine/sulfadoxine and tetracycline have been shown to increase halofantrine levels. *In vitro* studies suggest that diltiazem, erythromycin, ketoconazole, mefloquine, quinine, and quinidine might also increase the toxicity of halofantrine. Fatty food markedly increases halofantrine levels. Grapefruit juice has a similar effect.

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

A study in *animals* found that **ketoconazole** roughly doubled the AUC of halofantrine and inhibited its metabolism to the equipotent metabolite, desbutylhalofantrine.[1] In *in vitro* studies, **ketoconazole** markedly inhibited the metabolism of halofantrine by CYP3A4.[2,3] It has been suggested that the rise in halofantrine levels could reasonably be expected to increase toxicity.[2,3] Other CYP3A4 inhibitors, such as **diltiazem** and **erythromycin**, also inhibited the metabolism of halofantrine *in vitro*,[3] which is in line with their known clinical effects on other CYP3A4 substrates. It would therefore seem prudent to be cautious if any of these drugs, or other known CYP3A4 inhibitors (see 'Table 1.4', (p.6), for a list), are given with halofantrine, as raised halofantrine levels may increase its adverse cardiac effects, see *Drugs that prolong the QT interval*, below. *In vitro* studies[2,3] also found that **quinine** and **quinidine** had moderate inhibitory effects on halofantrine metabolism by CYP3A4, but note that these drugs are not known to be clinically significant inhibitors of this isoenzyme. Probably of more importance is the potential for additive cardiac effects, see *Drugs that prolong the QT interval*, below.

(b) Drugs that prolong the QT interval

Halofantrine, in therapeutic doses, can prolong the QT interval in the majority of patients, causing ventricular arrhythmias in a very small number. By 1993, worldwide, 14 cases of cardiac arrhythmias associated with halofantrine had been reported, and 8 patients were known to have died. In order to reduce the likelihood of arrhythmias, in 1994 the CSM in the UK advised that halofantrine should not be taken with drugs that may induce arrhythmias. They named **chloroquine**, **mefloquine**, **quinine**, **tricyclic antidepressants**, **antipsychotics**, **certain antiarrhythmics**, **terfenadine** and **astemizole**, as well as drugs causing electrolyte disturbances.[4] Although not listed, it would seem prudent to avoid other drugs that prolong the QT interval. For a list, see 'Table 9.2', (p.290)'.

Animal studies found that although **mefloquine** alone did not significantly alter the QTc interval, it enhanced the effects of halofantrine by increasing blood levels.[5] Similarly, a study in patients with malaria found that the risk of clinically relevant QT prolongation was increased twofold when halofantrine was used after **mefloquine** failure (7 of 10 patients), when compared with use as primary treatment (18 of 51 patients). However, the authors note that their population had longer baseline QT intervals than the average population, which may have made them more susceptible to the effects of halofantrine[6] The manufacturers of **mefloquine**[7,8] contraindicate the concurrent use of halofantrine, and the sequential use of halofantrine after **mefloquine** treatment.

(c) Food

A study in 6 healthy subjects found that the maximum plasma levels and AUC of a single 250-mg dose of halofantrine were increased by about 6.6-fold and 2.9-fold, respectively, when given with a **fatty meal** rather than in a fasting state. The AUC of the metabolite desbutylhalofantrine was also increased.[9] *Animal* data suggest that **fats** may reduce the presystemic metabolism of halofantrine.[1] As this is likely to increase the risk of halofantrine-induced arrhythmias (see *Drugs that prolong the QT interval*, above), halofantrine should not be taken with **meals**, but should be taken on an empty stomach.[4]

(d) Grapefruit juice or Orange juice

A crossover study in 12 healthy subjects given halofantrine 500 mg with 250 mL of either water, orange juice or grapefruit juice (standard strength), found that grapefruit juice increased the AUC and peak plasma levels of halofantrine by 2.8-fold and 3.2-fold, respectively. The QTc interval increased by 17 milliseconds with halofantrine, and by 31 milliseconds when grapefruit juice was also given. Orange juice did not affect the pharmacokinetics or pharmacodynamics of halofantrine.[10] These data suggest that grapefruit juice should be avoided by patients taking halofantrine due to the increased risk of arrhythmias.[10]

(e) Pyrimethamine/Sulfadoxine

In a preliminary study in healthy subjects, pyrimethamine/sulfadoxine (*Fansidar*) raised the AUC_{0-6} and peak plasma levels of halofantrine by about 60%, without changing the overall AUC. This might lead to an increased incidence of arrhythmias,[11] see *Drugs that prolong the QT interval*, above.

(f) Tetracyclines

A study in 8 healthy subjects found that **tetracycline** 500 mg twice daily for 7 days increased the maximum plasma levels, AUC and elimination half-life of a single 500-mg dose of halofantrine by 146%, 99%, and 73%, respectively. Increases in the major metabolite of halofantrine also occurred in the presence of **tetracycline**.[12] As both halofantrine and **tetracycline** are excreted into the bile, competition for this elimination route may result in increased plasma levels. There may be an increased risk of halofantrine toxicity if it is used with higher doses of tetracycline.[12]

Hydroxyquinoline (Oxyquinoline) + Zinc oxide

The presence of zinc oxide inhibits the therapeutic effects of hydroxyquinoline in ointments.

Clinical evidence

The observation that a patient had an allergic reaction to hydroxyquinoline in ointments with a paraffin base, but not a zinc oxide base, prompted further study of a possible incompatibility. The subsequent study in 13 patients confirmed that zinc oxide reduces the eczematogenic (allergic) properties of the hydroxyquinoline. However, it also inhibits its antibacterial and antimycotic effects, and appears to stimulate the growth of *Candida albicans*.[1]

Mechanism

It seems almost certain that the zinc ions and hydroxyquinoline form chelates, which have little or no antibacterial properties.[1,2]

Importance and management

The documentation is limited but the reaction appears to be established. There is no point in using zinc oxide to reduce the allergic properties of hydroxyquinoline if, at the same time, the therapeutic effects disappear.

Ivermectin + Food

The bioavailability of ivermectin is significantly increased by food.

Clinical evidence, mechanism, importance and management

In a study, 11 subjects were given ivermectin 30 mg after overnight fasting three times a week for one week and then a single 30-mg dose of ivermectin 20 minutes after a **high-fat breakfast**. The AUC and maximum plasma levels of ivermectin were increased by around 2.6-fold and threefold, respectively, by food.[1] The manufacturers recommend that ivermectin is taken on a empty stomach with water.[2]

1. Guzzo CA, Furtek CI, Porras AG, Chen C, Tipping R, Clineschmidt CM, Sciberras DG, Hsieh JY-K, Lasseter KC,. Safety, tolerability, and pharmacokinetics of escalating high doses of ivermectin in healthy adult subjects. *J Clin Pharmacol* (2002) 42, 1122–33.
2. Stromectol (Ivermectin). Merck & Co., Inc. US Prescribing information, September 2008.

Ivermectin + Levamisole

Levamisole may markedly increase the bioavailability of ivermectin. Ivermectin does not alter the pharmacokinetics of levamisole.

Clinical evidence, mechanism, importance and management

A study in 28 healthy subjects given levamisole 2.5 mg/kg, alone or with ivermectin 200 micrograms/kg, found that ivermectin had no effect on the AUC or maximum plasma level of levamisole. However, the AUC of ivermectin was twofold higher in patients given levamisole, when compared with historical values in subjects who had received ivermectin alone.[1] An associated study in 44 patients with *Onchocerca volvulus* infections found that levamisole given with ivermectin was neither macrofilaricidal nor more effective against microfilariae and adult worms than ivermectin alone. In addition, patients taking both drugs had a higher incidence of pruritus, arthralgia and fever than those taking ivermectin alone.[1] Concurrent use need not be avoided, but it would seem prudent to be alert for an increase in adverse effects if both drugs are thought to be necessary.

1. Awadzi K, Edwards G, Opoku NO, Ardrey AE, Favager S, Addy ET, Attah SK, Yamuah LK, Quartey BT. The safety, tolerability and pharmacokinetics of levamisole alone, levamisole plus ivermectin, and levamisole plus albendazole, and their efficacy against *Onchocerca volvulus*. *Ann Trop Med Parasitol* (2004) 98, 595–614.

Ivermectin + Orange juice

Orange juice modestly reduces the bioavailability of ivermectin.

Clinical evidence, mechanism, importance and management

A study in 16 healthy subjects found that the AUC and peak plasma levels of a single 150-micrograms/kg dose of ivermectin were reduced by 36% and 39%, respectively, when the ivermectin was given with orange juice (750 mL over 4 hours) rather than with water. The mechanism for the reduced bioavailability is not known but it does not seem related to P-glycoprotein activity.[1] The clinical relevance of these changes is uncertain, although with an AUC decrease of this size, a reduction in the efficacy of ivermectin given for systemic infections may be a possibility. Further study is needed.

1. Vanapalli SR, Chen Y, Ellingrod VL, Kitzman D, Lee Y, Hohl RJ, Fleckenstein L. Orange juice decreases the oral bioavailability of ivermectin in healthy volunteers. *Clin Pharmacol Ther* (2003) 73, P94.

Ivermectin + Praziquantel

No clinically significant pharmacokinetic interaction appears to occur between praziquantel and ivermectin.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 23 healthy subjects were given a single dose of praziquantel 40 mg/kg alone or with single doses of a combination of albendazole 400 mg and ivermectin 200 micrograms/kg. The pharmacokinetics of ivermectin and praziquantel were not significantly affected by concurrent use, except for a small 10% reduction in praziquantel volume of distribution. No serious adverse effects were reported.[1] Modest effects were seen on the pharmacokinetics of albendazole, see 'Albendazole + Praziquantel', p.237.

From this study it would appear that the concurrent use of ivermectin and praziquantel has no clinically significant effects on the pharmacokinetics of either drug. No additional precautions appear to be necessary if both drugs are given.

1. Na-Bangchang K, Kietinun S, Pawa KK, Hanpitakpong W, Na-Bangchang C, Lazdins J. Assessments of pharmacokinetic drug interactions and tolerability of albendazole, praziquantel and ivermectin combinations. *Trans R Soc Trop Med Hyg* (2006) 100, 335–45.

Lumefantrine + CYP2D6 substrates

The manufacturer of artemether/lumefantrine[1] notes that *in vitro* data indicate that lumefantrine significantly inhibits CYP2D6. As a consequence, they contraindicate the use of co-artemether in patients taking any drug that is metabolised by CYP2D6, and they give flecainide, metoprolol, imipramine, amitriptyline, clomipramine as examples (for a list of CYP2D6 substrates, see 'Table 1.3', (p.6)). These contraindications seem unnecessarily restrictive, especially since none of the drugs they give as examples are contraindicated with other established inhibitors of CYP2D6. Until more is known, it would be prudent to closely monitor the effects of any CYP2D6 substrate in patients for whom artemether/lumefantrine is considered the antimalarial drug of choice.

1. Riamet (Artemether/Lumefantrine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2007.

Mefloquine + Ampicillin

Ampicillin modestly increases the plasma levels of mefloquine and reduces its half-life.

Clinical evidence, mechanism, importance and management

In a study, 8 healthy subjects were given ampicillin 250 mg four times daily for 5 days, with a single 750-mg dose of mefloquine on day 2. The maximum plasma level and 5-day AUC of mefloquine were increased by 34% and 49%, respectively, although the $AUC_{0-\infty}$ was not significantly increased. Ampicillin reduced the half-life of mefloquine from 17.7 to 15.3 days. No increase in adverse events was seen. These pharmacokinetic effects may be due to an increase in mefloquine bioavailability, possibly due to a reduction in its enterohepatic recycling.[1] The clinical relevance of these changes is uncertain, but the authors consider that the changes in elimination are unlikely to be clinically significant, since these occur after the resolution of malaria.[1]

1. Karbwang J, Na Bangchang K, Back DJ, Bunnag D. Effect of ampicillin on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* (1991) 40, 631–3.

Mefloquine + Artemisinin derivatives

Artemether pretreatment may modestly reduce mefloquine levels, whereas artemisinin does not affect the pharmacokinetics of mefloquine. If mefloquine is given shortly after artesunate its levels are lowered, but giving mefloquine two days in to artesunate treatment appears to raise mefloquine levels. The levels of lumefantrine were modestly reduced by mefloquine pretreatment, but the levels of artemether and of mefloquine were not affected. No adverse effects on the QT interval were seen.

Clinical evidence, mechanism, importance and management

(a) Artemether

In a study, 15 patients with acute uncomplicated falciparum malaria were given a single 750-mg dose of mefloquine, either alone or 24 hours after a single 300-mg dose of artemether. The AUC of mefloquine was reduced by 27%, when compared with 7 patients receiving mefloquine alone. However, the addition of artemether improved the rate of parasite clearance, and cure rates were similar between the groups.[1] Another study in 8 healthy subjects found the pharmacokinetics of single doses of artemether 300 mg and mefloquine 750 mg were not significantly affected by concurrent use. No serious adverse effects were reported.[2]

(b) Artemether/Lumefantrine

In a study, 42 healthy subjects were given 6 doses of artemether/lumefantrine 80/480 mg over 60 hours, starting 12 hours after a short course of mefloquine (3 doses totalling 1 g given over 12 hours). The pharmacokinetics of mefloquine and artemether were unaffected by sequential use, but the maximum plasma concentrations and AUC of lumefantrine were reduced by 29% and 41%, respectively. However, given that the plasma levels of lumefantrine are usually highly variable, these changes were not thought large enough to affect the efficacy of treatment.[3]

In another study, similar sequential use of these drugs did not affect the QT interval, and drug levels were also considered adequate for treatment.[4] The authors considered that adverse effects on the QT interval are unlikely to occur if artemether/lumefantrine is given after mefloquine prophylaxis or treatment.

These data indicate that sequential use of mefloquine then artemether/lumefantrine is unlikely to require any special precautions. The manufacturer of artemether/lumefantrine notes that prolongation of the QT interval was seen in about 5% of patients in clinical studies, although they say this could be disease related. They state that, due to the limited data on safety and efficacy, artemether/lumefantrine should not be given concurrently with any other antimalarial unless there is no other treatment option.[5]

(c) Artemisinin

Another study in patients with falciparum malaria found no significant pharmacokinetic interaction between artemisinin and mefloquine. In this study, patients received mefloquine 750 mg alone or artemisinin 500 mg daily for 3 days with a single 750-mg dose of mefloquine either on day 1 or day 4. There was no difference in overall efficacy between treatments, although those given artemisinin with mefloquine on the first day of treatment had the fastest parasite clearance rates.[6]

(d) Artesunate

A study, in 20 patients with acute uncomplicated falciparum malaria given mefloquine (750 mg followed after 6 hours by 500 mg), found that the levels of mefloquine were reduced by 27% and its clearance rate was increased 2.6-fold when the doses of mefloquine were given 6 and 12 hours after artesunate 200 mg. However, the patients who received the combination had shorter fever clearance and parasite clearance times than those given mefloquine alone, although the cure rate was lower for combined treatment (66%) than for mefloquine alone (75%). To prevent the pharmacokinetic interaction resulting in a reduction in its efficacy, the authors of this study recommended that mefloquine should be given when artesunate and its metabolites have cleared the circulation (the authors suggest possibly 24 hours after a dose).[7] This suggestion is supported by a study looking at the efficacy of mefloquine with artesunate, which found that the AUC of mefloquine was about 30% higher in 22 children given mefloquine on day 2 of artesunate treatment, when compared with 24 children given mefloquine on day 0 (before artesunate was started). Both groups were given mefloquine without food.[8]

In a more recent study, 179 patients with falciparum malaria were given a single 4-mg/kg dose of artesunate with a single 15-mg/kg dose of mefloquine taken either with, 8 hours, or 24 hours after the artesunate dose, found that the pharmacokinetics of mefloquine and artesunate were not affected by the timing of the doses.[9] Another pharmacokinetic study in 25 healthy subjects also found no evidence of an interaction when a single 250-mg dose of mefloquine was given at the same time as artesunate 200 mg daily for 3 days.[10]

The combined use of artesunate and mefloquine is one of the recommended treatment options in the WHO guidelines for the treatment of uncomplicated falciparum malaria, and for uncomplicated vivax malaria in selected areas.[11]

(e) Other artemisinin derivatives

In a single-dose crossover study, 10 healthy subjects were given either mefloquine 750 mg, dihydroartemisinin 300 mg (exact derivative not specified) or both drugs together. The pharmacokinetics of the drugs were unchanged on concurrent use, except for the rate of absorption of mefloquine, which was increased. Also the activity of these drugs against *Plasmodium falciparum* was synergistic, rather than additive.[12] A study in 12 patients with acute uncomplicated falciparum malaria, given either two doses of dihydroartemisinin (exact derivative not specified) 300 mg 24 hours apart, with a single 750-mg dose of mefloquine either 6 hours after the first dose of dihydroartemisinin or with the last dose of dihydroartemisinin, found no evidence of a pharmacokinetic interaction.[13]

Mefloquine + Azoles

Ketoconazole increased the AUC of mefloquine by 79%. The clinical relevance of this is uncertain, but an increase in adverse events is possible.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects a single 500-mg dose of mefloquine, given on day 5 of a 10-day course of ketoconazole 400 mg daily, increased the mefloquine AUC by 79%, the maximum level by 64% and the half-life by 34%, when compared to mefloquine alone. A 28% decrease in the AUC of the carboxylic metabolite was also seen. No significant adverse effects were reported.[1] It is probable that ketoconazole inhibits the metabolism of mefloquine by cytochrome P450 isoenzyme CYP3A4. Although the clinical relevance of this increase in mefloquine levels is not known, it seems possible that it could increase the risk of adverse effects in some patients. Until more is known, it may be prudent to be cautious in the use of mefloquine in patients taking ketoconazole.

Note that many azoles have inhibitory effects on CYP3A4, see under 'azole antifungals', (p.233). If the suggested mechanism is correct, these azoles may interact similarly, although there are no clinical reports of an interaction.

Mefloquine + Cimetidine

The levels of mefloquine may be modestly increased and/or its elimination modestly reduced by cimetidine.

Clinical evidence, mechanism, importance and management

A single 500-mg dose of mefloquine was given to 10 healthy subjects before and after they took cimetidine 400 mg twice daily for 28 days. Cimetidine had no effect on the AUC or serum levels of mefloquine, but the mefloquine half-life increased by 50% (from 9.6 to 14.4 days) and the oral clearance decreased by almost 40%.[1] In another study mefloquine was given to 6 healthy subjects and 6 patients with peptic ulcers, before and after cimetidine 400 mg twice daily for 3 days. In contrast to the first study, cimetidine increased the maximum plasma levels of mefloquine by about 42% and 20% and increased the AUC by about 37% and 32%, in the healthy subjects and patients, respectively. The elimination half-life was increased, but not to a significant extent.[2]

The findings of the first study suggest that cimetidine (a recognised enzyme inhibitor) reduces the metabolism of the mefloquine by the liver,[1] whereas the second study suggests that cimetidine may increase the rate of mefloquine absorption without significantly inhibiting its elimination.[2]

These two studies produced different findings, and an interaction is therefore not established. Nevertheless, the changes seen in both studies were modest, and unlikely to be clinically relevant in most patients taking lower doses of chloroquine for malaria prophylaxis. With higher doses of mefloquine used to treat malaria, to be on the safe side, prescribers should be alert for any evidence of increased mefloquine adverse effects (e.g. dizziness, nausea, vomiting, and abdominal pain) and psychiatric or neurological reactions during concurrent use. Note that the CSM in the UK say that any patient given mefloquine [for malaria prophylaxis] should be informed about its neurological adverse effects, and advised that, if these occur, they should seek medical advice about the use of alternative antimalarials before the next dose is due.[3]

Mefloquine + Metoclopramide

Although metoclopramide increases the rate of absorption and peak levels of a single-dose of mefloquine, the gastrointestinal adverse effects of mefloquine are possibly reduced.

Clinical evidence, mechanism, importance and management

When 7 healthy subjects took a 10-mg dose of metoclopramide 15 minutes before a single 750-mg dose of mefloquine, the absorption half-life of the mefloquine was reduced from 3.2 to 2.4 hours and the peak blood levels were raised by 31%. However, although the rate of absorption was increased, the total amount absorbed was unchanged. A possible reason for these changes is that metoclopramide increases gastric emptying causing mefloquine to reach the small intestine more quickly, which would increase the rate of absorption. Despite these changes, the toxicity of mefloquine (e.g. dizziness, nausea, vomiting, and abdominal pain) was noted to be reduced.[1] The modest increase in peak levels is probably not clinically relevant, especially with prophylactic mefloquine doses.

Mefloquine + Miscellaneous

An isolated report describes cardiopulmonary arrest in a patient taking mefloquine with propranolol. The WHO have issued a warning about the concurrent use of mefloquine with antiarrhythmics, antihistamines, beta blockers, calcium-channel blockers, digoxin, phenothiazines, pimozide, tricyclic antidepressants and some related antimalarials.

Clinical evidence, mechanism, importance and management

The WHO[1] warns, that the use of mefloquine with **antiarrhythmics**, **beta blockers**, **calcium-channel blockers**, **antihistamines**, **antidepressants** (class not specified, the manufacturers specify **tricyclic antidepressants**[2]), **digoxin**, **pimozide** and **phenothiazines** may increase the risk of arrhythmias.[1] The manufacturers of mefloquine also give these warnings, pointing out that the interactions are theoretical, and that clinically significant QTc prolongation has not been found with mefloquine alone.[2,3] Note that, of the classes mentioned, class Ic and class III antiarrhythmics, sotalol, astemizole and terfenadine are most frequently associated with QT-prolongation, and these drugs are therefore likely to present the greatest risk.[1] No formal studies on the possible adverse effects of combining any of the above drugs with mefloquine seem to have been done. One 1990 review[4] and the US prescribing information[3] briefly mention a single case of cardiopulmonary arrest (with full recovery[3]) when a patient taking **propranolol** was given a single dose[4] of mefloquine. It has been suggested that the concurrent use of beta blockers and mefloquine may also lead to bradycardia, which is an uncommon adverse effect of mefloquine,[2,3] and a known effect of the beta blockers. However, there do not appear to be any reports of an adverse interaction in the literature. It remains to be confirmed whether the effects of mefloquine and these other drugs on cardiac function are normally additive, and whether the outcome

is clinically important, although a case has been reported of the successful use of digoxin and sotalol in the treatment of mefloquine-induced atrial flutter with AV 1:1 conduction.[5] Until more is known it would seem prudent to follow the cautionary advice issued by the WHO and the manufacturers of mefloquine. Drugs that may prolong the QT interval are listed in 'Table 9.2', (p.290). Note that some quinolones can prolong the QT interval, and may also increase the risk of convulsions if given with mefloquine, see 'Mefloquine + Quinolones' p.263.

For mention that halofantrine should not be used with or after mefloquine, because of a clinically significant lengthening of the QT interval, which may be due to a pharmacokinetic interaction, see 'Halofantrine + Miscellaneous', p.258, and for mention of adverse cardiac effects when mefloquine is given with chloroquine, quinine, or quinidine, see 'Mefloquine + Quinine and related drugs', below.

Mefloquine + Primaquine

Although one study suggested that primaquine can increase both the peak serum levels and adverse effects of mefloquine, other studies have generally found no important interaction.

Clinical evidence

A preliminary report of a randomised, crossover study, in 14 healthy subjects given mefloquine 1 g, found that the addition of primaquine 15 or 30 mg raised the peak serum levels of mefloquine by 48% and 29%, respectively. Those taking the larger dose of primaquine had a transient increase in peak primaquine serum levels, and its conversion to its inactive carboxyl metabolite was also increased. Significant CNS symptoms were also experienced by those taking the larger dose of primaquine.[1]

However, these results contrast with another single-dose study in 8 healthy subjects, who were given mefloquine 750 mg with primaquine 45 mg. No increased adverse effects attributable to concurrent use were seen, and mefloquine pharmacokinetics (including the peak level) were not altered by primaquine.[2] Similarly, in a study in patients with malaria, there was no change in mefloquine pharmacokinetics when it was given with primaquine.[3] In another group in this study, the only difference in mefloquine pharmacokinetics was an 11% shorter terminal elimination half-life in those taking primaquine with mefloquine and pyrimethamine/sulfadoxine, when compared with those taking mefloquine with pyrimethamine/sulfadoxine.[3] Similarly, in another study in children given mefloquine with pyrimethamine/sulfadoxine, the addition of primaquine had no effect on the pharmacokinetics of mefloquine, and there were no serious adverse effects.[4]

The pharmacokinetics of a single 45-mg dose of primaquine were not altered by a single 10-mg/kg oral dose of mefloquine in healthy subjects.[5]

Mechanism

In vitro studies suggest that primaquine is a potent inhibitor of mefloquine metabolism.[6]

Importance and management

The bulk of the evidence suggests there is no important alteration in the pharmacokinetics or effect of mefloquine when it is given with primaquine. After treatment of vivax malaria, primaquine is used to eradicate hepatic parasites, so producing a radical cure, and the manufacturer of mefloquine specifically advises this.[7,8]

Mefloquine + Pyrimethamine/Sulfadoxine

Pyrimethamine/sulfadoxine caused a modest increase in exposure to mefloquine in healthy subjects, but had no effect on mefloquine exposure in patients.

Clinical evidence, mechanism, importance and management

In healthy subjects, a comparison of the pharmacokinetic parameters of a single 750-mg dose of mefloquine, given alone or in combination with pyrimethamine/sulfadoxine, found that the only difference was a 33% increase in mean residence time and 27% increase in the half-life of mefloquine.[1] However, in a further study in patients with malaria, there was no difference in any pharmacokinetic parameter of mefloquine 750 mg between 15 patients taking mefloquine alone and 16 patients taking mefloquine with pyrimethamine/sulfadoxine.[2] In both of these studies there was considerable inter-individual variability in the pharmacokinetics of mefloquine.[1,2] In another study in healthy subjects, the mefloquine AUC was increased by a non-significant 13% when mefloquine was given as a combination tablet containing mefloquine, sulfadoxine and pyrimethamine when compared with mefloquine given alone.[3]

These studies suggest that, at the most, a small increase in exposure to mefloquine may occur when it is given with pyrimethamine/sulfadoxine. It would seem that this is unlikely to be clinically relevant, especially in view of the inter-individual variability in mefloquine pharmacokinetics.

Mefloquine + Quinine and related drugs

Mefloquine serum levels may possibly be increased by quinine. In theory, there is an increased risk of convulsions if mefloquine is given with quinine, quinidine, or chloroquine.

Clinical evidence, mechanism, importance and management

Mefloquine 750 mg was given to 7 healthy subjects either alone, or followed 24 hours later by quinine 600 mg. The combination did not affect the pharmacokinetics of either drug, but the number of adverse effects and the period of prolongation of the QT interval was greater with the combination, although no symptomatic cardiotoxicity was seen.[1] This absence of a change in pharmacokinetics is contrary to earlier *in vitro* data and unpublished clinical observations,[2] which suggested that quinine may inhibit the metabolism of mefloquine, thereby raising its serum levels. Another study in 13 patients with uncomplicated falciparum malaria given quinine dihydrochloride 10 mg/kg as a one-hour infusion and simultaneous oral mefloquine 15 mg/kg found no evidence of a pharmacokinetic interaction, but postural hypotension was common. The QTc interval was prolonged by 12%, although no clinically significant cardiovascular interaction was reported.[3]

The manufacturers of mefloquine and the WHO say that mefloquine should not be given with quinine or related compounds (e.g. **quinidine**, **chloroquine**) since this could increase the risk of ECG abnormalities and

convulsions.[4-6] They suggest that patients initially given intravenous quinine for 2 to 3 days should delay mefloquine until at least 12 hours after the last dosing of quinine to minimise interactions leading to adverse events.[4,5] However, there seem to be no documented adverse reports of this interaction leading to convulsions.

Mefloquine + Quinolones

Three non-epileptic patients had convulsions when they were given mefloquine and a quinolone. Also, some quinolones, such as moxifloxacin, prolong the QT interval and concurrent use with mefloquine might theoretically result in additive effects.

Clinical evidence, mechanism, importance and management

A large scale survey in India of the adverse effects of mefloquine identified 3 cases of convulsions out of a total of 150 patients also taking **ciprofloxacin**, **ofloxacin** or **sparfloxacin**. All 3 patients were not epileptic, and had no family history of epilepsy. All were being treated for fever, which was due to *Plasmodium vivax* in one case, *P. falciparum* in the second, and was not established in the third. None of the patients had severe or complicated malaria, which suggests that the convulsions were not solely a result of the disease state. The **ofloxacin** was given 2 days before the mefloquine, and the other two quinolones were given together with the mefloquine.[1] The reason for the seizures is not known, but seizures are among the recognised adverse effects of both mefloquine and these quinolones. These adverse, apparently additive, effects are rare, but prescribers should be aware of the potential increased risk of convulsions when prescribing these drugs together.

Some quinolones may cause clinically relevant prolongation of the QT interval, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290. Although mefloquine alone has not been shown to cause a clinically relevant lengthening of the QT interval, caution has still been recommended when it is combined with some other drugs that may prolong the QT interval, see 'Mefloquine + Miscellaneous', p.261. It would therefore be prudent to extend this caution to these quinolones.

1. Mangalvedhekar SS, Gogtay NJ, Wagh VR, Waran MS, Mane D, Kshirsager NA. Convulsions in non-epileptics due to mefloquine-fluoroquinolone co-administration. *Natl Med J India* (2000) 13, 47.

Mefloquine + Rifampicin (Rifampin)

Rifampicin significantly reduces the plasma concentrations of mefloquine.

Clinical evidence, mechanism, importance and management

In a crossover study, 7 healthy subjects were given rifampicin 600 mg daily for 7 days with a single 500-mg dose of mefloquine on day 7. The maximum plasma level of mefloquine was reduced by 19% and its AUC was decreased by 68%. Rifampicin, a potent enzyme-inducer, was thought to have lowered mefloquine levels by inducing the cytochrome P450 isoenzyme CYP3A4 in the liver and gut wall, thereby increasing mefloquine metabolism. The clinical relevance of this reduction in mefloquine levels is uncertain, but the authors suggest that simultaneous use of rifampicin and mefloquine should be avoided to prevent treatment failure and the risk of *Plasmodium falciparum* resistance to mefloquine.[1] Until more is known, this would seem a sensible precaution.

1. Ridtitid W, Wongnawa M, Mahatthanatrakul W, Chaipol P, Sunbhanich M. Effect of rifampicin on plasma concentrations of mefloquine in healthy volunteers. *J Pharm Pharmacol* (2000) 52, 1265–9.

Mefloquine + Tetracycline

Mefloquine serum levels are modestly increased by tetracycline.

Clinical evidence, mechanism, importance and management

In a study in 20 healthy Thai men, the maximum serum levels of a single 750-mg dose of mefloquine were increased by 38% (from 1.16 to 1.6 mg/mL) by tetracycline 250 mg four times daily for one week. The AUC was increased by 30% and the half-life reduced from 19.3 to 14.4 days, without any evidence of an increase in adverse effects. It is suggested that mefloquine levels are increased because its enterohepatic recycling is reduced by competition with tetracycline for biliary excretion.[1] The authors of the report concluded that concurrent use of mefloquine and tetracycline may be valuable for treating multi-drug resistant falciparum malaria because higher mefloquine levels are associated with a more effective response. However, more study is needed to confirm these findings. There seems to be no reason for avoiding concurrent use.

1. Karbwang J, Na Bangchang K, Back DJ, Bunnag D, Rooney W. Effect of tetracycline on mefloquine pharmacokinetics in Thai males. *Eur J Clin Pharmacol* (1992) 43, 567–9.

Metrifonate + Antacids or H_2-receptor antagonists

The pharmacokinetics of metrifonate do not appear to affected by an antacid containing aluminium/magnesium hydroxide, or by pretreatment with cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Antacids

A single-dose study in healthy subjects found that the AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by the concurrent use of an **aluminium/magnesium hydroxide**-containing antacid.[1] Therefore no special precautions seem necessary with concurrent use.

(b) H_2-receptor antagonists

In a study in healthy subjects the AUC and maximum level of metrifonate and its pharmacologically active metabolite were not altered by pretreatment with either **cimetidine** or **ranitidine**.[1] Based on these results it seems unlikely that other H_2-receptor antagonists will interact with metrifonate.

1. Heinig R, Boettcher M, Herman-Gnjidic Z, Pierce CH. Effects of magnesium/aluminium hydroxide–containing antacid, cimetidine or ranitidine on the pharmacokinetics of metrifonate and its metabolite DDVP. *Clin Drug Invest* (1999) 17, 67–77.

Piperazine + Chlorpromazine

An isolated case of convulsions in a child was attributed to the use of piperazine followed by chlorpromazine.

Clinical evidence, mechanism, importance and management

A child given piperazine for pin worms developed convulsions when chlorpromazine was given several days later.[1] In a subsequent *animal* study using piperazine and chlorpromazine 4.5 or 10 mg/kg, many of the *animals* died from respiratory arrest after severe clonic convulsions.[1] However, a later *animal* study did not confirm these findings[2] and it is by no means certain whether the adverse reaction in the child was due to an interaction or not. Given that both drugs may cause convulsions, there is probably enough evidence to warrant caution if they are used concurrently.

2. Armbrecht BH. Reaction between piperazine and chlorpromazine. *N Engl J Med* (1970) 282, 1490–1.

Praziquantel + Antiepileptics; Enzyme-inducing

Phenytoin, phenobarbital and carbamazepine markedly reduce the serum levels of praziquantel. Fosphenytoin would be expected to interact similarly.

Clinical evidence

(a) Carbamazepine, Phenobarbital or Phenytoin

A comparative study of patients taking long-term phenytoin or carbamazepine and healthy subjects (10 in each group), both given a single 25-mg/kg oral dose of praziquantel, found that phenytoin and carbamazepine reduced the AUC of praziquantel by about 74% and 90%, respectively, and reduced its maximum serum levels by 76% and 92%, respectively, when compared with the healthy subjects.[1] Another study also reported low praziquantel levels (maximum levels of 42 to 540 nanograms/mL with undetectable trough levels) in patients given praziquantel 15 mg/kg daily 3 times daily for 15 days and also taking phenytoin (4 patients) or phenobarbital (8 patients). However, in this study praziquantel was still found to be very effective for neurocysticercosis, with all patients showing a marked improvement.[2]

(b) Phenytoin/Phenobarbital and Cimetidine

A patient with neurocysticercosis taking phenytoin and phenobarbital for a seizure disorder had no response to praziquantel (four courses in doses of up to 50 mg/kg daily). Praziquantel 50 mg/kg daily and dexamethasone 12 mg daily were started, and, after one week, cimetidine 400 mg four times daily was added. The patient's serum praziquantel levels more than doubled with the addition of cimetidine (maximum serum levels raised from 350 nanograms/mL to 826 nanograms/mL) and the AUC rose about fourfold, and became similar to that found in control subjects taking praziquantel alone. The patient showed marginal improvement, and continued to slowly improve over the following 4 months.[3]

Mechanism

Not established. Praziquantel appears to be metabolised by the cytochrome P450 isoenzymes CYP1A2, CYP2C19 and CYP3A4.[4] These antiepileptics and 'dexamethasone', (p.265), have cytochrome P450 enzyme-inducing effects and can therefore increase the metabolism of praziquantel. 'Rifampicin (Rifampin)', (p.266), another potent inducer of cytochrome P450, also markedly reduces praziquantel levels. Conversely, 'cimetidine', (p.265), an enzyme inhibitor, appears to oppose this effect. However, the fact that praziquantel was still effective in one study suggests that praziquantel metabolites might be active.[2]

Importance and management

Direct information appears to be limited to the reports cited, but the pharmacokinetic interactions appear to be established. However, the clinical relevance of the interaction is uncertain. When treating systemic worm infections such as neurocysticercosis some authors advise increasing the praziquantel dosage from 25 mg/kg to 50 mg/kg if potent enzyme inducers such as carbamazepine or phenytoin are being used, in order to reduce the risk of treatment failure.[1] A 45 mg/kg daily dose was effective in one study in 11 patients taking antiepileptics, despite low praziquantel levels,[2] but a 50 mg/kg daily dose was not effective in another case.[3] The recommended dose for the treatment of neurocysticercosis is 50 mg/kg daily in 3 divided doses.[5] Adding cimetidine may reduce the effect of enzyme-inducing antiepileptics. However, the authors of the case above[3] were not sure whether the improvement they saw was in fact due to the cimetidine or simply part of the natural history of the disease. It is clear that 'cimetidine', (p.265), alone can markedly increase praziquantel levels. One Canadian manufacturer of praziquantel advises that the reduction in praziquantel levels may also occur with **fosphenytoin**.[6] As fosphenytoin is a prodrug of phenytoin, this seems a reasonable prediction, and similar precautions should be considered.

Note that the interaction with enzyme-inducing antiepileptics is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

Praziquantel + Azoles

Ketoconazole increases praziquantel levels. Miconazole increases the bioavailability of praziquantel in *rats*, and other azoles are also predicted to interact.

Clinical evidence

In a randomised, crossover study, 10 healthy subjects were given a single dose of praziquantel 20 mg/kg alone or after pretreatment with **ketoconazole** 400 mg daily for 5 days. **Ketoconazole** significantly increased the AUC and maximum plasma levels of praziquantel by 93% and 102%, respectively. The total clearance was decreased by 58% but the half-life was only slightly prolonged. No adverse effects were reported with praziquantel alone; however, mild headache and gastrointestinal adverse effects (including nausea and vomiting) were reported when patients were pretreated with **ketoconazole**.[1]

A study in *rats* has reported that **miconazole** also increases praziquantel bioavailability.[2]

Mechanism

Praziquantel is metabolised by the cytochrome P450 isoenzyme CYP3A4, which is potently inhibited by ketoconazole. Concurrent use therefore decreases praziquantel metabolism, resulting in raised levels. All azoles inhibit this isoenzyme (although the extent varies, see under 'azoles', (p.233)), and would therefore be expected to interact.

Importance and management

Information on this interaction is limited, but it is in line with the known metabolism of praziquantel and the inhibitory effects of ketoconazole. All azoles inhibit this isoenzyme (although the extent varies, see under 'azoles', (p.233)), and would therefore be expected to interact similarly. Although there is no direct information, it is possible that concurrent use may lead to an improved clinical outcome, as has been reported for 'cimetidine', (p.265), which also raises praziquantel levels. However, the study with ketoconazole found that concurrent use increased adverse effects, and so it would seem prudent to monitor for praziquantel adverse effects if an azole is also given.

Praziquantel + Chloroquine

Chloroquine reduces the bioavailability of praziquantel.

Clinical evidence

A single 40-mg/kg oral dose of praziquantel was given to 8 healthy subjects alone, and 2 hours after chloroquine 600 mg. Chloroquine reduced the AUC and maximum serum levels of praziquantel by 65% and 59%, respectively. There were large individual variations in levels, and one subject was not affected.

Mechanism

Not understood.

Importance and management

Evidence is limited, but the effect appears to be established. The result of this interaction could be that some patients will not achieve high enough

serum praziquantel levels to treat systemic worm infections such as schistosomiasis. After taking chloroquine, the praziquantel serum levels of 4 out of the 8 subjects (50%) did not reach the threshold of 0.3 micrograms/mL for about 6 hours (which is required to effectively kill schistosomes), compared with only 2 of 8 (25%) during the control period. The authors conclude that an increased dosage of praziquantel should be considered if chloroquine is given (they do not suggest how much), particularly in anyone who does not respond to initial treatment with praziquantel.[1] More study of this interaction is needed.

Note that this interaction is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

1. Masimirembwa CM, Naik YS, Hasler JA. The effect of chloroquine on the pharmacokinetics and metabolism of praziquantel in rats and in humans. *Biopharm Drug Dispos* (1994) 15, 33–43.

Praziquantel + Cimetidine

Cimetidine can double the serum levels of praziquantel, and may improve its efficacy in neurocysticercosis.

Clinical evidence

In a randomised, crossover study, 8 healthy subjects were given three 25-mg/kg oral doses of praziquantel at 2-hourly intervals with cimetidine 400 mg given 1 hour before each dose of praziquantel. Cimetidine roughly doubled the praziquantel serum levels and AUC.[1,2] A further study in patients with neurocysticercosis found that this short regimen of praziquantel with cimetidine (which increased plasma levels of praziquantel by about threefold), had similar efficacy to the traditional regimen of 50 mg/kg daily in divided doses for 15 days.[3] Of the 6 patients receiving praziquantel with cimetidine, the clinical cure rate was 83%, compared with only 50% in 6 patients receiving praziquantel alone.[3]

Mechanism

Uncertain. An *in vitro* study has shown praziquantel to be a substrate for several cytochrome P450 isoenzymes including CYP1A2, CYP2C19 and CYP3A4.[4] Cimetidine, a potent inhibitor of cytochrome P450, probably inhibits the metabolism of praziquantel.

Importance and management

Direct information appears to be limited to the reports cited, but the interaction appears to be established. It is clear that cimetidine can markedly increase praziquantel levels, and the authors say that concurrent use can reduce treatment for neurocysticercosis from 2 weeks to 1 day.[1,3] One case report suggests that the concurrent use of cimetidine contributed to the resolution of refractory neurocysticercosis in a patient treated with high-dose praziquantel 100 mg/kg daily, although no pharmacokinetic data for praziquantel were reported.[5]

Cimetidine has been tried to reverse the effects of 'antiepileptics', (p.264), and 'corticosteroids', (below), which reduce praziquantel levels.

5. Yee T, Barakos JA, Knight RT. High-dose praziquantel with cimetidine for refractory neurocysticercosis: a case report with clinical and MRI follow-up. *West J Med* (1999), 170, 112–15.

Praziquantel + Corticosteroids

The continuous use of dexamethasone can halve serum praziquantel levels and may reduce its efficacy.

Clinical evidence

Eight patients with parenchymal brain cysticercosis taking praziquantel 50 mg/kg (in three divided doses every 8 hours) had a 50% reduction in the praziquantel steady-state serum levels (from 3.13 to 1.55 micrograms/mL) when given **dexamethasone** 8 mg every 8 hours.[1] Another patient with recurrent neurocysticercosis, who did not respond to praziquantel 50 mg/kg daily, was successfully treated with high-dose praziquantel 100 mg/kg daily, **dexamethasone** 12 mg daily and cimetidine 800 mg daily. As dexamethasone was thought to reduce the plasma levels of praziquantel, 'cimetidine', (above), was added to try to reverse this effect, as it has been reported to increase the bioavailability of praziquantel.[2] However, some patients have responded well to praziquantel, despite low serum levels.[3]

Mechanism

Uncertain. It has been suggested that dexamethasone is an inducer of the cytochrome P450 isoenzyme CYP3A4, and might therefore reduce levels of praziquantel, which is, in part, metabolised by this route. Potent CYP3A4 inducers such as 'phenytoin', (p.264), and 'rifampicin (rifampin)', (p.266), also significantly reduce the levels of praziquantel. Conversely, 'cimetidine', (above), an inhibitor of cytochrome P450, may reverse this effect.

Importance and management

Information seems to be limited but the pharmacokinetic interaction would appear to be established. However, the extent to which it affects the clinical outcome of treatment for systemic worm infections such as cysticercosis is unknown as the optimum praziquantel levels required are still uncertain, and it is also possible that the metabolites of praziquantel might be active.[3] The authors of one report suggest that dexamethasone should not be given continuously with praziquantel but only used transiently to resolve inflammatory reactions to praziquantel treatment.[1] Alternatively, limited information suggests the addition of cimetidine may allow dexamethasone to be used.[2]

Intravenous **methylprednisolone** has also been used for acute corticosteroid therapy with praziquantel, and oral **prednisone** has been used long-term to prevent further tissue damage associated with inflammation[4,5] but the effect of these corticosteroids on the plasma levels of praziquantel do not appear to have been studied.

The interaction with dexamethasone is of no importance when praziquantel is used for intestinal worm infections (where its action is a local effect on the worms in the gut).

Praziquantel + Food

Food increases the bioavailability of praziquantel.

Clinical evidence, mechanism, importance and management

The maximum plasma levels and AUC of a single 1.8-g dose of praziquantel were increased by 243% and 180% when it was given immediately after a **high-fat** meal and by 515% and 271% after a **high-carbohydrate** meal, respectively.[1] In another study in healthy Sudanese men, when praziquantel was given with food, the AUC was 2.6-fold higher than when it was given in the fasted state.[2]

A further study in patients with neurocysticercosis found that taking praziquantel 25 mg/kg every 2 hours for 3 doses with a **high-carbohydrate** diet increased the plasma levels of praziquantel, and provided an adequate clinical alternative to the traditional regimen of 50 mg/kg daily in divided doses for 15 days.[3] In 6 patients who took praziquantel with food, the clinical cure rate was 83%, compared with only 50% in 6 patients who took praziquantel while fasting.[3]

On the basis of the above studies, if praziquantel is used for systemic worm infections, administration with **food** is advisable, and this is recommended by the manufacturers.[4]

Praziquantel + Grapefruit juice

Grapefruit juice increases the AUC of praziquantel.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study in 18 healthy subjects a single 1.8-g dose of praziquantel was given with 250 mL of **grapefruit juice** or water. Grapefruit juice increased maximum plasma level and AUC of praziquantel by about 63% and 90%, respectively, when compared with water.[1] The authors suggested that grapefruit juice probably increased the absorption of praziquantel. The clinical effect of this interaction has not been assessed: it may lead to improved efficacy, but it may also lead to an increase in praziquantel adverse effects (e.g. headache, diarrhoea, dizziness, and drowsiness). Until more is known it may be prudent to be alert for an increase in praziquantel adverse effects in patients that drink grapefruit juice. When compared with other studies, the authors noted that the effect of grapefruit juice was comparable to that of 'cimetidine', (p.265), and less than that of 'food', (p.265).

1. Castro N, Jung H, Medina R, González-Esquivel D, Lopez M, Sotelo J. Interaction between grapefruit juice and praziquantel in humans. *Antimicrob Agents Chemother* (2002) 46, 1614–16.

Praziquantel + Rifampicin (Rifampin)

Rifampicin markedly reduces the levels, and therefore probably the efficacy, of praziquantel.

Clinical evidence, mechanism, importance and management

A study in 10 subjects found that pretreatment with rifampicin 600 mg daily for 5 days markedly reduced the AUC and maximum level of a single 40-mg/kg dose of praziquantel. Seven of the subjects had undetectable praziquantel levels (less than 12.5 nanograms/mL), and the other 3 had an 85% reduction in the AUC of praziquantel. The same subjects were then given three doses of praziquantel 25 mg/kg at intervals of 8 hours, alone, and after pretreatment with rifampicin, as above. In this multiple-dose study, 5 of the 10 subjects had undetectable praziquantel levels, and the remainder had an 80% reduction in AUC.[1] Praziquantel is metabolised by various cytochrome P450 isoenzymes including CYP3A4, and it is likely that rifampicin induced the metabolism of praziquantel by this isoenzyme. Although efficacy has not been assessed, the authors concluded that the levels of praziquantel after rifampicin pretreatment were less than those considered necessary for anthelmintic activity. They therefore recommend that the combination should be avoided,[1] a stance which is also taken by one of the manufacturers of praziquantel.[2]

2. Biltricide (Praziquantel). Bayer HealthCare Pharmaceuticals Inc. US Prescribing information, August 2007.

Primaquine + Food

Food slightly increases the bioavailability of primaquine.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects found that giving a single 30-mg dose of primaquine with food (two bread rolls and 30 g of butter) increased the AUC and maximum plasma concentration of primaquine by 14% and 26%, respectively when compared to administration in the fasting state. These small increases are unlikely to increase the risk of adverse effects.[1] Primaquine should usually be taken with a meal to minimise gastrointestinal adverse effects such as abdominal cramps, and it appears that this advice may also slightly improve the bioavailability.

1. Cuong BT, Binh VQ, Dai B, Duy DN, Lovell CM, Rieckmann KH, Edstein MD. Does gender, food or grapefruit juice alter the pharmacokinetics of primaquine. *Br J Clin Pharmacol* (2006) 61, 682–9.

Primaquine + Grapefruit juice

Grapefruit juice may increase the levels of primaquine, which may be significant in some individuals.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects found that 300 mL of grapefruit juice (concentrated grapefruit juice diluted to 50%) increased the mean AUC and maximum plasma concentration of primaquine by 19% and 23%, respectively. These changes are relatively minor; however, the authors note that although some individuals showed no interaction, some had up to a twofold increase in primaquine bioavailability.[1]

Evidence is limited to the study, and the general significance of this interaction is unclear. The authors of this study suggest that it may be prudent to avoid drinking grapefruit juice while taking primaquine, due to a lack of further information, particular on the effects of more concentrated juice, and also due to the unpredictability of this interaction.[1] This would appear to be sensible advice until further evidence is available.

1. Cuong BT, Binh VQ, Dai B, Duy DN, Lovell CM, Rieckmann KH, Edstein MD. Does gender, food or grapefruit juice alter the pharmacokinetics of primaquine. *Br J Clin Pharmacol* (2006) 61, 682–9.

Primaquine + Mepacrine (Quinacrine)

Theoretically, mepacrine would be expected to elevate the serum levels of primaquine, because it increased the levels of a formerly used drug pamaquine, which is structurally similar, but there do not seem to be any reports confirming or disproving this.

Clinical evidence, mechanism, importance and management

Patients given pamaquine (a formerly used antimalarial that was a predecessor of primaquine, and almost identical in structure), had grossly elevated pamaquine plasma levels when they were also given mepacrine.[1,2] The reason is unknown. On theoretical grounds primaquine might be expected to interact with mepacrine similarly, but there seem to be no reports confirming that a clinically important interaction actually takes place. However, the US manufacturer contraindicates the concurrent use of primaquine with mepacrine and also the use of primaquine in patients who have recently taken mepacrine.[3]

3. Primaquine phosphate. Sanofi-Aventis. US Prescribing information, January 2008.

Primaquine + Quinine

Quinine does not appear to affect the pharmacokinetics of primaquine.

Clinical evidence, mechanism, importance and management

In a study in 7 subjects, quinine 10 mg/kg three times daily had no effect on the pharmacokinetics of a single 45-mg dose of primaquine, except for a 50% increase in the AUC of the carboxyprimaquine metabolite. The combination was effective for the treatment of malaria with no complications and no adverse effects reported.[1]

Usually quinine is used only for the treatment of falciparum malaria, and

primaquine is used only to eliminate the liver stages of vivax and ovale malarias, and therefore the drugs are generally unlikely to be taken together. However, quinine may be used when the infective species is unknown or the infection mixed, when subsequent primaquine may then be required. The limited data from the above study suggest that no special precautions would be required in this situation.

Proguanil + Antacids

The absorption of proguanil is markedly reduced by magnesium trisilicate, and therefore the efficacy of proguanil may be reduced. Other antacids such as aluminium hydroxide may interact similarly.

Clinical evidence

Magnesium trisilicate reduced the AUC of a 200-mg dose of proguanil by about 65% in 8 healthy subjects, as assessed by salivary proguanil levels.[1]

Mechanism

In vitro tests showed that magnesium trisilicate adsorbed proguanil. Two other antacids, **aluminium hydroxide** and light **magnesium carbonate** also adsorbed proguanil, but to a lesser extent.[1]

Importance and management

The interaction between proguanil and magnesium trisilicate appears to be established, but its clinical importance does not seem to have been assessed. Given the extent of the reduction in levels, the antimalarial effects of proguanil might be expected to be reduced. One way to minimise the interaction is to separate the dosage of proguanil and magnesium trisilicate as much as possible (2 to 3 hours has been shown to be sufficient with other drugs that interact with antacids in this way) to reduce admixture in the gut; this is also suggested by the manufacturers of proguanil.[2] There do not appear to be any clinical studies to see if other antacids behave similarly, but *in* vitro *studies* suggest aluminium hydroxide and magnesium carbonate may. Therefore similar precautions for these antacids may be prudent.

2. Paludrine (Proguanil hydrochloride). AstraZeneca UK Ltd. UK Summary of product characteristics, April 2005.

Proguanil + Chloroquine

Chloroquine appears to increase the incidence of mouth ulcers in those taking proguanil by 50%. Both drugs were given as antimalarial prophylaxis.

Clinical evidence, mechanism, importance and management

Following the observation that mouth ulcers appeared to be common in those taking prophylactic antimalarials, an extensive study was undertaken in 628 servicemen in Belize. Of those taking proguanil 200 mg daily, 24% developed mouth ulcers, and in those also taking chloroquine base 150 to 300 mg weekly, 37% developed mouth ulcers. The incidence of diarrhoea was also increased from 63% among those who did not develop ulcers to 83% in those that did develop ulcers (any treatment). The reasons are not understood. The authors of the study suggested that these two drugs should not be given together unnecessarily for prophylaxis against *Plasmodium falciparum*.[1] However, chloroquine plus proguanil is an established prophylactic regimen that is commonly recommended in regions where there is some chloroquine resistance.

1. Drysdale SF, Phillips-Howard PA, Behrens RH. Proguanil, chloroquine, and mouth ulcers. *Lancet* (1990) 1, 164.

Proguanil + Cimetidine or Omeprazole

There is some evidence that omeprazole and cimetidine can moderately reduce the production of cycloguanil, the active metabolite of proguanil.

Clinical evidence

(a) Cimetidine

In one study, 4 patients with peptic ulcer disease and 6 healthy subjects were given a single 200-mg dose of proguanil on the last day of a 3-day course of cimetidine 400 mg twice daily. In both groups the half-life and AUC of proguanil were significantly increased, but only the healthy subjects had an increase in the maximum serum concentration (of 89%). In both groups these pharmacokinetic changes resulted in lower levels of the active metabolite, cycloguanil.[1] This decrease in cycloguanil levels supported the findings of an earlier study, which had found a 30% decrease in the urinary recovery of cycloguanil when proguanil and cimetidine were given together.[2]

(b) Omeprazole

A steady-state study in 12 healthy subjects taking proguanil 200 mg daily found that omeprazole 20 mg daily roughly halved the AUC of cycloguanil, the active metabolite of proguanil.[3] However, an earlier study found that omeprazole 20 mg had no effect on the urinary recovery of cycloguanil (or proguanil) following a single 200-mg dose of proguanil.[2]

Mechanism

Cimetidine and omeprazole increase the gastric pH, which may lead to an increase in the absorption of proguanil. Cimetidine[1,2] and omeprazole[3] are also thought to inhibit the metabolism of proguanil, due to their inhibitory effects on the cytochrome P450 isoenzyme CYP2C19.

Importance and management

Evidence is limited, but roughly in line with the known pharmacokinetic effects of these drugs. The differences between the healthy subjects and patients with peptic ulcer disease seen in one study may have been because the disease itself alters the effects of the cimetidine in some way.[1] Patients with peptic ulcer disease are also likely to have an increased gastric pH, which will lead to altered proguanil absorption. The clinical relevance of all these findings is still unclear, although the implication is that decreased cycloguanil levels may lead to inadequate malaria prophylaxis. However, a subsequent clinical study reported that subjects who were lacking or had low levels of CYP2C19 (and who therefore had relatively low cycloguanil levels) did not have an increased risk of failure of proguanil prophylaxis.[4] Similarly, treatment of malaria with proguanil was as effective in 62 patients who were lacking or had low levels of CYP2C19 as in 33 patients with normal levels of this isoenzyme, independent of cycloguanil levels.[5] This suggests that any interaction with omeprazole or cimetidine via this mechanism would be unlikely to be clinically relevant, and therefore dosage adjustments would not be expected to be necessary in patients given proguanil with cimetidine or omeprazole.

Proguanil + Fluvoxamine

The conversion of proguanil to its active metabolite is markedly inhibited by fluvoxamine in patients who have normal levels of CYP2C19. However, there is some evidence this may not be of any clinical relevance.

Clinical evidence

Twelve healthy subjects, 6 of whom had normal levels of CYP2C19 and 6 of whom were lacking or deficient in CYP2C19, were given proguanil 200 mg daily for 8 days, followed by fluvoxamine 100 mg for 8 days, with a single 200-mg dose of proguanil on day 6. In the subjects with normal CYP2C19 levels it was found that fluvoxamine reduced the total clearance of proguanil by about 40%. The partial clearance of proguanil via its two metabolites was also reduced, by 85% for cycloguanil, and by 89% for 4-chlorophenylbiguanide. The concentrations of these two metabolites in the plasma were hardly detectable while fluvoxamine was being taken. No pharmacokinetic interaction occurred in any of the subjects lacking or deficient in CYP2C19.[1]

Mechanism

Proguanil, which is thought to be a prodrug, is metabolised to its active metabolite, cycloguanil, by the cytochrome P450 isoenzyme CYP2C19. This isoenzyme is inhibited by fluvoxamine, which prevents proguanil from being activated.[2]

Importance and management

Information appears to be limited to the studies cited, the purpose of which was to confirm that fluvoxamine is an inhibitor of CYP2C19. However, they also demonstrate that proguanil, which is a prodrug, will not be effectively converted into its active form in patients who have normal levels of CYP2C19 (extensive metabolisers) if fluvoxamine is also being taken, making them effectively poor metabolisers (i.e. like those subjects lacking or deficient in CYP2C19). There are as yet no reports of treatment failures due to this interaction, but if the activity of proguanil is virtually abolished by fluvoxamine, as the authors suggest,[2] then proguanil would also be expected to be ineffective in the proportion of the population that are poor metabolisers. However, a subsequent clinical study reported that subjects who were poor metabolisers of proguanil did not have an increased risk of failure of proguanil prophylaxis.[3] Similarly, treatment of malaria with proguanil was as effective in 62 patients who were CYP2C19 poor metabolisers as in 33 patients who were extensive metabolisers, independent of cycloguanil levels.[4] This suggests any interaction with fluvoxamine may not be clinically relevant.

Pyrantel + Piperazine

Piperazine is expected to oppose the anthelmintic actions of pyrantel.

Clinical evidence, mechanism, importance and management

Pyrantel acts as an anthelmintic because it depolarises the neuromuscular junctions of some intestinal nematodes causing the worms to contract. This paralyses the worms so that they are dislodged by peristalsis and expelled in the faeces. Piperazine also paralyses nematodes but it does so by causing hyperpolarisation of the neuromuscular junctions. These two pharmacological actions oppose one another, as was shown in two *in vitro* pharmacological studies. Strips of whole *Ascaris lumbricoides,* which contracted when exposed to pyrantel, failed to do so when also exposed to piperazine.[1] Parallel electrophysiological studies using *Ascaris* cells confirmed that the depolarisation due to pyrantel (which causes the paralysis) was opposed by piperazine.[1]

In practical terms this means that piperazine does not add to the anthelmintic effect of pyrantel on *Ascaris* as might be expected, but opposes it. For this reason it is recommended that concurrent use should be avoided, but direct clinical evidence confirming that combined use is ineffective seems to be lacking.

It seems reasonable to extrapolate the results of these studies on *Ascaris lumbricoides* (roundworm) to the other gastrointestinal parasites for which pyrantel is used, i.e. *Enterobius vermicularis* (threadworm or pinworm), *Ancylostoma duodenale*, *Necator americanus* (hookworm) and *Trichostrongylus* spp. However, this does not appear to have been studied.

Pyrimethamine ± Sulfadoxine + Artemisinin derivatives

Artemether raises pyrimethamine plasma levels, but this does not appear to cause an increase in adverse effects. Artesunate does not appear to affect the pharmacokinetics of pyrimethamine or sulfadoxine.

Clinical evidence, mechanism, importance and management

(a) Artemether

In a crossover study, 8 healthy subjects were given a single-dose of either artemether 300 mg, pyrimethamine 100 mg, or both drugs together. Although there were large inter-individual variations in the pharmacokinetics of pyrimethamine, its maximum plasma level was raised by 44%. As there was no corresponding increase in adverse effects the authors suggest that the interaction may be of benefit.[1] More study is warranted to confirm this result.

(b) Artesunate

A study in 16 healthy subjects found that artesunate (200 mg on day 1 then 100 mg daily for 4 days) had no significant effects on the pharmacokinetics of pyrimethamine/sulfadoxine 75 mg/1500 mg taken on day 1. However, the pharmacokinetics of artesunate were not investigated in this study.[2] No particular dose adjustments of pyrimethamine/sulfadoxine appear to be required if artesunate is also given. Note that artesunate combined with pyrimethamine/sulfadoxine is one of the artemisinin-based combinations recommended by the WHO for the treatment of malaria.[3]

Pyrimethamine + Co-trimoxazole or Sulfonamides

Serious pancytopenia and megaloblastic anaemia have occasionally occurred in patients given pyrimethamine with either co-trimoxazole or other sulfonamides.

Clinical evidence

A woman taking pyrimethamine 50 mg weekly as malaria prophylaxis, developed petechial haemorrhages and widespread bruising within 10 days of starting to take co-trimoxazole (trimethoprim 320 mg with sulfamethoxazole 800 mg) daily for a urinary-tract infection. She was found to have gross megaloblastic changes and pancytopenia in addition to being obviously pale and ill. After withdrawal of the two drugs she responded rapidly to hydroxocobalamin and folic acid. She was subsequently given chloroquine for malaria prophylaxis.[1]

Similar cases have been described in other patients taking pyrimethamine with co-trimoxazole,[2-4] **sulfafurazole (sulfisoxazole)**,[5] or other sulfonamides.[6]

Mechanism

Uncertain, but a reasonable surmise can be made. Pyrimethamine and **trimethoprim** are both **folate antagonists** and both selectively inhibit the actions of the enzyme dihydrofolate reductase, which leads to the eventual synthesis of the nucleic acids needed for the production of new cells. This may result in folate deficiency and the development of megaloblastic anaemia. The sulfonamides inhibit another part of the same synthetic chain. The adverse reactions seen would seem to reflect a gross reduction of the normal folate metabolism caused by the combined actions of both

drugs. Megaloblastic anaemia and pancytopenia are among the adverse effects of both pyrimethamine and, more rarely, co-trimoxazole.

Importance and management

Information seems to be limited to the reports cited, but the interaction appears to be established. Its incidence is unknown. Pyrimethamine is usually given with a sulfonamide for toxoplasmosis (sulfadiazine) and malaria (sulfadoxine). Caution should be used in prescribing these combinations, especially in the presence of other drugs, such as 'folate antagonists', (below), or disease states that may predispose to folate deficiency. Note that the manufacturer of sulfadoxine/pyrimethamine (*Fansidar*), which is indicated for the prophylaxis and treatment of malaria, recommends that with the concurrent use of folate antagonists, such as other sulfonamides, trimethoprim, co-trimoxazole and some antiepileptics, should be avoided.[7] When high-dose pyrimethamine is used for the treatment of toxoplasmosis, the manufacturers recommend that all patients should receive a folate supplement, preferably calcium folinate, to reduce the risk of bone marrow depression.[8,9]

Pyrimethamine ± Sulfonamides + Drugs that affect folate metabolism

Serious pancytopenia and megaloblastic anaemia may occur in patients given pyrimethamine and/or sulfonamides with other drugs that inhibit folate metabolism.

Clinical evidence, mechanism, importance and management

Pyrimethamine is known to inhibit folate metabolism, which is associated with a risk of adverse effects (in particular anaemias and pancytopenia). Pyrimethamine is usually given with a sulfonamide for toxoplasmosis (sulfadiazine) and malaria (sulfadoxine), which is known to increase the risk of additive haematological toxicity even further. The manufacturer of sulfadoxine/pyrimethamine (*Fansidar*), recommends that the concurrent use of folate antagonists (they name other sulfonamides, trimethoprim and some antiepileptics) should be avoided.[1] This seems a prudent precaution, as adverse haematological effects have been seen with the use of pyrimethamine and 'sulfonamides', (p.268), and folate deficiency is a known adverse effect of a number of 'antiepileptics', (p.596). Other drugs known to be folate antagonists include methotrexate and pemetrexed, but note that these drugs are often given with folate supplements to limit their toxicity. If the concurrent use of pyrimethamine and a drug that inhibits folate metabolism cannot be avoided it would seem prudent to consider the use of a folate supplement, preferably folinic acid.

1. Fansidar (Sulfadoxine/Pyrimethamine). Roche Pharmaceuticals. US Prescribing information, August 2004.

Pyrimethamine ± Sulfadoxine + Zidovudine

Pyrimethamine does not appear to alter zidovudine pharmacokinetics, and zidovudine does not appear to alter the prophylactic efficacy of pyrimethamine/ sulfadoxine for toxoplasmosis. However, the combination of pyrimethamine and zidovudine may increase the risk of myelosuppression.

Clinical evidence, mechanism, importance and management

The addition of pyrimethamine (200 mg loading dose then 50 mg daily) and folinic acid 10 mg daily to zidovudine had no effect on zidovudine pharmacokinetics, based on data from 10 HIV-positive patients for whom zidovudine pharmacokinetics were available before and after starting pyrimethamine. Of 26 patients receiving the combination, 5 developed leucopenia and one discontinued treatment because of anaemia.[1]

A study in patients with AIDS found that zidovudine 250 mg four times daily did not adversely affect the prevention of toxoplasma encephalitis with pyrimethamine/sulfadoxine (*Fansidar*), one tablet twice weekly for up to 8 months.[2] *In vitro* and *animal* data have shown that the combination of zidovudine and pyrimethamine caused synergistic decreases in lymphocyte and neutrophil numbers.[3]

The manufacturers of pyrimethamine note that the concurrent use of zidovudine may increase the risk of bone marrow depression.[4,5] They say that if signs of folate deficiency develop, then pyrimethamine should be discontinued and folinic acid given. Note that the prophylactic use of a folate supplement, preferably folinic acid, is recommended for all patients with toxoplasmosis taking high-dose pyrimethamine, to reduce the risk of bone marrow suppression.[4,5]

Quinine + Artemether/Lumefantrine

No clinically significant pharmacokinetic interaction appears to occur between quinine and co-artemether. Quinine-induced QTc prolongation may be enhanced by artemether.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in healthy subjects, 6 doses of artemether/lumefantrine 80/480 mg were given to 14 subjects, over a period of 60 hours, followed 2 hours after the last dose by intravenous quinine 10 mg/kg (to a maximum of 600 mg) over 2 hours. Another two groups, each containing 14 subjects, received quinine or artemether/lumefantrine, with placebo. The pharmacokinetics of lumefantrine and quinine were unaffected by combined use but the AUC and plasma levels of artemether and its active metabolite dihydroartemisinin appeared to be lower when artemether/lumefantrine was given with quinine. However, the levels of artemether before quinine use in this group were also lower, and this reduction in artemether levels in the presence of quinine was not considered clinically significant. The transient prolongation of the QTc interval noted with quinine (average and peak increases of 3 and 6 milliseconds, respectively) was slightly greater when quinine was given after artemether/lumefantrine (average and peak increases 7 milliseconds and 15 milliseconds, respectively).[1] Both quinine and artemether are known to prolong the QT interval. In general, it is advised that the concurrent use of drugs that prolong the QT interval should be avoided (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). However, the authors of this study considered that the modest increased risk of QTc prolongation was outweighed by the potential benefit of the combined treatment in complicated or multidrug-resistant falciparum malaria.[1] If the combination is used, close cardiac monitoring is recommended.[2]

2. Riamet (Artemether/Lumefantrine). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, October 2007.

Quinine + Colestyramine

A single-dose study suggests that colestyramine may not alter the pharmacokinetics of quinine.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, colestyramine 8 g did not alter the pharmacokinetics of quinine 600 mg. The authors warn that this lack of interaction may have been because only single doses were used, and suggest continuing to separate the administration of the two drugs until a lack of interaction is demonstrated in a multiple dose study.[1] It is usually recommended that other drugs are taken 1 hour before or 4 to 6 hours after colestyramine.

1. Ridtitid W, Wongnawa M, Kleekaew A, Mahatthanatrakul W, Sunbhanich M. Cholestyramine does not significantly decrease the bioavailability of quinine in healthy volunteers. *Asia Pac J Pharmacol* (1998) 13, 123–7.

Quinine + Fluvoxamine

Fluvoxamine has no effect on the pharmacokinetics of quinine.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, fluvoxamine 25 mg was given both 12 hours and 1 hour before a single 500-mg dose of quinine hydrochloride, followed by a further 4 doses of fluvoxamine, given every 12 hours.[1] Fluvoxamine had no effect on the apparent oral clearance of quinine and caused a minor 6% increase in the AUC of 3-hydroxyquinine, with no effect on the AUC of various other metabolites.[1,2]

Fluvoxamine is a known inhibitor of the cytochrome P450 isoenzymes CYP1A2 and to some extent CYP2C19, and it appears that this has little effect on the pharmacokinetics of quinine. No dose adjustments are necessary on concurrent use.

2. Mirghani RA, Hellgren U, Bertilsson L, Gustafsson LL, Ericsson Ö. Metabolism and elimination of quinine in healthy volunteers. *Eur J Clin Pharmacol* (2003) 59, 423–7.

Quinine + Food

A study in 7 healthy subjects found that neither a low nor a high-salt diet affected the pharmacokinetics of a single 600-mg dose of quinine sulfate.[1]

1. Newton P, Simpson A, Wanwimolruk S, Maliakal P, Villegas L, Kuypers D, White NJ. Oral quinine pharmacokinetics and dietary salt intake. *Eur J Clin Pharmacol* (2001) 57, 111–13.

Quinine + Grapefruit juice

Grapefruit juice had no effect on the pharmacokinetics of quinine in healthy subjects. An isolated case of torsade de pointes has been reported following the excessive intake of grapefruit juice and quinine-containing tonic water in a patient with a history of long QT syndrome.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, 200 mL of full-strength grapefruit juice, half-strength grapefruit juice, or orange juice was given twice daily for 11 doses with a single 600-mg dose of quinine sulfate, given on day 6 with the last dose of fruit juice. There were no significant differences in the pharmacokinetics of quinine between the three treatments, although the maximum level of the 3-hydroxymetabolite was slightly reduced (by 19%) with full-strength grapefruit juice compared with orange juice or half-strength grapefruit juice.[1] An isolated report describes a diabetic patient with a history of long QT syndrome who was found to have torsade de pointes arrhythmia after admission to hospital with polydipsia. It was discovered that because of the polydipsia, she had been drinking excessive quantities of grapefruit juice and quinine-containing tonic water. Two days after discontinuing these drinks, the torsade de pointes disappeared.[2]

Grapefruit juice is a known inhibitor of intestinal cytochrome P450 isoenzyme CYP3A4, and it appears that this has little effect on the pharmacokinetics of quinine, in healthy human subjects. It would seem that, in general, patients taking quinine may safely drink grapefruit juice if they wish.[1] The case report introduces an element of caution, but it should be noted that its clinical relevance is unclear because the patient did not take quinine without grapefruit juice, and so the arrhythmia may have been caused by the use of quinine in a patient with long QT syndrome, and not an interaction.

2. Hermans K, Stockman D, Van den Branden F. Grapefruit and tonic: A deadly combination in a patient with the long QT syndrome. *Am J Med* (2003) 114, 511–12.

Quinine + H_2-receptor antagonists

The clearance of quinine is reduced by cimetidine, but not ranitidine.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects **cimetidine** 200 mg three times daily and 400 mg at night for one week reduced the clearance of quinine by 27%, increased its half-life from 7.6 to 11.3 hours, and increased its AUC by 42%. Peak quinine levels were unchanged. No interaction was seen when **cimetidine** was replaced by **ranitidine** 150 mg twice daily.[1] The probable reason for this effect is that **cimetidine** (a recognised enzyme inhibitor) reduces the hepatic metabolism of quinine by the cytochrome P450 isoenzyme CYP3A4. **Ranitidine** does not inhibit hepatic enzymes and therefore does not interact. It therefore seems likely that other H_2-receptor antagonists (that also lack enzyme-inhibitory effects) will not interact, although this needs confirmation.

The clinical importance of the modest interaction between cimetidine and quinine is uncertain, but prescribers should be alert for any evidence of quinine adverse effects if cimetidine is also given.

1. Wanwimolruk S, Sunbhanich M, Pongmarutai M and Patamasucon P. Effects of cimetidine and ranitidine on the pharmacokinetics of quinine. *Br J Clin Pharmacol* (1986) 22, 346–50.

Quinine + Isoniazid

A study in 9 healthy subjects found that the clearance of a single 600-mg dose of quinine sulfate was not significantly affected by pretreatment with isoniazid 300 mg daily for one week.[1] No additional precautions therefore seem necessary if quinine is given with isoniazid; however, bear in mind that isoniazid is usually used in combination with 'rifampicin (rifampin)', (p.271), which may reduce the efficacy of quinine.

1. Wanwimolruk S, Kang W, Coville PF, Viriyayudhakorn S, Thitiarchakul S. Marked enhancement by rifampicin and lack of effect of isoniazid on the elimination of quinine in man. *Br J Clin Pharmacol* (1995) 40, 87–91.

Quinine + Ketoconazole

Ketoconazole modestly decreases the clearance of quinine.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects ketoconazole 100 mg twice daily was given for 3 days with a single 500-mg dose of quinine hydrochloride one hour after the second dose of ketoconazole. Ketoconazole decreased the apparent oral clearance of quinine by 31% and decreased the AUC of the major metabolite 3-hydroxyquinine by 30%,[1] with increases in the AUCs of various other metabolites.[2]

Ketoconazole inhibits the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of quinine to its major metabolite 3-hydroxyquinine. CYP3A5 may possibly also play some part.[3] This pharmacokinetic interaction would appear to be established, but of unknown clinical relevance. The modest increase in 3-hydroxyquinine levels seen is probably unlikely to be of much significance.

Quinine + Miscellaneous

Urinary alkalinisers can reduce the urinary excretion of quinine in man, and antacids can reduce the absorption of quinine in *animals*.

Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminium/magnesium hydroxide gel reduces the absorption of quinine from the gut of *rats* and reduces quinine blood levels by 50 to 70%.[1] This appears to occur because **aluminium hydroxide** slows gastric emptying, and because **magnesium hydroxide** forms an insoluble precipitate with quinine, both of which reduce quinine absorption. However, there seem to be no clinical reports of a reduction in the therapeutic effectiveness of quinine due to the concurrent use of antacids.

(b) Urinary alkalinisers

The excretion of unchanged quinine is virtually halved (from 17.4% to 8.9%) if the urine is alkalinised. This is because in alkaline urine more of the quinine exists in the non-ionised (lipid soluble) form, which is more easily reabsorbed by the kidney tubules.[2] However, there seem to be no reports of adverse effects arising from changes in excretion due to this interaction, and no special precautions seem to be necessary.

2. Haag HB, Larson PS, Schwartz JJ. The effect of urinary pH on the elimination of quinine in man. *J Pharmacol Exp Ther* (1943) 79, 136–9.

Quinine + Rifampicin (Rifampin)

Rifampicin induces the metabolism of quinine, which may result in subtherapeutic quinine levels.

Clinical evidence

A study in 9 healthy subjects found that the clearance of a single 600-mg dose of quinine sulfate was increased more than sixfold by pretreatment with rifampicin 600 mg daily for 2 weeks. The elimination half-life of quinine was decreased from about 11 hours to 5.5 hours.[1] In another study, in patients with uncomplicated falciparum malaria, quinine sulfate 10 mg/kg three times daily was given either alone (30 patients) or with rifampicin 15 mg/kg daily (29 patients) for 7 days. Peak plasma levels of quinine during monotherapy were attained within 2 days of treatment and remained within the therapeutic range for the 7-day treatment period. Levels of the main metabolite of quinine, 3-hydroxyquinine, followed a similar pattern. In patients taking quinine with rifampicin, quinine was more extensively metabolised and, after the second day of treatment, quinine levels were sharply reduced to below therapeutic levels. Although patients who received rifampicin with quinine had shorter parasite clearance times than those who received quinine alone (suggesting rifampicin may enhance the antimalarial activity of quinine) recrudescence rates (the reappearance of the disease after a period of inactivity) were 5 times higher suggesting increased resistance to quinine treatment.[2]

A report describes a patient with myotonia, controlled with quinine, whose symptoms worsened within 3 weeks of starting to take rifampicin for the treatment of tuberculosis. Peak quinine levels were found to be low, but rose again when the rifampicin was stopped. Control of the myotonia was regained 6 weeks later.[3]

Mechanism

Acute malaria reduces the metabolic clearance of quinine (by a reduction in hepatic mixed function oxidase activity, mainly the cytochrome P450 isoenzyme CYP3A4) and recovery from malaria is associated with a sharp decline in quinine levels. Rifampicin induces the cytochrome P450 isoenzymes and this probably antagonised their inhibition by acute malaria, resulting in increased quinine metabolism.

Importance and management

Although there is limited evidence, this interaction would appear to of clinical importance. The authors of one of the studies[2] suggest that rifampicin should not be given with quinine for the treatment of malaria. Increased quinine doses should be considered if the concurrent use of rifampicin is considered essential.

1. Wanwimolruk S, Kang W, Coville PF, Viriyayudhakorn S, Thitiarchakul S. Marked enhancement by rifampicin and lack of effect of isoniazid on the elimination of quinine in man. *Br J Clin Pharmacol* (1995) 40, 87–91.

3. Osborn JE, Pettit MJ, Graham P. Interaction between rifampicin and quinine: case report. *Pharm J* (1989) 243, 704.

Quinine + Tetracyclines

Doxycycline does not appear to alter the pharmacokinetics of quinine. Tetracycline increases quinine levels leading to improved efficacy in malaria.

Clinical evidence, mechanism, importance and management

(a) Doxycycline

In a study in 13 patients with acute falciparum malaria, the addition of intravenous doxycycline to intravenous quinine did not affect the pharmacokinetics of quinine, when compared with 13 patients taking quinine alone.[1] In contrast, *in vitro*, doxycycline appears to be a potent inhibitor of quinine metabolism.[2] However, given the above evidence from their use in patients, no special precautions would seem to be necessary on concurrent use, and the combination is one of the treatments recommended in the WHO guidelines for the treatment of malaria.[3]

(b) Tetracycline

A study in patients with acute falciparum malaria found that the levels of quinine 600 mg every 8 hours were about doubled by tetracycline 250 mg every 6 hours, when compared with quinine alone. Quinine levels were above the MIC for malaria with the combination but not with quinine alone. Two of 8 patients treated with quinine alone had malaria recrudescence (the reappearance of the disease after a period of inactivity) compared with none of 8 patients receiving the combination.[4] *In vitro* tetracycline is also a potent inhibitor of quinine metabolism.[2] The authors considered that this pharmacokinetic interaction might be part of the explanation why the combination has been found to be more effective than quinine alone.[4] Quinine with tetracycline is one of the combinations recommended by WHO for the treatment of malaria.[3]

Quinine + Tobacco

Quinine pharmacokinetics and efficacy were unchanged by smoking in one study. In contrast, in another study, otherwise healthy smokers appeared to clear quinine from the body much more quickly than non-smokers; however, quinine metabolism is reduced in patients with falciparum malaria, which may negate this effect.

Clinical evidence

A comparative study found that in 10 smokers (averaging 17 cigarettes daily) the AUC of a single 600-mg dose of quinine sulfate was reduced by 44%, the clearance was increased by 77% and the half-life was shortened (from 12 to 7.5 hours), when compared with 10 non-smokers.[1] In contrast, in a study in patients with uncomplicated falciparum malaria taking quinine sulfate 10 mg/kg three times daily for 7 days, there was no significant

difference in fever clearance time, parasite clearance time, and cure rate between 10 regular smokers and 12 non-smokers. In addition pharmacokinetic parameters did not differ significantly between the smokers and non-smokers.[2]

Mechanism

Tobacco smoke contains polycyclic aromatic compounds and other substances, which are potent inducers of the liver enzymes that metabolise quinine. It is not yet clear which cytochrome P450 isoenzymes are affected. Smoking induces CYP1A, but the formation of the major metabolite of quinine, 3-hydroxyquinine, is catalysed by CYP3A, which suggests that other metabolic pathways of quinine are affected by smoking.[3]

Importance and management

Information seems to be limited but the pharmacokinetic interaction would appear to be established in healthy subjects. However, the clinical study in patients with falciparum malaria suggests that any pharmacokinetic differences are more limited probably due to the additional effect the disease has on quinine metabolism, and that smoking status does not appear to affect the clinical outcome of quinine treatment for malaria. The systemic clearance of quinine in acute falciparum malaria may be reduced by up to two-thirds, when compared with healthy subjects, as malaria reduces hepatic microsomal enzyme activity. The authors say that this reduction in the clearance of quinine outweighs the possible effects of smoking-induced clearance.[2]

Terbinafine + H_2-receptor antagonists

Although cimetidine modestly increases the AUC of terbinafine no clinically relevant interactions appear to have been reported. Limited evidence suggests that ranitidine does not interact with terbinafine.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects **cimetidine** 400 mg twice daily for 5 days increased the AUC of a single 250-mg dose of terbinafine by 34% and reduced its clearance by 30%.[1] The likely reason is that **cimetidine** (a known enzyme inhibitor) reduces the metabolism of terbinafine by the liver. However, it seems that this modest increase in the serum levels of terbinafine is of little or no clinical relevance. This is supported by a large scale post-marketing survey of patients taking terbinafine that found no interactions were reported in patients also taking **cimetidine** or **ranitidine** (number unknown).[2] The UK manufacturer of terbinafine recommends that the dose of terbinafine may need adjusting (presumably reduced) if drugs that inhibit cytochrome P450 are given,[3] but the evidence available suggests that this will not be necessary with cimetidine. Evidence regarding an interaction with other H_2-receptor antagonists is lacking, but there seems to be no reason to suspect that they will interact.

Terbinafine + Miscellaneous

Terbinafine may raise the levels of drugs that are substrates of CYP2D6.

Clinical evidence, mechanism, importance and management

In vitro studies suggest that terbinafine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6. It may therefore be expected to increase the plasma levels of other drugs that are substrates of this enzyme. The manufacturers specifically mention tricyclic antidepressants,[1] SSRIs,[1] **beta blockers**,[1,2] **antiarrhythmics** (including class Ia,[1] Ib,[1] and Ic[1,2]) and **MAO-B inhibitors**.[1,2] Of these predictions the tricyclics have been seen to interact markedly (see 'Tricyclic antidepressants + Terbinafine', p.1515) and the SSRI paroxetine has been seen to interact modestly (see 'SSRIs + Terbinafine', p.1493). Note that only some beta blockers would be expected to interact, as they are not all substrates for CYP2D6 (see 'Table 22.1', (p.995)), and only some antiarrhythmics would be expected to interact (namely **flecainide**, **mexiletine** and **propafenone**, which are known clinically relevant CYP2D6 substrates). There appear to be no reported interactions between **selegiline** or **rasagiline** and CYP2D6 inhibitors, so the clinical relevance of this prediction is unclear.

Until more is known it would seem wise to be aware of the possibility of an increase in adverse effects if any of these drugs is given with terbinafine and consider a dose reduction if necessary. See 'Table 1.3', (p.6), for a list of drugs that are known to be clinically relevant substrates of CYP2D6.

2. Lamisil (Terbinafine hydrochloride) Novartis Pharmaceuticals Corp. US Prescribing information, November 2005.

Terbinafine + Rifampicin (Rifampin)

The plasma levels of terbinafine are reduced by rifampicin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that rifampicin 600 mg daily for 6 days halved the AUC of terbinafine and roughly doubled its clearance.[1] Rifampicin is a potent enzyme inducer, which increases the metabolism of many drugs. Be alert, therefore, for the need to increase the dosage of terbinafine if rifampicin is given.

9

Antiarrhythmics

This section is mainly concerned with the class I antiarrhythmics, which also possess some local anaesthetic properties, and with class III antiarrhythmics. Antiarrhythmics that fall into other classes are dealt with under 'beta blockers', (p.995), 'digitalis glycosides', (p.1077), and 'calcium-channel blockers', (p.1025). Some antiarrhythmics that do not fit into the Vaughan Williams classification (see 'Table 9.1', (below)) are also included in this section (e.g. adenosine). Interactions in which the antiarrhythmic drug is the affecting substance, rather than the drug whose activity is altered, are dealt with elsewhere.

Predicting interactions between two antiarrhythmics

It is difficult to know exactly what is likely to happen if two antiarrhythmics are used together. The hope is always that a combination will work better than just one drug, and many studies have confirmed that hope, but sometimes the combinations are unsafe. Predicting unsafe combinations is difficult, but there are some very broad general rules that can be applied if the general pharmacology of the drugs is understood.

If drugs with similar effects are used together, whether they act on the myocardium itself or on the conducting tissues, the total effect is likely to be increased (additive). The classification of the antiarrhythmics in 'Table 9.1', (below) helps to predict what is likely to happen, but remember that the classification is not rigid, and therefore drugs in one class can share some characteristics with others. The following sections deal with some examples.

(a) Combinations of antiarrhythmics from the same class

The drugs in class Ia can prolong the QT interval; combining drugs from this class would be expected to have an increased effect on the QT interval. This prolongation carries the risk of causing torsade de pointes arrhythmias (see the monograph, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). It would also be expected that the negative inotropic effects of quinidine would be additive with procainamide or any of the other drugs within class Ia. Therefore, for safety, it is sometimes considered best to avoid drugs that fall into the same subclass or only to use them together with caution.

(b) Combinations of antiarrhythmics from different classes

Class III antiarrhythmics such as amiodarone can also prolong the QT interval; they would therefore be expected to interact with drugs in other classes that do the same, namely class Ia drugs (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). Verapamil is a class IV antiarrhythmic, and has negative inotropic effects; it can therefore interact with other drugs with similar effects, such as sotalol, which is a class III antiarrhythmic. For safety, always consider the whole drug profile and take care with any two drugs, from any class, that share a common pharmacological action.

Table 9.1 Antiarrhythmics (modified Vaughan Williams classification)

Class I: Membrane stabilising drugs (a) Ajmaline, Cibenzoline,* Disopyramide, Hydroquinidine, Procainamide, Quinidine (b) Aprindine, Lidocaine, Mexiletine, Tocainide (c) Flecainide, Propafenone Class I, but not easily fitting the above subgroups – Moracizine
Class II: Beta blocker activity Atenolol, Bretylium,† Propranolol
Class III: Inhibitors of depolarisation Amiodarone, Azimilide, Bretylium,† Cibenzoline,* Dofetilide, Dronedarone, Ibutilide, Sotalol
Class IV: Calcium-channel blocker activity Cibenzoline,* Diltiazem, Verapamil
Drugs not fitting into this classification Adenosine

*Cibenzoline has class Ia, and also some class III and IV activity

†Bretylium has class II and III activity

Adenosine + Dipyridamole

Dipyridamole reduces the bolus dose of adenosine necessary to convert supraventricular tachycardia to sinus rhythm by about fourfold. Profound bradycardia occurred in one patient taking dipyridamole when an adenosine infusion was given for myocardial stress testing.

Clinical evidence

(a) Adenosine bolus for supraventricular tachycardia

Adenosine by rapid intravenous bolus (10 to 200 micrograms/kg in stepwise doses) was found to restore sinus rhythm in 10 of 14 episodes of tachycardia in 7 patients with supraventricular tachycardia (SVT). The mean dose required was 8.8 mg, compared with only 1 mg in two patients also taking oral dipyridamole.[1] Another study in 6 patients found that dipyridamole (560 microgram/kg intravenous bolus, followed by a continuous infusion of 5 micrograms/kg/minute) reduced the minimum effective bolus dose of intravenous adenosine required to stop the SVT from 68 micrograms/kg to 17 micrograms/kg in 5 patients. In the other patient, dipyridamole alone stopped the SVT.[2]

Other studies in healthy subjects have clearly shown that dipyridamole reduces the dose of adenosine required to produce an equivalent cardiovascular effect by fourfold[3] or even six- to sixteenfold.[4] A brief report describes a woman with paroxysmal SVT who lost ventricular activity for 18 seconds when given adenosine 6 mg intravenously. She was also taking dipyridamole [dose unstated], which was considered to have contributed to the loss of ventricular function.[5] Another report describes 3 of 4 patients who had heart block of 3, 9 and 21-second duration, respectively, when given adenosine 3 to 6 mg by central venous bolus. The patient with the most profound heart block was also receiving dipyridamole, which was thought to have contributed to the reaction.[6]

(b) Adenosine infusion for myocardial stress testing

A 79-year-old woman taking a combination of low-dose aspirin and extended-release dipyridamole (*Aggrenox*) became profoundly bradycardic (36 bpm), dizzy and almost fainted 2 minutes after the start of an adenosine infusion for radionuclide myocardial imaging. Adenosine was stopped, and she recovered within 2 minutes. The last dose of *Aggrenox* had been taken 12 hours previously.[7] However, note that bradycardia is a known adverse effect of adenosine.[8,9]

Mechanism

Not fully understood. Part of the explanation is that dipyridamole increases plasma levels of endogenous adenosine by inhibiting its uptake into cells.[2,4,10]

Importance and management

An established interaction. Patients will need much less adenosine to treat arrhythmias while taking dipyridamole. It has been suggested that the initial dose of adenosine should be reduced by twofold[5] or fourfold.[2] The UK manufacturers actually advise the avoidance of adenosine in patients taking dipyridamole. If it must be used for supraventricular tachycardia in a patient taking dipyridamole, they recommend that the adenosine dose should be reduced about fourfold.[8]

The UK manufacturers advise the avoidance of adenosine for stress testing in patients taking dipyridamole. If adenosine is considered necessary, they suggest that the dipyridamole should be stopped 24 hours before testing, or the dose of adenosine should be greatly reduced.[9] This may be insufficient for extended-release dipyridamole preparations: the authors of the above report recommend stopping dipyridamole several days before testing.[7] Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects resulting from the use of adenosine infusions in myocardial imaging, see 'Adenosine + Xanthines', below.

Adenosine + Nicotine

Nicotine appears to enhance the effects of adenosine, but the clinical relevance of this is unclear.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, **nicotine chewing gum** 2 mg (approximately equal to one cigarette) increased the circulatory effects of a 70 micrograms/kg per minute infusion of adenosine. The 5.5 bpm increase in heart rate due to nicotine was further increased to 14.9 bpm by adenosine, and the 7 mmHg diastolic blood pressure rise due to nicotine was reduced to 1.1 mmHg by adenosine.[1] In another study, in 7 healthy subjects, **nicotine chewing gum** 2 mg increased chest pain and the duration of AV block when it was given with intravenous bolus doses of adenosine.[2] What this means in practical terms is uncertain, but be aware that the effects of adenosine may be modified to some extent by nicotine-containing products (**tobacco smoking**, **nicotine gum**, etc.).

Adenosine + Xanthines

Caffeine and theophylline can inhibit the effects of adenosine infusions used in conjunction with radionuclide myocardial imaging. Aminophylline has been used to terminate persistent adverse effects of adenosine infusions, but adenosine may still be effective for terminating supraventricular tachycardia in patients taking xanthines.

Clinical evidence

(a) Adenosine bolus for supraventricular tachycardia

It is usually considered that an adenosine bolus for the termination of paroxysmal supraventricular tachycardia will be ineffective in patients taking xanthines. However, one case describes a man taking **theophylline** (serum level 8 nanograms/mL) in whom adenosine 9 mg terminated supraventricular tachycardia. Two previous adenosine doses, one of 3 mg and one of 6 mg had not been effective.[1] Another report found that high adenosine doses, of 400 to 800 micrograms/kg (usual dose 50 to 200 micrograms/kg), were required to revert supraventricular tachycardia in a preterm infant receiving **theophylline**.[2]

(b) Adenosine infusion

Experimental studies in healthy subjects, on the way xanthine drugs possibly interact with adenosine, have found that **caffeine** and **theophylline** reduced the increased heart rate and the changes in blood pressure caused by infusions of adenosine,[3-6] and attenuated adenosine-induced vasodilatation.[7,8] **Theophylline** also attenuated adenosine-induced respiratory effects and chest pain.[5,6] Similarly, an adenosine infusion antagonised the haemodynamic effects of a single dose of **theophylline** in healthy subjects, but did not reduce the metabolic effects (reductions in plasma potassium and magnesium).[5]

Mechanism

Caffeine and theophylline have an antagonistic effect on adenosine receptors.[9] They appear to have opposite effects on the circulatory system: caffeine and theophylline cause vasoconstriction whereas adenosine infusions generally cause vasodilatation.[3] Consequently their concurrent use is likely to result in an interaction.

Importance and management

Adenosine bolus injections for the termination of paroxysmal supraventricular tachycardia may still be effective in patients receiving xanthines. The usual dose schedule should be followed. However, note that adenosine has induced bronchospasm. The US manufacturers[10,11] state that adenosine preparations, whether used for supraventricular tachycardia or myocardial imaging, should be avoided in patients with bronchoconstriction or bronchospasm (e.g. asthma), and used cautiously in those with obstructive pulmonary disease not associated with bronchospasm (e.g. emphysema, bronchitis). The UK manufacturers similarly recommend that the product used for supraventricular tachycardia[12] should be avoided in asthma, and warn that adenosine may precipitate or aggravate bronchospasm. They also contraindicate the use of adenosine for diagnostic imaging[13] in both asthma and other obstructive pulmonary disease associated with bronchospasm. Whether an adenosine bolus can stop theophylline-induced supraventricular tachycardia appears not to have been studied.

The manufacturers of adenosine also state that theophylline, aminophylline and other xanthines should be avoided for 24 hours before using an adenosine infusion in conjunction with radionuclide myocardial imaging, and that xanthine-containing drinks (tea, coffee, chocolate, cola drinks etc.) should be avoided for at least 12 hours before imaging.[13] In a recent study in 70 patients, measurable caffeine serum levels were found in 74% of patients after 12 hours of self-reported abstention from caffeine-containing products. Patients with caffeine serum levels of at least 2.9 mg/L had significantly fewer stress symptoms (chest tightness, chest pain, headache, dyspnoea, nausea, dizziness) than those with lower serum levels. The authors suggest that a 12-hour abstention from caffeine-containing products may be insufficient, and could result in false-negative results.[14] Xanthines, such as intravenous aminophylline, have been used to terminate persistent adverse effects of adenosine infusion given for myocardial imaging.[13]

Ajmaline + Miscellaneous

An isolated report describes cardiac failure in a patient given ajmaline with lidocaine. Quinidine causes a very considerable increase in ajmaline levels, whereas phenobarbital appears to cause an increase in ajmaline clearance.

Clinical evidence, mechanism, importance and management

(a) Lidocaine

A woman had a marked aggravation of her existing cardiac failure when she was given ajmaline orally and lidocaine intravenously for repeated ventricular tachycardias.[1] The general relevance of this isolated case is uncertain.

(b) Phenobarbital

The clearance of intravenous ajmaline was almost twice as high in 3 patients also taking phenobarbital when compared with 5 patients who were not taking phenobarbital. Therefore the clinical effects of ajmaline would be expected to be diminished in those taking phenobarbital.[2] The clinical relevance of this interaction does not appear to have been established. Nevertheless, it would seem prudent to monitor concurrent use to ensure ajmaline remains effective.

(c) Quinidine

A single-dose study[3] in 4 healthy subjects found that the concurrent use of quinidine 200 mg with ajmaline 50 mg increased the AUC of ajmaline 10- to 30-fold and increased its maximum plasma concentration from 18 nanograms/mL to 141 nanograms/mL. Another single-dose study in 5 healthy subjects found that the metabolism of ajmaline was inhibited by quinidine, possibly because the quinidine becomes competitively bound to the enzymes that metabolise ajmaline.[4] This marked rise in ajmaline levels is likely to increase its adverse effects, and concurrent use should probably be avoided.

Amiodarone + Anaesthesia

There is some evidence that the presence of amiodarone possibly increases the risk of complications (atropine-resistant bradycardia, hypotension, decreased cardiac output) during general anaesthesia. All of these cases were with fentanyl-based anaesthesia, but other studies have shown no problems with fentanyl-based anaesthesia.

Clinical evidence

(a) Evidence for complications

Several case reports[1-4] and two studies[5,6] suggest that severe intra-operative complications (atropine-resistant bradycardia, myocardial depression, hypotension) may occur in patients receiving amiodarone. One of the studies, a comparative retrospective review of patients (16 receiving amiodarone 300 to 800 mg daily and 30 controls) having operations under anaesthesia (mainly open-heart surgery), found that the incidence of slow nodal rhythm, complete heart block or pacemaker dependency rose from 17% in controls to 66% in amiodarone-treated patients. Intra-aortic balloon pump augmentation (reflecting poor cardiac output) was 50% in the amiodarone group compared with 7% in the control group, and a state of low systemic vascular resistance with normal to high cardiac output occurred in 13% of the amiodarone-treated patients, but not in the control patients. Overall there were 3 fatalities; all of these patients had received amiodarone and had been on cardiopulmonary bypass during surgery. **Fentanyl** was used for all of the patients, often combined with diazepam, and sometimes also **isoflurane**, **enflurane** or **halothane**.[5]

Another study of 37 patients receiving amiodarone (mean dose about 250 mg daily) found no problems in 8 patients undergoing non-cardiac surgery. Of the 29 patients undergoing cardiac surgery, 52% had postoperative arrhythmias and 24% required a pacemaker, which was not considered exceptional for the type of surgery. However, one patient having coronary artery bypass surgery had fatal vasoplegia (a hypotensive syndrome), which was considered to be amiodarone-related. This occurred shortly after he was taken off cardiopulmonary bypass. Anaesthesia in all patients was **fentanyl**-based.[6] It was suggested in one case report that serious hypotension in 2 patients taking amiodarone undergoing surgery may have been further compounded by the presence of an **ACE inhibitor**.[3] For interactions between ACE inhibitors and anaesthetics see 'Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists', p.102.

(b) Evidence for no complications

The preliminary report of a study in 21 patients taking amiodarone (mean dose 538 mg daily) and undergoing defibrillator implantation suggested that haemodynamic changes during surgery were not significantly different from those in matched controls not taking amiodarone.[7] Similarly, another study found no difference in haemodynamic status or pacemaker

dependency between patients taking short-term amiodarone 600 mg daily for one week then 400 mg daily for 2 weeks before surgery and a control group not taking amiodarone, during valve replacement surgery with **thiopental-fentanyl** anaesthesia.[8] In a double-blind study, there was no significant difference in haemodynamic instability during **fentanyl-isoflurane** anaesthesia between patients randomised to receive short-term amiodarone (3.4 g over 5 days or 2.2 g over 24 hours) or placebo before cardiac surgery. In this study, haemodynamic instability was assessed by fluid balance, use of dopamine or other vasopressors, and use of a phosphodiesterase inhibitor or intra-aortic balloon pump.[9]

A case report describes the successful use of epidural anaesthesia with **fentanyl** then **chloroprocaine** during labour and caesarean section in a woman who had been taking amiodarone long-term. The only haemodynamic change of possible note was that the patient had a drop in systemic vascular resistance from high to almost normal levels shortly after receiving **fentanyl** during the first stage of labour, and again when **fentanyl** was given for postoperative pain relief.[10] Another case report describes the successful use of epidural anaesthesia using incremental doses of lidocaine 2% with adrenaline and **fentanyl** 100 micrograms for caesarean section in a woman receiving high-dose amiodarone (1600 mg daily) for fetal supraventricular tachycardia.[11]

Mechanism

In vitro and *in vivo* studies in *animals* suggest that amiodarone has additive cardiodepressant and vasodilator effects with volatile anaesthetics such as halothane, enflurane and isoflurane.[2,12] The manufacturer notes that fentanyl is a substrate for the cytochrome P450 isoenzyme CYP3A4, and that amiodarone might inhibit CYP3A4, thereby increasing the toxicity of fentanyl.[13]

Importance and management

The assessment of this interaction is complicated by the problem of conducting studies in anaesthesia, most being retrospective and using matched controls. The only randomised study used short-term amiodarone to assess its safety in the prevention of post-operative atrial fibrillation, and its findings may not be relevant to patients taking long-term amiodarone.[9] It appears that potentially severe complications may occur in some patients taking amiodarone who undergo general anaesthesia, including bradycardia unresponsive to atropine, hypotension, conduction disturbances, and decreased cardiac output. It has been suggested that anaesthetists should take particular care in patients taking amiodarone who undergo surgery on cardiopulmonary bypass.[14] Amiodarone persists in the body for many weeks, which usually means it cannot be withdrawn before surgery, especially if there are risks in delaying surgery,[6] or the amiodarone is being used for serious arrhythmias.[14] A possible pharmacokinetic interaction exists between fentanyl and amiodarone, which could contribute to the interactions seen, and further study is needed on this.

Amiodarone + Beta blockers

The concurrent use of amiodarone and beta blockers can be beneficial; however, hypotension, bradycardia, ventricular fibrillation and asystole have been seen in a few patients given amiodarone with propranolol, metoprolol or sotalol (for sotalol, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). Torsade de pointes developed in two patients taking amiodarone and atenolol, but other factors may have contributed to the development of the arrhythmia. Amiodarone may inhibit the metabolism of beta blockers metabolised by CYP2D6, such as metoprolol, which might be a factor in the interaction.

Clinical evidence

(a) Case reports of problems

A 64-year-old woman with hypertrophic cardiomyopathy taking amiodarone 1.2 g daily and **atenolol** 50 mg daily had her **atenolol** replaced by **metoprolol** 100 mg daily. Within 3 hours she complained of dizziness, weakness and blurred vision. On examination she was found to be pale and sweating with a pulse rate of 20 bpm. Her systolic blood pressure was 60 mmHg. Atropine 2 mg did not produce chronotropic or haemodynamic improvement. She responded to isoprenaline (isoproterenol).[1] In a review of torsade de pointes in patients taking amiodarone long-term, two elderly patients developed torsade de pointes 3 and 5 weeks after **atenolol** 25 mg daily was added. Bradycardia was observed in one patient and hypokalaemia probably contributed to the arrhythmia in the other patient.[2] Severe hypotension has been reported in another patient taking **sotalol** when intravenous amiodarone (total dose 250 mg) was given.[3] Another report describes cardiac arrest in one patient taking amiodarone, and severe bradycardia and ventricular fibrillation (requiring defibrillation) in another, within 1.5 hours and 2 hours of starting to take **propranolol**.[4]

(b) Clinical studies showing benefits

In contrast to the above case reports, a placebo-controlled study to assess the efficacy of amiodarone in preventing atrial fibrillation in elderly patients undergoing open-heart surgery found that in the amiodarone group, atrial fibrillation occurred in 12 of 77 patients (16%) also receiving beta blockers (about 80% were taking **metoprolol** and about 10% **atenolol** and the rest taking unnamed drug) and in 15 of 43 (35%) who did not receive or tolerate beta blockers. The combination of amiodarone and beta blockers may be associated with a lower risk of cerebrovascular accidents and ventricular tachycardia.[5] An analysis of data from two large clinical studies of the use of amiodarone for post-myocardial infarction arrhythmias found that the combination of unnamed beta blockers and amiodarone was beneficial (reduced cardiac deaths, arrhythmic deaths and resuscitated cardiac arrest) compared with either drug alone, or neither drug. Discontinuation of amiodarone because of excessive bradycardia was no more frequent when beta blockers were also given, although more patients taking amiodarone discontinued beta blockers than those taking placebo.[6] Similarly, in the analysis of another study in ischaemic heart failure, the benefits of **carvedilol** were still apparent in those patients already receiving amiodarone, and the combination was not associated with a greater incidence of adverse effects (worsened heart failure, hypotension or dizziness, bradycardia or atrioventricular block) than either drug alone.[7]

(c) Pharmacokinetics

In one study, 10 elderly patients (9 with symptomatic atrial fibrillation and one with an implanted defibrillator and frequent ventricular tachycardia) taking **metoprolol** (mean daily dose 119 mg) were also given amiodarone 1.2 g daily for 6 days. The **metoprolol** AUC and plasma levels were increased by about 80% and 75%, respectively, by the amiodarone, the extent varying by CYP2D6 genotype.[8] None of the patients included in the study were poor metabolisers (that is, those lacking CYP2D6).

In another study in 120 patients with cardiac arrhythmias taking **metoprolol**, the concurrent use of amiodarone in an average dose of 170 mg daily for one month in 30 patients increased the **metoprolol** serum concentration to dose ratio. Furthermore, the **metoprolol** dose was higher in those patients receiving **metoprolol** alone.[9] In another study by the same authors in patients with heart failure receiving **carvedilol**, it was found that the serum concentration to dose ratio for ***R*-carvedilol** was not affected by amiodarone given for 14 days. However, the serum concentration to

dose ratio for ***S*-carvedilol** and the serum ***S*- to *R*-carvedilol** ratio was significantly lower in the group given **carvedilol** alone than in the group given **carvedilol** and amiodarone,[10] suggesting that amiodarone inhibits the metabolism of ***S*-carvedilol**.

Mechanism

Not understood. The clinical picture is that of excessive beta-blockade, and additive pharmacodynamic effects are possible. Bradycardia associated with beta blockers and amiodarone can induce early after-depolarisations and facilitate torsade de pointes.[2] In addition, amiodarone and its metabolite, desethylamiodarone, increase the levels of metoprolol by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP2D6.[8,9] Other beta blockers that are also substrates of CYP2D6, and which could therefore be similarly affected, include carvedilol and propranolol. However, the study with carvedilol suggests that other factors (e.g. other isoenzymes (CYP2C9), P-glycoprotein) may also be involved.[10]

Importance and management

The reports of adverse reactions cited here emphasise the need for caution when amiodarone is used with beta blockers. The manufacturers of amiodarone recommend that the combination should not be used[11] or used with caution[12] because potentiation of negative chronotropic properties and conduction-slowing effects may occur. However, the concurrent use of beta blockers and amiodarone is not uncommon and may be therapeutically useful. The authors of one of the analyses suggest that post-myocardial infarction, if possible, beta blockers should be continued in patients for whom amiodarone is indicated.[6] A pharmacokinetic interaction between amiodarone and beta blockers that are substrates of CYP2D6, such as metoprolol, also appears to be established. Although this interaction with other moderate inhibitors of CYP2D6 is generally not thought to be clinically relevant (e.g. see 'Beta blockers + SSRIs', p.1019), it is possible that this pharmacokinetic interaction plays some part in the adverse reactions sometimes seen, or even in the clinical benefits.[5,8]

Note that the concurrent use of sotalol presents a greater risk than that of other beta blockers, as it may prolong the QT interval. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for more information.

Amiodarone + Calcium-channel blockers

Increased cardiac depressant effects would be expected if amiodarone is used with diltiazem or verapamil. One case of sinus arrest and serious hypotension occurred in a woman taking diltiazem when she was given amiodarone.

Clinical evidence, mechanism, importance and management

A woman with compensated congestive heart failure, paroxysmal atrial fibrillation and ventricular arrhythmias was taking furosemide and **diltiazem** 90 mg every 6 hours. Four days after amiodarone 600 mg every 12 hours was added, she developed sinus arrest and a life-threatening low cardiac output state (systolic blood pressure 80 mmHg) with oliguria. **Diltiazem** and amiodarone were stopped and she was treated with pressor drugs and ventricular pacing. She had previously had no problems when taking **diltiazem** or **verapamil** alone, and later she took amiodarone 400 mg daily alone without incident. This reaction is thought to be caused by the additive effects of both drugs on myocardial contractility, and on sinus and atrioventricular nodal function.[1] Before this isolated case report was published, another author predicted this interaction with **diltiazem** or **verapamil** on theoretical grounds, and warned of the risks if dysfunction of the sinus node (bradycardia or sick sinus syndrome) is suspected, or if partial AV block exists.[2] The manufacturers state that amiodarone should not be used,[3] or used with caution,[4] with certain calcium-channel blockers (**diltiazem**, **verapamil**) because potentiation of negative chronotropic properties and conduction-slowing effects may occur. Note that **diltiazem** has been used for rate control in patients developing postoperative atrial fibrillation despite the use of prophylactic amiodarone.[5] There do not appear to be any reports of adverse effects attributed to the use of amiodarone with the dihydropyridine class of calcium-channel blockers (e.g. **nifedipine**), which typically have little or no negative inotropic activity at usual doses.

Amiodarone + Chloroquine

In theory the concurrent use of chloroquine and amiodarone may increase the risk of torsade de pointes, but there appears to be no published cases of an interaction.
106 Clinical evidence, mechanism, importance and management

Some UK manufacturers of amiodarone and chloroquine contraindicate the concurrent use of these drugs because of the risk of torsade de pointes,[1,2] whereas another warns of an increased risk of arrhythmias.[3] Chloroquine may cause arrhythmias and ECG changes when used alone, particularly in high doses[2,3] and for prolonged periods (e.g. for rheumatoid arthritis);[2] however, chloroquine is not generally considered a high risk for causing cardiovascular toxicity, especially when given at the correct dose and administered appropriately.[4] There appears to be only one isolated report of QT prolongation in a patient taking chloroquine, but this was secondary to long term use (17 years) for systemic lupus erythematosus,[5] and no published cases of an interaction with amiodarone. Furthermore, the US manufacturers of amiodarone and chloroquine do not include any warnings about QT prolongation on concurrent use.[6,7] An interaction is therefore not established.

Amiodarone + Cimetidine

Cimetidine possibly causes a modest rise in the serum levels of amiodarone in some patients.

Clinical evidence, mechanism, importance and management

The preliminary report of one study in 12 patients noted that the mean serum levels of amiodarone 200 mg twice daily rose by an average of 38%, from 1.4 micrograms/mL to 1.93 micrograms/mL, when cimetidine 1.2 g daily was given for a week. The desethylamiodarone levels rose by 54%. However, these increases were not statistically significant (possibly due to the small sample size), and only 8 of the 12 patients had any rise.[1]

It is possible that cimetidine (a non-specific enzyme inhibitor) may reduce the metabolism of amiodarone leading to the increased levels seen.

Information seems to be limited to this study but this interaction may be clinically important in some patients. Monitor the effects when cimetidine is started, being alert for amiodarone adverse effects (e.g. bradycardia, taste disturbances, tremor, nausea). Remember that amiodarone has a very long half-life of 25 to 100 days, so that the results of the one-week study cited here may possibly not adequately reflect the magnitude of this interaction. There does not appear to have been anything further published on this.

1. Hogan C, Landau S, Tepper D, Somberg J. Cimetidine-amiodarone interaction. *J Clin Pharmacol* (1988) 28, 909.

Amiodarone + Colestyramine

Colestyramine appears to reduce the serum levels of amiodarone.

Clinical evidence

In a study in 11 patients, 4 doses of colestyramine 4 g were given at one-hour intervals starting 1.5 hours after a single 400-mg dose of amiodarone. The serum amiodarone levels measured 7.5 hours later were reduced by about 50%.[1] In a further study, the amiodarone half-life was shorter in 3 patients given colestyramine 4 g daily after discontinuing long-term amiodarone (23.5, 29 and 32 days, respectively) compared with the half-life in 8 patients discontinuing amiodarone and not given colestyramine (35 to 58 days).[1]

Mechanism

This interaction probably occurs because colestyramine binds with amiodarone in the gut, thereby reducing its absorption. It may also affect the enterohepatic recirculation of amiodarone.[1] This is consistent with the way colestyramine interacts with other drugs.

Importance and management

Information is very limited but a reduced response to amiodarone may be expected. Separating the dosages to avoid admixture in the gut would reduce or prevent any effects on absorption from the gut, but not the effects due to reduced enterohepatic recirculation. Monitor concurrent use closely for amiodarone efficacy and consider an alternative to colestyramine, or raise the amiodarone dosage if necessary.

Amiodarone + Co-trimoxazole

Some predict that co-trimoxazole (trimethoprim with sulfamethoxazole) increases the risk of QT prolongation and ventricular arrhythmias with amiodarone, but clinical evidence for this is sparse.

Clinical evidence, mechanism, importance and management

The UK manufacturer of amiodarone contraindicates the concurrent use of co-trimoxazole (trimethoprim with sulfamethoxazole), as they state that it prolongs the QT interval and increases the risk of torsade de pointes.[1] However, one UK manufacturer of co-trimoxazole similarly states that concurrent use increases the risk of ventricular arrhythmias, but does not specifically contraindicate concurrent use.[2] Co-trimoxazole is not generally associated with causing significant QT interval prolongation and torsade de pointes, and only three isolated cases appear to have been reported for co-trimoxazole alone,[3-5] of these, one was in a 90-year-old woman,[3] and another was in a patient genetically predisposed to QT prolongation.[4] Furthermore, the US manufacturer[6] of amiodarone and one other UK manufacturer[7] of co-trimoxazole make no mention of any possible interaction. An interaction is therefore not established.

Amiodarone + Disopyramide

The risk of QT interval prolongation and torsade de pointes is increased if amiodarone is given with disopyramide.

Clinical evidence

A brief report describes 2 patients who developed torsade de pointes when they were given amiodarone with disopyramide. Their QT intervals became markedly prolonged to somewhere between 500 and 600 milliseconds.[1] In another study, 2 patients who had been taking disopyramide 300 mg daily for a number of months developed prolonged QT intervals, increasing from 450 milliseconds to 640 milliseconds and from 390 milliseconds to 680 milliseconds respectively, and developed torsade de pointes 2 days and 5 days respectively, after starting amiodarone 800 mg daily.[2] However, one early report also described the successful and apparently safe use of amiodarone 100 to 600 mg daily with disopyramide 300 to 500 mg daily,[3] although the results of long-term follow-up were not reported in all cases.

Mechanism

Amiodarone is a class III antiarrhythmic and can prolong the QT interval. Disopyramide is a class Ia antiarrhythmic and also prolongs the QT interval. Their additive effects can result in the development of torsade de pointes.

Importance and management

An established and potentially serious interaction. In general, class Ia antiarrhythmics such as disopyramide (see 'Table 9.2', (p.290)) should be avoided or used with great caution with amiodarone because of their additive effects in delaying conduction. The manufacturers of amiodarone contraindicate[4] or urge caution[5] if it is used with class Ia antiarrhythmics. If amiodarone is started in a patient taking disopyramide, they suggest the dose of disopyramide should be reduced by 30 to 50% several days after the addition of amiodarone, and that the continued need for disopyramide should be monitored, and withdrawal attempted. If disopyramide is given to a patient already taking amiodarone, the initial dose of disopyramide should be about half of the usual recommended dose.[5]

See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, and for the interactions of other class Ia antiarrhythmics with amiodarone see 'Procainamide + Amiodarone', p.306, and 'Quinidine + Amiodarone', p.312.

Amiodarone + Grapefruit juice

Grapefruit juice inhibited the metabolism of oral amiodarone, and *decreased* its effects on the PR and QTc interval.

Clinical evidence

A single 17-mg/kg oral dose of amiodarone was given to 11 healthy subjects on two occasions, once with water and once with grapefruit juice (300 mL taken three times on the same day). Grapefruit juice completely inhibited the metabolism of amiodarone to its major metabolite *N*-desethylamiodarone and increased the amiodarone AUC by 50% and increased its peak serum level by 84%. The effect of amiodarone on the PR and QTc intervals was *decreased*.[1]

Mechanism

It is likely that grapefruit juice inhibits the cytochrome P450 isoenzyme CYP3A4 in the intestinal mucosa, thus inhibiting the formation of *N*-desethylamiodarone from oral, but probably not intravenous, amiodarone.

Importance and management

The interaction between amiodarone and grapefruit juice appears to be established, but its clinical consequences remain to be determined. *N*-desethylamiodarone is known to be active, so this could possibly result in decreased activity. In addition, high amiodarone concentrations may increase toxicity. Conversely, a reduction in QT prolongation is potentially beneficial.[1] However, further study is needed to establish any beneficial effect. The US manufacturer recommends that grapefruit juice should not be taken during treatment with oral amiodarone.[2]

Amiodarone + Haloperidol

A retrospective study describes QT prolongation on the concurrent use of amiodarone and haloperidol.

Clinical evidence, mechanism, importance and management

A retrospective analysis identified 49 patients who were given amiodarone (mean daily dose 771 mg) with haloperidol (mean daily dose 11 mg) and a total of 381 instances of concurrent use (classified as haloperidol administration by any route within 24 hours of amiodarone administration by any route). Most patients were already taking amiodarone when haloperidol (intravenous haloperidol in 96% of patients) was given, with a mean increase in the QTc interval of 9.8 milliseconds. No ventricular arrhythmias were reported.[1] Both drugs are known to prolong the QT interval, and concurrent use is contraindicated by the UK manufacturers of amiodarone and haloperidol.[2,3] In contrast, the US manufacturer of amiodarone does not contraindicate the use of haloperidol, but advises that the concurrent use of amiodarone and any QT-prolonging drugs should only be undertaken after careful risk assessment.[4] For a further discussion of the risks of QT prolongation and the concurrent use or two or more QT-prolonging drugs, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Amiodarone + Lithium

Hypothyroidism developed very rapidly in two patients taking amiodarone when lithium was added.

Clinical evidence, mechanism, importance and management

A patient who had taken amiodarone 400 mg daily for more than a year developed acute manic depression. He was given lithium 600 mg daily (salt unknown), but within 2 weeks he developed clinical signs of hypothyroidism, which were confirmed by clinical tests. He made a complete recovery within 3 weeks of stopping amiodarone while continuing lithium.[1] Similarly, another patient rapidly developed hypothyroidism, when taking amiodarone with lithium (dose and salt unknown). It resolved when the amiodarone was stopped.[1] Both lithium and amiodarone on their own can cause hypothyroidism (amiodarone can also cause hyperthyroidism). In these two cases the effects appear to have been additive, and very rapid.

These two cases appear to be the first and only reports of this interaction. Its general importance is therefore still uncertain. Note that lithium has been tried for the treatment of amiodarone-induced hyperthyroidism,[2,3] and regular monitoring of thyroid status is recommended throughout amiodarone treatment.[4,5] It would therefore seem prudent to be extra vigilant for any signs of hypothyroidism (lethargy, weakness, depression, weight gain, hoarseness) in any patient given both drugs.

Lithium therapy has rarely been associated with cardiac QT prolongation, and consequently the UK manufacturer of amiodarone contraindicates combined use.[4] However, note that QT-prolongation associated with lithium is usually as a result of lithium toxicity. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Amiodarone + Macrolides

Torsade de pointes occurred in a man taking amiodarone when he was also given intravenous erythromycin. QT prolongation occurred in another patient when azithromycin was added to long-term amiodarone.

Clinical evidence

A 76-year-old man taking amiodarone 200 mg daily had a prolonged QT interval and a syncopal episode with torsade de pointes 24 hours after starting a course of intravenous **erythromycin lactobionate** (1 g every 6 hours). This occurred on rechallenge.[1] Marked QT prolongation and increased QT dispersion occurred when **azithromycin** was given to a patient taking amiodarone long-term, and resolved when the **azithromycin** was stopped.[2]

Mechanism

Amiodarone alone can prolong the QT interval and increase the risk of torsade de pointes. Of the macrolides, *intravenous* erythromycin is known to prolong the QT interval, and there is also some evidence that clarithromycin may prolong the QT interval.[3] Amiodarone and these macrolides may therefore have additive effects on the QT interval.

Importance and management

In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de pointes arrhythmias (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). For this reason, the UK manufacturer of amiodarone contraindicates the concurrent use of *intravenous* erythromycin.[4] The authors of the above report suggest that the combination of azithromycin and amiodarone should be used with caution,[2] and this should probably also apply to **clarithromycin** until more is known. The US manufacturer recommends that a careful risk assessment should be undertaken if amiodarone is to be given with a macrolide.[5]

Amiodarone + Metronidazole

An isolated report describes QT interval prolongation and torsade de pointes in a patient given metronidazole and amiodarone.

Clinical evidence, mechanism, importance and management

An elderly patient taking metronidazole 500 mg three times daily for antibacterial-associated colitis and amiodarone (as an initial bolus of 450 mg followed by 900 mg daily) for paroxysmal atrial fibrillation developed marked QTc interval prolongation and torsade de pointes. Metronidazole and amiodarone were withdrawn and defibrillation was required to restore sinus rhythm. The QTc interval gradually decreased to normal over 6 days.[1]

It was suggested that metronidazole may have inhibited the metabolism of amiodarone by the cytochrome P450 isoenzyme CYP3A4 resulting in higher levels which are associated with QT interval prolongation and torsade de pointes.[1] However, some pharmacokinetic studies have found that metronidazole is not an inhibitor of CYP3A4/5 and suggest that increases in plasma levels of CYP3A4 substrates in the presence of metronidazole are not the result of CYP3A4 inhibition.[2] Furthermore, amiodarone was not given alone, so it is unclear if the effects seen were as a result of an interaction, of simply an adverse effect of the amiodarone. No general conclusions can be drawn from this isolated case.

Amiodarone + Orlistat

Orlistat modestly reduces the absorption of amiodarone.

Clinical evidence, mechanism, importance and management

A randomised, placebo-controlled study in 16 healthy subjects found that orlistat 120 mg three times daily reduced the AUC and peak serum level of a single 1.2-g dose of amiodarone by 23% and 27%, respectively. Levels of its active metabolite, desethylamiodarone, were similarly reduced. The half-life and time to maximum serum level were not significantly altered. It was suggested that orlistat, which inhibits dietary fat absorption, may also reduce the absorption of amiodarone, which is a lipophilic drug.[1]

Although this modest reduction in amiodarone levels is unlikely to be clinically relevant, the manufacturer of orlistat recommends clinical and ECG monitoring during concurrent use.[2]

Amiodarone + Oxygen

High-dose oxygen may increase the risks of amiodarone-induced postoperative adult respiratory distress syndrome.

Clinical evidence, mechanism, importance and management

A retrospective review of 20 patients who underwent cardiac surgery found that pulmonary complications were more common in those receiving amiodarone (73% versus 25%). Moreover, the incidence of pulmonary complications in patients taking amiodarone was higher in those exposed to 100% oxygen (6 of 7) than those not exposed to this concentration of oxygen (2 of 4).[1]

Four other patients taking amiodarone (without preoperative amiodarone pulmonary toxicity), developed postoperative toxicity, and 2 patients died. The common intraoperative factor in the 4 patients was exposure to high inspired oxygen concentrations.[2] A further two reports describe 3 patients taking amiodarone who developed acute onset unilateral adult respiratory distress syndrome after receiving 100% oxygen ventilation of one lung during surgery.[3,4]

Life-threatening pulmonary complications occurred in 4 patients with diagnosed amiodarone pulmonary toxicity who subsequently underwent cardiothoracic surgery: 2 patients died. These 4 patients were compared with 13 other patients taking amiodarone (only one of whom had preoperative amiodarone pulmonary toxicity) who were undergoing similar surgery and who did not develop pulmonary complications. The comparison indicated that *preoperative* amiodarone pulmonary toxicity appears to be a risk factor in the development of pulmonary complications, but other additional factors could include pump-oxygenator time and oxygen toxicity.[5]

The UK manufacturer of amiodarone suggests caution in patients receiving high-dose oxygen,[6] and the US manufacturer recommends that the determinants of oxygen delivery to the tissues should be closely monitored.[7] Others have suggested that the concentration of oxygen should be maintained at the lowest possible level consistent with adequate oxygenation.[1,3,4]

Amiodarone + Protease inhibitors

A case report describes increased amiodarone levels in a patient given indinavir. Other protease inhibitors are predicted to interact similarly.

Clinical evidence

A patient taking amiodarone 200 mg daily was also given zidovudine, lamivudine, and **indinavir** for 4 weeks, as post HIV-exposure prophylaxis after a needlestick injury. Amiodarone serum levels increased, from 0.9 mg/L before antiretroviral prophylaxis, to 1.3 mg/L during prophylaxis, and gradually decreased to 0.8 mg/L during the 77 days after stopping prophylaxis. Although the reference range for amiodarone levels is not established, these levels were not outside those usually considered to achieve good antiarrhythmic control.[1]

Mechanism

Protease inhibitors such as indinavir are inhibitors of cytochrome P450 enzymes and pharmacokinetic interactions are therefore possible. It was considered that the increase in serum amiodarone in this case was due to decreased metabolism of amiodarone, although no decrease in the serum levels of desethylamiodarone were observed.[1]

Importance and management

Although in the case cited the interaction was not clinically relevant, the authors considered that it could be important in patients with higher initial amiodarone levels. They recommend monitoring amiodarone if indinavir is also given.[1] In general the UK manufacturers of protease inhibitors suggest that they may increase amiodarone levels, and contraindicate concurrent use. The exception is **atazanavir**/**ritonavir**,[2] where caution and increased monitoring, including taking amiodarone levels, where possible, is recommended. Similarly the US manufacturers of the protease inhibitors generally contraindicate concurrent use. The exceptions are **amprenavir**,[3] **atazanavir**,[4] **darunavir**/**ritonavir**,[5] **fosamprenavir**[6] and **lopinavir**/**ritonavir**,[7] where the manufacturers recommend increased

monitoring, including taking amiodarone levels, where possible. Amiodarone adverse effects include bradycardia, taste disturbances, tremor and nausea.

Amiodarone + Quinolones

Torsade de pointes has been reported in two patients taking amiodarone and levofloxacin. Post-marketing surveillance identified two similar cases with amiodarone and sparfloxacin. An increased risk of this arrhythmia would also be expected if amiodarone is used with gatifloxacin or moxifloxacin.

Clinical evidence, mechanism, importance and management

Torsade de pointes occurred in a patient taking **levofloxacin** and amiodarone.[1] The same authors subsequently encountered a second case of this reaction.[2] The Adverse Events Reporting System database of the FDA in the US was reviewed for cases of torsade de pointes associated with quinolones up until May 2001. In total, 37 cases of torsade de pointes were identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval. Of the 19 cases, 4 cases were noted in patients taking amiodarone and a quinolone (unspecified, but **ciprofloxacin**, **gatifloxacin**, **levofloxacin**, **moxifloxacin**, and **ofloxacin** were assessed).[3] These 4 cases possibly include the two with **levofloxacin** mentioned above.

During post-marketing surveillance of **sparfloxacin** in France over a period of 8 months (about 750 000 patients) serious adverse cardiovascular effects were reported in 7 patients. All 7 patients had underlying risk factors including 3 patients who were also receiving amiodarone. Of these, 2 patients had documented QT prolongation and ventricular tachycardia.[4]

Amiodarone can prolong the QT interval and increase the risk of torsade de pointes. Of the quinolones used clinically, **gatifloxacin**, **moxifloxacin**, and **sparfloxacin** are known to prolong the QT interval (see 'Table 9.2', (p.290)). There is also evidence that **levofloxacin** may prolong the QT interval.[2,3]

In general the concurrent use of two or more drugs that prolong the QT interval should be avoided, because this increases the risk of torsade de pointes arrhythmias (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). The quinolones that prolong the QT interval should probably be avoided in patients taking amiodarone: moxifloxacin is specifically contraindicated.[5] **Ciprofloxacin** appears to have less effect on the QT interval.[3] Nevertheless, in the UK the manufacturer of amiodarone suggests that the concurrent use of any quinolone should be avoided.[5]

Amiodarone + Rifampicin (Rifampin)

A case report suggests that rifampicin may decrease the serum levels of amiodarone and its metabolite *N*-desethylamiodarone.

Clinical evidence, mechanism, importance and management

A woman with congenital heart disease, and atrial and ventricular arrhythmias managed by an implanted cardioverter defibrillator, epicardial pacing and amiodarone 400 mg daily, experienced deterioration in the control of her condition. She developed palpitations and experienced a shock from the defibrillator. Her amiodarone serum levels were 40% lower than 2 months previously, and her *N*-desethylamiodarone levels were undetectable. It was noted that 5 weeks earlier rifampicin 600 mg daily had been started to treat an infection of the pacing system. The amiodarone dose was doubled, but the palpitations continued. Amiodarone and *N*-desethylamiodarone levels increased after rifampicin was discontinued.[1] Rifampicin is a potent enzyme inducer and it may have increased the metabolism and clearance of amiodarone. Evidence appears to be limited to this case, but it is in line with the way both drugs are known to interact with other substances. An interaction would therefore seem to be established. It would be prudent to monitor concurrent use for amiodarone efficacy, taking amiodarone and metabolite levels, where possible.

1. Zarembski DG, Fischer SA, Santucci PA, Porter MT, Costanzo MR, Trohman RG. Impact of rifampin on serum amiodarone concentrations in a patient with congenital heart disease. *Pharmacotherapy* (1999) 19, 249–51.

Amiodarone + Sertraline

In an isolated report, a slight to moderate rise in plasma amiodarone levels was attributed to the concurrent use of sertraline.

Clinical evidence, mechanism, importance and management

A depressed patient taking amiodarone 200 mg twice daily had his treatment with carbamazepine 200 mg twice daily and sertraline 100 mg daily stopped, just before ECT treatment. After 4 days it was noted that his plasma amiodarone levels had fallen by nearly 20%. The authors of the report drew the conclusion that while taking all three drugs, the amiodarone levels had become slightly raised due to the enzyme inhibitory effects of the sertraline, despite the potential enzyme-inducing activity of the carbamazepine.[1] The patient had no changes in his cardiac status while amiodarone levels were reduced. Furthermore, a change of 20% would usually be considered to be within the normal fluctuation of drug levels. Therefore an interaction, particularly a clinically relevant interaction, seems unlikely.

1. DeVane CL, Gill HS, Markowitz JS, Carson WH. Awareness of potential drug interactions may aid avoidance. *Ther Drug Monit* (1997) 19, 366–7.

Amiodarone + Tolvaptan

Tolvaptan does not appear to affect the pharmacokinetics of amiodarone.

Clinical evidence, mechanism, importance and management

In a study in 17 patients with stable arrhythmias taking amiodarone 200 mg daily, single 30- or 90-mg doses of tolvaptan had no effect on the AUC or maximum plasma concentrations of amiodarone or its metabolite, desethylamiodarone. The pharmacokinetics of tolvaptan did not appear to differ, when compared with historical control data. No clinically relevant ECG changes were reported on concurrent use.[1]

Therefore, no amiodarone dose adjustment would be expected to be needed on the concurrent use of tolvaptan.

1. Shoaf SE, Elizari MV, Wang Z, Sekar K, Grinfeld LR, Barbagelata NA, Lerman J, Bramer SL, Trongé J, Orlandi C. Tolvaptan administration does not affect steady state amiodarone concentrations in patients with cardiac arrhythmias. *J Cardiovasc Pharmacol Ther* (2005) 10, 165–71.

Amiodarone + Trazodone

Two reports describe the development of torsade de pointes in patients taking trazodone and amiodarone; in one case trazodone was added to amiodarone, and in the other case amiodarone was added to trazodone.

Clinical evidence, mechanism, importance and management

A 74-year-old woman with a pacemaker, taking nifedipine, furosemide, aspirin and amiodarone 200 mg daily, began to have dizzy spells but no loss of consciousness soon after starting trazodone (initially 50 mg and

eventually 150 mg daily by the end of 2 weeks). Both the amiodarone and trazodone were stopped when she was hospitalised. She had a prolonged QTc interval and recurrent episodes of torsade de pointes, which were controlled by increasing the ventricular pacing rate. The QTc interval shortened and she was later discharged taking amiodarone without the trazodone, with an ECG similar to that seen 4 months before hospitalisation.[1] In a review of torsade de pointes in patients taking amiodarone long-term, one elderly female patient who had taken trazodone 50 mg daily for 2 years developed torsade de pointes 2 months after amiodarone 200 mg daily was added. The authors noted that hypokalaemia in this patient may have contributed to the arrhythmia.[2]

No general conclusions can be drawn from this apparent interaction, but prescribers should be aware of these cases. The manufacturer notes that trazodone does have the potential to be arrhythmogenic.[3]

Aprindine + Amiodarone

Serum aprindine levels can be increased by amiodarone.

Clinical evidence, mechanism, importance and management

The serum aprindine levels of 2 patients rose, accompanied by signs of toxicity (e.g. nausea, ataxia), when they were also given amiodarone. One of them, taking aprindine 100 mg daily, had a progressive rise in trough serum levels from 2.3 mg/L to 3.5 mg/L over a 5-week period, when given 1.2 g and later 600 mg of amiodarone daily. Even when the aprindine dose was reduced, serum levels remained higher than before amiodarone was started.[1] The authors say that those taking both drugs generally need less aprindine than those taking aprindine alone. This interaction has been briefly reported elsewhere.[2]

The reason for the rise in aprindine levels is not understood. Nevertheless it would seem prudent to monitor the effects of concurrent use and reduce the dose of aprindine as necessary.

Azimilide + Miscellaneous

Ketoconazole (a CYP3A4 inhibitor) did not alter the pharmacokinetics of azimilide to a clinically relevant extent, and azimilide did not affect the pharmacokinetics of omeprazole (a CYP2C19 substrate) to a clinically relevant extent. Interactions with other CYP3A4 inhibitors and CYP2C19 substrates are therefore considered unlikely.

A case report describes QT prolongation in a patient given azimilide and ciprofloxacin. Azimilide does not appear to interact to a clinically relevant extent with digoxin or food, and its antiarrhythmic effects are unaffected by isoprenaline (isoproterenol).

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

A patient with a history of myocardial infarction and with an implanted cardioverter-defibrillator (ICD) who was taking several drugs including azimilide 125 mg daily, was admitted to hospital because of worsening heart failure. On day 6 he developed a urinary-tract infection and was given ciprofloxacin 250 mg twice daily, but after 2 doses he developed QTc interval prolongation (increase from 470 milliseconds on admission to 754 milliseconds) and multiple episodes of torsade de pointes followed by ICD shocks. Azimilide and ciprofloxacin were withdrawn and he was given metoprolol but he also required ICD reprogramming. It was suggested that this occurred as a result of the additive effects of both drugs on the QT interval.[1]

(b) Digoxin

A study in 18 healthy subjects found that the concurrent use of azimilide and digoxin had only minor effects on the pharmacokinetics of both drugs (azimilide renal clearance increased by 36%, digoxin maximum serum level and AUC increased by 21% and 10%, respectively). In this study, azimilide 175 mg was given orally daily for 4 days then 100 mg on day 5 and digoxin was given as a loading dose of 750 micrograms on day one then as 250 micrograms daily for 4 days. Azimilide alone increased the QTc: this effect was decreased by 2 to 4% by digoxin. These effects are unlikely to be clinically relevant.[2]

(c) Food

A study in 30 healthy subjects given azimilide in the fasted state or after a high-fat meal found that the high-fat meal decreased the maximum serum levels of azimilide by 19%, but the extent of absorption was the same. Azimilide may be given without regard to meal times.[3]

(d) Isoprenaline (Isoproterenol)

In a placebo-controlled study, patients with cardiovascular disorders were given an infusion of isoprenaline, titrated from 0.5 micrograms/minute up to a maximum of 4 micrograms/minute until the heart rate reached 125% of baseline (up to a maximum 120 bpm). This dose of isoprenaline was then given again, but with an infusion of azimilide, as a loading dose of 4.5 mg/kg over 15 minutes followed by a continuous infusion of 0.625 mg/kg per hour. It was found that azimilide maintained its class III antiarrhythmic effect in the presence of isoprenaline, and at increased heart rate.[4]

(e) Ketoconazole

In a randomised, placebo-controlled study, 21 healthy subjects were given ketoconazole 200 mg daily with a single 125-mg dose of azimilide on day 8. Ketoconazole affected the AUC, maximum blood levels, half-life and clearance of azimilide by less than 20%. Azimilide is partly metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by ketoconazole. The minor changes in azimilide pharmacokinetics with ketoconazole are not considered to be clinically important, and clinically significant pharmacokinetic interactions with other CYP3A4 inhibitors are not expected.[5]

(f) Omeprazole

In a randomised, placebo-controlled study, 40 healthy subjects (extensive metabolisers of the cytochrome P450 isoenzyme CYP2C19, that is, those that have normal levels of this isoenzyme) were given azimilide 125 mg every 12 hours for 3 days, then daily for 5 days. Azimilide reduced the AUC of a single 20-mg dose of omeprazole given on day 8 by 12%, which is not clinically relevant. There was no change in the metabolite-to-parent AUC suggesting that azimilide had no effect on the metabolism of omeprazole by CYP2C19.[6]

The authors note that *in vitro* studies suggested that of the cytochrome P450 isoenzymes, azimilide had the lowest inhibitory concentration against CYP2C19. On this basis they suggest that azimilide is also unlikely to interact with drugs metabolised by CYP1A2, CYP2C9, CYP2D6 and CYP3A4.[6]

Bretylium + Miscellaneous

The pressor effects of adrenaline (epinephrine) and noradrenaline (norepinephrine) are increased in the presence of bretylium. Amfetamine and protriptyline antagonise the blood pressure lowering effect of bretylium.

Clinical evidence

(a) Adrenaline (Epinephrine) or Noradrenaline (Norepinephrine)

In 4 healthy subjects, a dose of bretylium sufficient to produce postural hypotension enhanced the pressor effect of noradrenaline. A similar effect was found with adrenaline.[1]

(b) Amfetamine

When 7 patients with hypertension, taking bretylium 600 mg to 4 g daily were given a single 25-mg dose of amphetamine, 6 patients had a rise in blood pressure.[2]

(c) Protriptyline

An experimental study found that protriptyline can return the blood pressure to normal in patients taking bretylium, without reducing its antiarrhythmic efficacy.[3]

Mechanism

Animal studies have shown that bretylium reduces blood pressure via its blocking effects on adrenergic neurones similar to guanethidine.[4,5] Bretylium therefore enhances the effects of directly-acting sympathomimetics such as noradrenaline (norepinephrine), and is antagonised by drugs with indirect sympathomimetic activity such as the amfetamines and tricyclic antidepressants.

Importance and management

Although documentation is limited, based on the known pharmacology of bretylium, these interactions would appear to be established. The use of bretylium is limited to the short-term control of ventricular arrhythmias. In this situation, if directly-acting sympathomimetics such as noradrenaline (norepinephrine) are required to reverse bretylium-induced hypotension, this should be undertaken with caution since their effects may be enhanced.

Bretylium is no longer used for the treatment of hypertension, therefore the interactions with amfetamines and tricyclics are unlikely to be of much general relevance.

Cibenzoline (Cifenline) + H_2-receptor antagonists

Cimetidine increases the plasma levels of cibenzoline. Ranitidine does not interact with cibenzoline.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, **cimetidine** 1.2 g daily raised the maximum plasma levels of a single 160-mg dose of cibenzoline by 27%, increased its AUC by 44%, and prolonged its half-life by 30%. **Ranitidine** 300 mg daily had no effect.[1] The probable reason for the rise in cibenzoline levels is that **cimetidine**, an enzyme inhibitor, reduces the metabolism of the cibenzoline by the liver, whereas **ranitidine**, which is not an enzyme inhibitor, does not affect cibenzoline metabolism. The clinical importance of this interaction is not known but be alert for increased cibenzoline adverse effects.

Disopyramide + Antacids

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of disopyramide.

Clinical evidence, mechanism, importance and management

In a study in 10 patients, a single 11-g dose of an **aluminium phosphate** antacid had no statistically significant effect on the pharmacokinetics of a single 200-mg oral dose of disopyramide. However the antacid appeared to reduce the absorption of disopyramide to some extent in individual subjects.[1] The clinical importance of this interaction is uncertain, but probably small.

Disopyramide + Azoles

Ketoconazole increased the levels of disopyramide *in vitro*. Other azole antifungals would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

An *in vitro* study[1] found that **ketoconazole** inhibits the metabolism of disopyramide, although there do not appear to be any case reports or clinical studies of an interaction. Disopyramide is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is an inhibitor. Therefore concurrent use would be expected to increase disopyramide levels and adverse effects. The UK manufacturer of **ketoconazole** contraindicates the concurrent use of disopyramide, as this increase in disopyramide levels may increase the risk of developing QT prolongation and torsade de pointes.[2] As **itraconazole** is also a potent inhibitor of CYP3A4, the UK manufacturer[3] contraindicates its concurrent use in patients taking disopyramide for non-life threatening indications, whereas the US manufacturer advises caution during concurrent use.[4] Other azole antifungals inhibit CYP3A4 to varying degrees (see 'azole antifungals', (p.233)) and therefore they would also be expected to interact with disopyramide. If the concurrent use of disopyramide and an azole is necessary, it would seem prudent to monitor the patient for an increase in disopyramide adverse effects (such as dry mouth, blurred vision, urinary retention and nausea).

Disopyramide + Beta blockers

Severe bradycardia has been described after the use of disopyramide with beta blockers including practolol, pindolol, and metoprolol; in some cases this was fatal. Atenolol modestly decreased disopyramide clearance in one study. Oral propranolol and disopyramide have been given together without any increase in negative inotropic effects or pharmacokinetic changes in healthy subjects.

A patient given disopyramide and intravenous sotalol developed asystole. For more information on the effects of giving sotalol with disopyramide, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Clinical evidence

Two patients with supraventricular tachycardia (180 bpm) were given, firstly intravenous **practolol** (20 mg and 10 mg, respectively) and shortly afterwards with disopyramide (150 mg and 80 mg, respectively). The first patient rapidly developed sinus bradycardia of 25 bpm, lost consciousness and became profoundly hypotensive. He did not respond to 600 micrograms of atropine, but later his heart rate increased to 60 bpm while a temporary pacemaker was being inserted.[1] He was successfully treated with disopyramide 150 mg alone for a later episode of tachycardia. The second patient also developed severe bradycardia and asystole, despite the use of atropine. He was resuscitated with adrenaline (epinephrine) but later died.[1]

Severe bradycardia has been reported in another patient, also given intravenous **practolol** and then disopyramide.[2] Another patient developed severe bradycardia and died when given **pindolol** 5 mg and disopyramide

250 mg (both orally) for supraventricular tachycardia.[3] Another patient taking oral disopyramide 250 mg twice daily developed asystole when given a total of 60 mg of intravenous **sotalol**.[4]

A patient with hypertrophic obstructive cardiomyopathy and paroxysmal atrial fibrillation taking disopyramide 450 mg daily developed hypotension, bradycardia and cardiac conduction disturbances 5 days after starting **metoprolol** 50 mg daily.[5]

Atenolol 100 mg daily has been shown to increase the steady-state disopyramide levels from 3.46 micrograms/mL to 4.25 micrograms/mL and reduce the clearance of disopyramide by 16% in healthy subjects and patients with ischaemic heart disease.[6] None of the subjects developed any adverse reactions or symptoms of heart failure, apart from one of the subjects who had transient first degree heart block.[6]

In contrast, studies in healthy subjects have found that the negative inotropic effects were no greater when oral **propranolol** and disopyramide were used concurrently,[7] nor were the pharmacokinetics of either drug affected.[8]

Mechanism

Not understood. Both disopyramide and the beta blockers can depress the contractility and conductivity of the heart muscle.

Importance and management

An interaction between disopyramide and beta blockers is established. It seems to occur rarely, but is potentially very serious; fatalities have been reported. The US manufacturers of disopyramide suggest that the combination of disopyramide and beta blockers should generally be avoided, except in the case of life-threatening arrhythmias unresponsive to a single drug.[9]

Note that the concurrent use of sotalol presents a greater risk than that of other beta blockers, as it may prolong the QT interval. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Disopyramide + H_2-receptor antagonists

Cimetidine may slightly increase the serum levels of oral disopyramide, but does not affect the pharmacokinetics of intravenous disopyramide. Ranitidine appears not to interact with disopyramide.

Clinical evidence, mechanism, importance and management

In a study in 7 healthy subjects, oral **cimetidine** 400 mg twice daily for 14 days did not alter the pharmacokinetics of a single 150-mg intravenous dose of disopyramide.[1] Another study, in 6 healthy subjects, found that a single 400-mg dose of **cimetidine** increased the AUC of a single 300-mg oral dose of disopyramide by 9% and increased the maximum serum levels by 19%, but did not significantly affect the metabolism of disopyramide. **Ranitidine** 150 mg was found not to interact significantly.[2]

The reasons for the slight increase in disopyramide levels are not known, but the authors of the report suggest that **cimetidine** may have increased disopyramide absorption.[2] **Cimetidine** is only a weak inhibitor of disopyramide metabolism *in vitro*.[3] The changes described are unlikely to be clinically important, but this should probably be confirmed in a more clinically realistic situation, using multiple oral doses of both drugs.

Disopyramide + Macrolides

Erythromycin appears to raise disopyramide levels; concurrent use has led to QT prolongation, cardiac arrhythmias and heart block. The concurrent use of clarithromycin and disopyramide has led to torsade de pointes, ventricular fibrillation and severe hypoglycaemia, and the concurrent use of azithromycin and disopyramide has led to ventricular fibrillation.

Clinical evidence

(a) Azithromycin

A patient taking disopyramide 150 mg three times daily developed ventricular tachycardia requiring cardioversion 11 days after starting azithromycin 250 mg daily.[1] Her disopyramide level was found to have risen from 2.6 micrograms/mL to 11.1 micrograms/mL.

(b) Clarithromycin

A 74-year-old woman who had been taking disopyramide 200 mg twice daily for 7 years collapsed with ventricular fibrillation 6 days after starting to take omeprazole 40 mg, metronidazole 800 mg and clarithromycin 500 mg daily. After successful resuscitation, her QTc interval, which had never previously been above 440 milliseconds, was found to have risen to 625 milliseconds. Her disopyramide plasma level was also elevated (4.6 micrograms/mL) and the half-life was markedly prolonged (40 hours). The QTc interval normalised as her plasma disopyramide levels fell.[2] A 76-year old woman taking disopyramide developed torsade de pointes when given clarithromycin 200 mg twice daily. Hypokalaemia (potassium 2.8 mmol/L) probably contributed to this case.[3]

An episode of torsade de pointes occurred in another elderly woman taking disopyramide 5 days after starting clarithromycin 250 mg twice daily.[4]

A haemodialysis patient, receiving disopyramide 50 mg daily because of paroxysmal atrial fibrillation, was hospitalised with hypoglycaemic coma after also taking clarithromycin 600 mg daily. Serum disopyramide levels increased from 1.5 to 8 micrograms/mL during treatment with clarithromycin. QT and QTc intervals were prolonged, but torsade de pointes did not occur.[5] Hypoglycaemic coma has also been reported in another patient taking disopyramide with clarithromycin.[6]

(c) Erythromycin

A woman with ventricular ectopy taking disopyramide (300 mg alternating with 150 mg every 6 hours) developed new arrhythmias (ventricular asystoles and later torsade de pointes) within 36 hours of starting erythromycin lactobionate 1 g intravenously every 6 hours, and cefamandole. Her QTc interval had increased from 390 to 600 milliseconds and her serum disopyramide level was found to be 16 micromol/L. The problem resolved when the disopyramide was stopped and bretylium given, but returned again when disopyramide was restarted. It resolved again when the erythromycin was stopped.[7] Another patient with ventricular tachycardia, well controlled over 5 years with disopyramide 200 mg four times daily, developed polymorphic ventricular tachycardia within a few days of starting erythromycin 500 mg four times daily. His QTc interval had increased from 430 milliseconds to 630 milliseconds and serum disopyramide levels were found to be elevated at 30 micromol/L. The problem resolved when both drugs were withdrawn and antiarrhythmics given.[7]

Mechanism

Not fully established. An *in vitro* study using human liver microsomes indicated that erythromycin inhibits the metabolism (mono-*N*-dealkylation) of disopyramide which, *in vivo*, would be expected to reduce its loss from the body and increase its serum levels.[8] Clarithromycin probably does the same. The increased serum levels of disopyramide can result in adverse effects such as QT prolongation and torsade de pointes, and may result in enhanced insulin secretion and hypoglycaemia.[5,6] Both intravenous

erythromycin[9] and clarithromycin[10] alone have been associated with prolongation of the QT interval and torsade de pointes. Therefore, disopyramide and macrolides may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

Importance and management

An established interaction, although it is probably rare. Even so the effects of concurrent use should be well monitored if clarithromycin or erythromycin is added to disopyramide, being alert for the development of raised plasma disopyramide levels and prolongation of the QT interval. The manufacturer of disopyramide[11] recommends avoiding the combination of disopyramide and macrolides that inhibit the cytochrome P450 isoenzyme CYP3A, and this would certainly be prudent in situations where close monitoring is not possible. Although direct clinical information is lacking, *in vitro* studies with human liver microsomes[8] indicate that **josamycin** is likely to interact similarly, and **telithromycin** might also be expected to interact in the same way. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Disopyramide + Phenobarbital

Serum disopyramide levels are reduced by phenobarbital.

Clinical evidence

In a study in 16 healthy subjects, phenobarbital 100 mg daily for 21 days reduced the half-life and AUC of a single 200-mg dose of disopyramide by about 35%. The apparent metabolic clearance more than doubled, and the fraction recovered in the urine as metabolite increased. There were no significant differences seen between subjects who smoked and non-smoking subjects.[1]

Mechanism

It seems probable that phenobarbital (a known enzyme inducer) increases the metabolism of disopyramide by the liver, and thereby increases its loss from the body.

Importance and management

This interaction between phenobarbital and disopyramide appears to be established, but its clinical importance is uncertain. The extent to which it would reduce the control of arrhythmias by disopyramide is unknown, but monitor the effects and, where possible, the serum levels of disopyramide if phenobarbital is added or withdrawn. The manufacturer of disopyramide[2] recommends avoiding using it in combination with inducers of the cytochrome P450 subfamily CYP3A, such as phenobarbital. Other **barbiturates** would be expected to interact similarly.

2. Rythmodan Capsules (Disopyramide). Sanofi-Aventis. UK Summary of product characteristics, February 2009.

Disopyramide + Phenytoin

Serum disopyramide levels are reduced by phenytoin and may fall below therapeutic levels.

Clinical evidence

Eight patients with ventricular tachycardia taking disopyramide 600 mg to 2 g daily had a 54% fall in their serum disopyramide levels (from a mean of 3.99 micrograms/mL to 1.82 micrograms/mL) when they were also given phenytoin 200 to 600 mg daily for a week. Two of the patients who responded to disopyramide and underwent Holter monitoring had a 53- and 2000-fold increase in ventricular premature beat frequency as a result of this interaction.[1]

In other reports, 3 patients who had low levels of disopyramide and high levels of its metabolite were noted to be taking phenytoin,[2] and one patient taking phenytoin required an unusually high dose of disopyramide.[3] A marked fall in serum disopyramide levels (75% in one case) was seen in 2 patients who took phenytoin 300 to 400 mg daily for up to 2 weeks.[4] Pharmacokinetic studies[3,5] in a total of 12 healthy subjects confirm this interaction. In addition, one healthy patient with epilepsy, taking phenytoin, had a disopyramide AUC and elimination half-life that were 50% lower than those in control subjects.[5]

Mechanism

Phenytoin, which is a known enzyme-inducer, increases the metabolism of the disopyramide by the liver. Although the major metabolite (*N*-dealkyldisopyramide) also possesses antiarrhythmic activity, the net effect is a reduction in arrhythmic control.[1]

Importance and management

The interaction between disopyramide and phenytoin is established and of clinical importance. Some loss of arrhythmic control can occur during concurrent use. Disopyramide adverse effects (e.g. dry mouth, blurred vision, urinary retention and nausea), because of the potential for high metabolite levels, and the antiarrhythmic response should be well monitored. An increase in the dose of disopyramide may be necessary. The interaction appears to resolve fully within 2 weeks of withdrawing the phenytoin. Note that the manufacturer of disopyramide[6] recommends avoiding using it in combination with inducers of the cytochrome P450 subfamily CYP3A, such as phenytoin.

Disopyramide + Protease inhibitors

Disopyramide levels may be increased by ritonavir. Other protease inhibitors may interact similarly.

Clinical evidence, mechanism, importance and management

Direct, published evidence (from case reports or clinical studies) of an interaction between disopyramide and the protease inhibitors appears to be lacking; however, a review of protease inhibitor interactions reports that **ritonavir** may increase the plasma levels of disopyramide more than threefold.[1] Furthermore, the manufacturer of ritonavir states that cardiac adverse effects have been reported on the concurrent use of disopyramide.[2]

Disopyramide is partially metabolised by the cytochrome P450 isoenzyme CYP3A4, of which **ritonavir** is a potent inhibitor, and therefore concurrent use would be expected to result in raised disopyramide levels, which may increase the risk of arrhythmias and other adverse effects, Note that the protease inhibitors as a group are inhibitors of CYP3A4, to varying degrees, and may be expected to interact similarly.

An interaction between the protease inhibitors and disopyramide is therefore considered to be established, despite the general lack of direct data. The manufacturer of disopyramide states that concurrent use is not recommended, because the outcome of concurrent use is not known.[3] They also state that as the protease inhibitors (they name **ritonavir**, **indinavir** and **saquinavir**) are substrates of CYP3A4, they may compete with disopyramide for metabolism by CYP3A4, possibly resulting in increased serum levels of these drugs.[3] However, note that drug interactions by this mechanism do not generally result in a clinically relevant interaction. Other known inhibitors of CYP3A4, such as some macrolides (see 'Disopyramide + Macrolides', p.284) have been reported to increase disopyramide levels and this has resulted in serious adverse effects. It would therefore seem prudent to monitor any patient taking both disopyramide and a protease inhibitor for an increase in disopyramide adverse effects (such as dry mouth, blurred vision, urinary retention and nausea).

3. Rythmodan Capsules (Disopyramide). Sanofi-Aventis. UK Summary of product characteristics, February 2009.

Disopyramide + Quinidine

Disopyramide serum levels may be slightly raised by quinidine. Both drugs prolong the QT interval, and this effect may be additive on combined use.

Clinical evidence, mechanism, importance and management

In a study in 16 healthy subjects, quinidine 200 mg four times daily increased the peak serum levels of a single 150-mg dose of disopyramide by 20% from 2.68 micrograms/mL to 3.23 micrograms/mL. The effect was smaller (14%) when disopyramide 150 mg four times daily was given. Serum quinidine levels were decreased by 26%. However, there was no change in the half-life of either drug. Both quinidine and disopyramide caused a slight lengthening of the QTc interval, and when quinidine was added to disopyramide additional lengthening of the QT interval occurred. The frequency of adverse effects such as dry mouth, blurred vision, urinary retention and nausea were also somewhat increased.[1]

The mechanism of the effect on serum levels is not understood. If both drugs are given, the antimuscarinic adverse effects of disopyramide may be increased; consider decreasing the disopyramide dose if these are troublesome. Disopyramide and quinidine are both class Ia antiarrhythmics that prolong the QT interval, and, in general, such combinations should be avoided (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

Disopyramide + Rifampicin (Rifampin)

The plasma levels of disopyramide can be reduced by rifampicin.

Clinical evidence

In a study in 11 patients with tuberculosis, rifampicin for 14 days approximately halved the plasma levels of a single 200- or 300-mg dose of disopyramide.[1] The disopyramide AUC was reduced by about two-thirds and the half-life was reduced from 5.9 to 3.25 hours. A woman who had been taking rifampicin for 2 weeks started taking disopyramide 100 mg every 8 hours but only achieved a subtherapeutic level of 0.9 micromol/L. The dose of disopyramide was increased to 300 mg every 8 hours, and the rifampicin was discontinued. Three days after discontinuing rifampicin the disopyramide level was 3.6 micromol/L and after 5 days it was 8.1 micromol/L. The patient was eventually stabilised taking disopyramide 250 mg every 8 hours.[2]

Mechanism

The most probable explanation is that rifampicin (a well-known enzyme inducer) increases the metabolism of the disopyramide by the liver so that it is cleared from the body much more quickly.

Importance and management

Information seems to be limited to these studies, but they indicate that the dosage of disopyramide will need to be increased in most patients taking rifampicin. Note that the manufacturer of disopyramide[3] recommends avoiding using it in combination with inducers of the cytochrome P450 subfamily CYP3A, such as rifampicin.

Disopyramide + Verapamil

Profound hypotension and collapse has occurred in a small number of patients taking verapamil who were also given disopyramide.

Clinical evidence, mechanism, importance and management

A group of clinicians who had used single 400-mg oral doses of disopyramide successfully and with few adverse effects for reverting acute supraventricular arrhythmias, reported 5 cases of profound hypotension and collapse. Three of the patients developed severe epigastric pain. All 5 had previous myocardial disease and/or were taking myocardial depressants, either beta blockers or verapamil in small quantities [not specified].[1]

On the basis of this report, reports of studies in *animals*,[2] and from the known risks associated with the concurrent use of beta blockers (see 'Disopyramide + Beta blockers', p.283), the UK manufacturer warns about combining disopyramide and other drugs [such as verapamil] that may have additive negative inotropic effects.[3] However, they do point out that in some specific circumstances combinations of antiarrhythmic drugs may be beneficial; they specifically name verapamil for the control of atrial fibrillation).[3] However, the US manufacturer advises that until more data is available, disopyramide should not be given within 48 hours before or 24 hours after verapamil.[4]

Dofetilide + Antacids

Antacids (aluminium/magnesium hydroxide) appear not to interact with dofetilide.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that pretreatment with **aluminium/magnesium hydroxide** (*Maalox*) 30 mL, given 10 hours, 2 hours and 0.5 hours before dofetilide, did not affect the pharmacokinetics of a single 500-microgram dose of dofetilide, or the dofetilide-induced change in QTc interval.[1] No special precautions appear to be necessary.

1. Vincent J, Gardner MJ, Baris B, Willavize SA. Concurrent administration of omeprazole and antacid does not alter the pharmacokinetics and pharmacodynamic of dofetilide in healthy subjects. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Diuretics

Hydrochlorothiazide and hydrochlorothiazide/triamterene modestly increase dofetilide plasma exposure. Concurrent use increased the QT interval prolongation seen with dofetilide alone.

Clinical evidence

The manufacturer notes that the concurrent use of dofetilide 500 micrograms twice daily with **hydrochlorothiazide** 50 mg daily for 7 days increased the dofetilide AUC by 14% and increased the QTc interval by 48 milliseconds.[1] Similar results were seen with the same dose of dofetilide given with **hydrochlorothiazide**/**triamterene** 50/100 mg daily (18% increase in AUC, and 38 millisecond increase in QTc).[1]

Mechanism

Triamterene might be expected to increase dofetilide plasma levels by competing for its renal tubular secretion (see 'Dofetilide + Miscellaneous', below), but the effect of its combination with hydrochlorothiazide was no greater than with hydrochlorothiazide alone. Why hydrochlorothiazide should increase dofetilide levels is unclear. An increase in dofetilide levels would be expected to increase the QT interval, but the increase seen here was much greater than expected by the change in plasma levels. The manufacturer suggests that a reduction in serum potassium could have contributed to the extent of QT prolongation.[1] This makes sense for hydrochlorothiazide (a potassium-depleting diuretic), but the combination with triamterene (a potassium-sparing diuretic) might therefore have been expected to have less effect on the QT interval.

Importance and management

On the basis of the above findings, the manufacturer contraindicates the use of dofetilide with hydrochlorothiazide alone or in combination with triamterene.[2] Given the increase in QT interval, a risk factor for torsade de pointes, this appears a prudent precaution. Further study is needed. Any diuretic that depletes serum potassium (such as the **loop diuretics**) might be expected to increase the risk of QT prolongation and torsade de pointes with dofetilide, and serum potassium should be monitored.[2]

2. Tikosyn (Dofetilide). Pfizer Labs. US Prescribing information, November 2006.

Dofetilide + H_2-receptor antagonists

Cimetidine markedly increases plasma dofetilide levels, and increases dofetilide-induced QT prolongation and the risk of torsade de pointes. Dofetilide appears not to interact with ranitidine.

Clinical evidence

A placebo-controlled study in 24 healthy subjects found that **cimetidine** 400 mg twice daily given with dofetilide 500 micrograms twice daily for 7 days decreased the renal clearance of dofetilide by 44%, increased its AUC by 58%, and increased its peak blood levels by 50%, without significantly altering the QTc interval.[1] In a further study it was found that **cimetidine** 100 mg twice daily or 400 mg twice daily for 4 days reduced the renal clearance of a single 500-microgram dose of dofetilide by 13% and 33%, respectively. In addition, the respective **cimetidine** doses increased the QTc interval by 22% and 33%. Conversely, **ranitidine** 150 mg twice daily did not significantly affect the pharmacokinetics or pharmacodynamics of dofetilide.[2]

Mechanism

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.[3,4] Drugs that inhibit this mechanism, such as cimetidine, increase dofetilide plasma levels.[2,3] There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de pointes.[3]

Importance and management

An established interaction. Because of the likely increased risk of torsade de pointes, the manufacturer contraindicates the use of cimetidine in patients taking dofetilide. This would seem to be a prudent precaution. This applies equally to cimetidine at non-prescription doses, and patients taking dofetilide should be warned to avoid this. No special precautions appear to be necessary with ranitidine.

Dofetilide + Ketoconazole

Ketoconazole markedly increases the plasma levels of dofetilide. This is likely to be associated with an increased risk of dofetilide-induced QT prolongation and torsade de pointes.

Clinical evidence

The manufacturer of dofetilide notes that ketoconazole 400 mg daily, given with dofetilide 500 micrograms twice daily for 7 days, increased the dofetilide peak levels by 53% in men and 97% in women, and increased the AUC by 41% in men and 69% in women.[1] Ketoconazole decreased the renal clearance of dofetilide by 31% and the non-renal clearance by 40%, resulting in a reduction in total clearance of 35%.[2]

Mechanism

Ketoconazole may inhibit the active renal tubular secretion mechanism by which dofetilide is eliminated, so reducing its loss from the body.[1,2] Ketoconazole also inhibits the metabolism of dofetilide[2] by the cytochrome P450 isoenzyme CYP3A4. Both of these mechanisms contribute to the increase in dofetilide plasma levels. There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de pointes.[1]

Importance and management

An established interaction. Because of the likely increased risk of torsade de pointes, the manufacturer contraindicates the use of ketoconazole in patients taking dofetilide. This would seem to be a prudent precaution.

Dofetilide + Miscellaneous

The manufacturer of dofetilide cautions about the use of various drugs that may have the potential to increase dofetilide plasma levels, so increasing the risk of QT prolongation and arrhythmias. Use with other drugs that prolong the QT interval should be avoided.

Clinical evidence, mechanism, importance and management

(a) Drugs that affect renal secretion

At least 50% of a dofetilide dose is eliminated unchanged in the urine by an active renal tubular secretion mechanism.[1,2] Some drugs that inhibit this mechanism have been shown to increase dofetilide plasma levels (e.g. see 'Dofetilide + H_2-receptor antagonists', above). The manufacturer contraindicates their concurrent use since there is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which is a risk factor for torsade de pointes.[1] The manufacturer also contraindicates the use of other drugs that may inhibit the renal mechanism by which dofetilide is eliminated, such as **prochlorperazine** and **megestrol**,[1] although these have not been directly studied. Furthermore, the manufacturer suggests[1] that there is a potential for dofetilide plasma levels to be increased by other drugs undergoing active renal secretion (e.g. **amiloride**, **metformin** and **triamterene**), but this needs confirmation in direct studies (see also 'Dofetilide + Diuretics', p.286). Until then, these drugs should be used cautiously with dofetilide.

(b) Inhibitors of hepatic metabolism

Dofetilide is partially metabolised by the liver, primarily by the cytochrome P450 isoenzyme CYP3A4.[3] The manufacturer suggests[1] that there is a potential for dofetilide plasma levels to be increased by inhibitors of CYP3A4, and this has been shown for ketoconazole (see 'Dofetilide + Ketoconazole', p.287). They recommend caution with other CYP3A4 inhibitors and specifically name **macrolides**, **azoles**, **protease inhibitors**, **amiodarone**, **diltiazem**, **grapefruit juice**, and **nefazodone**. They also name **SSRIs**, **cannabinoids**, **norfloxacin**, **quinine** and **zafirlukast**, but with the exception of the SSRI **fluvoxamine** (and possibly **fluoxetine**), these drugs do not usually appear to cause clinically relevant interactions by this mechanism.

(c) Other drugs that prolong the QT interval

Dofetilide is a class III antiarrhythmic that prolongs the QT interval and can cause torsade de pointes arrhythmia. In general, use of two or more drugs that prolong the QT interval should be avoided. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

(d) Other drugs

Studies in healthy subjects have shown that **amlodipine**, **glibenclamide**, and **HRT** (**conjugated oestrogens** plus **medroxyprogesterone**) do not affect the pharmacokinetics of dofetilide.[1] The pharmacokinetics of **propranolol** 40 mg twice daily and **oral contraceptives** are not affected by dofetilide.[1]

Dofetilide + Omeprazole

Omeprazole appears not to interact with dofetilide.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that pretreatment with omeprazole 40 mg (10 or 2 hours before dofetilide) did not affect the pharmacokinetics of a single 500-microgram dose of dofetilide or the dofetilide-induced change in QTc interval.[1] No special precautions appear to be necessary.

1. Vincent J, Gardner MJ, Baris B, Willavize SA. Concurrent administration of omeprazole and antacid does not alter the pharmacokinetics and pharmacodynamic of dofetilide in healthy subjects. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Phenytoin

The concurrent use of dofetilide and phenytoin does not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 24 healthy subjects were given phenytoin, to achieve steady-state plasma levels of 8 to 20 micrograms/mL, and then dofetilide 500 micrograms twice daily. No changes in phenytoin pharmacokinetics or cardiac effects were seen.[1] Another study by the same researchers in 24 subjects given dofetilide 500 micrograms every 12 hours found that phenytoin 300 mg daily did not have a clinically important effect on either the pharmacokinetics of dofetilide or on its cardiovascular pharmacodynamics (QTc, PR, QRS, RR intervals).[2] These findings confirm those of an *in vitro* study[3] showing that dofetilide did not inhibit the cytochrome P450 isoenzyme CYP2C9, thus suggesting that dofetilide is unlikely to affect the metabolism of phenytoin. No additional precautions therefore seem necessary on concurrent use.

3. Walker DK, Alabaster CT, Congrave GS, Hargreaves MB, Hyland R, Jones BC, Reed LJ, Smith DA. Significance of metabolism in the disposition and action of the antidysrhythmic drug, dofetilide. *In vitro* studies and correlation with *in vivo* data. *Drug Metab Dispos* (1996) 24, 447–55.

Dofetilide + Theophylline

The concurrent use of theophylline and dofetilide does not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

Studies in healthy subjects found that the concurrent use of theophylline 450 mg every 12 hours and dofetilide 500 micrograms every 12 hours did not alter the steady-state pharmacokinetics of either drug.[1,2] In addition, the increase in the QTc interval was no greater with the combination than with dofetilide alone.[1] No additional precautions appear to be necessary if both drugs are given. Aminophylline does not appear to have been studied, but it would be expected to behave in much the same way as theophylline.

2. Gardner MJ, Ashton HM, Willavize SA, Vincent J. The effects of orally administered theophylline on the pharmacokinetics and pharmacodynamics of dofetilide. *Clin Pharmacol Ther* (1996) 59, 182.

Dofetilide + Trimethoprim

Trimethoprim markedly increases the plasma levels of dofetilide. This is likely to be associated with an increased risk of dofetilide-induced QT prolongation and torsade de pointes.

Clinical evidence, mechanism, importance and management

The manufacturer of dofetilide notes that trimethoprim 160 mg (in combination with sulfamethoxazole 800 mg) twice daily given with dofetilide 500 micrograms twice daily for 4 days increased the peak levels of dofetilide by 93% and increased its AUC by 103%.[1] Trimethoprim inhibits the active renal tubular secretion mechanism by which dofetilide is eliminated, so reducing its loss from the body. There is a linear relationship between plasma dofetilide concentrations and prolongation of the QT interval, which increases the risk of torsade de pointes.[1] For this reason, the manufacturer contraindicates the use of trimethoprim in patients taking dofetilide. This would seem to be a prudent precaution.

1. Tikosyn (Dofetilide). Pfizer Labs. US Prescribing information, November 2006.

Dofetilide + Verapamil

Verapamil transiently increases dofetilide plasma levels and QTc prolongation, and has been associated with an increased risk of torsade de pointes.

Clinical evidence

A study in 12 healthy subjects found that verapamil 80 mg three times daily given with dofetilide 500 micrograms twice daily for 3 days caused a 42% increase in the peak plasma levels of dofetilide (from 2.4 nanograms/mL to 3.43 nanograms/mL). There was a 26% increase in the AUC_{0-4}, which was associated with a transient simultaneous increase in the QTc interval of 20 milliseconds for dofetilide alone and 26 milliseconds for the combination. However, the AUC_{0-8} was not significantly different.[1] The manufacturer notes that an analysis of clinical study data for dofetilide revealed a higher occurrence of torsade de pointes when verapamil was used with dofetilide.[2]

Mechanism

Verapamil is postulated to interact with dofetilide by increasing its rate of absorption by increasing hepatic blood flow.[1] There is a linear relationship

between plasma dofetilide concentrations and prolongation of the QT interval, which is a risk factor for torsade de pointes.[2]

Importance and management

The use of verapamil with dofetilide appears to be associated with a transient increase in dofetilide plasma concentrations, and an increased risk of torsade de pointes. For this reason, the combination is contraindicated.

1. Johnson BF, Cheng SL, Venitz J. Transient kinetic and dynamic interactions between verapamil and dofetilide, a class III antiarrhythmic. *J Clin Pharmacol* (2001) 41, 1248–56.
2. Tikosyn (Dofetilide). Pfizer Labs. US Prescribing information, November 2006.

Dronedarone + Miscellaneous

Dronedarone exposure is increased by diltiazem, grapefruit juice, ketoconazole (17-fold increase) and verapamil, all CYP3A4 inhibitors. Other CYP3A4 inhibitors would be expected to interact similarly. Dronedarone exposure is decreased by rifampicin (rifampin), a CYP3A4 inducer, and other CYP3A4 inducers would be expected to interact similarly. Dronedarone increases the exposure to simvastatin, diltiazem, nifedipine and verapamil, all CYP3A4 substrates: other CYP3A4 substrates (such as tacrolimus, sirolimus and other calcium-channel blockers) are predicted to interact similarly. Dronedarone is also predicted to increase the exposure to CYP2D6 substrates (such as the tricyclics). Pantoprazole and losartan do not appear to affect the pharmacokinetics of dronedarone and dronedarone does not appear to affect the pharmacokinetics of oral hormonal contraceptives, theophylline, warfarin or losartan.

Clinical evidence, mechanism, importance and management

(a) Calcium-channel blockers

Dronedarone exposure was increased by about 40 to 70% by **diltiazem** and **verapamil**.[1] Dronedarone is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4, of which diltiazem and verapamil are both inhibitors. Exposure to **diltiazem**, **nifedipine** and **verapamil** was increased by 40 to 50% by dronedarone.[1] Dronedarone is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which these drugs are metabolised. Concurrent use therefore raises their levels. Note that other calcium-channel blockers are also substrates for CYP3A4 and would therefore be expected to interact similarly. Note that additive bradycardia and cardiac depression may also occur with the concurrent use of dronedarone and calcium-channel blockers that affect heart rate, such as **verapamil** or **diltiazem**. This is similar to the interaction of amiodarone with **verapamil** or **diltiazem**, see 'Amiodarone + Calcium-channel blockers', p.277.

(b) CYP2D6 substrates

Dronedarone is an inhibitor of the cytochrome P450 isoenzyme CYP2D6 and as such may increase exposure to drugs metabolised by this route. This has been seen with metoprolol, see 'Beta blockers + Dronedarone', p.1005). Other CYP2D6 substrates (the manufacturers name the **tricyclic antidepressants** and **SSRIs**) may be expected to interact similarly.[1] For a list of CYP2D6 substrates, see 'Table 1.3', (p.6).

(c) CYP3A4 inducers

Rifampicin (**rifampin**) decreased dronedarone exposure by 80% and its use with dronedarone should be avoided.[1] Dronedarone is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4 and the concurrent use of other CYP3A4 inducers is also not recommended. The manufacturer of dronedarone specifically names **carbamazepine**, **phenobarbital**, **phenytoin** and **St John's wort**.[1] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

(d) CYP3A4 inhibitors

The AUC and maximum plasma concentration of dronedarone were increased 17-fold and 9-fold, respectively, by repeated doses of **ketoconazole**.[1] Dronedarone is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a potent inhibitor. Concurrent use therefore leads to raised dronedarone levels. The manufacturer of dronedarone contraindicates its use with potent CYP3A4 inhibitors, and specifically names the azoles **itraconazole**, **ketoconazole** and **voriconazole**, **ciclosporin**, the macrolides **clarithromycin** and **telithromycin**, **nefazodone** and **ritonavir**. However, note that **ciclosporin** is not usually considered to be a potent CYP3A4 inhibitor. For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

Grapefruit juice also increased the AUC and maximum plasma concentration of dronedarone 3-fold and 2.5-fold, respectively, and the manufacturers state that it should be avoided in patients taking dronedarone.[1]

(e) CYP3A4 substrates

The plasma concentrations of **sirolimus**, **tacrolimus** and other CYP3A4 substrates with a narrow therapeutic index, may be increased by dronedarone, particularly after oral administration. As such, the manufacturer recommends that plasma concentrations are monitored and doses adjusted accordingly.[1] Note that dronedarone has a modest effect on the pharmacokinetics of the calcium-channel blockers, which are CYP3A4 substrates (see *Calcium-channel blockers*, above). For a list of CYP3A4 substrates see 'Table 1.4', (p.6).

(f) Digoxin

The manufacturer of dronedarone states that the exposure to digoxin was increased 2.5-fold by dronedarone.[1] Digoxin is a substrate of the drug transporter protein P-glycoprotein, which is inhibited by dronedarone. Furthermore, both drugs can cause bradycardia, and additive bradycardia and AV block may possibly occur on concurrent use. Because of this, the manufacturer advises that the need for digoxin should be reviewed and if considered necessary, the digoxin dose should be halved and plasma levels monitored closely. The patient should also be monitored for any signs of digoxin toxicity[1] (e.g. bradycardia, nausea, vomiting). This is similar to the interaction of digoxin and amiodarone, to which dronedarone is structurally related. Consider also 'Digoxin and related drugs + Amiodarone', p.1081.

Digoxin may be used as a probe drug to assess the effects of other drugs on P-glycoprotein, and therefore the manufacturers of dronedarone suggest that it may raise the levels of other P-glycoprotein substrates.

(g) Hormonal contraceptives

The manufacturers of dronedarone state that, in healthy subjects, the concentrations of **ethinylestradiol** and **levonorgestrel** (given as an oral combined hormonal contraceptive) were not affected by the concurrent use of dronedarone.[1]

(h) Statins

The manufacturers of dronedarone state that the exposure to **simvastatin** and its active metabolite, simvastatin acid, was increased fourfold and twofold, respectively, by dronedarone.[1] Dronedarone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of **simvastatin** and some other statins. This interaction is similarly to that seen with amiodarone, which is structurally related to dronedarone. Until more is known it may be prudent to follow the recommendations given for the use of amiodarone with the statins. See 'Statins + Amiodarone', p.1320.

(i) Warfarin

The exposure to *S*-warfarin was increased by 20% when healthy subjects were also given dronedarone 600 mg twice daily (note this is higher than the recommended dose of 400 mg twice daily). The exposure to *R*-warfarin was unaffected and there was no clinically significant increase in INR.[1] In addition, in clinical studies in patients with atrial fibrillation or atrial flutter, no excessive risk of bleeding (compared with placebo) was observed when dronedarone was given with oral anticoagulants (drugs not specified).[1]

(j) Other drugs

The manufacturer of dronedarone states that the pharmacokinetics of dronedarone were not affected by **pantoprazole**, the steady-state exposure to **theophylline** was not affected by dronedarone, and no interaction has been seen between **losartan** and dronedarone.[1]

Drugs that prolong the QT interval + Drugs that lower potassium levels

The combined use of drugs that can cause hypokalaemia (e.g. amphotericin B, corticosteroids, thiazide and loop diuretics, and stimulant laxatives) and drugs that prolong the QT interval (e.g. class Ia and class III antiarrhythmics; see 'Table 9.2', p.290)

Table 9.2 Drugs causing QT prolongation and torsade de pointes

High risk	*Some risk*
Amisulpride	Clarithromycin (increase in QTc interval less than 5 milliseconds; rare case reports of torsade de pointes)
Antiarrhythmics, class Ia (ajmaline, cibenzoline, disopyramide, hydroquinidine, procainamide, quinidine)	Chlorpromazine (rare case reports of torsade de pointes)
Antiarrhythmics, class III (amiodarone, azimilide, cibenzoline, dofetilide,† dronedarone, ibutilide,† sotalol†)	Erythromycin oral (see also high risk)
Arsenic trioxide (40% of patients had a QTc interval greater than 500 milliseconds)	Gatifloxacin (increase in QTc interval less than 10 milliseconds)
Artemisinin derivatives (artemisinin, artemether/lumefantrine - 5% of patients had an asymptomatic prolongation of QTc intervals by greater than 30 milliseconds, with an actual QTc of greater than 450 milliseconds in males and greater than 470 milliseconds in females)	Levofloxacin (rare case reports of torsade de pointes)
Astemizole† (if metabolism inhibited)	Lithium (greater risk if levels raised)
Cisapride† (if metabolism inhibited)	Methadone (in doses greater than 100 mg)
Droperidol†	Moxifloxacin (increase in QTc interval less than 10 milliseconds)
Erythromycin intravenous (see also some risk)	Pentamidine intravenous (case reports of torsade de pointes)
Halofantrine†	Quinine (greater risk with higher doses and intravenous use)
Haloperidol (also increased in high doses and with intravenous use)	Spiramycin
Ketanserin (30% of patients had an increase of greater than 30 milliseconds in a clinical trial)	Tricyclics (prolongation of QTc interval greater than 10 milliseconds, most notable risk occurs with clomipramine, risk with other tricyclics largely seems to be in overdose)
Mesoridazine†	
Pimozide†	
Ranolazine (dose-related QTc interval prolonged by up to 15 milliseconds, or more if metabolism inhibited)	
Sertindole†	
Sparfloxacin (10 millisecond increase in clinical trials)	
Terfenadine† (if metabolism inhibited)	
Thioridazine†	

†indicates drug suspended/restricted in some countries because of this effect
This list is not exhaustive

should be well monitored because hypokalaemia increases the risk of torsade de pointes. There appear to be only a few reports of this interaction, for example, see 'Beta blockers + Potassium-depleting drugs', p.1016. Note that stimulant laxatives only tend to cause hypokalaemia in cases of misuse or overuse.

Drugs that prolong the QT interval + Other drugs that prolong the QT interval

The concurrent use of more than one drug that prolongs the QT interval increases the risk of torsade de pointes, which may lead to life-threatening ventricular arrhythmias. The risk varies with different combinations of drugs that prolong the QT interval, and with the presence of other risk factors for this effect.

Clinical evidence, mechanism, importance and management

If the QT interval on the ECG becomes excessively prolonged, ventricular arrhythmias can develop, in particular a type of polymorphic tachycardia known as torsade de pointes. On the ECG this arrhythmia can appear as an intermittent series of rapid spikes during which the heart fails to pump effectively, the blood pressure falls and the patient will feel dizzy and may possibly lose consciousness. Usually the condition is self-limiting but it may progress and degenerate into ventricular fibrillation, which can cause sudden death.

There are a number of reasons why QT interval prolongation can occur. These include:

- increasing age
- female sex
- congenital long QT syndrome
- cardiac disease
- thyroid disease
- some metabolic disturbances (hypocalcaemia, hypokalaemia, hypomagnesaemia)

Another important cause is the use of various QT-prolonging drugs including some antiarrhythmics, antipsychotics, antihistamines, antimalarials and others.[1,2] These drugs all appear to cause this effect by blocking the rapid component of the delayed rectifier (repolarisation) potassium channel.

At what degree of prolongation of corrected QT (QTc) interval torsade de pointes is likely to develop is uncertain. However a QTc interval exceeding 500 milliseconds is generally considered of particular concern, but this is not an exact figure. In addition, there is uncertainty about what constitutes an important change in QTc interval from baseline, although, in general, increases of 30 to 60 milliseconds should raise concern, and increases of over 60 milliseconds raise clear concerns about the potential for arrhythmias. Because of these uncertainties, many drug manufacturers and regulatory agencies contraindicated the concurrent use of drugs known to prolong the QT interval, and a 'blanket' warning was often issued because the QT prolonging effects of the drugs are expected to be additive. Regulatory guidance for the assessment of risk of a non-antiarrhythmic drug states that drugs causing an increase in mean

QT/QTc interval of around 5 milliseconds or less do not appear to cause torsade de pointes. Data on drugs causing mean increases of around 5 milliseconds and less than 20 milliseconds are inconclusive, and some drugs causing this have been associated with proarrhythmic risk. Drugs with an increase of more than 20 milliseconds have a substantially increased likelihood of being proarrhythmic.[3,4] The extent of the drug-induced prolongation usually depends on the dose of the drug and the particular drugs in question.

'Table 9.2', (p.290) is a list of drugs that are known to prolong the QT interval and cause torsade de pointes. Note that this list is not exhaustive of all the drugs that have ever been reported to be associated with QT interval prolongation and torsade de pointes. For some of the drugs listed, QT prolongation is a fairly frequent effect when the drug is used alone, and it is well accepted that use of these drugs requires careful monitoring (e.g. a number of the antiarrhythmics). For other drugs, QT prolongation is rare, but because of the relatively benign indications for these drugs, the risk-benefit ratio is considered poor, and use of these drugs has been severely restricted or discontinued (e.g. astemizole, terfenadine, cisapride). For others there is less clear evidence of the risk of QT prolongation (e.g. clarithromycin, chlorpromazine). Drugs that have only been associated with isolated cases of torsade de pointes, and drugs that are commonly considered to cause QT prolongation, but for which there does not appear to be any published evidence to support this effect (e.g. **chloroquine**), are not usually included in this table. Specific reports of additive QT-prolonging effects with or without torsade de pointes are covered in individual monographs.

Drugs that do not themselves prolong the QT interval, but potentiate the effect of drugs that do (e.g. by pharmacokinetic mechanisms, lowering serum potassium, or by causing bradycardia) are not included in 'Table 9.2', (p.290). The interactions of these drugs (e.g. azole antifungals with cisapride, astemizole, or terfenadine, and potassium-depleting diuretics with sotalol) are dealt with in individual monographs. However, note that some drugs, for example the macrolide antibacterials, may cause QT prolongation by dual mechanisms: they appear to have both the intrinsic ability to prolong the QT interval, and they may inhibit the metabolism of drugs that prolong the QT interval.[5]

General references discussing the problems of QT-prolongation are given below.[6-15]

The consensus of opinion is that the concurrent use of drugs that have a high risk of prolonging the QTc interval should be avoided because of the risk of additive effects, leading to the possible development of serious and potentially life-threatening torsade de pointes. However, under certain circumstances (e.g. in the treatment of life-threatening arrhythmias) concurrent use may be unavoidable. In this situation close ECG monitoring, and a careful consideration of other risk factors present is essential. With drugs that have some risk of prolonging the QTc interval, some caution is appropriate, particularly in patients with other risk factors for QTc prolongation.

Flecainide + Amiodarone

Serum flecainide levels are increased by amiodarone. An isolated report describes a patient taking amiodarone who developed torsade de pointes when given flecainide.

Clinical evidence

Amiodarone (1.2 g daily for 10 to 14 days then 600 mg daily) was given to 7 patients taking oral flecainide 200 to 500 mg daily. The trough plasma levels of flecainide were increased by about 50%, and the flecainide dose was reduced by one-third (averaging a reduction from 325 to 225 mg daily) to keep the flecainide levels constant. Observations in two patients suggest that the interaction begins soon after the amiodarone is added, and it takes 2 weeks or more to develop fully.[1]

Other authors have reported this interaction, and suggest reducing the flecainide dose by between one-third to one-half when amiodarone is added.[2-5] Another study found that amiodarone raised steady-state flecainide plasma levels by 37% in extensive CYP2D6 metabolisers (that is, those with normal levels of this isoenzyme), and by 55% in poor CYP2D6 metabolisers (that is, those lacking this isoenzyme).[6] In a later report of this study the authors concluded that these differences were not clinically important, and that CYP2D6 phenotype does not affect the extent of the interaction between flecainide and amiodarone.[7]

An isolated report describes a patient taking amiodarone who developed torsade de pointes when also given flecainide.[8]

Mechanism

Amiodarone inhibits the cytochrome P450 isoenzyme CYP2D6 by which flecainide is metabolised, so that the flecainide is metabolised by the liver more slowly. Other mechanisms may also be involved.[7]

Importance and management

An established interaction, but the documentation is limited. Reduce the flecainide dosage by one-third to one-half if amiodarone is added.[1-5,7] Monitor for flecainide adverse effects (dizziness, nausea, and tremor) and, where possible, consider monitoring flecainide levels. There seems to be no need to treat extensive metabolisers differently from poor metabolisers.[7] Remember that the interaction may take 2 weeks or more to develop fully, and also that amiodarone is cleared from the body exceptionally slowly so that this interaction may persist for some weeks after it has been withdrawn.

Flecainide + Antiepileptics; Enzyme-inducing

Limited data suggests that carbamazepine, phenytoin or phenobarbital may modestly increase flecainide clearance. Primidone and fosphenytoin may interact similarly.

Clinical evidence, mechanism, importance and management

Preliminary findings of a controlled study in 6 patients with epilepsy taking **phenytoin** or **phenobarbital** found that the pharmacokinetics of a single 2-mg/kg intravenous dose of flecainide were not generally different from those in a group of 7 healthy subjects not taking these antiepileptics. However, a 25 to 30% shorter flecainide half-life and decreased urinary clearance of unchanged drug were noted.[1] The manufacturer notes there is limited data indicating similar changes in flecainide elimination associated with **carbamazepine**.[2]

These changes are modest and the authors of the first study suggest that an adjustment of the flecainide dose may not be required in those also taking **phenytoin** or **phenobarbital**. These findings probably also apply to **primidone**, which is, in part, metabolised to phenobarbital, and **fosphenytoin**, a prodrug of phenytoin.

Flecainide + Antihistamines

There are no published cases of an interaction between flecainide and non-sedating antihistamines, but it has been suggested that the concurrent use of mizolastine or terfenadine may increase the risk of ventricular arrhythmias.

Clinical evidence, mechanism, importance and management

The UK manufacturer of flecainide advises avoiding the concurrent use of **mizolastine** and **terfenadine** due to an increased risk of ventricular arrhythmias.[1] Similarly, the manufacturer of **mizolastine**[2] contraindicates its use with drugs known to prolong the QT interval, and gives the examples of class I and III antiarrhythmics. Note that, of the class 1 antiarrhythmics, only the class 1a antiarrhythmics are generally considered to cause QT prolongation: flecainide is a class 1c antiarrhythmic.

Terfenadine and possibly mizolastine can cause QT prolongation, but usually only when their levels are raised; however flecainide is not known to affect their metabolism. There appear to be no published reports of an interaction between these drugs, and therefore an interaction is not established.

Flecainide + Benziodarone

A single case report describes ECG changes in a patient taking flecainide with benziodarone.

Clinical evidence, mechanism, importance and management

A 71-year-old woman who had undergone kidney transplantation 7 years earlier and who was taking amlodipine, losartan, furosemide, chlortalidone, calcitriol, aspirin, prednisone, ciclosporin, cyclophosphamide and insulin was also taking flecainide, which controlled her paroxysmal atrial fibrillation. Atorvastatin was then restarted for hypercholesterolaemia and benziodarone 100 mg daily (because of intolerance to allopurinol) was added to treat hyperuricaemia. Three days later she presented with asthenia and poor overall condition and later an ECG showed a number of ECG changes including QTc interval prolongation of 482 milliseconds (22% increase) and PR interval prolongation of 203 milliseconds (18% increase). Creatinine levels were about 127 micromol/L, creatine phosphokinase 354 units/L and urea 155 mg/dL. Atorvastatin was stopped because of mild rhabdomyolysis and flecainide and benziodarone were both discontinued because an interaction was also suspected. Symptoms resolved within 48 hours, with the ECG then becoming similar to baseline. Flecainide was restarted and the dose gradually increased to 100 mg daily.[1]

It was suggested that benziodarone may inhibit the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of flecainide.[1] Note that benziodarone is chemically related to amiodarone, which has a similar effect, see 'Flecainide + Amiodarone', p.291. Mild renal impairment in the patient may also have contributed to reduced flecainide elimination.

This is an isolated case and more study is needed to establish an interaction. Nevertheless, because of the similarities to amiodarone, monitoring may be prudent if flecainide and benziodarone are given concurrently.

Flecainide + Cimetidine

Cimetidine can increase flecainide plasma levels.

Clinical evidence

In a study in 8 healthy subjects, cimetidine 1 g daily for a week increased the AUC of a single 200-mg dose of flecainide by 28%. The fraction of flecainide excreted unchanged in the urine was increased by 20%, but the total renal clearance was not altered.[1] In another study, in 11 patients, cimetidine 1 g daily for 5 days almost doubled the plasma levels of flecainide 200 mg daily measured 2 hours after the morning dose.[2]

Mechanism

Uncertain, but it is thought that the cimetidine reduces the hepatic metabolism of flecainide.[1,2]

Importance and management

An established but not extensively documented interaction. The clinical importance appears not to have been assessed, but be alert for the need to reduce the flecainide dose if cimetidine is added. Flecainide adverse effects include dizziness, nausea, and tremor. Caution is recommended in patients with renal impairment, as the interaction is likely to be enhanced.[1]

Flecainide + Colestyramine

An isolated report describes reduced plasma flecainide levels in a patient given colestyramine. However, small studies have not found an interaction.

Clinical evidence, mechanism, importance and management

A patient taking flecainide 100 mg twice daily had unusually low trough plasma levels (100 nanograms/mL) while taking colestyramine 4 g three times daily. When he stopped taking the colestyramine his plasma flecainide levels rose. However, a later study in 3 healthy subjects given flecainide 100 mg daily and colestyramine 4 g three times daily, found little or no evidence of an interaction (steady-state flecainide levels of 63.1 nanograms/mL and 59.1 nanograms/mL without and with colestyramine, respectively). *In vitro* studies also did not find any binding between flecainide and colestyramine that might result in reduced absorption from the gut.[1] The authors however postulate that the citric acid contained in the colestyramine formulation might have altered the urinary pH, which could have increased the renal clearance of the flecainide.[1]

Information seems to be limited to this preliminary report. Its general importance seems to be minor, nevertheless the outcome of concurrent use should be monitored so that any unusual cases can be identified. Note that it is generally recommended that other drugs should be given one hour before or 4 to 6 hours after colestyramine.

1. Stein H, Hoppe U. Is there an interaction between flecainide and cholestyramine? *Naunyn Schmiedebergs Arch Pharmacol* (1989) 339 (Suppl), R114.

Flecainide + Food

The absorption of flecainide is not significantly altered if it is taken with food in adults, but it may possibly be reduced by milk in infants.

Clinical evidence, mechanism, importance and management

In a study in healthy adult subjects, food had no significant effect on the rate or extent of absorption of a single 200-mg dose of flecainide.[1]

A premature baby being treated for refractory atrio-ventricular tachycardia with high doses of flecainide (40 mg/kg daily or 25 mg every 6 hours) developed flecainide toxicity (seen as ventricular tachycardia) when his **milk feed** was replaced by **dextrose 5%**. His serum flecainide levels approximately doubled. It was concluded that the **milk** had reduced flecainide absorption.[2] **Milk**-fed infants may therefore possibly need a reduced dose of flecainide if **milk** intake is reduced or stopped, but more study is needed to establish an interaction. Nevertheless, it would be prudent to monitor the effects of altering **milk** intake. Adult patients may take flecainide without regard to meals.

2. Russell GAB, Martin RP. Flecainide toxicity. *Arch Dis Child* (1989) 64, 860–2.

Flecainide + Protease inhibitors

Ritonavir may increase the levels of flecainide. A number of ritonavir-boosted protease inhibitors are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Direct evidence (from case reports or clinical studies) of an interaction between flecainide and the protease inhibitors is lacking; however, a review of protease inhibitor interactions reports that the plasma levels of flecainide may be increased by **ritonavir**.[1] Flecainide is metabolised by the cytochrome P450 isoenzyme CYP2D6, of which ritonavir is an inhibitor, leading to an increase in flecainide levels, which may increase the risk of arrhythmias and other adverse effects. As a result the manufacturers of **ritonavir** contraindicate its use with flecainide.[2,3] **Ritonavir** is commonly used to boost the activity of other protease inhibitors, until more is known, it may be prudent to avoid or use caution on the use of **ritonavir**-boosted protease inhibitors: the manufacturers of **fosamprenavir**,[4,5] **saquinavir**[6,7] and **tipranavir**,[8,9] all of which should be given with ritonavir, contraindicate the concurrent use of flecainide. Similarly, the UK manufacturer of **indinavir** contraindicates the concurrent use of flecainide.[10]

If the concurrent use of flecainide and a protease inhibitor is necessary, it would be prudent to closely monitor patients for an increase in flecainide adverse effects (such as dizziness, nausea, and tremor), adjusting the dose as necessary.

Flecainide + Quinidine or Quinine

Quinidine and quinine cause a modest reduction in the clearance of flecainide.

Clinical evidence, mechanism, importance and management

(a) Quinidine

In a study in 6 healthy subjects, a single 50-mg oral dose of quinidine given the night before a single 150-mg intravenous dose of flecainide decreased the flecainide clearance by 23%. The flecainide half-life was increased by 22% and its AUC by 28%.[1] In another study, 5 patients who were extensive CYP2D6 metabolisers (that is, those with normal levels of this isoenzyme) and taking long-term flecainide were given quinidine 50 mg every 6 hours for 5 days. The plasma levels and clearance of *S*-(+)-flecainide were unchanged, but plasma levels of *R*-(−)-flecainide increased by about 15% and its clearance reduced by 15%. The effects of the flecainide were slightly but not significantly increased.[2] Quinidine inhibits the cytochrome P450 isoenzyme CYP2D6, which is concerned with the metabolism of flecainide. Therefore concurrent use may modestly decrease flecainide metabolism and increase its levels. The clinical importance of this interaction is uncertain, but it is probably minor.

(b) Quinine

In a study, 10 healthy subjects were given three 500-mg doses of quinine over 24 hours then a single 150-mg intravenous infusion of flecainide (given over 30 minutes). Quinine increased the AUC of flecainide by 21% and reduced its systemic clearance by 17%. Renal clearance remained unchanged. The increases in the PR and QRS intervals caused by flecainide were slightly, but not significantly, increased by quinine.[3] The evidence suggests that quinine reduces the metabolism of flecainide. The clinical importance of this interaction is uncertain but it is probably minor.

Flecainide + SSRIs

Paroxetine slightly increases flecainide levels, and an isolated case report describes raised flecainide levels and adverse effects in a patient taking paroxetine. Escitalopram and fluoxetine are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

(a) Escitalopram

Although studies *in vitro* did not reveal an inhibitory effect of escitalopram on CYP2D6, limited clinical data for 'desipramine', (p.1513), and 'metoprolol', (p.1019), suggest a modest inhibitory effect.[1] The UK manufacturer of escitalopram recommends caution if it is given with drugs that are mainly metabolised by this enzyme, and that have a narrow therapeutic index. They specifically name flecainide.[1]

(b) Fluoxetine

The manufacturers of fluoxetine warn that drugs predominantly metabolised by CYP2D6, and which have a narrow therapeutic index, should be initiated at or adjusted to the low end of their dose range in patients taking fluoxetine. This will also apply if fluoxetine has been taken in the previous 5 weeks because of its long elimination half-life.[2,3] They specifically mention flecainide.[2,3]

(c) Paroxetine

In a study, 21 healthy Korean subjects with differing levels of the cytochrome P450 isoenzyme CYP2D6 were given paroxetine 20 mg daily for 7 days with a single 200-mg dose of flecainide on day 15. Paroxetine slightly increased the AUC of flecainide, by 29%, in the extensive metabolisers (that is, those with normal levels of CYP2D6) and by 17% in the intermediate metabolisers (those with reduced levels of CYP2D6), but did not significantly affect the AUC in poor metabolisers (that is, those with low levels or lacking in CYP2D6), when compared with a single dose of flecainide alone. The pharmacokinetics of flecainide alone did not differ significantly between the different metaboliser groups.[4]

A case report describes a 69-year-old patient who had been stable taking paroxetine 40 mg daily for at least 5 years, who developed confusion and paranoia about 2 weeks after starting to take flecainide 100 mg twice daily. On admission she had a flecainide plasma concentration of 1360 micrograms/L (therapeutic range 200 to 1000 micrograms/L). The symptoms resolved 3 days after paroxetine was stopped and the flecainide dose was reduced to 50 mg twice daily.[5]

Flecainide is metabolised by the cytochrome P450 isoenzyme CYP2D6. This route of metabolism can be inhibited by paroxetine, a moderate inhibitor of CYP2D6, resulting in raised flecainide levels. However, this

interaction is not apparent in the small percentage of the population who lack this isoenzyme.

The limited data available suggest a modest interaction may occur between flecainide and paroxetine; however its clinical significance does not appear to have been assessed. The slight increase in flecainide levels seen may be of clinical significance in some patients, such as those with renal impairment. It would seem prudent to be alert for an increase in flecainide adverse effects (such as dizziness, nausea, and tremor) if paroxetine is also given, and consider a flecainide dose reduction if necessary.

Flecainide + Thiazide diuretics

An isolated report describes cardiotoxicity in a patient taking flecainide, which was associated with an electrolyte imbalance caused by bendroflumethiazide.

Clinical evidence, mechanism, importance and management

A patient taking **bendroflumethiazide** developed syncope, weakness and fatigue 2 months after starting flecainide. He also had ECG changes (marked QRS widening) and gross hyponatraemia and hypokalaemia, which was consistent with flecainide cardiotoxicity exacerbated by electrolyte disturbances. The symptoms resolved when the electrolyte balance was corrected.

Flecainide acts by a use-dependent block of sodium channels and hypertonic sodium salts have been used to reverse flecainide toxicity. Data in *animals* suggest flecainide may reduce salt absorption in the bowel.[1] This report suggests hyponatraemia as well as hypokalaemia may contribute to flecainide toxicity.

Although this appears to be the only report of an interaction, it serves as a reminder that electrolytes should be carefully controlled in patients taking flecainide, and this is particularly important when other drugs that may cause electrolyte disturbances, such as the thiazides, are given.

1. Khavandi A, Walker PR. Flecainide cardiotoxicity precipitated by electrolyte imbalance. Caution with thiazide diuretics. *Emerg Med J* (2007) 24, e26.

Flecainide + Tobacco

Tobacco smokers need larger doses of flecainide than non-smokers to achieve the same therapeutic effects.

Clinical evidence

Prompted by the chance observation that smokers appeared to have a reduced pharmacodynamic response to flecainide than non-smokers, a meta-analysis[1] was undertaken of the findings of 7 pre-marketing pharmacokinetic studies and 5 multicentre efficacy studies in which flecainide had been studied and in which the smoking habits of the subjects or patients had been also been recorded. In the pharmacokinetic studies, the clearance of flecainide was found to be about 50% higher in smokers than in non-smokers. In the efficacy studies, average clinically effective flecainide doses were found to be 338 mg daily for smokers and 288 mg daily for non-smokers, while trough plasma concentrations of flecainide were 1.74 nanograms/mL and 2.18 nanograms/mL per mg dose for the smokers and non-smokers, respectively. This confirmed that smokers needed higher doses of flecainide to achieve the same steady-state serum levels.[1]

Mechanism

The probable reason for this interaction is that some components of tobacco smoke stimulate the cytochrome P450 enzymes in the liver concerned with the *O*-dealkylation of flecainide, so that it is cleared from the body more quickly.[1]

Importance and management

An established interaction. Smokers seem likely to need higher doses of flecainide than non-smokers, but the way in which this interaction was identified suggests that in practice no specific action needs to be taken to accommodate it. It may be most relevant if a patient taking flecainide abruptly stops smoking. In this situation be alert for flecainide adverse effects (e.g. dizziness, nausea, tremor), and be aware that it is likely that the dose of flecainide will need to be reduced.

Flecainide + Urinary acidifiers or alkalinisers

The excretion of flecainide is increased if the urine is made acidic (e.g. with ammonium chloride) and reduced if the urine is made alkaline (e.g. with sodium bicarbonate).

Clinical evidence

Six healthy subjects were given a single 300-mg oral dose of flecainide on two occasions. On the first occasion flecainide was taken after **ammonium chloride** 1 g orally every 3 hours, and 2 g at bedtime, for a total of 21 hours to make the urine acidic (pH range 4.4 to 5.4). On the second occasion flecainide was taken after **sodium bicarbonate** 4 g every 4 hours for a total of 21 hours (including night periods) to make the urine alkaline (pH range 7.4 to 8.3). Over the next 32 hours, 44.7% of unchanged flecainide appeared in the acidic urine, but only 7.4% in alkaline urine.[1] This compares with 25% found by other researchers when urinary pH was not controlled.[1] A later similar study from the same research group broadly confirmed these findings; the elimination half-life of the flecainide was 10.7 hours in acidic urine and 17.6 hours in alkaline urine.[2] Another study also confirmed the effect of urinary pH on the excretion of flecainide, and found that the fluid load and the urinary flow rate had little effect on flecainide excretion.[3]

In a study in healthy adult subjects, three 15-mL doses of *Aldrox* (280 mg of **aluminium hydroxide** per 5 mL) had no significant effect on the rate or extent of absorption of a single 200-mg dose of flecainide.[4]

Mechanism

In alkaline urine at pH 8, much of the flecainide exists in the kidney tubules in the non-ionised form (non-ionised fraction 0.04), which is more readily reabsorbed. In acidic urine at pH 5 more exists in the ionised form (non-ionised fraction 0.0001), which is less readily reabsorbed and is therefore lost in the urine.[3]

Importance and management

Established interactions, but their clinical importance is uncertain. The effects of these changes on the subsequent control of arrhythmias by flecainide in patients seem not to have been studied, but the outcome should be well monitored if patients are given drugs that alter urinary pH to a significant extent (such as ammonium chloride, sodium bicarbonate). Large doses of some **antacids** may possibly do the same, but one study suggests that aluminium hydroxide may not interact in this way.

Flecainide + Verapamil

Although flecainide and verapamil have been used together successfully, serious and potentially life-threatening cardiogenic shock and asystole have been seen in a few patients, because the cardiac depressant effects of the two drugs can be additive.

Clinical evidence

A man with triple coronary vessel disease taking flecainide 200 mg daily for recurrent ventricular tachycardia, developed severe cardiogenic shock within 2 days of increasing the flecainide dose to 300 mg daily and within one day of starting verapamil 80 mg daily. His blood pressure fell to 60/40 mmHg and he had an idioventricular rhythm of 88 bpm.[1] Another patient with atrial flutter and fibrillation was given digitalis and verapamil 120 mg three times daily. He was also given flecainide 150 mg daily for 10 days, but 3 days after the dose was raised to 200 mg daily he fainted, and later developed severe bradycardia (15 bpm) and asystoles of up to 14 seconds. He later died.[1]

Another report describes atrioventricular block when a patient with a pacemaker took digoxin, flecainide and verapamil.[2]

Two earlier studies in patients[3] and healthy subjects[4] had found that the pharmacokinetics of flecainide and verapamil were only minimally affected by concurrent use, but the PR interval was increased by both drugs. Furthermore, additive depressant effects were seen on heart contractility and AV conduction, although no serious adverse responses occurred.

Mechanism

Flecainide and verapamil have little or no effects on the pharmacokinetics of each other,[3,4] but they can apparently have additive depressant effects on the heart (negative inotropic and chronotropic) in both patients and healthy subjects.[1,3,4] Verapamil alone[5,6] and flecainide alone[7,8] have been responsible for asystole and cardiogenic shock in a few patients. In the cases cited above[1-3] the cardiac depressant effects were particularly serious because the patients already had compromised cardiac function.

Importance and management

An established interaction, but the incidence of serious adverse effects is probably not great. The additive cardiac depressant effects are probably of little importance in many patients, but may represent 'the last straw' in a few who have seriously compromised cardiac function. The authors of one of the reports cited[1] advise careful monitoring if both drugs are used and emphasise the potential hazards of combining **class Ic antiarrhythmics** and verapamil.

Ibutilide + Amiodarone

Two reports describe the successful use of ibutilide and amiodarone for cardioversion. Both ibutilide and amiodarone can prolong the QT interval, and concurrent use would be expected to result in additive effects.

Clinical evidence, mechanism, importance and management

Intravenous ibutilide 2 mg has been used for cardioversion of atrial fibrillation or flutter in 70 patients taking long-term amiodarone. The QT interval was further prolonged (from 371 to 479 milliseconds). Only one patient had an episode of non-sustained torsade de pointes. Ibutilide was effective within 30 minutes of infusion in 39% of patients with atrial flutter, and 54% of patients with fibrillation.[1] A further report also found the use of ibutilide in 46 patients receiving amiodarone for atrial flutter and fibrillation as effective and safe as use of ibutilide alone (in 28 patients).[2]

The authors of one report[1] suggest that ibutilide may be useful for cardioversion in those already taking amiodarone. However, it is generally recommended that the concurrent use of two drugs that prolong the QT interval should be avoided. The manufacturer of ibutilide specifically recommends that other class III antiarrhythmics should not be given within 4 hours of an ibutilide infusion, and that ibutilide should not be given within five half-lives of these antiarrhythmics.[3] The concern is that a prolongation of the QT interval is associated with an increased risk of torsade de pointes, which is potentially life-threatening. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Ibutilide + Calcium-channel blockers

Calcium-channel blockers (predominantly non-dihydropyridine type) have not altered the safety or efficacy of ibutilide in clinical studies.

Clinical evidence, mechanism, importance and management

Retrospective analysis of three clinical studies found that calcium-channel blockers did not alter the ECG effects (QT prolongation) or the efficacy of ibutilide. In these three studies, 68 of the 130 patients taking ibutilide were also taking calcium-channel blockers. The report did not specify which calcium-channel blockers were used, except to say that only 12 of the 68 (19%) were taking a dihydropyridine-type.[1]

In vitro studies have shown that **nifedipine** (a dihydropyridine) attenuated the effects of ibutilide.[2] The findings of the above report[1] suggest that this may not be clinically important. However, since so few patients were taking a dihydropyridine, an effect specific to dihydropyridines cannot be excluded. Further study is needed.

Ibutilide + Class Ic antiarrhythmics

Some evidence suggests that patients taking ibutilide have a less marked increase in QT interval, without a change in efficacy, when they are also given propafenone or flecainide.

Clinical evidence, mechanism, importance and management

The increase in QTc interval after intravenous ibutilide 2 mg was less in patients taking **propafenone** (5 patients) or **flecainide** (1 patient) than in 85 other patients who had taken ibutilide alone (34 milliseconds versus 65 milliseconds). The effect appeared to be dose-related, with higher propafenone doses causing the largest attenuation in the ibutilide-induced QT prolongation. The efficacy of ibutilide was unaltered.[1] In another study, 71 patients with atrial fibrillation or atrial flutter receiving either **propafenone** 300 to 900 mg daily or **flecainide** 100 to 300 mg daily underwent cardioversion with a single intravenous dose of ibutilide 1 mg over 10 minutes, followed if necessary by a further dose after an interval of 10 minutes. Torsade de pointes occurred in one patient with profound sinus node suppression after cardioversion, but the mean increase in the QT interval in response to ibutilide was attenuated (20 ± 54 milliseconds compared to reported range of 47 to 90 milliseconds) without a decrease in efficacy. However, the authors note that the risk of sustained torsade de pointes in this study appears to be similar to that seen in other studies of ibutilide.[2] In a further study in 100 patients with atrial fibrillation, undergoing elective cardioversion with either intravenous ibutilide (1 mg with a further 1 mg if required), or oral **propafenone** 600 mg plus intravenous ibutilide, cardioversion was achieved in 41% of 51 patients given ibutilide alone and about 71% of 49 patients given ibutilide and **propafenone**. Increases in the QTc interval were similar in both groups, but one case of torsade de pointes requiring electrical cardioversion occurred in one patient given ibutilide and **propafenone**.[3] A further report also found that the

use of ibutilide in 30 patients receiving **propafenone** for atrial flutter and fibrillation was as effective and safe as use of ibutilide alone (in 28 patients).[4]

Ibutilide, a class III antiarrhythmic, is known to increase the QT interval, so increasing the risk of torsade de pointes. Class Ic antiarrhythmics such as **propafenone** and **flecainide** generally shorten the QT interval. It is possible that class Ic antiarrhythmics may usefully attenuate the risk of torsade de pointes with ibutilide,[1] and ibutilide may be useful in restoring sinus rhythm in patients taking class Ic antiarrhythmics.[2,3] However, the cases of torsade de pointes add a note of caution, and further study is needed.

Ibutilide + Miscellaneous

Ibutilide can prolong the QT interval, therefore caution has been advised about the concurrent use of other drugs that can do the same. Ibutilide is reported not to interact with beta blockers or digoxin.

Clinical evidence, mechanism, importance and management

No specific drug interaction studies appear to have been undertaken with ibutilide, which is a class III antiarrhythmic, but because it can prolong the QT interval it has been recommended that other drugs that can do the same should be administered with caution, because of the potential additive effects.[1] The manufacturer of ibutilide[2] specifically recommends that class Ia and other class III antiarrhythmics should not be given within 4 hours of an ibutilide infusion, and that ibutilide should not be given within five half-lives of these antiarrhythmics (but see also, 'Ibutilide + Amiodarone', p.295). The concern is that a prolongation of the QT interval is associated with an increased risk of torsade de pointes, which is potentially life-threatening. The manufacturer of ibutilide specifically names **phenothiazines**, **tricyclic** and **tetracyclic antidepressants**, and **antihistamines**.[2] For further discussion of QT prolongation, and for further examples of drugs that prolong the QT interval, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

The concurrent use of **beta blockers** and **digoxin** during clinical studies is reported not to affect the safety or efficacy of ibutilide;[1,2] however, note that **sotalol** is known to prolong the QT interval.

Ibutilide is said not to affect the cytochrome P450 isoenzymes CYP3A4 or CYP2D6 and so metabolic interactions with drugs affected by these enzymes would not be expected.[1]

Lidocaine + Amiodarone

One man receiving intravenous lidocaine had a seizure about two days after starting to take amiodarone. Another man with sick sinus syndrome taking amiodarone had a sinoatrial arrest during placement of a pacemaker under local anaesthesia with lidocaine. There is conflicting evidence as to whether or not amiodarone affects the pharmacokinetics of intravenous lidocaine.

Clinical evidence

An elderly man taking digoxin, enalapril, amitriptyline and temazepam was treated for monomorphic ventricular tachycardia, firstly with procainamide, later replaced by a 2 mg/minute infusion of lidocaine, to which oral amiodarone 600 mg twice daily was added. After 12 hours his lidocaine level was 5.4 mg/L (reference range 1.5 to 5 mg/L), but 53 hours later he developed a seizure and his lidocaine level was found to have risen to 12.6 mg/L. A tomography brain scan found no abnormalities that could have caused the seizure and it was therefore attributed to the toxic lidocaine levels.[1]

An elderly man with long standing brady-tachycardia was successfully treated for atrial flutter firstly with a temporary pacemaker (later withdrawn) and 600 mg amiodarone daily. Ten days later, and 25 minutes after a permanent pacemaker was inserted under local anaesthesia with 15 mL of 2% lidocaine, severe sinus bradycardia and long sinoatrial arrest developed. He was effectively treated with atropine plus isoprenaline, and cardiac massage.[2]

Six patients with symptomatic cardiac arrhythmias took part in a two-phase study. Initially, lidocaine 1 mg/kg was given intravenously over 2 minutes. In phase I, loading doses of amiodarone 500 mg daily for 6 days were given, followed by the same lidocaine dose. After 19 to 21 days, when the total cumulative amiodarone dose was 13 g, the same lidocaine dose was given again (phase II). The lidocaine AUC increased by about 20% and the systemic clearance decreased by about 20%. The elimination half-life and distribution volume at steady-state were unchanged. The pharmacokinetic parameters of lidocaine in phase II were the same as those in phase I, indicating that the interaction occurs early in the loading phase of amiodarone use.[3] This is in contrast to an earlier study, in which the pharmacokinetics of a bolus dose of lidocaine 1 mg/kg over 2 minutes were not altered in 10 patients who had taken amiodarone 200 to 400 mg daily (following a loading dose of 800 or 1200 mg) for 4 to 5 weeks.[4]

Mechanism

An *in vitro* study found that amiodarone may competitively inhibit lidocaine metabolism and *vice versa*. The interaction *in vivo* may be due to inhibition of the cytochrome P450 isoenzyme CYP3A4 by amiodarone and/or its main metabolite desethylamiodarone.[4] CYP3A4 is partially involved in the metabolism of lidocaine.

The authors of the report describing the sinoatrial arrest suggest that this occurred because of a synergistic depression by both drugs of the sinus node.

Importance and management

A pharmacokinetic interaction between lidocaine and amiodarone is not established. However, in the study that did find an interaction, the effects were slight, and would not be expected to be clinically relevant. The two reports of adverse interactions and the study in patients with arrhythmias illustrate the importance of good monitoring if both drugs are used as there is the possibility of a pharmacodynamic interaction. The manufacturer of some topical lidocaine preparations notes that although specific interaction studies of topical lidocaine with class III antiarrhythmics such as amiodarone have not been undertaken, caution and close monitoring is also important with topical lidocaine products especially if large doses are applied.[5,6]

Lidocaine + Atropine

Atropine delays the absorption of lidocaine, but does not significantly alter its peak levels.

Clinical evidence, mechanism, importance and management

A study in 4 healthy subjects found that the absorption of a single 400-mg oral dose of lidocaine was delayed when it was given at the same time as intramuscular atropine 600 micrograms. Peak plasma lidocaine levels were reduced by atropine but not to a significant extent. Atropine probably delayed lidocaine absorption by inhibition of gastric emptying.[1]

These pharmacokinetic changes are relatively minor, and would not be expected to alter the clinical effects of lidocaine.

1. Adjepon-Yamoah KK, Scott DB, Prescott LF. The effect of atropine on the oral absorption of lidocaine in man. *Eur J Clin Pharmacol* (1974) 7, 397–400.

Lidocaine + Barbiturates

Plasma lidocaine levels following slow intravenous injection may be modestly lowered by phenobarbital and other barbiturates.

Clinical evidence

In a study, 7 patients with epilepsy were given a single 2-mg/kg dose of lidocaine by slow intravenous injection (rate about 100 mg over 15 minutes), firstly while taking their usual antiepileptic drugs and sedatives (including phenytoin, barbiturates, phenothiazines, benzodiazepines) and secondly after taking only **phenobarbital** 300 mg daily for 4 weeks. The same lidocaine dose was also given to 6 control subjects who had not received any drugs. When compared with the levels in the 6 control subjects, plasma lidocaine levels were somewhat lower when the patients took their standard antiepileptic treatment (18% and 29% lower at 30 and 60 minutes, respectively). When plasma lidocaine levels achieved during the **phenobarbital** phase were compared with those achieved during the standard antiepileptic treatment they were found to be 10 to 25% higher, suggesting that the effect of combined treatment caused a greater reduction in lidocaine levels than **phenobarbital**.[1]

Mechanism

Not fully understood. One suggestion is that the barbiturates increase the activity of the liver microsomal enzymes, thereby increasing the rate of metabolism of the lidocaine.[1]

Importance and management

Direct information is very limited. It may be necessary to increase the dose of lidocaine to achieve the desired therapeutic response in patients taking phenobarbital or other barbiturates.

1. Heinonen J, Takki S, Jarho L. Plasma lidocaine levels in patients treated with potential inducers of microsomal enzymes. *Acta Anaesthesiol Scand* (1970) 14, 89–95.

Lidocaine + Beta blockers

The plasma levels of lidocaine after intravenous, and possibly oral, use can be increased by propranolol. Isolated cases of toxicity attributed to this interaction have been reported. Nadolol and penbutolol possibly interact similarly, but there is uncertainty about metoprolol. Atenolol and pindolol appear not to interact.

Clinical evidence

(a) Atenolol

A study in 7 healthy subjects pretreated with oral atenolol 50 mg daily for a week found that it did not affect the clearance of lidocaine after oral or intravenous use.[1]

(b) Metoprolol

In 6 healthy subjects, pretreatment with metoprolol 100 mg twice daily for 2 days did not affect the pharmacokinetics of a single intravenous dose of lidocaine.[2] Similarly, another study in 7 healthy subjects did not find any changes in the pharmacokinetics of a single oral or intravenous dose of lidocaine after pretreatment with metoprolol 100 mg every 12 hours for a week.[1] In contrast, another study found that the clearance of a single intravenous dose of lidocaine was reduced by 31% by pretreatment with metoprolol 50 mg every 6 hours for a day.[3]

(c) Nadolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with nadolol 160 mg daily for 3 days raised the steady-state plasma lidocaine levels by 28% (from 2.1 to 2.7 micrograms/mL) and reduced its plasma clearance by 17%.[4]

(d) Penbutolol

In 7 healthy subjects, pre-treatment with penbutolol 60 mg daily significantly increased the volume of distribution of a single 100-mg intravenous dose of lidocaine, thus prolonging its elimination half-life. However, the reduction in clearance of lidocaine was not statistically significant.[5]

(e) Pindolol

A study in 8 healthy subjects found that pretreatment with intravenous pindolol 23 micrograms/kg did not affect the clearance of intravenous lidocaine.[6]

(f) Propranolol

A study in 6 healthy subjects receiving 30-hour infusions of lidocaine at a rate of 2 mg/minute found that pretreatment with propranolol 80 mg every 8 hours for 3 days raised the steady-state plasma lidocaine levels by 19% (from 2.1 to 2.5 micrograms/mL) and reduced its plasma clearance by 16%.[4] Other similar studies have found a 23 to 30% increase in steady-state serum lidocaine levels and a 15 to 46% reduction in plasma clearance due to the concurrent use of propranolol.[3,6,7] Two cases of lidocaine toxicity attributed to a lidocaine-propranolol interaction[8] were revealed by a search of the adverse drug reaction file of the FDA in the US in 1981. A further case of lidocaine toxicity (seizures) has been described in a man taking propranolol after the accidental *oral* ingestion of lidocaine for oesophageal anaesthesia. High serum levels of lidocaine were detected.[9]

(g) Unnamed beta blockers

A matched study in 51 cardiac patients taking a variety of beta blockers (including **propranolol**, **metoprolol**, **timolol**, **pindolol**) found no significant differences in either total or free concentrations of lidocaine during a lidocaine infusion, but there was a trend towards increased bradycardia with the concurrent use of a beta blocker.[10]

Mechanism

Not fully agreed. There is some debate about whether the increased serum lidocaine levels largely occur because of the decreased cardiac output caused by the beta blockers, which decreases the flow of blood through the liver thereby reducing the metabolism of the lidocaine,[4] or because of direct liver enzyme inhibition.[11] An *in vitro* study in *animal* tissue found that propranolol significantly decreased the binding of lidocaine to liver tissue, so that concurrent use may increase the free fraction of lidocaine excreted by the liver. Further study of this *in vitro* model is required.[12] There may also be a pharmacodynamic interaction, with an increased risk of myocardial depression.[10]

Importance and management

The interaction between lidocaine and propranolol is established and possibly of some clinical relevance. Monitor the effects of concurrent use and reduce the intravenous lidocaine dose if necessary to avoid toxicity. The situation with other beta blockers is less clear. Nadolol appears to interact like propranolol, but it is uncertain whether metoprolol interacts or not. Atenolol and pindolol are reported not to cause a pharmacokinetic interaction. It has been suggested that a higher intravenous loading dose (but not a higher maintenance dose) of lidocaine may be needed if penbutolol is used.[5] The suggestion has been made that a significant pharmacokinetic interaction is only likely to occur with non-selective beta blockers without intrinsic sympathomimetic activity[11] e.g. nadolol or propranolol. Aside from the pharmacokinetic interactions, a pharmacodynamic interaction is possible, and so it would be prudent to monitor the effects of concurrent use with any beta blocker.

Note that local anaesthetic preparations of lidocaine often contain adrenaline (epinephrine), which may interact with beta blockers, see 'Beta blockers + Inotropes and Vasopressors', p.1011.

Lidocaine + Cocaine

Limited evidence suggests intravenous lidocaine use in patients with cocaine-associated myocardial infarction is not associated with significant toxicity.

Clinical evidence, mechanism, importance and management

A retrospective study, covering a 6-year period in 29 hospitals, identified 29 patients (27 available for review) who received lidocaine for prophylaxis or treatment of cocaine-associated myocardial infarction. No patient exhibited bradycardia, sustained ventricular tachycardia or ventricular fibrillation, and no patients died.[1]

Both lidocaine and cocaine exhibit class I antiarrhythmic effects and are proconvulsants. Lidocaine may potentiate the cardiac and CNS adverse effects of cocaine. Therefore the use of lidocaine for cocaine-associated myocardial infarction is controversial. The lack of adverse effects in this study may have been due to delays of more than 5 hours between last exposure to cocaine and the use of lidocaine. These authors[1] and others[2,3] consider that the cautious use of lidocaine does not appear to be contraindicated in patients with cocaine-associated myocardial infarction who require an antiarrhythmic. However, extra care should be taken in patients who receive lidocaine shortly after cocaine.[1]

Lidocaine + Dextromethorphan

Intravenous lidocaine does not affect the pharmacokinetics of dextromethorphan.

Clinical evidence, mechanism, importance and management

Although *in vitro* data suggested that lidocaine inhibited oxidative metabolism reactions mediated by the cytochrome P450 isoenzyme CYP2D6, a later *in vivo* study in 16 patients found that, while being given an infusion of lidocaine (serum level range 3.2 to 55.9 micromol/L), the metabolism of a single 30-mg dose of dextromethorphan remained unchanged. All of the patients were extensive CYP2D6 metabolisers (that is, those with normal levels of this isoenzyme). Dextromethorphan is also used as a probe drug for CYP2D6 activity, and it was therefore concluded that lidocaine is unlikely to affect the metabolism of drugs that are extensively metabolised by this isoenzyme.[1]

1. Bartoli A, Gatt G, Chimienti M, Corbellini D, Perrucca E. Does lidocaine affect oxidative dextromethorphan metabolism *in vivo*? *G Ital Chim Clin* (1993/4) 18, 125–9.

Lidocaine + Disopyramide

***In vitro* studies suggest that disopyramide can increase the levels of unbound lidocaine, but it is not known whether their combined effects have a clinically important cardiac depressant effect in practice.**

Clinical evidence, mechanism, importance and management

An *in vitro* study using serum taken from 9 patients receiving intravenous lidocaine for severe ventricular arrhythmias found that there was an average 20% increase in the free (unbound) fraction of lidocaine when disopyramide in a concentration of 14.7 micromol/L was added.[1] This appears to occur because disopyramide can displace lidocaine from its binding sites on plasma proteins (alpha-1-acid glycoprotein).

The importance of this possible displacement interaction in clinical practice is uncertain. The suggestion made by the authors[1] is that, although lidocaine has only a minor cardiac depressant effect, a transient 20% increase in levels of free and active lidocaine plus the negative inotropic effects of the disopyramide might possibly be hazardous in patients with reduced cardiac function.

1. Bonde J, Jensen NM, Burgaard P, Angelo HR, Graudal N, Kampmann JP, Pedersen LE. Displacement of lidocaine from human plasma proteins by disopyramide. *Pharmacol Toxicol* (1987) 60, 151–5.

Lidocaine + Erythromycin

Erythromycin may markedly increase the levels of oral lidocaine, but it causes only a minor increase in the levels of intravenous lidocaine.

Clinical evidence

In a randomised, crossover study, 9 healthy subjects were given erythromycin 500 mg three times daily or placebo daily for 4 days. Erythromycin increased the AUC and peak plasma levels of a single 1-mg/kg *oral* dose of lidocaine by 50% and 40%, respectively. Erythromycin also markedly increased the AUC of the main metabolite of lidocaine, monoethylglycinexylidide (MEGX) by 60%.[1]

In a similar study,[2] erythromycin had no effect on the AUC or peak plasma level of a single 1.5-mg/kg *intravenous* dose of lidocaine, but still increased the AUC of MEGX by 70%. In yet another study, erythromycin ethylsuccinate 600 mg three times daily for 5 doses had a minor effect on the pharmacokinetics of a single 1-mg/kg *intravenous* dose of lidocaine (an 18% decrease in clearance), and caused a 33% increase in the AUC of MEGX. There was no difference in the results from the 10 healthy subjects and the 20 patients with biopsy proven cirrhosis who were entered into the study.[3]

In another study, 9 healthy subjects were given fluvoxamine 100 mg daily alone or with erythromycin 500 mg three times daily for 5 days, with a single *intravenous* dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.[4] The same study was repeated in 8 healthy subjects who were given a single *oral* dose of lidocaine 1 mg/kg on day 6. The AUC and peak levels of lidocaine were increased by 305% and 220% by fluvoxamine and by 360% and 250% by concurrent fluvoxamine and erythromycin. The half-life of lidocaine was increased by fluvoxamine and fluvoxamine with erythromycin from 2.4 hours, to 3.1 hours and 3.8 hours, respectively. Fluvoxamine alone and fluvoxamine with erythromycin decreased the peak levels of MEGX by 50% and 30%, respectively.[5]

Mechanism

Erythromycin is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, an isoenzyme partially involved in the metabolism of lidocaine. Erythromycin appears to markedly reduce the first-pass metabolism of oral lidocaine so that its plasma levels rise.[1] The increase in the main metabolite monoethylglycinexylidide (MEGX) could be due to either an increase in the production of this metabolite, or the inhibition of its further metabolism. Fluvoxamine is an inhibitor of CYP1A2, which is also involved in lidocaine metabolism. Lidocaine clearance is reduced by fluvoxamine and further decreased by the concurrent use of erythromycin.

Importance and management

Information regarding an interaction between *oral* lidocaine and erythromycin seems limited, and as lidocaine is not usually given orally the practical importance is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. Thus, in a patient taking erythromycin, the toxicity of *oral* lidocaine may be markedly increased.

There appears to be more evidence regarding the interaction between *intravenous* lidocaine and erythromycin; however, some studies suggest that no increase in exposure occurs, and in others, only moderate pharmacokinetic changes were found. Therefore the increase in *intravenous* lidocaine

levels would not be expected to be clinically relevant. However, further study is required to assess the significance of the increase in MEGX during prolonged intravenous lidocaine infusions.

Lidocaine + Fluvoxamine

Fluvoxamine reduces the clearance of intravenous lidocaine. The bioavailability of oral lidocaine is increased by fluvoxamine.

Clinical evidence

In a study, 9 healthy subjects were given fluvoxamine 100 mg daily alone, or with erythromycin 500 mg three times daily for 5 days, with a single *intravenous* dose of lidocaine 1.5 mg/kg on day 6. The clearance of lidocaine was reduced 41% by fluvoxamine and 53% by concurrent fluvoxamine and erythromycin.[1] The same study was repeated in 8 healthy subjects, who were given a single *oral* dose of lidocaine 1 mg/kg on day 6. The AUC and peak levels of lidocaine were increased by 305% and 220%, respectively, by fluvoxamine and by 360% and 250%, respectively, by concurrent fluvoxamine and erythromycin. The half-life of lidocaine was increased by fluvoxamine and fluvoxamine with erythromycin, from 2.4 hours, to 3.1 hours and 3.8 hours, respectively. Fluvoxamine alone and fluvoxamine with erythromycin decreased the peak levels of the main metabolite of lidocaine, monoethylglycinexylidide (MEGX) by 50% and 30%, respectively.[2]

Mechanism

The cytochrome P450 isoenzymes CYP1A2 and CYP3A4 are involved in the first-pass metabolism of lidocaine. An *in vitro* study found that fluvoxamine (a CYP1A2 inhibitor) was a more potent inhibitor of lidocaine metabolism than erythromycin (a CYP3A4 inhibitor).[3] Therefore fluvoxamine decreases the clearance of lidocaine, and erythromycin has a modest additional effect.

Importance and management

Information regarding an interaction between *oral* lidocaine and fluvoxamine seems limited, and as lidocaine is not usually given orally the practical importance is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. Thus, in a patient taking fluvoxamine, the toxicity of *oral* lidocaine may be markedly increased.

Similarly, the evidence for an interaction between *intravenous* lidocaine and fluvoxamine is also limited; however, what is known suggests that the exposure to intravenous lidocaine will only be modestly increased, and possibly not of clinical relevance. However, further study is required to assess the significance of the decrease in MEGX during prolonged intravenous lidocaine infusions.

Lidocaine + H_2-receptor antagonists

Cimetidine modestly reduces the clearance of intravenous and possibly oral lidocaine, and raises its serum levels in some patients. Ranitidine appears to have minimal effects on lidocaine clearance.

Clinical evidence

(a) Cimetidine

In one study, 15 patients were given a 1-mg/kg intravenous loading dose of lidocaine followed by a continuous infusion of 2 or 3 mg/minute over 26 hours. At 6 hours the patients started taking oral cimetidine (initial dose 300 mg intravenously, then 300 mg every 6 hours). After 26 hours (20 hours after cimetidine was started) the serum levels of lidocaine were 30% higher (5.6 micrograms/mL) than in a control group of 6 patients (4.3 micrograms/mL). The most substantial rise in levels occurred in the first 6 hours after cimetidine was started. Six patients developed toxic serum lidocaine levels (over 5 micrograms/mL) and two (with levels of 10 and 11 micrograms/mL) experienced lethargy and confusion attributed to lidocaine toxicity, which disappeared when the lidocaine was stopped.[1]

In a study, patients with suspected myocardial infarction were given a 2 mg/minute infusion of lidocaine, and then, 11 to 20 hours later, two 300-mg oral doses of cimetidine 4 hours apart. Serum lidocaine levels, taken 24 hours after the initial cimetidine dose, had risen by 28%, and unbound levels had risen by 18%. In three of these patients whose diagnosis of myocardial infarction was subsequently confirmed, rises in total and unbound lidocaine serum levels of 24% and 9% occurred.[2] In contrast, a study in 6 patients with suspected myocardial infarction given lidocaine infusions, followed later by a cimetidine infusion, did not find a significant increase in the plasma accumulation of lidocaine.[3]

Studies in healthy subjects[4,5] have similarly found that oral cimetidine 300 mg four times daily increases the peak levels of intravenous lidocaine (by 50%) and/or decreases its clearance (by 30%), and adverse effects (light-headedness, paraesthesia), developed.[4] However, other studies in healthy subjects have found that cimetidine 300 mg four times daily has no effect on intravenous lidocaine clearance.[6,7]

Cimetidine pretreatment increased the *oral* bioavailability of lidocaine by 35% in healthy subjects, and reduced the apparent oral clearance by 42%.[8] Another study found that 2 days of cimetidine pretreatment increased the AUC of lidocaine by 52% after the aerosol application of lidocaine 120 mg (12 sprays of *Xylocaine* 10%) to the oropharynx.[9]

An 89-year-old man with congestive heart failure taking oral cimetidine had two seizures 10 to 15 minutes after accidental *oral* ingestion of lidocaine solution for oesophageal anaesthesia. He had a high serum lidocaine level of 7.8 micrograms/mL.[10]

(b) Ranitidine

A study in 10 healthy subjects given 150 mg ranitidine twice daily for 5 days found that it increased the systemic clearance of lidocaine by 9%, but did not alter its oral clearance.[11] In two other studies, ranitidine 150 mg twice daily for 1 to 2 days did not change the clearance of intravenous lidocaine.[6,12]

Mechanism

Not established. It seems possible that the metabolism of lidocaine is reduced both by a fall in blood flow to the liver and by direct inhibition of the activity of the liver microsomal enzymes. As a result its clearance is reduced and its serum levels rise.

Importance and management

The interaction between intravenous lidocaine and cimetidine is well studied and established, but the effects appear modest. Nevertheless, some studies report an increase in the adverse effects of lidocaine. The interaction may possibly be of less importance in patients following a myocardial infarction because of the increased amounts of alpha-1-acid glycoprotein, which alters the levels of bound and free lidocaine.[2] Nevertheless, it would seem prudent to monitor all patients closely for evidence of toxicity (e.g. bradycardia, hypotension, pins and needles) and, where possible, check serum lidocaine levels. A reduced infusion rate may be needed. Ranitidine would appear to be a suitable alternative to cimetidine.

For interactions of cimetidine and lidocaine, when lidocaine was used as a local anaesthetic, see 'Anaesthetics, local + H_2-receptor antagonists', p.123.

Lidocaine + Itraconazole

Itraconazole may markedly increase the plasma levels of oral lidocaine, but not intravenous lidocaine or inhaled lidocaine.

Clinical evidence

In a randomised, crossover study, 9 healthy subjects were given either itraconazole 200 mg daily or placebo for 4 days. Itraconazole increased the AUC and peak plasma levels of a single 1-mg/kg oral dose of lidocaine by 75% and 55%, respectively. Itraconazole did not affect the concentration of the main metabolite of lidocaine, monoethylglycinexylidide (MEGX).[1] In similar studies, itraconazole had no effect on the AUC and peak plasma levels of lidocaine or MEGX after 1.5-mg/kg intravenous[2] or nebulised[3] doses of lidocaine.

Mechanism

Itraconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, which is partially involved in the metabolism of lidocaine. Itraconazole appears to markedly reduce the first-pass metabolism of oral lidocaine so that its plasma levels rise.[1]

Importance and management

Information about an interaction between itraconazole and lidocaine seems to be limited, and as lidocaine is not usually given orally the practical importance of any interaction is minor. However, lidocaine is used for oro-pharyngeal topical anaesthesia, and there have been cases of toxicity after accidental ingestion. There is also a possibility of accidental oral ingestion during inhalation of lidocaine. In patients taking itraconazole, the toxicity of oral lidocaine may be markedly increased. Be alert for lidocaine adverse effects (e.g. bradycardia, hypotension, pins and needles).

Lidocaine + Mexiletine

Mexiletine may increase the toxicity of lidocaine.

Clinical evidence, mechanism, importance and management

A patient with cardiomyopathy taking mexiletine 300 mg twice daily developed lidocaine CNS toxicity within one hour of receiving a total of 600 mg of oral lidocaine for oesophageal burning. Her lidocaine concentration was raised at 26.9 micrograms/mL.[1] Similarly, involuntary motion and muscular stiffness occurred in a man taking oral mexiletine after he received an intravenous infusion of lidocaine for one day.[2] Studies in *animals* have shown that the concurrent use of mexiletine and intravenous lidocaine results in a decrease in the total clearance of lidocaine and an increase in its plasma levels. It appeared that this was due to mexiletine displacing the tissue binding of lidocaine and reducing its distribution.[3] Mexiletine is an oral lidocaine analogue, so it is perhaps not surprising the two drugs may interact. The combination should be used with caution, especially during the initial stages of treatment. Where possible, lidocaine levels should be closely monitored. Note that, when lidocaine is used topically, particularly in large doses, additive systemic toxicity may occur in patients also receiving mexiletine and caution with this combination is therefore advised.[4-6]

Lidocaine + Omeprazole

Omeprazole does not appear to alter the pharmacokinetics of intravenous lidocaine.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, omeprazole 40 mg daily for one week did not affect the AUC or half-life of a single 1-mg/kg intravenous dose of lidocaine or those of its main metabolite methylglycinexylidine.[1] This study suggests that no special precautions are required during concurrent use.

1. Noble DW, Bannister J, Lamont M, Andersson T, Scott DB. The effect of oral omeprazole on the disposition of lignocaine. *Anaesthesia* (1994) 49, 497–500.

Lidocaine + Opioids

Morphine given as an intravenous bolus does not alter the levels of lidocaine given as a continuous intravenous infusion. A case of respiratory depression has been reported when intravenous lidocaine was given to a patient who had been given fentanyl and morphine.

Clinical evidence, mechanism, importance and management

A double-blind study in 10 patients who were receiving continuous lidocaine infusions during suspected myocardial infarction found that a 10-mg intravenous bolus dose of **morphine sulfate** did not significantly alter the steady-state serum levels of lidocaine.[1] However, in one case, respiratory depression occurred within 5 minutes of giving intravenous lidocaine for an episode of ventricular tachycardia in a patient who had been given spinal **fentanyl** and **morphine**: the last dose of opioid had been given 4 hours previously. Naloxone successfully reversed this.[2] This appears to be an isolated case, and its clinical relevance is unknown.

For a report of respiratory depression with a local anaesthetic injection of lidocaine and alphaprodine, see 'Opioids + Local anaesthetics', p.191.

2. Jensen E, Nader ND. Potentiation of narcosis after intravenous lidocaine in a patient given spinal opioids. *Anesth Analg* (1999) 89, 758–9.

Lidocaine + Phenytoin

The incidence of central toxic adverse effects may be increased following the concurrent intravenous infusion of lidocaine and phenytoin. Sinoatrial arrest has been reported in one patient. Phenytoin may slightly reduce the levels of intravenous lidocaine, and markedly reduce the levels of oral lidocaine.

Clinical evidence

A study in 5 patients with suspected myocardial infarction, given lidocaine 0.5 to 3 mg/minute intravenously for at least 24 hours, followed by additional intravenous injections or infusions of phenytoin, found that the

plasma levels of both drugs remained unchanged but the incidence of adverse effects (vertigo, nausea, nystagmus, diplopia, impaired hearing) were unusually high.[1] However, in another study, lidocaine 2 mg/kg was given intravenously to 7 patients with epilepsy taking their usual antiepileptics (including phenytoin, barbiturates, phenothiazines, benzodiazepines), and to 6 control subjects. Plasma lidocaine levels were 27% and 43% lower in the patients at 30 and 60 minutes, respectively.[2] Another study found that the clearance of intravenous lidocaine was slightly greater in patients taking antiepileptics than in healthy subjects (850 mL/minute compared with 770 mL/minute) but this difference was not statistically significant.[3] Other studies in patients with epilepsy and healthy subjects have found that phenytoin halves the bioavailability of *oral* lidocaine.[3,4]

Sinoatrial arrest occurred in a man with heart block following a suspected myocardial infarction, after he received intravenous lidocaine 1 mg/kg over one minute, followed 3 minutes later by phenytoin 250 mg given over 5 minutes. The patient lost consciousness and his blood pressure could not be measured, but he responded to a 200-microgram dose of isoprenaline (isoproterenol).[5]

Mechanism

Phenytoin and lidocaine appear to have additive cardiac depressant actions. The reduced lidocaine serum levels are possibly due to liver enzyme induction; when lidocaine is given orally the marked reduction in levels results from the stimulation of hepatic first-pass metabolism by phenytoin.[3,4] In addition, patients taking antiepileptics including phenytoin had higher plasma concentrations of alpha-1-acid glycoprotein, which may result in a lower free fraction of lidocaine in the plasma.[6]

Importance and management

Information regarding an interaction between intravenous lidocaine and phenytoin is limited and its importance is not well established. However, the case of sinoatrial arrest emphasises the need to exercise caution when giving two drugs that have cardiac depressant actions.

The reduction in the serum levels of intravenous lidocaine in patients taking antiepileptics, including phenytoin, is small and appears not to be of any clinical significance. The reduction in the bioavailability of oral lidocaine is larger, but as lidocaine is not usually given orally, the practical importance of this interaction would also seem to be small.

Lidocaine + Procainamide

An isolated case of delirium has been described in a patient given intravenous lidocaine with procainamide.

Clinical evidence, mechanism, importance and management

A man with paroxysmal tachycardia, taking oral procainamide 1 g every 5 hours and receiving increasing doses of lidocaine by intravenous infusion (550 mg within 3.5 hours), became restless, noisy and delirious when given a further 250 mg intravenous dose of procainamide.[1] The symptoms disappeared within 20 minutes of discontinuing the lidocaine. The reason for this reaction is not understood but the symptoms suggest that the neurotoxic effects of the two drugs might be additive. Other studies in patients have found that lidocaine plasma levels are unaffected by intravenous or oral procainamide.[2] If both drugs are given it would be prudent to be alert for CNS adverse effects, and, where possible, consider stopping one of the drugs if these become troublesome.

Lidocaine + Propafenone

Propafenone has minimal effects on the pharmacokinetics of intravenous lidocaine, but the severity and duration of the CNS adverse effects of lidocaine are increased by propafenone.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects, who had been taking propafenone 225 mg every 8 hours for 4 days, were given a continuous infusion of lidocaine 2 mg/kg per hour for 22 hours. Propafenone increased the AUC of lidocaine by 7% and reduced its clearance by 7%. One poor metaboliser of propafenone (that is, a subject lacking the cytochrome P450 isoenzyme CYP2D6) had an increase in lidocaine clearance. Increases in the PR and QRS intervals of 10 to 20% were also seen. Combined use increased the severity and duration of adverse effects (lightheadedness, dizziness, paraesthesia, lethargy, somnolence). One subject withdrew from the study as a result.[1] In another study, the concurrent use of lidocaine (100 mg bolus then a 2 mg/minute infusion) and propafenone (1 or 2 mg/kg infusion) produced a minor additional negative inotropic effect (which was not statistically significant) and reversed the prolongation in atrial and ventricular refractoriness produced by propafenone alone.[2]

There would therefore appear to be no marked or important pharmacokinetic interaction between these two drugs, but the increased CNS adverse effects may be poorly tolerated by some individuals, and cardiac depressant effects may be additive.

Lidocaine + Protease inhibitors

Ritonavir may increase levels of lidocaine more than threefold. Other protease inhibitors may interact similarly.

Clinical evidence, mechanism, importance and management

Direct evidence (from case reports or clinical studies) of an interaction between lidocaine and the protease inhibitors is lacking; however, a review of protease inhibitor interactions reports that the plasma levels of lidocaine may be increased more than threefold by **ritonavir**.[1] The same review also states that **indinavir**, **nelfinavir** and **saquinavir** may interact similarly. Lidocaine is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ritonavir is a potent inhibitor. Concurrent use therefore raises lidocaine levels. All protease inhibitors are, to varying degrees, inhibitors of this isoenzyme, and would therefore be expected to raise lidocaine levels.

Evidence for an interaction between lidocaine and protease inhibitors is limited, but a rise in lidocaine levels would be expected from the known pharmacology of these drugs. A threefold increase in the levels of lidocaine would be expected to increase the risk of lidocaine adverse effects, including arrhythmias. The manufacturer of **darunavir**[2] contraindicates its concurrent use with lidocaine. Similarly, the manufacturers of **indinavir**,[3] **nelfinavir**[4] and **tipranavir**[5,6] contraindicate the concurrent use of drugs with a narrow therapeutic range that are metabolised by CYP3A4, which could reasonably be expected to include lidocaine.

If the concurrent use of lidocaine and a protease inhibitor cannot be avoided, it would seem prudent to monitor the outcome of concurrent use closely for lidocaine adverse effects (e.g. light-headedness, paraesthesia), monitoring lidocaine levels if possible. Reduce the lidocaine dose as necessary.

Lidocaine + Rifampicin (Rifampin)

Rifampicin slightly increases the clearance of intravenous lidocaine.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, rifampicin 600 mg daily for 6 days increased the clearance of a 50-mg intravenous dose of lidocaine by 15%. In addition, plasma concentrations of the main metabolite of lidocaine, monoethylglycinexylidide (MEGX) increased by 34%, although this did not reach statistical significance.[1] Using cultured human hepatocytes it was found that rifampicin increases the metabolism of lidocaine, probably because it induces the cytochrome P450 isoenzyme CYP3A4, which is partially concerned with the metabolism of lidocaine to MEGX.[2] These modest changes in lidocaine pharmacokinetics are unlikely to be of much importance, particularly as the intravenous lidocaine dose is usually titrated to effect.

Lidocaine + Tobacco

Tobacco smoking reduces the bioavailability of oral, but not intravenous, lidocaine.

Clinical evidence, mechanism, importance and management

A study in 9 subjects found that the bioavailability of oral lidocaine was markedly lower in smokers. The AUC of lidocaine was almost 70% lower in the 4 smokers than in the 5 non-smokers. However, when the lidocaine was given intravenously only moderate differences were seen.[1] The reduced lidocaine AUC in the smokers probably occurs due to liver enzyme induction caused by components of tobacco smoke. With oral lidocaine this could result in increased first-pass hepatic clearance. In the case of intravenous lidocaine, first-pass clearance is bypassed, and the enzyme induction was opposed by a smoking-related decrease in hepatic flow. In practical terms this interaction is unlikely to be of much importance as lidocaine is not usually given orally.

Lidocaine + Tocainide

A report describes a tonic-clonic seizure in a man during the period when his treatment was being changed from intravenous lidocaine to oral tocainide.

Clinical evidence, mechanism, importance and management

An elderly man taking furosemide and co-trimoxazole experienced a tonic-clonic seizure while his treatment with intravenous lidocaine was being changed to oral tocainide, although the serum levels of both antiarrhythmics remained within their therapeutic ranges. The patient became progressively agitated and disorientated about 8 hours after starting oral tocainide 600 mg every 6 hours while still receiving lidocaine 2 mg/minute intravenously. About one hour later he had a seizure. The patient subsequently tolerated each drug separately, at concentrations similar to those that preceded the seizure, without problems.[1] A study in *animals*[2] found that tocainide reduces the lidocaine serum levels at which seizures occur by about 45%. Tocainide is no longer widely available, but the US manufacturer previously noted that the concurrent use of lidocaine and tocainide may cause an increased incidence of adverse effects, including CNS adverse reactions such as seizure, because the two drugs have similar pharmacodynamic effects.[3] Great care must therefore be exercised if tocainide is given during lidocaine use. Note that, when lidocaine is used topically, particularly at large doses, additive systemic toxicity may occur in patients also receiving tocainide and caution with this combination is therefore also advised.[4]

Mexiletine + Amiodarone

Amiodarone does not affect the clearance of mexiletine; concurrent use can be clinically useful.

Clinical evidence, mechanism, importance and management

In 10 patients the clearance of mexiletine was found to be unchanged when assessed after 1, 3 and 5 months of the concurrent use of amiodarone. In addition, the clearance of mexiletine did not differ between these patients and 155 other patients not taking amiodarone.[1]

Torsade de pointes has been described in a patient taking amiodarone and mexiletine (a class Ib antiarrhythmic).[2] The manufacturers of mexiletine say that this seems to be an isolated case.[3] The two drugs have been used together successfully.[4,5]

Class Ib antiarrhythmics are usually associated with shortening of the QT interval, and could therefore be expected to reduce QT prolongation and the risk of torsade de pointes seen with amiodarone. This has been seen with sotalol in *animals* (see 'Mexiletine + Beta blockers', p.303) and quinidine (see 'Mexiletine + Quinidine', p.304).

Mexiletine + Antacids, Atropine or Metoclopramide

The rate of absorption of mexiletine is slowed by atropine, and hastened by metoclopramide, but the extent of the absorption is unaltered.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, the antacid almasilate (*Gelusil*), given one hour before a single 400-mg dose of mexiletine, resulted in a slight delay in absorption (time to maximum concentration prolonged from 1.7 hours to 2.9 hours), but had no effect on the extent of absorption.[1]

A study in 8 healthy subjects found that a single 600-microgram dose of intravenous atropine reduced the rate of absorption of a single 400-mg oral dose of mexiletine, but the mexiletine AUC remained unaffected. Intravenous metoclopramide 10 mg hastened the absorption of mexiletine but similarly did not affect the AUC. Metoclopramide may reverse the effect of diamorphine on plasma mexiletine levels. See 'Mexiletine + Opioids', p.303.

The achievement of steady-state mexiletine levels depends on the extent of absorption, not on its rate, and therefore it seems very unlikely that these drugs will affect the antiarrhythmic effects of mexiletine during long-term use.[2] However, these drugs may cause variations in the antiarrhythmic effects of initial oral mexiletine doses, which may be a problem if rapid control of the arrhythmia is essential. In general, no special precautions would appear necessary.

Mexiletine + Beta blockers

The concurrent use of mexiletine and beta blockers can be clinically useful. Mexiletine may reduce the QT-prolonging effects of sotalol.

Clinical evidence, mechanism, importance and management

A study in 4 patients found that a combination of mexiletine and **propranolol** 240 mg daily was more effective in blocking ventricular premature depolarisation (VPD) and ventricular tachycardia than mexiletine alone, and did not increase adverse effects. Plasma mexiletine concentrations were not significantly altered by **propranolol**.[1] Similar efficacy was reported for **metoprolol** with mexiletine.[2] Success in decreasing VPDs was noted in 30% of 44 patients taking mexiletine and a beta blocker [unspecified] compared with only 14% of 185 subjects taking mexiletine alone.[3] A study in *animals* found that mexiletine reduced the QT prolonging effect of **sotalol** and reduced the risk of torsade de pointes.[4] This is in line with the known effects of mexiletine, and a similar effects would be expected clinically.

Mexiletine + Fluconazole

Fluconazole does not affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

Six healthy subjects were given a single 200-mg dose of mexiletine before and after taking fluconazole 200 mg daily for 7 days. Two of the subjects were given fluconazole 400 mg daily for a further 7 days. No significant changes in the pharmacokinetics of mexiletine were seen.[1] The clinical outcome of concurrent use in patients was not studied, but there appear to be no adverse reports in the literature. No special precautions appear to be necessary if these drugs are used concurrently.

Mexiletine + H_2-receptor antagonists

The pharmacokinetics of mexiletine are not altered by cimetidine or ranitidine. Cimetidine can reduce the gastric adverse effects of mexiletine.

Clinical evidence, mechanism, importance and management

The peak and trough plasma mexiletine levels of 11 patients were unaltered when they were given **cimetidine** 300 mg four times daily for a week, and the frequency and severity of the ventricular arrhythmias for which they were being treated remained unchanged. Moreover the gastric adverse effects of mexiletine were reduced in half of the patients.[1] This study in patients confirms the findings of two other studies using **cimetidine** or **ranitidine** in healthy subjects.[2,3] There would seem to be no problems associated with giving these drugs concurrently, and some advantages.

Mexiletine + Omeprazole

Omeprazole does not appear to affect the pharmacokinetics of mexiletine.

Clinical evidence, mechanism, importance and management

A crossover study in 9 healthy Japanese men found that when they were given mexiletine 200 mg after taking omeprazole 40 mg daily for 8 days, the serum concentration and AUC of mexiletine were unchanged. It was concluded that omeprazole does not affect the metabolism of mexiletine,[1] and no special precautions would seem to be needed if these drugs are used concurrently.

Mexiletine + Opioids

The absorption of mexiletine is reduced following myocardial infarction, and very markedly reduced and delayed if diamorphine or morphine is used concurrently. Other opioids may interact similarly.

Clinical evidence

A pharmacokinetic study found that the mean plasma levels of mexiletine (400 mg orally followed by 200 mg 2 hours later) in the first 3 hours were more than 50% lower in 6 patients who had suffered a myocardial infarction and who had been given **diamorphine** 5 to 10 mg or **morphine** 10 to 15 mg than in 4 patients who had not been given opioids. In addition, the $AUC_{0\text{-}8}$ was 39% lower in those who had received opioids.[1]

In a further study about the prophylactic use of mexiletine, the same authors found that plasma mexiletine levels 3 hours after the first oral dose were 31% lower in 10 patients who had received opioids than in 6 patients who had not received opioids. These patients were from a subset that were subsequently shown not to have had a myocardial infarction.[1] In another similar study of mexiletine in acute myocardial infarction, the use of **diamorphine** was associated with low plasma mexiletine levels at 3 hours, and a possible reduction in the efficacy of mexiletine. In this study, pretreatment with intravenous metoclopramide tended to reduce the effect of **diamorphine** on mexiletine absorption,[2] although this was not noted in the other report.[1]

Mechanism

The reduced absorption of mexiletine would seem to result from inhibition of gastric emptying by diamorphine and morphine. Other mechanisms probably contribute to the delayed clearance of mexiletine.

Importance and management

An established interaction although information is limited. The delay and reduction in the absorption of mexiletine would seem to limit the value of oral mexiletine during the first few hours after a myocardial infarction, particularly if morphine or diamorphine are used. The manufacturer suggests that a higher loading dose of oral mexiletine may be preferable in this situation. Alternatively, an intravenous dose of mexiletine may be given. In addition, they note that it may be necessary to titrate the dose against therapeutic effects and adverse effects.[3] There seems to be no information about other opioids, but if the mechanism of interaction is correct, then other opioids would be expected to interact similarly.

Mexiletine + Phenytoin

Plasma mexiletine levels are reduced by phenytoin. Fosphenytoin may be expected to interact similarly.

Clinical evidence

The observation that 3 patients had unusually low plasma mexiletine levels while taking phenytoin prompted a pharmacokinetic study in 6 healthy subjects. After taking phenytoin 300 mg daily for a week, the mean AUC and half-life of a single 400-mg dose of mexiletine were reduced by an average of about 50% (half-life reduced from 17.2 hours to 8.4 hours).[1]

Mechanism

The most likely explanation for the reduction in mexiletine levels is that phenytoin increases the metabolism of mexiletine by the cytochrome P450 isoenzyme CYP1A2.

Importance and management

Information seems to be limited to this report but the interaction appears to be established. It seems likely that the reduction in mexiletine levels will be clinically important in some individuals. Monitor for mexiletine efficacy, and, where possible, monitor mexiletine levels. Raise the dose if necessary. There seems to be no information about **fosphenytoin**, but as it is a prodrug of phenytoin, it seems likely that it will interact similarly.

1. Begg EJ, Chinwah PM, Webb C, Day RO, Wade DN. Enhanced metabolism of mexiletine after phenytoin administration. *Br J Clin Pharmacol* (1982) 14, 219–23.

Mexiletine + Propafenone

Propafenone raises mexiletine serum levels in some patients.

Clinical evidence, mechanism, importance and management

In one study in healthy subjects, propafenone reduced mexiletine clearance and increased plasma mexiletine concentrations in CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme), but had no effect in CYP2D6 poor metabolisers (that is, those lacking this isoenzyme). Propafenone effectively turned the extensive metabolisers into poor metabolisers. Mexiletine did not affect propafenone pharmacokinetics. In this study, overall changes in ECG parameters were minor during the concurrent use of mexiletine and propafenone.[1]

The authors suggested that the increased levels of mexiletine occurred because propafenone is an inhibitor of CYP2D6, and inhibits the metabolism of mexiletine by this pathway.[1] Although the use of the combination was not associated with significant ECG changes, the potentiation of drug effects could predispose to proarrhythmias in patients with ischaemic heart disease. The authors suggest that slow dose titration of the combination may decrease the risk of adverse effects.[1] If propafenone is given to a patient taking mexiletine it would seem prudent to monitor the outcome of concurrent use (e.g. for nausea, tremor, hypotension), and decrease the dose of mexiletine if necessary.

Mexiletine + Protease inhibitors

Ritonavir appears to increase the levels of mexiletine levels. Tipranavir would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

Direct evidence (from case reports or clinical studies) of an interaction between mexiletine and the protease inhibitors appears to be lacking; however, a review of protease inhibitor interactions reports that plasma levels of mexiletine may be increased 1.5- to 3-fold by **ritonavir**.[1] Mexiletine is primarily metabolised by the cytochrome P450 isoenzyme CYP2D6, of which **ritonavir** is an inhibitor. Concurrent use would therefore be expected to result in raised mexiletine levels, which may increase the risk of arrhythmias and other adverse effects. The manufacturer of ritonavir reports that cardiac adverse effects have been reported on concurrent use.[2] **Tipranavir** also inhibits CYP2D6 and would also be expected to interact with mexiletine in this way. The other protease inhibitors do not significantly affect CYP2D6 and would not be expected to increase mexiletine levels alone; however, they are usually given with low-dose **ritonavir** as a pharmacological booster. Therefore, until more is known, it would seem prudent to monitor any patient taking mexiletine with **ritonavir**, **tipranavir** or any **ritonavir**-boosted protease inhibitor for an increase in mexiletine adverse effects (such as nausea, tremor, hypotension), and titrate the mexiletine dose slowly, according to clinical response.

2. Norvir Soft Capsules (Ritonavir). Abbott Laboratories Ltd. UK Summary of product characteristics, October 2009.

Mexiletine + Quinidine

Mexiletine appears to limit the quinidine-induced increase in QT interval and the concurrent use of these drugs can be clinically useful. Quinidine raises mexiletine serum levels in some patients.

Clinical evidence, mechanism, importance and management

Mexiletine and quinidine given concurrently (in lower doses) were reported to be more effective than either drug alone,[1,2] and the incidence of adverse effects was reduced. Mexiletine limited the quinidine-induced increase in QT interval,[1] and may prevent ventricular tachycardias in response to quinidine, which may be due to a prolonged ventricular refractory period.[3] Two studies[4,5] in healthy subjects have found that quinidine reduces the metabolism and excretion of mexiletine in CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme). The total clearance of mexiletine was reduced by 24%.[5] Quinidine had no effect on mexiletine metabolism in CYP2D6 poor metabolisers (that is, those lacking this isoenzyme).

Quinidine is an inhibitor of CYP2D6, and inhibits the metabolism of mexiletine by this pathway. However, the effects appear modest and a clinically relevant adverse pharmacokinetic interaction seems unlikely.

Mexiletine + Quinolones

Ciprofloxacin slightly reduces the clearance of mexiletine, but this is unlikely to be clinically relevant. Mexiletine may reduce sparfloxacin-induced QT prolongation.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

A study in healthy subjects found that the oral clearance of a single dose of mexiletine was reduced by about 8 to 20% when it was given on day 3 of a 5-day course of ciprofloxacin 750 mg twice daily. This was due to a decrease in the metabolic clearance of mexiletine, which presumably occurred because ciprofloxacin inhibits the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of mexiletine.[1] It is unlikely that changes of this magnitude would be clinically relevant.

(b) Other quinolones

An *animal* study found that mexiletine may reduce the QT-prolonging effect of **sparfloxacin**.[2] This is in line with the known effects of mexiletine, and this effect would be expected to be replicated clinically, both with **sparfloxacin**, and other quinolones that prolong the QT interval (e.g. **gatifloxacin**, **moxifloxacin** and possibly **levofloxacin**).

1. Labbé L, Robitaille NM, Lefez C, Potvin D, Gilbert M, O'Hara G, Turgeon J. Effects of ciprofloxacin on the stereoselective disposition of mexiletine in man. *Ther Drug Monit* (2004) 26, 492–8.
2. Takahara A, Sugiyama A, Satoh Y, Hashimoto K. Effects of mexiletine on the canine model of sparfloxacin-induced long QT syndrome. *Eur J Pharmacol* (2003) 476, 115–22.

Mexiletine + Rifampicin (Rifampin)

The clearance of mexiletine is increased by rifampicin.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, rifampicin 600 mg daily for 10 days reduced the half-life of a single 400-mg dose of mexiletine by 40% (from 8.5 hours to 5 hours) and the AUC fell by 39%.[1] The probable reason for these pharmacokinetics changes is that the rifampicin (a known, potent enzyme-inducer) increases the metabolism and clearance of mexiletine. It seems likely that the mexiletine dosage will need to be increased during concurrent use. Monitor concurrent use well.

1. Pentikäinen PJ, Koivula IH, Hiltunen HA. Effect of rifampicin treatment on the kinetics of mexiletine. *Eur J Clin Pharmacol* (1982) 23, 261–6.

Mexiletine + SSRIs

Fluvoxamine markedly increases the AUC of mexiletine by inhibiting CYP1A2. Fluoxetine and paroxetine might also be expected to interact, by inhibiting CYP2D6, but sertraline seems unlikely to interact.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, **fluvoxamine** 50 mg twice daily for 7 days increased the AUC of a single 200-mg dose of mexiletine by 55%, and decreased its clearance by 37%.[1] It is likely that **fluvoxamine** increases the AUC of mexiletine by inhibiting the cytochrome P450 isoenzyme CYP1A2, which is partially responsible for the metabolism of mexiletine.[1] Many adverse effects of mexiletine are dose related, and therefore concurrent use should be monitored for adverse effects (e.g. nausea, tremor, hypotension), and the mexiletine dose reduced as necessary.

In an *in vitro* study using human liver microsomes, **paroxetine**, **fluoxetine**, and **sertraline** extensively inhibited the metabolism of mexiletine. Using a model to predict *in vivo* interactions, it was suggested that both **fluoxetine** and **paroxetine** may interact with mexiletine to a clinically relevant extent, whereas **sertraline** is less likely to interact.[2] This *in vitro* finding is supported by the interactions of these SSRIs with known CYP2D6 substrates (e.g. see 'Tricyclic and related antidepressants + SSRIs', p.1513). However, note that quinidine (a potent CYP2D6 inhibitor) had only modest effects on mexiletine metabolism (see 'Mexiletine + Quinidine', p.304), and therefore **fluoxetine** and **paroxetine**, which are modest CYP2D6 inhibitors see unlikely to interact to a clinically relevant extent. Nevertheless, until more is known it may be prudent to be alert for mexiletine adverse effects (e.g. nausea, tremor, hypotension) in patients given **fluoxetine** or **paroxetine**. If they develop, consider an interaction as a possible cause.

Mexiletine + Tobacco

Tobacco smoking reduces the elimination half-life of mexiletine but does not affect its absorption and distribution.

Clinical evidence, mechanism, importance and management

A study in 14 healthy subjects (6 smokers and 8 non-smokers) found that cigarette smoking had no effect on the absorption or distribution of a single 200-mg dose of mexiletine. However, smoking significantly reduced the elimination half-life of mexiletine from 11.1 hours to 7.2 hours. Cigarette smoking was also found to induce the conjugation of mexiletine with glucuronic acid and the hydroxylation of mexiletine to hydroxymethylmexiletine but had no effect on the formation of *p*-hydroxymexiletine.[1]

It seems likely that some constituents of tobacco smoke induced the metabolism of mexiletine, leading to the reduction in half-life seen. The clinical significance of this effect is not known, but as mexiletine is titrated to effect it would seem that any interaction would automatically be accounted for in smokers. If a patient taking mexiletine stops smoking, it may be prudent to be alert for mexiletine adverse effects (e.g. nausea, tremor, hypotension), and decrease the dose of mexiletine, according to clinical response.

Mexiletine + Urinary acidifiers or alkalinisers

Large changes in urinary pH caused by acidifying or alkalinising drugs can have a marked effect on the plasma levels of mexiletine in some patients.

Clinical evidence

In 4 healthy subjects, a single 200-mg intravenous dose of mexiletine was given, once when the urine was acidic (pH 5) after administration of **ammonium chloride**, and once when the urine was alkaline (pH 8) after administration of **sodium bicarbonate**. The plasma elimination half-life was significantly shorter when the urine was acidic (2.8 hours) compared with when it was alkaline (8.6 hours). In addition, the percentage of mexiletine excreted unchanged in the urine was 58% in acidic urine and less than 1% in alkaline urine.[1] Similar results were found in another study.[2] A further study in patients with uncontrolled urinary pHs (range 5.04 to 7.86) given mexiletine orally for 5 days found that the plasma concentration of mexiletine correlated with urine pH. In addition, it was predicted that a normal variation in pH could cause more than a 50% variation in plasma mexiletine levels.[3] A later comprehensive pharmacokinetic study in 5 healthy subjects found that the renal clearance of mexiletine was 4 mL/minute in alkaline urine (pH 8) compared with 168 mL/minute in acidic urine (pH 5.2). In two subjects, this resulted in an increase in mexiletine plasma concentrations of 61% and 96%, but in the other three subjects the increase was less than 20%. Non-renal clearance (metabolic clearance) increased in the three subjects with little change in plasma concentrations, but was unaffected in the two subjects with marked changes in plasma concentrations.[4]

Mechanism

Mexiletine is a basic drug, which undergoes greater reabsorption by the kidneys when in the non-ionised form in alkaline urine. Mexiletine is also extensively cleared from the body by liver metabolism and only about 10% is excreted unchanged in the urine at physiological pH, although this is variable. Any changes in the renal clearance of mexiletine that occur as a result of urinary pH changes might therefore be expected to be compensated for by an increase in metabolic clearance, but this does not seem to occur in all patients.[4]

Importance and management

Although changes in urinary pH can affect the amount of mexiletine lost in the urine, the effect of diet or the concurrent use of alkalinisers (sodium bicarbonate, **acetazolamide**) or acidifiers (ammonium chloride etc.) on the plasma concentrations of mexiletine does not appear to be predictable. There appear to be no reports of adverse interactions but concurrent use should be monitored. The UK manufacturer of mexiletine recommends that the concomitant use of drugs that markedly acidify or alkalinise the urine should be avoided.[5]

Moracizine + Cimetidine

Cimetidine increases the AUC of moracizine. Moracizine does not affect the pharmacokinetics of cimetidine.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, cimetidine 300 mg four times daily for 7 days halved the clearance of a single 500-mg dose of moracizine and increased both its half-life and AUC by 39%. It is believed that these pharmacokinetic changes occur because cimetidine reduces moracizine metabolism by the liver.[1] Despite the increase in plasma moracizine levels, the PR and QRS intervals were not further prolonged. It has been suggested that this effect may occur because some of the metabolites of moracizine, whose production is inhibited by cimetidine, could also be pharmacologically active. Moracizine is reported not to affect the pharmacokinetics of cimetidine. Concurrent use should be well monitored for moracizine adverse effects (e.g. dizziness, abdominal pain, blurred vision), but measuring plasma moracizine levels may be of limited value because of the potential effects of the moracizine metabolites.

Moracizine + Diltiazem

A pharmacokinetic interaction occurs between moracizine and diltiazem resulting in increased systemic availability of moracizine and decreased systemic availability of diltiazem.

Clinical evidence, mechanism, importance and management

After 16 healthy subjects took both diltiazem 60 mg and moracizine 250 mg every 8 hours for 7 days, the maximum plasma concentration of moracizine was increased by 89%, the AUC was increased by 121%, and clearance was decreased by 54%. In addition, the maximum plasma concentration and AUC of diltiazem decreased by 36% and its clearance was increased by 52%. The AUCs for the diltiazem metabolites were not significantly affected. No clinically significant changes in ECG parameters were seen. However, the frequency of adverse events (e.g. headache, dizziness, paraesthesia) was greater on concurrent use (76%) than with either drug alone (54% and 45% for moracizine and diltiazem, respectively).[1]

Diltiazem probably inhibits the hepatic metabolism of moracizine while moracizine increases that of diltiazem. The clinical significance of this interaction is not known. However, particular caution is advised if diltiazem and moracizine are given concurrently, in light of the increase in adverse events. Dose adjustments may also be required to obtain optimum therapeutic responses.[1]

Moracizine + Propranolol

Moracizine appears not to interact adversely with propranolol.

Clinical evidence, mechanism, importance and management

In controlled studies, the efficacy and tolerability of the combination of propranolol and moracizine was compared with either drug alone in patients with ventricular arrhythmias. The combination was well tolerated, with no evidence of any adverse interactions, nor any beneficial interactions. However, the dose of propranolol used was fairly low at 120 mg daily.[1,2]

Pirmenol + Cimetidine

In a study in 8 healthy subjects, cimetidine 300 mg four times daily for 8 days had no significant effect on the pharmacokinetics of a single 150-mg oral dose of pirmenol.[1] No clinically important pharmacokinetic interaction would therefore be expected in patients given both drugs.

1. Stringer KA, Lebsack ME, Cetnarowski-Cropp AB, Goldfarb AL, Radulovic LL, Bockbrader HN, Chang T, Sedman AJ. Effect of cimetidine administration on the pharmacokinetics of pirmenol. *J Clin Pharmacol* (1992) 32, 91–4.

Pirmenol + Rifampicin (Rifampin)

Rifampicin markedly increases the clearance of pirmenol.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, rifampicin 600 mg daily for 14 days markedly affected the pharmacokinetics of a single 150-mg dose of pirmenol.[1] The apparent plasma clearance increased sevenfold and the AUC decreased by 83%.[1] The probable reason for these pharmacokinetic changes is that rifampicin increases the hepatic metabolism of pirmenol. Monitor concurrent use well and anticipate the need to increase the dose of pirmenol if rifampicin is used concurrently. However, note that, with such a large reduction in pirmenol exposure it is possible that dose increases will be ineffective, and alternative antiarrhythmics should be considered.

Procainamide + Amiodarone

When procainamide and amiodarone are used together the QT interval prolonging effects are increased. Serum procainamide levels are increased by about 60% and procainamide metabolite levels are increased by about 30% by amiodarone.

Clinical evidence

In a study, 12 patients were stabilised taking procainamide (2 to 6 g daily, or about 900 mg every 6 hours). When amiodarone (600 mg loading dose every 12 hours for 5 to 7 days, then 600 mg daily) was also given their mean serum procainamide levels rose by 57% (from 6.8 to 10.6 micrograms/mL) and their serum levels of the metabolite *N*-acetylprocainamide (NAPA) rose by 32% (from 6.9 to 9.1 micrograms/mL). Procainamide levels increased by more than 3 micrograms/mL in 6 of the patients. The increases usually occurred within 24 hours, but in other patients they occurred as late as 4 or 5 days. Toxicity was seen in 2 patients. Despite lowering the procainamide doses by 20%, serum procainamide levels were still higher (at 7.7 micrograms/mL) than before the amiodarone was started.[1]

In another study, intravenous procainamide was given once before (at a mean dose of 13 mg/kg), and once during (at a 30% reduced dose: mean 9.2 mg/kg) the use of amiodarone 1.6 g daily for 7 to 14 days. Amiodarone decreased the clearance of procainamide by 23% and increased its elimination half-life by 38%. Both drugs prolonged the QRS and QTc intervals, and the extent of prolongation was significantly greater with the combination than with either drug alone.[2]

Mechanism

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs appear to be additive.

Importance and management

Information about an interaction between procainamide and amiodarone appears to be limited to these studies, but the interaction would seem to be established and clinically important. The authors of the pharmacokinetic studies, suggest that the dose of procainamide may need to be reduced by 20 to 50%. They also suggest that serum levels should be monitored and patients observed for adverse effects.[1,2] Remember that the interaction can develop within 24 hours.

Note that the concurrent use of two drugs that prolong the QT interval, such as amiodarone and procainamide, should generally be avoided. For

further discussion, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Procainamide + Antacids or Antidiarrhoeals

There is some inconclusive evidence that aluminium phosphate may possibly cause a small reduction in the absorption of procainamide. Kaolin-pectin appears to modestly reduce the bioavailability of procainamide.

Clinical evidence, mechanism, importance and management

A single 11-g dose of an **aluminium phosphate** antacid modestly reduced the AUC of a single 750-mg oral dose of procainamide by about 15%.[1] The clinical importance of this interaction is uncertain, but probably small.

In a study in 4 healthy subjects, **kaolin-pectin** was found to reduce the peak saliva concentrations and AUC of a single 250-mg dose of procainamide by about 30%. **Kaolin-pectin** and **magnesium trisilicate** absorbed procainamide *in vitro*.[2] The clinical importance of this is also uncertain, but the effects appear to be relatively modest. The same *in vitro* study found that *Simeco* (**co-dried aluminium hydroxide**/**magnesium carbonate** with **magnesium hydroxide** and **simeticone**) and *Pepto-Bismol* (**bismuth salicylate**) did not adsorb procainamide[2] which suggests that they are unlikely to interact, but this needs confirmation.

Procainamide + Beta blockers

The pharmacokinetics of procainamide are only slightly altered by propranolol and metoprolol. Both sotalol and procainamide have QT-interval prolonging effects, which may be additive if they are used together.

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 6 healthy subjects found that long-term treatment with **propranolol** (period and dose not stated) increased the procainamide half-life from 1.71 to 2.66 hours and reduced the plasma clearance by 16%.[1] A later study in 8 healthy subjects found that the pharmacokinetics of a single 500-mg dose of procainamide were only slightly altered by **propranolol** 80 mg three times daily or **metoprolol** 100 mg twice daily. The procainamide half-life of 1.9 hours increased to 2.2 hours with **propranolol**, and to 2.3 hours with **metoprolol**, but no significant changes in total clearance occurred. No changes in the AUC of the metabolite *N*-acetylprocainamide were seen.[2] It seems unlikely that a clinically important adverse pharmacokinetic interaction normally occurs between these drugs.

A clinical study describes the successful use of procainamide with **sotalol**.[3] However, both **sotalol** and procainamide can prolong the QT interval, and there may be an increased risk of torsade de pointes arrhythmias if they are used together, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Procainamide + H_2-receptor antagonists

Serum procainamide levels can be increased by cimetidine and toxicity may develop, particularly in those who have a reduced renal clearance, such as the elderly. Ranitidine and famotidine appear to interact with procainamide only minimally or not at all.

Clinical evidence

(a) Cimetidine

In one study, 36 elderly patients (aged 65 to 90 years) taking sustained-release oral procainamide every 6 hours had rises in mean steady-state serum levels of procainamide and its metabolite *N*-acetylprocainamide of 55% and 36%, respectively, after taking cimetidine 300 mg every 6 hours for 3 days. This was tolerated in 24 patients with serum procainamide and *N*-acetylprocainamide levels of less than 12 mg/L and less than 15 mg/L, respectively, without adverse effects. However, 9 patients had some mild adverse effects (nausea, weakness, malaise, PR interval increases of less than 20%), with serum procainamide and *N*-acetylprocainamide levels between 10 and 15 mg/L and 10 and 20 mg/L, respectively. Three patients experienced severe procainamide toxicity (e.g. ventricular rate above 150 bpm for between 30 seconds and 5 minutes) with serum procainamide and *N*-acetylprocainamide levels greater than 14 mg/L and 16 mg/L, respectively. These adverse effects were dealt with by stopping one or both drugs and symptoms resolved within 12 to 24 hours.[1] Another report describes an elderly man who developed procainamide toxicity after taking cimetidine 1.2 g daily. His procainamide dose was roughly halved (from 937.5 mg every 6 hours to 500 mg every 6 hours) to bring his serum procainamide and *N*-acetylprocainamide levels into the accepted therapeutic range.[2]

Four studies in healthy subjects have found that cimetidine increases the AUC of procainamide by 24 to 43%, and decreases its renal clearance by 31 to 40%,[3-6] these changes occurring even with single doses of cimetidine.[5] An increase in the steady-state levels of procainamide of 43% has been seen when cimetidine 1.2 g daily was also given.[6]

(b) Famotidine

In a study in 8 healthy subjects, famotidine 40 mg daily for 5 days did not affect the pharmacokinetics or pharmacodynamics of a single 5-mg/kg intravenous dose of procainamide.[7]

(c) Ranitidine

One study[8] found that ranitidine 150 mg twice daily for one day reduced the absorption of procainamide from the gut by 10% and reduced its renal excretion by 19%, increasing the procainamide and *N*-acetylprocainamide AUC by about 14%. Another study found no change in the steady-state pharmacokinetics of procainamide when ranitidine 150 mg twice daily was also given, except that ranitidine delayed the time to maximum plasma concentration (from 1.4 to 2.7 hours).[6] In a further study, in 13 healthy subjects, ranitidine 150 mg twice daily for 4 days caused no significant changes in the mean pharmacokinetics of oral procainamide 1 g. However, it appeared that subjects had either a modest 20% increase or decrease in procainamide clearance, with the direction of change related to their baseline procainamide clearance: the higher the baseline clearance the greater the decrease caused by ranitidine.[9]

Mechanism

Procainamide levels are increased because cimetidine reduces its renal excretion by about one-third or more, but the precise mechanism for this is uncertain. One suggestion is that it interferes with the active secretion of procainamide by the kidney tubules.[3,4]

Importance and management

The interaction between procainamide and cimetidine is established. Concurrent use should be undertaken with care because the safety margin of procainamide is low. Reduce the procainamide dosage as necessary. This is particularly important in the elderly because they have a reduced ability to clear both drugs. Ranitidine and famotidine appear not to interact to a clinically important extent, but it should be appreciated that what is known is based on studies in healthy subjects rather than patients.

Procainamide + Para-aminobenzoic acid (PABA)

A single case report found that para-aminobenzoic acid (PABA) increased the serum levels of procainamide and reduced the serum levels of the procainamide metabolite *N*-acetylprocainamide. In contrast, a later pharmacokinetic study in healthy subjects found that PABA had no effect on serum procainamide levels, and increased serum *N*-acetylprocainamide levels.

Clinical evidence, mechanism, importance and management

A 61-year-old man who had sustained ventricular tachycardia, which did not respond adequately to oral procainamide, was found to be a fast acetylator of procainamide, which resulted in particularly high serum levels of the procainamide metabolite (*N*-acetylprocainamide) in relation to his procainamide levels. When he was also given para-aminobenzoic acid (PABA) 1.5 g every 6 hours for 30 hours, to suppress the production of this metabolite, the serum level of procainamide increased, that of *N*-acetylprocainamide decreased, and control of his arrhythmia improved.[1] However, a later study in 10 healthy subjects, who were also fast acetylators of procainamide, found that PABA did not significantly affect the pharmacokinetics of procainamide. In addition, although PABA inhibited the production of *N*-acetylprocainamide, it also inhibited its renal excretion, so that the AUC and elimination half-life were increased. This suggests that PABA may in fact not be useful for increasing the efficacy and safety of procainamide.[2]

These contradictory findings are difficult to explain, but neither report suggests that concurrent use need be avoided.

Procainamide + Probenecid

In a study in 6 healthy subjects, the pharmacokinetics of a single 750-mg intravenous dose of procainamide and its effects on the QT interval were not altered by pretreatment with probenecid 2 g.[1] No special precautions appear to be necessary on concurrent use.

1. Lam YWF, Boyd RA, Chin SK, Chang D, Giacomini KM. Effect of probenecid on the pharmacokinetics and pharmacodynamics of procainamide. *J Clin Pharmacol* (1991) 31, 429–32.

Procainamide + Quinidine

A single case report describes a patient who developed a marked increase in his procainamide levels when he was also given quinidine. The combination prolongs the QT interval, and should generally be avoided because of the increased risk of torsade de pointes.

Clinical evidence

A man with sustained ventricular tachycardia taking high-dose intravenous procainamide 2 g every 8 hours had a 70% increase in his steady-state plasma procainamide levels, from 9.1 nanograms/mL to 15.4 nanograms/mL, when he also took quinidine gluconate 324 mg every 8 hours. The procainamide half-life increased from 3.7 hours to 7.2 hours and its clearance fell from 27 L/hour to 16 L/hour. His QTc interval increased by 30 milliseconds, to 678 milliseconds.[1] In another study in patients with ventricular arrhythmias, quinidine was given with procainamide. The doses were adjusted, based in part on the QT interval. The QTc interval was longer when both drugs were given (499 milliseconds) than with each drug alone (quinidine 470 milliseconds, procainamide 460 milliseconds) despite reducing the doses when both drugs were given (mean quinidine dose reduced by 28%; mean procainamide dose reduced by 32%).[2]

Mechanism

It has been suggested that the quinidine interferes with one or more of the renal pathways by which procainamide is cleared from the body.[1]

Importance and management

Information on the possible pharmacokinetic interaction between procainamide and quinidine seems to be limited to this report. Both quinidine and procainamide are class Ia antiarrhythmics and prolong the QT interval, an effect that is increased by concurrent use. Such combinations should generally be avoided because of the increased risk of torsade de pointes. For further discussion of this effect, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Procainamide + Quinolones

Ofloxacin and levofloxacin cause moderate increases in the serum levels of procainamide, whereas ciprofloxacin has a lesser effect. However, the ECG appears to be unaltered in studies in healthy subjects given these quinolones with procainamide. An increased risk of torsade de pointes would be expected if procainamide is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.

Clinical evidence

Nine healthy subjects were given a single 1-g oral dose of procainamide alone, then again with the fifth dose of **ofloxacin** (400 mg twice daily for five doses). **Ofloxacin** increased the AUC of procainamide by 27%, increased its maximum plasma levels by 21% (from 4.8 to 5.8 micrograms/mL) and reduced its total clearance by 22%, whereas the pharmacokinetics of the active metabolite of procainamide, *N*-acetylprocainamide, were not significantly altered.[1] In another study, 10 healthy subjects were given **levofloxacin** 500 mg daily or **ciprofloxacin** 500 mg twice daily, with a single 15-mg/kg intravenous dose of procainamide on day 5. **Levofloxacin** increased the AUC of procainamide by 21% and prolonged its half-life by about 19% (from 2.7 to 3.2 hours). The clearance of procainamide was reduced by 17% (range 4 to 46%) with renal clearance reduced by 26% (range 11 to 58%). The pharmacokinetics of *N*-acetylprocainamide were similarly affected. **Ciprofloxacin** caused only minor changes in procainamide and *N*-acetylprocainamide pharmacokinetics, although the renal clearance of procainamide was reduced by 15% (range 3 to 26%).[2]

Despite these pharmacokinetic changes, no ECG changes were detected. However, these studies[1,2] involved only single doses of procainamide with average maximum serum levels (about 4 to 6 micrograms/mL) at the lower end of the therapeutic range for procainamide, although in one study individual levels of up to 8.5 micrograms/mL were found.[1]

The QTc interval in an elderly patient with atrial fibrillation increased from 450 to 464 milliseconds 3 days after she was given a single intravenous dose of procainamide and also started taking **levofloxacin** 500 mg daily. Procainamide levels on day 3 were subtherapeutic (1.8 micrograms/mL). On day 4 the QTc interval had increased to 568 milliseconds, she developed polymorphic ventricular tachycardia, and by the evening the QTc interval had further increased to 577 milliseconds. **Levofloxacin** was discontinued on day 5 and the QTc interval returned to normal within 48 hours.[3] This effect was attributed to

levofloxacin, and an interaction with procainamide was not considered.

An analysis of the Adverse Events Reporting System database of the FDA in the US looked at cases of torsade de pointes associated with quinolones reported up until May 2001. The quinolones included in the analysis were **ciprofloxacin**, **ofloxacin**, **levofloxacin**, **gatifloxacin**, and **moxifloxacin**, and in total there were 37 cases identified, of which 19 occurred in patients also taking other drugs known to prolong the QT interval. One of these 19 cases was noted in a patient taking procainamide with a quinolone [unspecified].[4]

Mechanism

The probable reason for the pharmacokinetic interaction is that levofloxacin, ofloxacin and to a lesser extent ciprofloxacin, inhibit the secretion of unchanged procainamide by the kidney tubules via renal drug transporters. Levofloxacin also appears to inhibit the secretion of *N*-acetylprocainamide. Some quinolones can prolong the QT interval, and these effects may be additive with the QT-prolonging effects of procainamide.

Importance and management

These results suggest that ofloxacin and levofloxacin affect the pharmacokinetics of procainamide to a modest extent; ciprofloxacin has lesser effects. The large interpatient variation found in these studies suggests it is possible that many patients will not experience a clinically significant interaction. However, in slow acetylators of procainamide, in whom renal clearance contributes to a larger fraction of total clearance, and those receiving higher doses of procainamide (serum levels greater than 10 micrograms/mL), the use of ofloxacin or levofloxacin could result in a clinically relevant effect. Therefore, it would be prudent to monitor the outcome if procainamide is given with these quinolones.

Evidence for an interaction between QT-prolonging quinolones and procainamide is limited. Of the quinolones used clinically, gatifloxacin, moxifloxacin, **sparfloxacin** and possibly levofloxacin prolong the QT interval (see 'Table 9.2', (p.290)) and would be expected to increase the risk of torsade de pointes when used with procainamide. The concurrent use of two drugs that prolong the QT interval should generally be avoided, or undertaken with caution. For a further discussion of QT prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Procainamide + Sucralfate

Sucralfate does not appear to affect the absorption of procainamide.

Clinical evidence, mechanism, importance and management

In 4 healthy subjects, sucralfate 1 g taken 30 minutes before a single 250-mg dose of procainamide reduced the mean maximum salivary level of procainamide by 5.3%, but did not significantly affect either the AUC or the rate of absorption.[1] These results suggest that a clinically significant interaction between sucralfate and procainamide is unlikely.

Procainamide + Trimethoprim

Trimethoprim causes a marked increase in the plasma levels of procainamide and its active metabolite, *N*-acetylprocainamide.

Clinical evidence

Eight healthy subjects were given procainamide 500 mg every 6 hours for 3 days. The concurrent use of trimethoprim 200 mg daily increased the $AUC_{0\text{-}12}$ of procainamide and its active metabolite, *N*-acetylprocainamide (NAPA), by 63% and 51%, respectively. The renal clearance of procainamide and NAPA decreased by 47% and 13%, respectively. The QTc prolonging effects of procainamide were increased to a significant, but slight, extent by trimethoprim.[1] Another study found that trimethoprim 200 mg daily reduced the renal clearance of a single 1-g dose of procainamide and NAPA by 45% and 26%, respectively. The QTc interval was increased by 30 milliseconds to 430 milliseconds.[2]

Mechanism

Trimethoprim decreases the renal clearance of both procainamide and its active metabolite by competing for active tubular secretion. It may also cause a small increase in the conversion of procainamide to *N*-acetylprocainamide.[1]

Importance and management

An established interaction but its documentation is limited. The need to reduce the procainamide dose should be anticipated if trimethoprim is given to patients already taking stable doses of procainamide. In practice the effects may be greater than those found in the studies cited because the renal excretion of procainamide is slower in the elderly than in young healthy subjects. Remember too that the daily dose of trimethoprim in **co-trimoxazole** (trimethoprim 160 mg with sulfamethoxazole 800 mg) may equal or exceed the doses used in the studies cited.

Propafenone + Azoles

An isolated case report describes a man taking propafenone who had a seizure two days after taking ketoconazole. Limited evidence suggests ketoconazole may inhibit the metabolism of propafenone.

Clinical evidence

A man who had been taking captopril and hydrochlorothiazide for 6 years and propafenone 300 mg daily for 4 years, without problems, and without any history of convulsive episodes, experienced a tonic-clonic seizure while watching television. It was later found that he had started to take **ketoconazole** 2 days previously for the treatment of a candidal infection.[1] The preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without **ketoconazole** 200 mg found that the increase in propafenone AUC with **ketoconazole** was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity.[2]

Mechanism

The authors of the case report postulate that the ketoconazole may have inhibited the metabolism of the propafenone so that this patient, in effect, may have developed an overdose.[1] However, convulsions with propafenone, even in overdose, are extremely rare.[3] Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which propafenone is metabolised. Propafenone is also extensively metabolised by CYP2D6 but it was suggested that if CYP2D6 activity is low, propafenone metabolism may be shifted to the CYP3A4 pathway increasing the possibility of an interaction with ketoconazole.[2]

Importance and management

The general importance of this interaction is uncertain. As of 2006, there had been no other cases reported to the manufacturer of propafenone.[4] As available data suggest that an interaction can occur, it would seem prudent to keep this interaction in mind during concurrent use. There seems to be nothing documented about the effects of other azole antifungals, but as they can all affect CYP3A4 (to a greater or lesser extent, see

'Azoles', (p.233)) it would be prudent to consider the possibility of an interaction if any of them are given with propafenone.

Propafenone + Barbiturates

Phenobarbital increases the metabolism of propafenone and reduces its serum levels.

Clinical evidence, mechanism, importance and management

In a preliminary report of a study in 7 non-smoking subjects, **phenobarbital** 100 mg daily for 3 weeks reduced the levels of a single 300-mg dose of propafenone by 26 to 87% and reduced its AUC by 10 to 89%. The intrinsic clearance of propafenone was increased by 11 to 84%. The results in a further 4 heavy smokers were similar.[1] These changes probably occur because **phenobarbital** (a potent enzyme inducer) increases the metabolism of propafenone. The clinical importance of this interaction awaits assessment, but check that propafenone remains effective if **phenobarbital** is added (the increases seen suggest that it may be ineffective in some patients in the presence of phenobarbital), and monitor to ensure that toxicity does not occur if **phenobarbital** is stopped. If the suggested mechanism is correct, other barbiturates would be expected to interact similarly.

Propafenone + Cimetidine

Cimetidine appears to interact minimally with propafenone.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects (10 extensive metabolisers and 2 poor metabolisers of propafenone) given propafenone 225 mg every 8 hours found that the concurrent use of cimetidine 400 mg every 8 hours caused some changes in the pharmacokinetics and pharmacodynamics of the propafenone, with wide intersubject variability. Raised mean peak and steady-state plasma levels were seen (24% and 22%, respectively), but these did not reach statistical significance. A slight increase in the QRS duration also occurred.[1] However, none of the changes were considered clinically important.

1. Pritchett ELC, Smith WM, Kirsten EB. Pharmacokinetic and pharmacodynamic interactions of propafenone and cimetidine. *J Clin Pharmacol* (1988) 28, 619–24.

Propafenone + Erythromycin

Limited evidence suggests that erythromycin may inhibit the metabolism of propafenone.

Clinical evidence, mechanism, importance and management

The preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without erythromycin 250 mg found that the increase in the AUC of propafenone with erythromycin was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested[1] that low CYP2D6 activity shifts propafenone metabolism to the CYP3A4/1A2-mediated *N*-depropylpropafenone pathway increasing the interaction with erythromycin, which is an inhibitor of CYP3A4. This appears to be the only documentation of a possible interaction with erythromycin and its clinical significance is not certain. More study is needed.

1. Munoz CE, Ito S, Bend JR, Tesoro A, Freeman D, Spence JD, Bailey DG. Propafenone interaction with CYP3A4 inhibitors in man. *Clin Pharmacol Ther* (1997) 61, 154.

Propafenone + Grapefruit juice

Limited evidence suggests that grapefruit juice may inhibit the metabolism of propafenone.

Clinical evidence, mechanism, importance and management

Preliminary results of a study in 12 healthy subjects given a single 300-mg dose of propafenone with or without 250 mL of grapefruit juice found that the increase in the AUC of propafenone with grapefruit juice was greater in those with lower cytochrome P450 isoenzyme CYP2D6 activity. It was suggested[1] that in the presence of low CYP2D6 activity a greater proportion of propafenone is eliminated by metabolism by CYP3A4 and CYP1A2 and the effect of grapefruit juice is increased as it is an inhibitor of CYP3A4. The clinical significance of this finding is not certain. Further study is needed.

Propafenone + Protease inhibitors

Ritonavir may increase the levels of propafenone. Other protease inhibitors may interact similarly.

Clinical evidence, mechanism, importance and management

Direct evidence (from case reports or clinical studies) of an interaction between propafenone and the protease inhibitors appears to be lacking; however, a review of protease inhibitor interactions reports that the plasma levels of propafenone may be increased by **ritonavir**.[1] Similarly, **indinavir**, **nelfinavir** and **saquinavir** may increase plasma levels of propafenone.[1]

Propafenone is metabolised by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4, of which **ritonavir** is an inhibitor, to its active metabolites, 5-hydroxypropafenone and *N*-depropylpropafenone. Concurrent use may therefore lead to an increase in propafenone levels and a possible increase in adverse effects such arrhythmias.

Evidence for an interaction between **ritonavir** and propafenone is limited, but what is said to occur is in line with the known pharmacokinetics of these drugs. Because of the risk of serious adverse effects, the manufacturers of **ritonavir** contraindicate concurrent use.[2,3] The UK manufacturer of propafenone also contraindicates concurrent use, but limits this to the use of high-dose ritonavir (800 to 1200 mg daily).[4] **Tipranavir** is also an inhibitor of CYP2D6 and CYP3A4, and its use with propafenone is similarly contraindicated.[5,6]

Most other protease inhibitors inhibit CYP3A4 but do not significantly affect CYP2D6, and would not be expected to interact with propafenone to the same extent as ritonavir. However, some patients may have reduced or low levels of CYP2D6 (poor metabolisers). In these patients, metabolism of propafenone by CYP3A4 may be of more importance and a more significant interaction with the other protease inhibitors is possible (see also 'Propafenone + Azoles', p.309). The manufacturers of **fosamprenavir**,[7] **indinavir**,[8] and **saquinavir**[9,10] contraindicate their use with propafenone. The US manufacturer of **darunavir** recommends caution and monitoring propafenone levels, where possible.[11] Other manufacturers of protease inhibitors do not appear to specifically mention the possibility of an interaction with propafenone. As low-dose ritonavir is commonly used with other protease inhibitors as a pharmacological booster, it would seem prudent to avoid the concurrent use of propafenone with ritonavir-boosted protease inhibitors if possible. However if concurrent use is necessary, it would be prudent to closely monitor for an increase in propafenone adverse effects.

Propafenone + Quinidine

Quinidine doubles the plasma levels of propafenone and halves the levels of its active metabolite in some patients. This interaction has been utilised clinically.

Clinical evidence

Nine patients taking propafenone for frequent isolated ventricular ectopic beats, firstly had their dose reduced to 150 mg every 8 hours and then 4 days later the steady-state pharmacokinetics of propafenone were determined at this new dose. Quinidine was then added at a dose of 50 mg every 8 hours, and after a further 4 days the steady-state plasma propafenone levels in 7 CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme) had more than doubled from 408 nanograms/mL to 1100 nanograms/mL, and concentrations of the metabolite 5-hydroxypropafenone had approximately halved. However, the ECG intervals and arrhythmia frequency were unaltered. The steady-state plasma propafenone levels remained unchanged in the other 2 patients with low levels of CYP2D6 (poor metabolisers).[1]

The same research group conducted a similar study in healthy subjects, which confirmed that quinidine increased the plasma levels of propafenone in extensive but not poor metabolisers. In addition, it was found that quinidine increased the extent of the beta-blockade caused by the propafenone in extensive metabolisers to approach that seen in poor metabolisers.[2] Another study found that the inhibition of propafenone metabolism by low-dose quinidine also occurs in Chinese as well as Caucasian patients.[3] [CYP2D6 shows pronounced interethnic differences in expression.] A further study found that combining low-dose quinidine (150 mg daily) with standard doses of propafenone in patients with atrial fibrillation resulted in a similar control of the arrhythmia as increasing the propafenone dose, but caused less gastrointestinal adverse effects.[4]

Mechanism

Quinidine inhibits the 5-hydroxylation of propafenone by the cytochrome P450 isoenzyme CYP2D6 in the liver of extensive metabolisers so that it is cleared more slowly. Its plasma levels are doubled as a result, but the overall antiarrhythmic effects remain effectively unchanged, possibly because the production of its active metabolite (5-hydroxypropafenone) is simultaneously halved.[1] Quinidine increases the beta-blocking effects of propafenone in extensive metabolisers because only the parent drug, and not the metabolites, has beta-blocking activity.[2]

Importance and management

Quinidine appears to raise propafenone levels, and may also affect the beta-blocking properties of propafenone in some patients. In one study the concurrent use of propafenone and quinidine was said to have an effect similar to increasing the propafenone dose.[4] More study is needed to clarify the importance of CYP2D6 metaboliser status.

Propafenone + Rifampicin (Rifampin)

Propafenone serum levels and therapeutic effects can be markedly reduced by rifampicin.

Clinical evidence

A man with ventricular arrhythmias successfully treated with propafenone had a marked fall in his plasma propafenone level from 993 nanograms/mL to 176 nanograms/mL within 12 days of starting to take rifampicin 450 mg twice daily. Levels of the two active metabolites of propafenone were altered; 5-hydroxypropafenone levels were reduced from 195 nanograms/mL to 64 nanograms/mL and *N*-depropylpropafenone levels were increased from 110 nanograms/mL to 192 nanograms/mL. His arrhythmias returned, but 2 weeks after stopping the rifampicin his arrhythmias had disappeared and the propafenone and its 5-hydroxy and *N*-depropyl metabolites had returned to acceptable levels (1411 nanograms/mL, 78 nanograms/mL and 158 nanograms/mL respectively).[1]

In a study in young healthy subjects, rifampicin 600 mg daily for 9 days reduced the bioavailability of a single 300-mg oral dose of propafenone from 30% to 10% in CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme), and from 81% to 48% in those with low levels of CYP2D6 (poor metabolisers). QRS prolongation decreased during enzyme induction. In contrast, in this study, rifampicin had no substantial effect on the pharmacokinetics of propafenone given intravenously.[2] Similar findings were reported in a further study by the same research group, in healthy elderly subjects.[3]

There is a report of rifampicin 600 mg daily being used to increase the metabolism of propafenone (as well as digoxin and warfarin) in a case of multiple drug overdosage in a 16-year-old female. She had ingested 15 tablets each containing propafenone 300 mg (equivalent to 90 mg/kg) but levels of propafenone were not obtained. Other treatments including gastric lavage, activated charcoal, cardiac pacing and plasma exchange were also used so the contribution of rifampicin treatment to the patient's recovery is not known.[4]

Mechanism

Propafenone is extensively metabolised by the cytochrome P450 isoenzyme CYP2D6, although CYP1A2 and CYP3A4 are also involved. Rifampicin induces the metabolism of propafenone by CYP1A2 and CYP3A4, and increases the phase II glucuronidation of propafenone. The effect of rifampicin on gastrointestinal clearance of propafenone was greater than that of its hepatic clearance.[2,3]

Importance and management

An established and clinically relevant metabolic drug interaction. The dose of oral propafenone is likely to need increasing during the concurrent use of rifampicin.[3] Alternatively, the authors of the case report[1] advise the use of another antibacterial, where possible, because of the probable difficulty in adjusting the propafenone dose.

Propafenone + SSRIs

In general, the SSRIs would be expected to inhibit the metabolism of propafenone, but the extent of this interaction varies by drug; fluoxetine and paroxetine would be expected to have the greatest effect, although fluvoxamine may also have a significant effect in some patients.

Clinical evidence

In a study in healthy subjects **fluoxetine** 20 mg daily for 10 days decreased the oral clearance of a single 400-mg dose of propafenone by 34% for both the *R*- and *S*-enantiomers. The peak plasma levels were increased by 39% for *S*-propafenone and by 71% for *R*-propafenone. However, there were no differences in the changes to the PR and QRS intervals.[1]

A case report describes an elderly woman who had been taking propafenone 900 mg daily for more than 10 years for paroxysmal atrial fibrilla-

tion, who experienced chest tightness and dizziness 3 months after starting to take **citalopram** 10 mg daily, increased after one month to 20 mg daily. The episodes became more frequent in the following months and she had several falls but no acute coronary event was diagnosed. She was given amlodipine, glyceryl trinitrate patches and warfarin, but after a fall she became delirious. Amlodipine and glyceryl trinitrate were discontinued and her dose of propafenone was reduced to 450 mg daily and **citalopram** was continued at 20 mg daily. The patient recovered well without any further symptoms during a one-year follow-up.[2]

Mechanism

Fluoxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is responsible for the metabolism of propafenone to its primary active metabolite 5-hydroxypropafenone. *In vitro* data have shown that, of the SSRIs, fluoxetine is the most potent inhibitor of propafenone 5-hydroxylation, followed by **paroxetine**. **Sertraline** and **fluvoxamine** have less effect on propafenone 5-hydroxylation, and citalopram has slight or no effects.[3] Although **fluvoxamine** only moderately inhibited propafenone 5-hydroxylation it did inhibit propafenone *N*-dealkylation[3] by inhibiting CYP1A2. This isoenzyme has only a minor role in the metabolism of propafenone, but it may assume greater importance in patients with low levels of CYP2D6 (poor metabolisers).[3]

Importance and management

Evidence for an interaction between **fluoxetine** and propafenone is limited. The study suggests that fluoxetine increases the peak propafenone levels without affecting the ECG, but as the overall propafenone exposure was not assessed, and as it was only a single-dose study, it is difficult to assess the clinical relevance of the interaction on the long-term use of both drugs. As with 'quinidine', (p.311), inhibition of 5-hydroxylation would be expected to increase the beta-blocking effects of propafenone, although note that fluoxetine is a less potent inhibitor of CYP2D6 than quinidine, and therefore its effects would be smaller. Until more is known, it would be prudent to use caution when giving fluoxetine with propafenone, monitoring for an increase in propafenone adverse effects (e.g. hypotension, bradycardia, dizziness, dry mouth) and consider decreasing the dose of propafenone if these become troublesome.

Evidence regarding an interaction with the other SSRIs is even more sparse. **Paroxetine** generally interacts in the same way as fluoxetine, and therefore similar precautions to those given for fluoxetine would be appropriate. **Fluvoxamine** would not generally be expected to interact, except for in patients who have low levels of CYP2D6. As it is unlikely that these patients will be known, it would seem prudent to monitor concurrent use in the same way as for fluoxetine.

The *in vitro* study with propafenone suggests that other SSRIs (**citalopram** (and therefore probably **escitalopram**) and **sertraline**) tend to have more minor, if any, effects on CYP2D6, and this is supported by the known clinical effects of these drugs on other CYP2D6 substrates (e.g. see 'Beta blockers + SSRIs', p.1019). Nevertheless, a modest increase in propafenone levels is possible, and the case report with citalopram reinforces this. Therefore, if propafenone adverse effects (e.g. hypotension, bradycardia, dizziness, dry mouth) develop in a patient taking one of these SSRIs, it may be prudent to consider an interaction as a possible cause.

Quinidine + Amiloride

A single study found that the antiarrhythmic activity of quinidine can be opposed by amiloride.

Clinical evidence

A study in 10 patients with inducible sustained ventricular tachycardia was carried out to see whether a beneficial interaction occurred between quinidine and amiloride. Patients were given oral quinidine until their trough serum levels reached 10 micromol/L, or the maximum well-tolerated dose was reached. After electrophysiological studies, oral amiloride 5 mg twice daily was started, and increased up to 10 mg twice daily (if serum potassium levels remained normal) for 3 days. The electrophysiological studies were then repeated. Unexpectedly, 7 of the 10 patients demonstrated adverse responses while taking both drugs. Three developed sustained ventricular tachycardia and 3 others had somatic adverse effects (hypotension, nausea, diarrhoea), which prevented further studies being undertaken. One patient had 12 episodes of sustained ventricular tachycardia while taking both drugs. Amiloride had no effect on quinidine levels.[1]

Mechanism

Not understood. The combination of quinidine and amiloride increased the QRS interval, but did not prolong the QT interval more than quinidine alone.

Importance and management

So far the evidence seems to be limited to this single study but it suggests that amiloride can oppose the antiarrhythmic activity of quinidine. The full clinical implications of this interaction are not known, but it would clearly be prudent to consider monitoring to confirm that the quinidine continues to be effective if amiloride is given.

1. Wang L, Sheldon RS, Mitchell B, Wyse DG, Gillis AM, Chiamvimonvat N, Duff HJ. Amiloride-quinidine interaction: adverse outcomes. *Clin Pharmacol Ther* (1994) 56, 659–67.

Quinidine + Amiodarone

The QT interval prolonging effects of quinidine and amiodarone are increased when they are used together, and torsade de pointes has occurred. Amiodarone increases quinidine levels.

Clinical evidence

In a study, 11 patients were stabilised taking quinidine in daily doses of 1.2 to 4.2 g. When they were also given amiodarone (600 mg every 12 hours for 5 to 7 days, then 600 mg daily) their mean serum quinidine levels rose by an average of 32%, from 4.4 to 5.8 micrograms/mL and 3 of them had a substantial increase of 2 micrograms/mL. Signs of toxicity (diarrhoea, nausea, vomiting, hypotension) were seen in some patients, and the quinidine dose was reduced in 9 patients, by an average of 37%. Despite the dose reduction, the quinidine serum levels were still higher at 5.2 micrograms/mL than before the amiodarone was started.[1]

A test in a healthy subject found that 3 days after amiodarone 600 mg was added to quinidine 1.2 g daily, the serum quinidine levels doubled and the relative QT interval was prolonged from 1 (no drugs) to 1.2 (quinidine alone) to 1.4 (quinidine plus amiodarone).[2] This report also described 2 patients with minor cardiac arrhythmias who developed QT prolongation and torsade de pointes when given both drugs.[2] A Russian study of the use of the combination in atrial fibrillation reported that one of 52 patients had a 50% increase in the QT interval resulting in torsade de pointes and subsequently ventricular fibrillation, which required repeated defibrillation over 6 hours.[3] A 76-year-old man taking quinidine and amiodarone had a number of episodes of loss of consciousness, and subsequently QT prolongation and torsade de pointes, which stopped when the quinidine was discontinued.[4]

Successful and uneventful concurrent use has been described in a report of 4 patients taking quinidine (dose not stated) and amiodarone 200 mg five times weekly.[5] Another report describes the successful use of a short course of quinidine to convert chronic atrial fibrillation to sinus rhythm in 9 of 15 patients taking long-term amiodarone. Patients were hospitalised and continuously monitored. No proarrhythmias occurred and the QT interval remained within acceptable limits.[6]

Mechanism

The mechanism behind the pharmacokinetic interaction is not understood. The QT prolonging effects of the two drugs would be expected to be additive.

Importance and management

An established and clinically important pharmacokinetic and pharmacodynamic interaction. The pharmacokinetic component appears to occur in most patients, and to develop rapidly. The study suggests that the dose of

quinidine may need to be reduced by 30 to 50% or more to keep quinidine at its pre-amiodarone level. Where possible, quinidine levels should be monitored.

The use of amiodarone with quinidine further prolongs the QT interval and increases the risk of torsade de pointes. The concurrent use of two drugs that prolong the QT interval should generally be avoided. For further discussion, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Quinidine + Antacids or Urinary alkalinisers

Large rises in urinary pH due to the concurrent use of some antacids, diuretics or alkaline salts can cause quinidine retention, which could lead to quinidine toxicity, but there seems to be only one case on record of an adverse interaction (with an aluminium/magnesium hydroxide antacid). Aluminium hydroxide alone appears not to interact with quinidine.

Clinical evidence

In a study in 4 subjects, the renal clearance of oral quinidine 200 mg every 6 hours was reduced by an average of 50% (from 53 to 26 mL/minute) when their urine was made alkaline (i.e. changed from pH 6 to 7, up to pH 7 to 8) with **sodium bicarbonate** and **acetazolamide** 500 mg twice daily. Below pH 6 their urinary quinidine level averaged 115 mg/L, whereas when urinary pH values rose above 7.5 the average urinary quinidine level was only 13 mg/L. The quinidine urinary excretion rate decreased from 103 micrograms/minute to 31 micrograms/minute. In 6 other subjects the rise in serum quinidine levels was reflected in a prolongation of the QT interval. Raising the urinary pH from about 6 to 7.5 in one individual increased serum quinidine levels from about 1.6 micrograms/mL to 2.6 micrograms/mL.[1]

A patient taking quinidine who took eight *Mylanta* tablets daily (**aluminium hydroxide** gel 200 mg, **magnesium hydroxide** 200 mg and simeticone 20 mg) for a week, with a little over one litre of fruit juice (orange and grapefruit) each day developed a threefold increase in serum quinidine levels (from 8 mg/L to 25 mg/L) and toxicity. However, note that the 'grapefruit juice', (p.317) may have contributed. In 6 healthy subjects, this dose of *Mylanta* for 3 days produced consistently alkaline urine in 4 subjects; the addition of fruit juice produced consistently alkaline urine in a further subject.[2]

In 4 healthy subjects, 30 mL of **aluminium hydroxide** gel (*Amphogel*) given with, and one hour after, a single 200-mg dose of quinidine sulphate had no effect on serum quinidine levels, AUC or excretion (urine pH ranged from 5 to 6.2).[3] Two similar single-dose studies in healthy subjects found that the absorption and elimination of 400 mg of quinidine sulfate[4] or 648 mg of quinidine gluconate[5] was unaffected by 30 mL **aluminium hydroxide** gel, although the change in quinidine AUC did vary from a decrease of 18% to an increase of 35% in one study.[5] Urinary pH was unaffected in both studies.[4,5]

Mechanism

Quinidine is excreted unchanged in the urine. In acid urine much of the quinidine excreted by the renal tubules is in the ionised (lipid-insoluble) form, which is unable to diffuse freely back into the cells and so is lost in the urine. In alkaline urine more of the quinidine is in the non-ionised (lipid-soluble) form, which freely diffuses back into the cells and is retained. In this way the pH of the urine determines how much quinidine is lost or retained and thereby governs the serum levels. *In vitro* data suggest that changes in pH and adsorption effects within the gut due to antacids could also affect the absorption of quinidine.[6,7]

Importance and management

An established interaction, but with the exception of the one isolated case cited,[2] there seem to be no reports of problems in patients given quinidine and antacids or urinary alkalinisers. However, in the case quinidine was given with grapefruit juice, which may potentially have had an effect of its own, see 'Quinidine + Grapefruit juice', p.317. Nevertheless it would be prudent to monitor the effects if drugs that can markedly change urinary pH are started or stopped. Avoid concurrent use, or reduce the quinidine dose as necessary.

It is difficult to predict which antacids, if any, are likely to increase the serum levels of quinidine. As noted above, aluminium hydroxide gel and magnesium hydroxide (*Mylanta*) alkalinises urine and may interact. Similarly, magnesium and aluminium hydroxide (*Maalox*) can raise the urinary pH by about 0.9 and could possibly interact.[8] Magnesium hydroxide (*Milk of magnesia*) and **calcium carbonate-glycine** (*Titralac*) raise the urinary pH by about 0.5, so that a smaller effect is likely.[8] Aluminium hydroxide gel (*Amphogel*) and **dihydroxyaluminium glycinate** (*Robalate*) are reported to have no effect on urinary pH,[8] and the studies above confirm aluminium hydroxide gel does not generally interact.

Quinidine + Antiepileptics

Serum quinidine levels can be reduced by phenytoin, phenobarbital or primidone. Fosphenytoin would be expected to interact similarly. Quinidine does not affect the metabolism of mephenytoin.

Clinical evidence

A man taking long-term **primidone** 500 mg daily was given quinidine sulfate 300 mg every 4 hours, but only attained a plasma quinidine level of 0.8 micrograms/mL with an estimated half-life of 5 hours. When **primidone** was discontinued, his quinidine level rose to 2.4 micrograms/mL and the half-life was 12 hours. **Phenobarbital** 90 mg daily was then started, and the quinidine level fell to 1.6 micrograms/mL with a half-life of 7.6 hours.

In another case, a woman required doses of quinidine sulfate of up to 800 mg every 4 hours to achieve therapeutic levels while taking **phenytoin**. When the **phenytoin** was stopped, quinidine toxicity occurred, and the dose was eventually halved. Further study was then undertaken in 4 healthy subjects. After taking either **phenytoin** (in doses adjusted to give levels of 10 to 20 micrograms/mL) or **phenobarbital** for 4 weeks the elimination half-life of a single 300-mg dose of quinidine sulfate was reduced by about 50% and the total AUC was reduced by about 60%.[1] Similar results were found with **phenytoin** in another study in 3 healthy subjects.[2] Other cases have also been reported with **phenytoin**, **primidone**, **pentobarbital** and **phenobarbital**.[3-6] In one case, when **phenytoin** was given with quinidine to a patient with recurrent ventricular tachycardia the quinidine levels fell by 44%.[3] In another report quinidine levels increased from a mean of 0.8 micrograms.mL to 2.2 micrograms/mL, 15 days after **pentobarbital** was discontinued.[4] Interestingly, in this case the patient was also taking digoxin, and stopping phenobarbital precipitated digoxin toxicity by causing an increase in quinidine levels.

A 3-year-old child taking both **phenobarbital** and **phenytoin** needed to take quinidine 300 mg every 4 hours to achieve therapeutic serum quinidine levels, and had an estimated quinidine half-life of only 1.4 hours.[5] Difficulty in achieving adequate serum quinidine levels was also reported in a woman taking **phenytoin** and **primidone**. Her quinidine half-life was 2.7 hours, about half that usually seen in adults.[6]

In a study in 10 healthy subjects, quinidine 200 mg had no effect on the metabolism (4-hydroxylation) of **mephenytoin** 100 mg.[7]

Mechanism

The evidence suggests that phenytoin, primidone or phenobarbital (all known enzyme-inducers) increase the hepatic metabolism of quinidine and thereby reduce its levels.[2]

Importance and management

Established interactions of clinical importance although the documentation is limited. The concurrent use of phenytoin (and therefore probably the prodrug, **fosphenytoin**), primidone, phenobarbital or any other barbiturate need not be avoided, but be alert for the need to increase the quinidine dose. If the antiepileptics are withdrawn the quinidine dose may need to be reduced to avoid quinidine toxicity. Where possible, quinidine serum levels should be monitored.

Quinidine + Aspirin

A patient and two healthy subjects given quinidine and aspirin had a two- to threefold increase in bleeding times. The patient developed petechiae and gastrointestinal bleeding.

Clinical evidence, mechanism, importance and management

A patient with a prolonged history of paroxysmal atrial tachycardia was given quinidine 800 mg daily and aspirin 325 mg twice daily. After a week he developed generalised petechiae and blood in his faeces. His prothrombin and partial prothrombin times were normal but the template bleeding time was more than 35 minutes (reference range 2 to 10 minutes). Further study in 2 healthy subjects found that quinidine 975 mg daily given alone for 5 days and aspirin 650 mg three times daily given alone for 5 days prolonged bleeding times by 125% and 163% respectively; given together for 5 days the bleeding times were prolonged by 288%.[1] The underlying mechanism for this increase in bleeding time is not totally understood but it is believed to be the outcome of the additive effects of the two drugs, both of which can reduce platelet aggregation,[1] although with quinidine this antiplatelet effect usually only occurs as the result of a hypersensitivity reaction.

This seems to be the only study of this adverse interaction, and its general importance is uncertain.

Quinidine + Azoles

Itraconazole increases the plasma levels of quinidine, and a case report suggests that ketoconazole may also raise quinidine levels. Other azoles are predicted to interact similarly. An isolated report describes QT prolongation in a patient taking hydroquinidine and itraconazole.

Clinical evidence

(a) Itraconazole

In a randomised, crossover study, 9 healthy subjects were given a single 100-mg dose of quinidine sulfate on the final day of a 4-day course of either itraconazole 200 mg daily or placebo. Itraconazole caused a 60% increase in the peak plasma quinidine levels, a 2.4-fold increase in its AUC, a 60% increase in its elimination half-life and a 50% decrease in its renal clearance.[1] Similarly, another study in 6 healthy subjects found that itraconazole 100 mg daily for 6 days reduced the total clearance of a single 200-mg dose of quinidine sulfate by 61%, increased its elimination half-life by 35%, and decreased its renal clearance by 60%.[2]

An isolated report describes QT prolongation after itraconazole was given to an elderly patient taking **hydroquinidine**. The QT interval returned to normal after hydroquinidine was withdrawn.[3]

(b) Ketoconazole

An elderly man with chronic atrial fibrillation, taking quinidine sulfate 300 mg four times daily, was also given ketoconazole 200 mg daily, for candidal oesophagitis after antineoplastic therapy. Within 7 days his plasma quinidine levels had risen from a range of 1.4 to 2.7 mg/L up to 6.9 mg/L (reference range 2 to 5 mg/L) but there was no evidence of toxicity. The elimination half-life of quinidine was found to be 25 hours (reference range in healthy subjects 6 to 7 hours). The quinidine dose was reduced to 200 mg twice daily, but it needed to be increased to the former dose by the end of a month, even though ketoconazole was continued at the same dose.[4]

Mechanism

The most likely explanation for the rises in quinidine levels is that itraconazole and ketoconazole inhibit the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4 in the gut wall and liver. Itraconazole may also inhibit the active secretion of quinidine by the renal tubules.[1,2] In the case with ketoconazole, it is unclear why the quinidine dose was subsequently returned to normal. Hydroquinidine is structurally related to quinidine and may interact similarly.

Importance and management

Direct information regarding an interaction between itraconazole and quinidine appears to be limited to these studies, but what is known suggests that this interaction is clinically important. The authors of one report advise that concurrent use of these drugs should therefore be well monitored and the dose of quinidine reduced accordingly.[1]

The isolated case with ketoconazole suggests that it may interact similarly, and other azoles (including **voriconazole**, **posaconazole** and possibly **fluconazole**) would also be expected to raise quinidine levels. Because of the risk of torsade de pointes with raised quinidine levels, the concurrent use of these azoles is generally contraindicated. Note that, a large proportion of **miconazole** oral gel (both prescription and non-prescription doses) may be swallowed, and therefore adequate systemic absorption may occur to produce an interaction.

Quinidine + Calcium-channel blockers

A few patients have had increases in their quinidine levels when stopping nifedipine, but in others no interaction has occurred. In contrast, one study suggests that quinidine serum levels may be slightly raised by nifedipine. Nifedipine levels may be modestly raised by quinidine.

Verapamil reduces the clearance of quinidine and in one patient the quinidine levels doubled and quinidine toxicity developed. Acute hypotension has also been seen in three patients taking quinidine when they were given verapamil intravenously. Felodipine and nisoldipine appear not to interact, and the situation with diltiazem is unclear.

Clinical evidence

(a) Diltiazem

A study in 10 healthy subjects given quinidine 600 mg twice daily and diltiazem 120 mg daily for 7 days found that concurrent use did not affect the pharmacokinetics of either drug.[1] These findings contrast with a crossover study in 12 healthy subjects. In this study, a single 60-mg dose of diltiazem was given before and after quinidine 100 mg twice daily for 5 doses, and a single 200-mg dose of quinidine was given before and after diltiazem 90 mg twice daily for 5 doses. The pharmacokinetics of diltiazem were unaffected by quinidine, but the AUC of quinidine was increased by 51% by diltiazem.[2] When quinidine was given after diltiazem pretreatment, there were significant increases in QTc and PR intervals, and a significant decrease in heart rate and diastolic blood pressure. Pretreatment with quinidine did not significantly alter the effects of diltiazem.[2]

(b) Felodipine

In a study in 12 healthy subjects, felodipine 10 mg daily for 3 days was found to have no clinically significant effect on the pharmacokinetics or haemodynamic and ECG effects of a single 400-mg dose of quinidine. Felodipine did cause a modest 22% decrease in the AUC of the quinidine metabolite 3-hydroxyquinidine.[3]

(c) Nifedipine

1. Nifedipine serum levels. In a study in 10 healthy subjects quinidine sulfate 200 mg every 8 hours increased the AUC of nifedipine by 37%, and heart rates were significantly increased. Quinidine levels were unchanged.[4] Another study found that quinidine had a modest inhibitory effect on the metabolism of nifedipine (half-life prolonged by 40%).[5] A further study in 12 healthy subjects found that the AUC of a single 20-mg dose of nifedipine was increased 16% by quinidine 200 mg and its clearance was reduced by 17%, but these modest changes were not considered clinically relevant.[6]

2. Quinidine serum levels. The quinidine serum levels of 2 patients taking quinidine sulfate 300 or 400 mg every 6 hours and nifedipine 10 or 20 mg every 6 or 8 hours doubled (from a range of 2 to 2.5 micrograms/mL up to 4.6 micrograms/mL and from 1.6 to 1.8 micrograms/mL up to 3.5 micrograms/mL, respectively) when the nifedipine was withdrawn. The increased serum quinidine levels were reflected in a prolongation of the QTc interval. However, in the first patient there had been no change in quinidine levels when nifedipine was initially added. Further, 4 other patients did not develop this interaction.[7] Two other reports[8,9] describe a similar response: the quinidine serum level doubled in one patient when the nifedipine was stopped,[8] and in the other it was found difficult to achieve adequate serum quinidine levels when nifedipine was added, even when the quinidine dosage was increased threefold. When the nifedipine was withdrawn, the quinidine levels rose once again.[9]

A study in 12 patients found no significant change in serum quinidine levels in the group as a whole when nifedipine was given, but one patient had a 41% decrease in quinidine levels.[10] Two other studies in healthy subjects found that the quinidine AUC was unchanged by nifedipine.[3,4]

A further study in 12 healthy subjects found that the AUC of a single 200-mg oral dose of quinidine sulfate was increased by 16% by nifedipine 20 mg. The quinidine clearance was reduced by 14% and the maximum serum level was raised by almost 20%. These modest changes were not considered clinically relevant.[6]

(d) Nisoldipine

An open, crossover study in 20 healthy subjects found that nisoldipine 20 mg had no effect on the bioavailability of quinidine gluconate 648 mg.[11]

(e) Verapamil

In a study in 6 healthy subjects, verapamil 80 mg three times daily for 3 days, decreased the clearance of a single 400-mg dose of quinidine sulfate by 32% and increased the half-life was by 35% (from 6.87 to 9.29 hours).[12]

A patient given quinidine gluconate 648 mg every 6 hours had an increase in serum quinidine levels from 2.6 micrograms/mL to 5.7 micrograms/mL after taking verapamil 80 mg every 8 hours for a week. He became dizzy and had blurred vision and was found to have atrioventricular block (heart rate 38 bpm) and a systolic blood pressure of 50 mmHg. In a subsequent study in this patient it was found that verapamil halved quinidine clearance and almost doubled its serum half-life.[13]

Three other patients given quinidine orally developed marked hypotension when given intravenous verapamil 2.5 or 5 mg (blood pressure reduced from 130/70 mmHg to 80/50 mmHg, systolic pressure reduced from 140 mmHg to 85 mmHg, and mean arterial pressure reduced from 100 mmHg to 60 mmHg, in the 3 patients respectively). In two of the patients, after quinidine was discontinued, the same dose of verapamil did not cause a reduction in blood pressure.[14]

Mechanism

Suggestions for how nifedipine could alter quinidine levels include changes in cardiovascular haemodynamics,[7] and effects on metabolism.[10] Quinidine possibly inhibits the metabolism of nifedipine by competing for metabolism by the cytochrome P450 isoenzyme CYP3A4.[5] The interaction with verapamil is probably due to an inhibitory effect of verapamil on the metabolism of quinidine (inhibition of cytochrome P450 isoenzyme CYP3A).[12,15] The marked hypotension observed may be related to the antagonistic effects of the two drugs on catecholamine-induced alpha-receptor induced vasoconstriction.[14]

Importance and management

The results of studies of the interaction between quinidine and **nifedipine** are somewhat contradictory, so that the outcome of concurrent use is uncertain. However, the increase in QTc interval seen in some patients suggests that some caution would be prudent. The increases in quinidine levels seen in the studies are generally modest, but the case reports suggest that greater increases may occur in some patients. Monitor concurrent use for quinidine adverse effects (e.g. nausea, diarrhoea, tinnitus) and decrease the dose accordingly. The increases in nifedipine levels are also modest, nevertheless, it would seem prudent to monitor for nifedipine adverse effects (e.g. greater than desired reductions in blood pressure, flushing, oedema) and reduce the nifedipine dose as necessary.

What is known about the interaction between quinidine and **verapamil** suggests that a reduction in the dose of the quinidine may be needed to avoid toxicity. If the verapamil is given intravenously, use with caution and be alert for evidence of acute hypotension. Monitor the effects of concurrent use closely. There is actually a fixed dose preparation containing verapamil and quinidine (*Cordichin*) available in Germany, which is used for the management of atrial fibrillation.

No interaction apparently occurs between quinidine and **felodipine** or **nisoldipine**. The situation with **diltiazem** is as yet uncertain but be alert for the need to reduce the quinidine dose.

Quinidine + Colesevelam

In a study in 25 subjects, a single 4.5-g dose of colesevelam had no significant effect on the pharmacokinetics of a single 324-mg dose

of quinidine [gluconate].[1] This suggests that colesevelam does not reduce the absorption of quinidine. No special precautions appear to be needed during concurrent use.

1. Donovan JM, Stypinski D, Stiles MR, Olson TA, Burke SK. Drug interactions with colesevelam hydrochloride, a novel, potent lipid-lowering agent. *Cardiovasc Drugs Ther* (2000) 14, 681–90.

Quinidine + Co-phenotrope (Atropine/Diphenoxylate)

Co-phenotrope slightly reduced the rate, but not the extent, of absorption of a single dose of quinidine.

Clinical evidence, mechanism, importance and management

In one study, 8 healthy subjects were given a single 300-mg dose of quinidine sulfate alone and after taking two tablets of co-phenotrope (atropine sulfate 25 micrograms, diphenoxylate 2.5 mg; *Lomotil*) at midnight on the evening before and another two tablets the next morning an hour before the quinidine.[1] It was found that the maximum plasma quinidine levels were reduced by 21% (from 2.1 to 1.65 micrograms/mL) by the co-phenotrope, the time to maximum level was prolonged from 0.89 hours to 1.21 hours, and there was a slight increase in elimination half-life from 5.7 hours to 6.8 hours. While these results were statistically significant, the changes were relatively small and it seems doubtful if they are clinically relevant, particularly as the extent of absorption was unchanged. However it needs to be emphasised that because the quinidine formulation used was an immediate-release preparation, these results may not necessarily apply to sustained-release preparations, and also may not apply if multiple doses of quinidine are used.

Quinidine + Diazepam

A single-dose study suggests that diazepam does not affect the pharmacokinetics of quinidine.

Clinical evidence, mechanism, importance and management

A comparative study in 8 healthy subjects found that the pharmacokinetics of a single 250-mg dose of quinidine sulfate was unaltered by a single 10-mg dose of diazepam.[1] This suggests that no dose adjustment of quinidine is likely to be needed in patients given diazepam, but this ideally needs confirmation by further studies using multiple doses of both drugs.

1. Rao BR, Rambhau D. Absence of a pharmacokinetic interaction between quinidine and diazepam. *Drug Metabol Drug Interact* (1995) 12, 45–51.

Quinidine + Diclofenac

Diclofenac inhibits the metabolism (*N*-oxidation) of quinidine but does not affect other pharmacokinetic parameters.

Clinical evidence, mechanism, importance and management

In an open study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of diclofenac 100 mg daily. Diclofenac reduced the *N*-oxidation of quinidine by 33%, but no other pharmacokinetic changes were found.[1] Diclofenac is a substrate for, and therefore a possible competitive inhibitor of the cytochrome P450 isoenzyme CYP2C9. These results suggest that CYP2C9 does not appear to have a major role in quinidine metabolism,[1] and so clinically relevant changes in quinidine pharmacokinetics with diclofenac would seem unlikely.

1. Damkier P, Hansen LL, Brøsen K. Effect of diclofenac, disulfiram, itraconazole, grapefruit juice and erythromycin on the pharmacokinetics of quinidine. *Br J Clin Pharmacol* (1999) 48, 829–38.

Quinidine + Disulfiram

Disulfiram does not affect the pharmacokinetics of quinidine.

Clinical evidence, mechanism, importance and management

In an open study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of disulfiram 200 mg daily. There were no changes in quinidine pharmacokinetics during disulfiram use.[1] Disulfiram is thought to be an inhibitor of the cytochrome P450 isoenzyme CYP2E1, but this isoenzyme does not appear to have a major role in quinidine metabolism.[1] Disulfiram therefore seems unlikely to have a clinically relevant effect on the pharmacokinetics of quinidine.

1. Damkier P, Hansen LL, Brøsen K. Effect of diclofenac, disulfiram, itraconazole, grapefruit juice and erythromycin on the pharmacokinetics of quinidine. *Br J Clin Pharmacol* (1999) 48, 829–38.

Quinidine + Erythromycin

Erythromycin can increase quinidine levels and cause a small further increase in the QTc interval.

Clinical evidence

Preliminary results of a randomised, placebo-controlled study in 12 subjects found that when a single 400-mg dose of quinidine was given after oral erythromycin 500 mg three times daily for 5 days, the AUC of the QTc interval was prolonged by about 6%.[1] In a parallel study by the same group, peak levels of quinidine were increased by 39% (from 587 nanograms/mL to 816 nanograms/mL), and the AUC was increased by 62% by day 5 of the erythromycin phase. Peak levels of the main metabolite of quinidine, 3-hydroxyquinidine, were significantly reduced.[2] Another study in 6 healthy subjects found that oral erythromycin 250 mg four times daily for 6 days reduced the total clearance of a single 200-mg dose of quinidine sulfate by 34% and increased its maximum serum concentration by 39%.[3]

A 74-year-old man with a history of cardiac disease (coronary artery bypass graft surgery, ventricular tachycardia) taking quinidine sulfate 200 mg every 6 hours and several other drugs, including mexiletine, was hospitalised with suspected infection of his implantable cardioverter defibrillator. Within 2 days of starting erythromycin lactobionate 500 mg every 6 hours and ceftriaxone 1 g daily, both intravenously, his trough serum quinidine levels had risen by about 50% from about 2.8 mg/L to 4.2 mg/L. On day 7, metronidazole 500 mg every 8 hours was added and the erythromycin dosage was doubled, and the patient experienced an episode of torsade de pointes. By day 12 his serum quinidine levels had further risen to 5.8 mg/L, whereupon the quinidine dosage was reduced by 25%. Because an interaction between quinidine and erythromycin had by then been suspected, the antibacterials were replaced by doxycycline and ciprofloxacin. By day 21, the quinidine serum levels had fallen to their former levels. The patient had a prolonged QTc interval of 504 milliseconds on admission, and this did not change.[4]

A 95-year-old man developed QT interval prolongation, torsade de pointes, with a subsequent cardiac arrest when given quinidine and erythromycin, both orally.[5]

Mechanism

Not fully understood, but erythromycin inhibits the metabolism of quinidine,[2] possibly by inhibition of the cytochrome P450 isoenzyme CYP3A4,[3] thereby reducing its clearance from the body and increasing its effects. There are also a number of cases on record of prolongation of the QT interval and torsade de pointes associated with the use of intravenous erythromycin alone.[6] Therefore, quinidine and erythromycin may have additive effects on the QT interval in addition to the pharmacokinetic interaction.

Importance and management

Information about this interaction appears to be limited to these reports, but it would appear to be established. If erythromycin is essential in a patient taking quinidine, the effects of concurrent use should be well moni-

tored, being alert for the development of raised plasma quinidine levels. Monitor for quinidine adverse effects (e.g. nausea, diarrhoea, tinnitus). The concurrent use of two drugs that prolong the QT interval should usually be undertaken with great caution. For further discussion, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

Quinidine + Fluvoxamine

Fluvoxamine appears to inhibit the metabolism and clearance of quinidine.

Clinical evidence, mechanism, importance and management

In a study, 6 healthy subjects were given a single 200-mg dose of quinidine sulfate before and on day 5 of a 6-day course of fluvoxamine 100 mg daily. The total apparent oral clearance of quinidine was reduced by 29%, and *N*-oxidation and 3-hydroxylation were reduced by 33% and 44%, respectively. The renal clearance and elimination half-life of quinidine were unchanged.[1] It was concluded that fluvoxamine inhibited the metabolism of quinidine by the cytochrome P450 isoenzyme CYP3A4, although a role for CYP1A2 and CYP2C19 was not excluded. The clinical relevance of these findings is unclear. However, it would seem prudent to monitor concurrent use for quinidine adverse effects (e.g. nausea, diarrhoea, tinnitus). More study is needed to assess the effect of multiple dosing and to establish the clinical significance of this interaction.

1. Damkier P, Hansen LL, Brøsen K. Effect of fluvoxamine on the pharmacokinetics of quinidine. *Eur J Clin Pharmacol* (1999) 55, 451–6.

Quinidine + Grapefruit juice

Grapefruit juice delays the absorption of quinidine and reduces its metabolism to some extent, but no clinically relevant adverse interaction seems to occur.

Clinical evidence, mechanism, importance and management

In one study, 12 healthy subjects were given quinidine sulfate 400 mg orally on two occasions, once with 240 mL of water and once with grapefruit juice. The pharmacokinetics of the quinidine were unchanged, except that its absorption was delayed (the time to reach maximum plasma concentrations was doubled from 1.6 hours to 3.3 hours) by grapefruit juice for reasons that are not understood. The AUC of the quinidine metabolite, 3-hydroxyquinidine was decreased by one-third, suggesting that grapefruit juice inhibits the metabolism of quinidine. No important changes in the QTc interval were seen.[1]

Similarly, another study in 6 healthy subjects found the total clearance of a single 200-mg dose of quinidine sulfate was reduced by 15% by 250 mL of grapefruit juice, with no change in its maximum level. There was a small reduction in metabolite formation suggesting only minor inhibition of metabolism.[2]

Grapefruit is known to inhibit the cytochrome P450 isoenzyme CYP3A4, which is involved with the metabolism of quinidine, so it seems likely that any interaction would occur via this pathway.[1,2] The effects of grapefruit juice appear to be modest, and these studies suggest that it is not usually necessary for patients on quinidine to avoid grapefruit juice. However, grapefruit juice may have contributed to raised quinidine levels and toxicity in a woman who took an antacid and one litre of fruit juice daily for a week, see 'Quinidine + Antacids or Urinary alkalinisers', p.313. It may therefore be prudent to be alert for an increase in quinidine adverse effects (e.g. nausea, diarrhoea, tinnitus), and consider avoiding grapefruit if these become troublesome.

Quinidine + H_2-receptor antagonists

Quinidine serum levels can rise and toxicity may develop in some patients when they take cimetidine. An isolated case of ventricular bigeminy (a form of arrhythmia) occurred in a patient taking quinidine and ranitidine.

Clinical evidence

In a study in 6 healthy subjects, **cimetidine** 300 mg four times daily for 7 days prolonged the elimination half-life of a single 400-mg dose of quinidine sulfate by 55%, from 5.8 to 9 hours, and decreased its clearance by 37%. Peak plasma levels were raised by 21%. These changes were reflected in ECG changes, with 51% and 28% increases in the mean areas under the QT and QTc time curves, respectively, but these were not considered to be statistically significant.[1]

A later study in healthy subjects, prompted by the observation of 2 patients who developed toxic quinidine levels when given **cimetidine**, found essentially the same effects. The AUC and half-life of quinidine were increased by 15% and 23%, respectively, and the clearance was decreased by 25% by **cimetidine** 300 mg four times daily.[2] A further study in 4 healthy subjects found that **cimetidine** 300 mg four times daily for 5 days prolonged the elimination half-life of quinidine by 54% and decreased its total clearance by 36%.[3,4] In one study, the addition of **cimetidine** prolonged the QT interval by 30% more than the effect of quinidine alone.[4] A case report describes marked increases in both quinidine and digitoxin concentrations in a woman also given **cimetidine**.[5] Similarly, quinidine levels increased by up to 50%, without causing any adverse effects, when a man taking quinidine was given **cimetidine**.[6]

Ventricular bigeminy (a form of arrhythmia) occurred when a man taking quinidine was given **ranitidine**. His serum quinidine levels remained unchanged.[7]

Mechanism

It was originally suggested that the cimetidine inhibits the metabolism of the quinidine by the liver so that it is cleared more slowly.[2] However, further data suggest that cimetidine successfully competes with quinidine for its excretion by the kidneys.[8]

Importance and management

The interaction between quinidine and cimetidine is established and of clinical importance. The incidence is unknown. Be alert for changes in the response to quinidine if cimetidine is started or stopped. Ideally the quinidine serum levels should be monitored (consider monitoring in response to adverse effects such as hypotension, tinnitus and diarrhoea) and reduce the quinidine dose as necessary. Reductions of 25% (oral) and 35% (intravenous) have been suggested.[3] Those at greatest risk are likely to be patients with impaired renal function, patients with impaired liver function, the elderly, and those with serum quinidine levels already at the top end of the therapeutic range.[2] The situation with ranitidine is uncertain.

Quinidine + Kaolin-pectin

There is some evidence that kaolin-pectin can reduce the absorption of quinidine and lower its serum levels.

Clinical evidence, mechanism, importance and management

When 4 healthy subjects were given 30 mL of kaolin-pectin (*Kaopectate*), after a single 100-mg dose of oral quinidine sulfate, the maximal salivary quinidine concentration was reduced by 54% and its AUC was reduced by 58%, without any effect on the rate of absorption.[1] There is a correlation between salivary and serum concentrations after single (but not repeated) doses of quinidine.[2] This is consistent with *in vitro* data showing that quinidine is adsorbed onto kaolin and pectin.[1,3] Documentation appears to be limited to these two studies, but be alert for the need to increase the quinidine dose if kaolin-pectin is used concurrently.

Quinidine + Laxatives

Quinidine plasma levels can be reduced by the anthraquinone laxative senna.

Clinical evidence, mechanism, importance and management

In a study in 7 patients with cardiac arrhythmias taking sustained-release quinidine bisulfate 500 mg every 12 hours, **senna** reduced plasma quinidine levels, measured 12 hours after the last dose of quinidine, by about 25%.[1] The modest reduction in quinidine levels might be of clinical importance in patients whose plasma levels are barely adequate to control their arrhythmia.

Quinidine + Lidocaine

A single case report describes a man taking quinidine who had sinoatrial arrest when he was given intravenous lidocaine.

Clinical evidence, mechanism, importance and management

A man with Parkinson's disease was given quinidine 300 mg every 6 hours for the control of ventricular ectopic beats. After receiving two doses he was given lidocaine as well, initially as a bolus of 80 mg, followed by an infusion of 4 mg/minute because persistent premature ventricular beats developed. Within 2.5 hours the patient complained of dizziness and weakness, and was found to have sinus bradycardia, sinoatrial arrest and an atrioventricular escape rhythm. Normal sinus rhythm resumed when the lidocaine was stopped. Whether quinidine was a contributing factor in this reaction is uncertain.[1] However, this case emphasises the need to exercise caution when giving two drugs that have cardiac depressant actions.

1. Jeresaty RM, Kahn AH, Landry AB. Sinoatrial arrest due to lidocaine in a patient receiving quinidine. *Chest* (1972) 61, 683–5.

Quinidine + Metoclopramide

Metoclopramide has been seen to both modestly increase quinidine levels and modestly decrease quinidine exposure.

Clinical evidence

A study of a possible interaction between quinidine and metoclopramide was prompted by the case of a patient who was taking sustained-release quinidine (*Quinidex*) and whose arrhythmia became uncontrolled when metoclopramide was added. In a crossover study, 9 healthy subjects were given metoclopramide 10 mg every 6 hours, for 24 hours before and 48 hours after a single 600- or 900-mg oral dose of quinidine sulfate or quinidine alone. It was found that metoclopramide caused a mean 10% decrease in the AUC of quinidine, although two subjects had decreases of 23% and 28%, respectively. The elimination rate constant was unaffected.[1]

Another study, in patients taking sustained-release quinidine bisulfate 500 mg every 12 hours, found that metoclopramide 10 mg three times daily increased the mean plasma levels measured 3.5 hours after the last dose of quinidine by almost 20%, from 1.6 to 1.9 micrograms/mL, and increased the levels at 12 hours by about 16%, from 2.4 to 2.8 micrograms/mL.[2]

Mechanism

Not understood. Metoclopramide alters both the gastric emptying time and gastrointestinal motility, which can affect quinidine absorption.

Importance and management

Direct information seems to be limited to these studies using different quinidine preparations. The outcome of concurrent use is uncertain, but any effect generally seems small in most patients.

Quinidine + Omeprazole

Omeprazole does not appear to alter the pharmacokinetics or QT-interval prolonging effects of quinidine.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, omeprazole 40 mg daily for one week had no effect on the pharmacokinetics of a single 400-mg dose of quinidine sulfate. In addition, the corrected QT interval was not significantly changed.[1] There would not appear to be the need for any special precautions during concurrent use.

1. Ching MS, Elliott SL, Stead CK, Murdoch RT, Devenish-Meares S, Morgan DJ, Smallwood RA. Quinidine single dose pharmacokinetics and pharmacodynamics are unaltered by omeprazole. *Aliment Pharmacol Ther* (1991) 5, 523–31.

Quinidine + Protease inhibitors

In theory, the protease inhibitors may increase the levels of quinidine. Quinidine does not affect indinavir levels.

Clinical evidence

In a study in which quinidine sulphate 200 mg was given to 10 healthy subjects, followed one hour later by a single 400-mg dose of **indinavir**, the pharmacokinetics of **indinavir** were not significantly affected.[1]

Direct evidence (from case reports or clinical studies) of an interaction between quinidine and the other protease inhibitors appears to be lacking; however, a review of protease inhibitor interactions reports that plasma levels of quinidine may be increased by **ritonavir**. The same review states that **nelfinavir** and **saquinavir** may interact similarly.[2]

Mechanism

Quinidine is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which nelfinavir, ritonavir and saquinavir are all inhibitors. Note that the protease inhibitors are all inhibitors of CYP3A4, to varying degrees, and therefore may be expected to interact similarly.

Importance and management

Clinical evidence of an interaction between quinidine and protease inhibitors is lacking; however, in theory, all protease inhibitors could raise quinidine levels. Raised levels of quinidine may increase the risk of arrhythmias and other adverse effects. The manufacturers of **ritonavir** contraindicate concurrent use with quinidine,[3,4] and for this reason, many of the manufacturers contraindicate the concurrent use of ritonavir-boosted protease inhibitors with quinidine. However, the UK manufacturers of **lopinavir**[5] and **saquinavir**[6] caution concurrent use and recommend monitoring of quinidine levels, where available. Note that quinidine adverse effects include nausea, diarrhoea, and tinnitus. In the US, most manufacturers advise caution and close monitoring of quinidine levels, with the exception of the manufacturers of **nelfinavir**,[7] **saquinavir**[8] and **tipranavir**,[9] who contraindicate the concurrent use of quinidine.

No dose adjustment of **indinavir** appears to be needed if the concurrent use of quinidine is necessary.

Quinidine + Quinolones

Ciprofloxacin does not normally appear to interact with quinidine to a clinically relevant extent. An increased risk of torsade de pointes might be expected if quinidine is used with gatifloxacin, moxifloxacin, or sparfloxacin, and possibly levofloxacin.

Clinical evidence, mechanism, importance and management

In a study in 7 healthy subjects, **ciprofloxacin** 750 mg daily for 6 days did not significantly affect the pharmacokinetics of a single 400-mg oral dose of quinidine sulfate, and QRS and QTc prolongation were not significantly changed. The decrease in clearance ranged from a decrease of 10% to an increase of 20%, with a mean 1% increase, which is unlikely to be clinically relevant.[1] However an isolated case report describes a woman who started taking quinidine gluconate 324 mg every 8 hours while she was taking **ciprofloxacin** and metronidazole. Her first trough serum quinidine level was 6.3 micrograms/mL, which was slightly above the reference range of 2 to 5 micrograms/mL, but she had no evidence of toxicity. Quinidine was continued unchanged, and her next trough serum quinidine level was only 2.3 micrograms/mL, 3 days after finishing the course of antibacterials. This effect was tentatively attributed to the possible enzyme inhibitory effects of **ciprofloxacin** and metronidazole. This case is far from clear and so no firm conclusions can be reached.[2] There would seem to be little reason for avoiding concurrent use.

Some quinolones can prolong the QT interval, and would be expected to increase the risk of torsade de pointes when used with quinidine. Of the quinolones used clinically, **gatifloxacin**, **moxifloxacin**, and **sparfloxacin** are known to prolong the QT interval (see 'Table 9.2', (p.290)). There is also evidence that **levofloxacin** may prolong the QT interval (see 'Amiodarone + Quinolones', p.281). The concurrent use of two drugs that prolong the QT interval should usually be avoided, or undertaken with great caution. For further discussion, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Quinidine + Rifamycins

The serum levels and therapeutic effects of quinidine can be markedly reduced by rifampicin.

Clinical evidence

It was noted that the control of ventricular arrhythmia deteriorated in a patient taking quinidine sulfate 800 mg daily within a week of **rifampicin** 600 mg daily being started. His serum quinidine level fell from 4 micrograms/mL to 0.5 micrograms/mL, and remained low despite doubling the quinidine dose to 1.6 g daily. The **rifampicin** was discontinued, and quinidine levels gradually increased over a week. Some signs of quinidine toxicity then occurred, and the quinidine dose was reduced back to 800 mg daily.[1] Further study in 4 healthy subjects found that **rifampicin** 600 mg daily for 7 days reduced the mean half-life of a single 6-mg/kg oral dose of quinidine sulfate by about 62% (from 6.1 hours to 2.3 hours) and reduced the AUC by 83%.[2] Similar findings were reported in 4 other subjects receiving the same dose of quinidine intravenously.[2]

Another case report describes a patient taking **rifampicin** who did not achieve adequate serum quinidine levels despite daily doses of quinidine of up to 3.2 g. When the **rifampicin** was stopped, ultimately, a reduced quinidine dose of 1.8 g daily achieved a serum level of 2 micrograms/mL, reflecting a 44% decrease in dose and a 43% increase in level.[3] In a further case, a patient taking quinidine and digoxin was given **rifampicin**: the quinidine levels fell, resulting in a fall in digoxin levels.[4]

Mechanism

Rifampicin is a potent enzyme-inducer, which markedly increases the metabolism of the quinidine by 3-hydroxylation and *N*-oxidation, thereby reducing its levels and effects.[5] It has been suggested that two of the quinidine metabolites (3-hydroxyquinidine and 2-oxoquinidinone) may be active, which might, to some extent, offset the effects of this interaction.[4]

Importance and management

An established and clinically important interaction, although documentation is limited. The dose of quinidine will need to be increased if rifampicin is given concurrently. Monitor the serum levels. Doubling the dose may not be sufficient.[2,4] An equivalent dosage reduction will be needed if the rifampicin is stopped. There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that **rifabutin** may possibly reduce the effects of a number of drugs, including quinidine.[6,7]

Quinidine + Sucralfate

An isolated report describes a marked reduction in serum quinidine levels, which was attributed to the concurrent use of sucralfate.

Clinical evidence, mechanism, importance and management

An elderly woman was found to have subtherapeutic levels of warfarin, digoxin and sustained-release quinidine (serum quinidine level 0.31 micromol/L), even though they were given 2 hours apart from sucralfate. On hospitalisation, a variety of other medications were then started for chest pain (glyceryl trinitrate, diltiazem, pethidine (meperidine), promethazine), and on day 4 the sucralfate was stopped. On day 5, her serum quinidine level was 5.55 micromol/L.[1] The patient denied non-compliance, and the suggestion was that sucralfate can bind with quinidine within

the gut and reduce its absorption. This isolated case appears to be the only report of an interaction between quinidine and sucralfate and its general importance is unclear.

Tocainide + Antacids or Urinary alkalinisers

Raising the pH of the urine (e.g. with some antacids, diuretics or alkaline salts) can modestly reduce the clearance of tocainide.

Clinical evidence

The preliminary findings of a study suggested that when 5 healthy subjects took 30 mL of an unnamed antacid four times daily for 48 hours before and 58 hours after a single 600-mg dose of tocainide, the urinary pH rose from 5.9 to 6.9, the total clearance of tocainide fell by 28%, the peak serum levels fell by 19% from 4.2 to 3.4 micrograms/mL, the AUC rose by 33% and the half-life was prolonged from 13.2 to 15.4 hours.[1]

Mechanism

Tocainide is a weak base so that its loss in the urine will be affected by the pH of the urine. Alkalinisation of the urine increases the number of non-ionised molecules available for passive reabsorption, thereby reducing the urinary loss and raising the serum levels.

Importance and management

An established interaction of uncertain but probably limited clinical importance. There seem to be no reports of adverse reactions in patients as a result of this interaction, but be alert for any evidence of increased tocainide effects if other drugs are given that can raise the urinary pH significantly (e.g. **sodium bicarbonate** and **acetazolamide**). Reduce the tocainide dosage if necessary. Of the antacids, **aluminium/magnesium hydroxide** (*Maalox*) can raise urinary pH by about 0.9 whereas **magnesium hydroxide** (*Milk of magnesia*) and **calcium carbonate-glycine** (*Titralac*) raise the pH by about 0.5. **Aluminium hydroxide** (*Amphogel*) and **dihydroxyaluminium glycinate** (*Robalate*) are reported to have no effect on urinary pH.[2]

Tocainide + H_2-receptor antagonists

There is some evidence that cimetidine can reduce the bioavailability and serum levels of tocainide. Ranitidine appears not to interact with tocainide.

Clinical evidence, mechanism, importance and management

In a preliminary report of a study in 11 healthy subjects, 4 days of treatment with **cimetidine** [dose not stated] had a small effect on the pharmacokinetics of tocainide 500 mg given intravenously over 15 minutes, which was not considered to be clinically important.[1] In another study, in 7 healthy subjects, **cimetidine** 300 mg four times daily for 2 days reduced the AUC of a single 400-mg oral dose of tocainide by about one-third. The peak serum levels were also reduced, from about 2.8 micrograms/mL to 1.7 micrograms/mL, but no changes in the half-life or renal clearance occurred.[2] The reasons for these modest changes, and their clinical importance are uncertain, but be alert for evidence of a reduced response to tocainide in the presence of **cimetidine**. **Ranitidine** 150 mg twice daily has been found not to interact.[2]

2. North DS, Mattern AL, Kapil RP, Lalonde RL. The effect of histamine-2 receptor antagonists on tocainide pharmacokinetics. *J Clin Pharmacol* (1988) 28, 640–3.

Tocainide + Phenobarbital

Phenobarbital does not appear to alter the pharmacokinetics of tocainide.

Clinical evidence, mechanism, importance and management

In a study in 6 healthy subjects, phenobarbital 100 mg daily for 15 days did not alter the AUC of a single 600-mg dose of tocainide. In addition, the percentage of the dose excreted unchanged in the urine and as the glucuronide metabolite did not differ.[1] Phenobarbital at this dose does not appear to alter the metabolism of tocainide. No tocainide dose adjustment appears to be necessary if phenobarbital is also given.

1. Elvin AT, Lalka D, Stoeckel K, du Souich P, Axelson JE, Golden LH, McLean AJ. Tocainide kinetics and metabolism: effects of phenobarbital and substrates of glucuronyl transferase. *Clin Pharmacol Ther* (1980) 28, 652–8.

Tocainide + Rifampicin (Rifampin)

Rifampicin decreases the half-life and AUC of tocainide.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, rifampicin 300 mg twice daily for 5 days reduced the AUC of a single 600-mg oral dose of tocainide by almost 30% and similarly reduced the half-life, from 13.2 hours to 9.4 hours.[1]

This response is consistent with the well-known enzyme-inducing effects of rifampicin. Information is limited to this single dose study, but the interaction would seem to be established, although its clinical importance is probably modest. Be alert for any evidence of a reduction in tocainide serum levels and effects if rifampicin is also given. Increase the dosage as necessary, remembering to reduce the tocainide dosage if the rifampicin is withdrawn.

10

Antibacterials

This section deals with interactions where the effects of the antibacterial are altered. In many cases the antibacterial drugs interact by affecting other drugs, and these interactions are dealt with elsewhere in this publication. Some of the macrolides and the quinolones are potent enzyme inhibitors; the macrolides exert their effects on the cytochrome P450 isoenzyme CYP3A4, whereas many quinolones inhibit CYP1A2. Rifampicin (rifampin) is a potent non-specific enzyme inducer and therefore lowers the levels of many drugs.

Many of the interactions covered in this section concern absorption interactions, such as the ability of the tetracyclines and quinolones to chelate with divalent cations. More information on the mechanism of these interactions can be found in 'Drug absorption interactions', (p.3).

Many monographs concern the use of multiple antibacterials. One of the great difficulties with these interactions is the often poor correlation between *in vitro* and *in vivo* studies, so that it is difficult to get a thoroughly reliable indication of how antibacterial drugs will behave together in clinical practice. Two antibacterials may actually be less effective than one on its own, because, in theory, the effects of a bactericidal drug, which requires actively dividing cells for it to be effective, may be reduced by a bacteriostatic drug. However, in practice this seems to be less important than might be supposed and there are relatively few well-authenticated clinical examples.

The antibacterials covered in this section are listed in 'Table 10.1', (below).

Table 10.1 Antibacterials

Group	*Drugs*
Aminoglycosides	Amikacin, Astromicin, Dibekacin, Dihydrostreptomycin, Framycetin, Gentamicin, Isepamicin, Kanamycin, Micronomicin, Neomycin, Netilmicin, Paromomycin, Sisomicin, Streptomycin, Tobramycin
Antimycobacterials and related drugs	Aminosalicylic acid (PAS), Capreomycin, Clofazimine, Cycloserine, Dapsone, Ethambutol, Ethionamide, Isoniazid, Methaniazide, Protionamide, Pyrazinamide, Rifabutin, Rifampicin (Rifampin), Rifamycin, Rifapentine, Rifaximin
Carbapenems	Biapenem, Doripenem, Ertapenem, Faropenem, Imipenem, Meropenem, Panipenem
Cephalosporins	Cefaclor, Cefadroxil, Cefalexin, Cefaloglycin, Cefaloridine, Cefalotin, Cefamandole, Cefapirin, Cefatrizine, Cefazolin, Cefbuperazone, Cefcapene, Cefdinir, Cefditoren, Cefepime, Cefetamet, Cefixime, Cefmenoxime, Cefmetazole, Cefminox, Cefodizime, Cefonicid, Cefoperazone, Ceforanide, Cefotaxime, Cefotetan, Cefotiam, Cefoxitin, Cefpiramide, Cefpirome, Cefpodoxime, Cefprozil, Cefradine, Cefsulodin, Ceftazidime, Cefteram, Ceftezole, Ceftibuten, Ceftizoxime, Ceftriaxone, Cefuroxime, Flomoxef, Latamoxef
Macrolides	Azithromycin, Clarithromycin, Dirithromycin, Erythromycin, Flurithromycin, Josamycin, Midecamycin, Rokitomycin, Roxithromycin, Spiramycin, Telithromycin, Troleandomycin
Penicillins	Amoxicillin, Ampicillin, Azidocillin, Azlocillin, Bacampicillin, Benzylpenicillin (Penicillin G), Carbenicillin, Carindacillin, Ciclacillin, Clometocillin, Cloxacillin, Dicloxacillin, Flucloxacillin, Mecillinam, Meticillin, Mezlocillin, Nafcillin, Oxacillin, Phenethicillin, Phenoxymethylpenicillin (Penicillin V), Piperacillin, Pivampicillin, Pivmecillinam, Procaine benzylpenicillin (Procaine penicillin), Propicillin, Sulbenicillin, Temocillin, Ticarcillin
Polypeptides	Bacitracin, Colistimethate sodium, Colistin, Polymyxin B, Teicoplanin, Vancomycin
Quinolones	Cinoxacin, Ciprofloxacin, Enoxacin, Fleroxacin, Flumequine, Gatifloxacin, Gemifloxacin, Grepafloxacin, Levofloxacin, Lomefloxacin, Moxifloxacin, Nadifloxacin, Nalidixic acid, Norfloxacin, Ofloxacin, Oxolinic Acid, Pazufloxacin, Pefloxacin, Pipemidic Acid, Rosoxacin, Rufloxacin, Sparfloxacin, Temafloxacin, Tosufloxacin, Trovafloxacin
Sulfonamides	Co-trimoxazole, Phthalylsulfathiazole, Sulfadiazine, Sulfadimidine (Sulfamethazine), Sulfafurazole (Sulfisoxazole), Sulfaguanidine, Sulfamerazine, Sulfamethizole, Sulfamethoxazole, Sulfametopyrazine, Sulfametrole
Tetracyclines	Chlortetracyline, Demeclocycline, Doxycycline, Lymecycline, Methacycline, Minocycline, Oxytetracycline, Rolitetracycline, Tetracycline, Tigecycline
Miscellaneous	Aztreonam, Carumonam, Chloramphenicol, Cilastatin, Clindamycin, Daptomycin, Fosfomycin, Fusidic acid, Lincomycin, Linezolid, Loracarbef, Methenamine, Metronidazole, Mupirocin, Nitrofurantoin, Novobiocin, Pristinamycin, Quinupristin/Dalfopristin, Retapamulin, Spectinomycin, Trimethoprim, Vancomycin

Aminoglycosides + Amphotericin B

One study in children suggested that amphotericin B decreased the clearance of amikacin and gentamicin. The concurrent use of aminoglycosides and amphotericin B can result in nephrotoxicity.

Clinical evidence, mechanism, importance and management

A study found that **amikacin** or **gentamicin** clearance was impaired in 12 of 17 children given amphotericin B. Serum creatinine increased by 50% or more in 3 of the children, but there was no significant increase in creatinine levels in 7 others. As a result, the aminoglycoside dose was decreased or the dose interval lengthened in 7 children.[1]

The renal function of 4 patients receiving moderate doses of **gentamicin** deteriorated when they were given amphotericin B. Both drugs are known to be nephrotoxic and it is suggested, on the basis of what was seen, that combined use may have had additive nephrotoxic effects.[2] A further retrospective analysis found that the use of **amikacin** tended to increase amphotericin B-related nephrotoxicity.[3]

A study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of amphotericin B significantly increased the risk of nephrotoxicity.[4]

The nephrotoxicity of various combinations of antibiotics was assessed in 171 patients with cancer (139 given a combination of aminoglycoside with penicillin or cephalosporin; 32 given amphotericin B or vancomycin with other antibacterials). The highest nephrotoxicity (based on changes in urea and electrolytes) was found in patients receiving amphotericin B with an aminoglycoside and a cephalosporin.[5]

Two other studies did not find that aminoglycosides increased the risk of amphotericin B-associated toxicity (defined as a 100% or greater increase in serum creatinine),[6,7] although in one of the studies[7] the frequency of concurrent aminoglycoside use may have been too low to identify any evidence of increased nephrotoxic risk.

A case report describes hypomagnesemic tetany, which developed in a patient who had received **gentamicin** for 9 days, followed immediately by an 8-day course of amphotericin B. Intravenous magnesium replacement resulted in immediate resolution of the tetany. The authors suggested that the hypomagnesemia had occurred due to the additive magnesium-lowering effects of **gentamicin** and amphotericin B.[8]

Aminoglycosides are generally considered to be nephrotoxic, and therefore it is generally recommended that other nephrotoxic drugs (such as amphotericin B) should be avoided. However, concurrent use may be essential. Renal function and drug levels should be routinely monitored during the use of an aminoglycoside, and it may be prudent to increase the frequency of such monitoring in the presence of amphotericin B. Lipid formulations of amphotericin B are less nephrotoxic than the conventional formulation.[9] One manufacturer notes there was significantly less nephrotoxicity in patients receiving an aminoglycoside with liposomal amphotericin B (*Ambisome*) compared with aminoglycosides and conventional amphotericin B.[10]

Aminoglycosides + Carbapenems

No pharmacokinetic interaction of importance appears to occur between the aminoglycosides and the carbapenems.

Clinical evidence, mechanism, importance and management

The suspicion that low **tobramycin** levels in one patient might have been due to an interaction with **imipenem** with **cilastatin** was not confirmed in a later *in vitro* study.[1] It has also been suggested that the nephrotoxic effects of **imipenem** and the **aminoglycosides** might possibly be additive.[2] However, a study in healthy subjects given single intravenous doses of **imipenem** and **amikacin** found there was a transient increase in **imipenem** levels but no effects on other pharmacokinetic parameters of either drug.[3] In a study in 12 healthy subjects the concurrent use of **tobramycin** and **biapenem** did not alter the pharmacokinetics of either drug.[4] There would seem to be no reason for avoiding concurrent use.

Aminoglycosides + Cephalosporins

The nephrotoxic effects of gentamicin and tobramycin can be increased by cefalotin. Nephrotoxicity may also occur when other aminoglycosides are given with cephalosporins.

Clinical evidence

(a) Cefaloridine

Acute renal failure has been reported in a patient given **gentamicin** and cefaloridine.[1] One study reported an increase in the incidence of nephrotoxicity when cefaloridine was given with **gentamicin** (or other unnamed aminoglycosides), although other factors such as excessive dose or pre-existing renal impairment were also associated with the increase in cephalosporin nephrotoxicity in most cases.[2]

(b) Cefalotin

A randomised, double-blind study[3] in patients with sepsis found the following incidence of definite nephrotoxicity;

- **gentamicin** with **cefalotin** 30.4% (7 of 23 patients),
- **tobramycin** with **cefalotin** 20.8% (5 of 24),
- **gentamicin** with methicillin 10% (2 of 20),
- **tobramycin** with methicillin 4.3% (1 of 23).

A very considerable number of studies and case reports confirm an increase in the incidence of nephrotoxicity when **gentamicin**[2,4-14] or **tobramycin**[15,16] are used with **cefalotin**. However, some other studies have found no increase in nephrotoxicity with the combination.[17-20]

(c) Other cephalosporins

The nephrotoxicity of various combinations of antibacterials was assessed in 171 patients with cancer. In those receiving an aminoglycoside with a third generation cephalosporin, the most nephrotoxic combinations were found to be **gentamicin** with **cefotaxime** (although another study did not find this combination to be nephrotoxic[21]) and **amikacin** with **ceftriaxone**, where 5 of 20 and 5 of 13 patients, respectively, had increased serum creatinine. The following combinations were found to be safer: **amikacin** with **cefoxitin** or **ceftazidime**; **gentamicin** with **cefoxitin**; and **netilmicin** with **cefotaxime**.[22]

Another study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of cephalosporins (including **cefazolin**, **cefotaxime**, **cefoxitin**, **cefamandole**, **cefuroxime**, **ceftriaxone**, and **ceftazidime**) significantly increased the risk of nephrotoxicity.[23]

Other adverse effects have also been reported. Hypokalaemia has also been described in patients taking cytotoxic drugs for leukaemia when they were given **gentamicin** and **cefalexin**,[24] and a study in healthy subjects found that **ceftazidime** may increase the levels of **amikacin**.[25]

In contrast, some studies have reported no adverse interactions between;

- **amikacin** and **cefepime**[26]
- **gentamicin** and **cefuroxime**,[27] or **cefazolin**,[20]
- **tobramycin** and **cefuroxime**,[28] **cefotaxime**,[29] **ceftazidime**[30] or **cefazolin**.[20]

Mechanism

Uncertain. The nephrotoxic effects of gentamicin and tobramycin are well documented, and some (mostly older) cephalosporins are known to be nephrotoxic, especially in high dose. However, it appears that doses that are well tolerated separately can become nephrotoxic when given together.[11]

Importance and management

The interaction between gentamicin and cefalotin is very well documented and potentially serious: there is less information about tobramycin with cefalotin, but they appear to interact similarly. The risk of nephrotoxicity is probably greatest if high doses of cefalotin are used in those with some existing renal impairment. One study suggests that short courses of treatment are sometimes justified,[12] but renal function should be very closely monitored and doses kept to a minimum. The combination of any aminoglycoside and cefalotin is probably best avoided in high-risk patients wherever possible.

The interaction between other aminoglycosides or cephalosporins is less well documented, but what is known suggests that they can, on occasion, interact similarly. Risk factors for this interaction are said to include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including leukaemia,[23,31] although their significance in practice has been questioned.[23] It seems likely that the routine monitoring of renal function that is advised with aminoglycosides should be adequate to detect any interaction, but if renal impairment develops the contribution of an interaction should be considered.

Aminoglycosides + Clindamycin

Three cases of acute renal failure have been tentatively attributed to the use of gentamicin with clindamycin, and another report identified the combination as a risk factor for nephrotoxicity. However, other reports note no increased risk of nephrotoxicity when gentamicin or tobramycin was given with clindamycin.

Clinical evidence, mechanism, importance and management

Acute renal failure has been reported in 3 patients with normal renal function when they were given **gentamicin** 3.9 to 4.9 mg/kg daily and clindamycin 0.9 to 1.8 mg/kg daily for 13 to 18 days. They recovered within 3 to 5 days of discontinuing the antibacterials[1] but in one patient acute renal failure only developed after the clindamycin was stopped. The reasons for the renal failure are not known, but given the long courses of **gentamicin** involved, the possibility that renal impairment occurred as an adverse effect of the aminoglycoside alone cannot be excluded. However, one report identified the concurrent use of clindamycin as one of several factors that increased the risk of aminoglycoside-associated nephrotoxicity.[2]

The use of clindamycin with an aminoglycoside seems to be a fairly commonly used combination, especially following abdominal trauma. A study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of clindamycin was not significantly associated with increased risk of nephrotoxicity.[3] This suggests that treatment with the combination is without nephrotoxic risk above and beyond that seen with an aminoglycoside alone. A short report has also indicated that the combination of **tobramycin** and clindamycin is not nephrotoxic.[4]

As renal function should be routinely monitored during the use of aminoglycosides, no additional precautions would be expected to be necessary if clindamycin is also given.

Aminoglycosides + Loop diuretics

The concurrent use of aminoglycosides and etacrynic acid should be avoided because their damaging actions on the ear can be additive. Even sequential use may not be safe. Bumetanide and piretanide have been shown to interact similarly in *animals*. Although some patients have developed nephrotoxicity and/or ototoxicity

while taking furosemide and an aminoglycoside, it has not been established that this was as a result of an interaction.

Clinical evidence

(a) Bumetanide

There seem to be no clinical reports of an interaction between aminoglycosides and bumetanide, but ototoxicity has been described in *animals* given **kanamycin** and bumetanide.[1,2]

(b) Etacrynic acid

Four patients with renal impairment became permanently deaf after they were given intramuscular **kanamycin** 1 to 1.5 g and intravenous etacrynic acid 50 to 150 mg. One patient also received **streptomycin**, and another also received oral **neomycin**. Deafness took between 30 minutes and almost 2 weeks to develop. In some cases deafness developed despite the doses being given on separate days, and in all cases it appeared irreversible.[3] A patient receiving **gentamicin** rapidly developed deafness when furosemide was replaced by intravenous etacrynic acid.[4]

There are other reports describing temporary, partial or total permanent deafness as a result of giving intravenous etacrynic acid with **gentamicin**,[5] intramuscular **kanamycin**,[5-7] oral **neomycin**,[8] or **streptomycin**.[6,9]

(c) Furosemide

An analysis of three, controlled, randomised, studies found that furosemide did not increase either aminoglycoside-induced nephrotoxicity, or ototoxicity: the aminoglycosides used were **amikacin**, **gentamicin**, and **tobramycin**. Nephrotoxicity developed in 20% (10 of 50 patients) given furosemide and 17% (38 of 222) not given furosemide. Auditory toxicity developed in 22% (5 of 23) given furosemide and 24% (28 of 119) not given furosemide.[4] Other clinical studies similarly suggest that furosemide does not increase aminoglycoside-associated renal damage.[10,11]

In contrast, a study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of furosemide increased the risk of nephrotoxicity.[12] A clinical study evaluating a possible interaction also found that furosemide increased aminoglycoside-induced renal damage,[13] and there are clinical reports claiming that concurrent use results in ototoxicity, but usually only small numbers of patients were involved and control groups were not included.[14-18] A retrospective study of neonates suggested the possibility of increased ototoxicity but no firm conclusions could be drawn.[19]

Studies in patients and healthy subjects have found that furosemide reduces the renal clearance of **gentamicin**[20,21] and can cause a rise in both serum **gentamicin**[21] and **tobramycin** levels.[22] In contrast, a study in 6 healthy subjects found that although the AUC of a single parenteral 1-mg/kg dose of **gentamicin** was not affected by the administration of a single 0.25-mg/kg dose of furosemide, its clearance was increased during the first 3 hours The authors suggest that the observed increased clearance may reduce the nephrotoxic potential of this combination in patients with normal renal function.[23]

Ototoxicity has been described in *animals* given **kanamycin** and furosemide.[1,2]

(d) Piretanide

A study in 6 healthy subjects found that although the AUC of a single parenteral 1-mg/kg dose of **gentamicin** was not affected by the use of a single 0.1-mg/kg dose of piretanide, its clearance was increased during the first 3 hours. The authors suggest that the observed increased clearance may reduce the nephrotoxic potential of this combination in patients with normal renal function.[23]

Ototoxicity has been described in *animals* given **kanamycin** and piretanide.[24]

Mechanism

Aminoglycosides or etacrynic acid alone can damage the ear and cause deafness, the site of action of the aminoglycosides being the hair cell and that of etacrynic acid the stria vascularis. It appears that the effects of concurrent use are additive. Other loop diuretics can similarly damage hearing. *Animal* studies have shown that intramuscular neomycin can cause a fivefold increase in the concentration of etacrynate in cochlear tissues, and it is possible that the aminoglycoside has some effect on the tissues, which allows the etacrynic acid to penetrate more easily.[25] Similar results have been found with gentamicin.[26]

Importance and management

The interaction between etacrynic acid and the aminoglycosides is well established and well documented. The concurrent or sequential use of etacrynic acid with parenteral aminoglycosides should be avoided because permanent deafness may result. Patients with renal impairment seem to be particularly at risk, most likely because the drugs are less rapidly cleared. Most of the reports describe deafness after intravenous use, but it has also been seen when etacrynic acid is given orally alone.[9] If it is deemed absolutely necessary to use etacrynic acid and an intravenous aminoglycoside, minimal doses should be used and the effects on hearing should be monitored continuously. Not every aminoglycoside has been implicated, but their ototoxicity is clearly established and they may be expected to interact in a similar way. For this reason the same precautions should be used.

Although there is ample evidence of an adverse interaction between furosemide and aminoglycosides in *animals*,[2,27] the weight of clinical evidence suggests that furosemide does not normally increase either the nephrotoxicity or ototoxicity of the aminoglycosides. Nevertheless as there is still some uncertainty about the safety of concurrent use it would be prudent to monitor for any evidence of changes in aminoglycoside serum levels, and renal or hearing impairment. The authors of the major study cited[4] suggest that an interaction may possibly occur if high dose infusions of furosemide are used. The same precautions would seem to be appropriate with bumetanide and piretanide. Note that it is generally advised that aminoglycosides should not be used with other drugs that may cause ototoxicity or nephrotoxicity, such as etacrynic acid and furosemide, but in some cases concurrent use may be unavoidable.

Aminoglycosides + Magnesium compounds

A neonate with elevated serum magnesium levels had a respiratory arrest when given gentamicin.

Clinical evidence

An infant born to a woman whose pre-eclampsia had been treated with magnesium sulfate was found to have muscle weakness and a serum magnesium concentration of 1.77 mmol/L. The neonate was given ampicillin 100 mg/kg intravenously and **gentamicin** 2.5 mg/kg intramuscularly every 12 hours, starting 12 hours after birth. Soon after the second dose of **gentamicin** she stopped breathing and needed intubation. The **gentamicin** was stopped and the child improved.[1] *Animal* studies support this interaction.[1]

Mechanism

Magnesium ions and the aminoglycosides have neuromuscular blocking activity, which can be additive (see also 'Neuromuscular blockers + Magnesium compounds', p.139 and 'Neuromuscular blockers + Aminoglycosides', p.127). In the case cited here it seems that it was enough to block the actions of the respiratory muscles.

Importance and management

Direct information about this interaction is very limited, but it is well supported by the recognised pharmacological actions of magnesium and the aminoglycosides, and their interactions with conventional neuromuscular blockers. The aminoglycosides as a group should be avoided in hypermagnesaemic infants needing antibacterial treatment. If this is not possible, the effects on respiration should be closely monitored.

Aminoglycosides + Miconazole

A report describes a reduction in tobramycin levels, which was attributed to the use of miconazole.

Clinical evidence, mechanism, importance and management

In 9 patients undergoing bone marrow transplantation intravenous miconazole significantly lowered the peak serum **tobramycin** levels, from 9.1 micrograms/mL to 6.7 micrograms/mL. Six patients needed **tobramycin** dose adjustments.[1] Miconazole was stopped in 4 patients, and **tobramycin** pharmacokinetic parameters returned to normal 4 to 8 days later. The reasons for this interaction are not understood. Although the use of **tobramycin** should be well monitored it would be prudent to increase the frequency in patients also given systemic miconazole (note that miconazole oral gel can have significant systemic absorption). There does not appear to be any information about other aminoglycosides and azole antifungals.

Aminoglycosides + NSAIDs

There are conflicting reports as to whether or not serum gentamicin and amikacin levels are raised by indometacin or ibuprofen in premature infants.

Clinical evidence

(a) Amikacin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given amikacin, found that the use of **indometacin** 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of amikacin. Trough and peak levels of amikacin were raised by 28% and 17%, respectively.[1]

In another study, preterm infants were given amikacin 20 mg/kg every 36 hours (gestational age less than 30 weeks) or every 24 hours (gestational age 30 to 31 weeks) with either **ibuprofen lysine** 10 mg/kg within 6 hours of birth, then a further 5 mg/kg dose 24 and 48 hours later, or placebo. The half-life of amikacin was increased from 12.4 hours to 16.4 hours and its clearance was reduced by 40% in infants who also received intravenous **ibuprofen lysine**.[2] Reductions in amikacin clearance, independent of gestational age were found by the same authors in another study in which preterm infants with gestational ages of between 24 and 34 weeks were given amikacin and **ibuprofen**.[3]

In contrast, another study in preterm infants given amikacin found no changes in its pharmacokinetics when **ibuprofen** or **indometacin** were given.[4]

(b) Gentamicin

A study in 10 preterm infants with gestational ages ranging from 25 to 34 weeks, who were given gentamicin, found that the use of **indometacin** 200 micrograms/kg every 8 hours, for up to 3 doses, caused a rise in the serum levels of gentamicin. Trough and peak levels of gentamicin were raised by 48% and 33%, respectively.[1] A later study[5] confirmed that **indometacin** (200 micrograms/kg given intravenously at 0 hours, then 100 micrograms/kg given at 12 hours and then 36 hours) decreased the clearance of 3-mg/kg daily doses of gentamicin by 23% in preterm infants weighing less than 1250 g.

In contrast, 8 out of 13 infants had no increase in their serum gentamicin levels when they were given **indometacin** 200 to 250 micrograms/kg every 12 hours for 3 doses. Of the remaining 5, slight to moderate rises occurred in 4, and a substantial rise occurred in just one.[6] In another study no significant changes in serum gentamicin levels were seen in 31 preterm newborns given parenteral **indometacin** 200 micrograms/kg every 12 hours for 3 doses.[7]

Mechanism

Aminoglycosides are excreted by renal filtration, which can be inhibited by indometacin or ibuprofen. This may result in the retention of the aminoglycoside.

Importance and management

Information seems to be limited to these conflicting studies, although supporting evidence for indometacin comes from the fact that it also causes the retention of digoxin in premature infants. The authors of one of the studies[6] suggest that the different results may be because aminoglycoside serum levels were lower in their study before the indometacin was given, and also because they measured the new steady-state levels after 40 to 60 hours instead of 24 hours. Whatever the explanation, concurrent use should be very closely monitored because toxicity is associated with raised aminoglycoside serum levels. It has been suggested that the aminoglycoside dose should be reduced before giving indometacin and aminoglycoside levels and renal function should be well monitored during concurrent use.[1] It has also been suggested that the dose interval of amikacin should be increased by at least 6 to 8 hours if ibuprofen lysine is also given during the first days of life.[2] Other aminoglycosides possibly behave similarly. This interaction does not seem to have been studied in adults.

Aminoglycosides + Penicillins

The use of piperacillin is reported to be a risk factor for aminoglycoside-associated nephrotoxicity. A reduction in serum aminoglycoside levels can occur if aminoglycosides and penicillins are

given to patients with severe renal impairment. No pharmacokinetic interaction of importance appears to occur with intravenous aminoglycosides and penicillins in those with normal renal function.
The serum levels of oral phenoxymethylpenicillin can be halved by oral neomycin.

Clinical evidence

A. Intravenous or intramuscular aminoglycosides

(a) Patients with renal impairment

A study in 6 patients with renal failure requiring dialysis, who were receiving intravenous **carbenicillin** 8 to 15 g daily in 3 to 6 divided doses, found that in the presence of the penicillin, serum **gentamicin** levels did not exceed 4 micrograms/mL. When the **carbenicillin** was stopped, serum **gentamicin** levels rose.[1]

Other reports similarly describe unusually low **gentamicin** levels in patients with impaired renal function, given **carbenicillin**,[2-5] **piperacillin**,[6] or **ticarcillin**.[3,5,7] The half-life of **gentamicin** has been reported to be reduced by **carbenicillin** or **piperacillin** by about one-half or one-third.[3,6,8] Similarly, unusually low **tobramycin** levels have been reported in patients with impaired renal function, who were given **carbenicillin**,[1] **piperacillin**[9] or **ticarcillin**.[7]

In 3 patients receiving long-term haemodialysis, **piperacillin** doubled the clearance of **tobramycin** 2 mg/kg, and reduced its half-life from 73 hours to 22 hours.[10] In one patient, the half-life of **tobramycin** was reduced from an expected 70 hours to 10.5 hours, and the serum level of **tobramycin** was unexpectedly low, when **piperacillin** was given.[9]

In contrast one study found that **piperacillin** or **piperacillin** with **tazobactam** did not affect the pharmacokinetics of **tobramycin** in subjects with renal impairment.[11] Similarly, **piperacillin** 4 g every 12 hours did not affect the pharmacokinetics of **netilmicin** 2 mg/kg in 3 patients receiving long-term haemodialysis.[10]

(b) Patients with normal renal function

A patient with normal renal function was given **gentamicin** 80 mg intravenously, with and without **carbenicillin** 4 g. The serum **gentamicin** concentration profiles in both cases were very similar.[2] No interaction was seen in 10 patients given **tobramycin** with **piperacillin**,[12] or in another 10 healthy subjects given daily **gentamicin** and **piperacillin** with **tazobactam**.[13] Only minimal pharmacokinetic changes were seen in 9 healthy subjects given **tobramycin** and **piperacillin** with **tazobactam**,[14] and 18 patients with cystic fibrosis (adults and children) given **tobramycin** with **ticarcillin**.[15] However, a study assessing the risk factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of **piperacillin**, but not **ticarcillin** or **carbenicillin** increased the risk of nephrotoxicity.[16]

B. Oral aminoglycosides

In 5 healthy subjects the serum concentrations of a 250-mg oral dose of **phenoxymethylpenicillin** were reduced by more than 50% after they took **neomycin** 3 g four times daily for 7 days. Normal penicillin pharmacokinetics were not seen until 6 days after the **neomycin** was withdrawn.[17]

Mechanism

The nephrotoxic effects of gentamicin and tobramycin are well documented. The reason why piperacillin but not carbenicillin or ticarcillin appears to increase the risk of nephrotoxicity in patients with normal renal function is not clear. One suggestion is that sodium loading may protect the kidney from tobramycin toxicity and piperacillin has only 40% as much sodium as ticarcillin.[16]

In vitro, the amino groups on the aminoglycosides and the beta-lactam ring on the penicillins interact chemically to form biologically inactive amides.[18] It has been suggested that this reaction may also occur in the plasma, causing a drop in the levels of active antibacterial.[8] The interaction occurs in those with poor renal function as the drugs persist in the plasma for longer, allowing a greater time for inactivation. This therefore means that the drug is lost more rapidly than has been accounted for by the renal function, and consequently lower than expected levels of the antibacterial result. However, the lack of interaction found in one study led to the conclusion that reported interactions in renal impairment may be due to *in vitro* inactivation after sample collection.[11]

In the case of phenoxymethylpenicillin, the levels are probably lowered because oral neomycin can cause a reversible malabsorption syndrome (histologically similar to nontropical sprue).

Importance and management

The concurrent use of piperacillin and aminoglycosides is reported to be a risk factor for nephrotoxicity in patients with normal renal function.[16,19] The nephrotoxic effects of gentamicin and tobramycin are well documented. Risk factors for nephrotoxicity include raised aminoglycoside trough levels, decreased albumin, male gender, advanced age, increased length of treatment, liver disease or ascites, and some other diseases, including leukaemia,[16,19] although their significance in practice has been questioned.[16] Renal function should be monitored if an aminoglycoside is given, but it may be prudent to increase the frequency of this monitoring if piperacillin is also given.

Other reports suggest that a pharmacokinetic interaction between parenteral aminoglycosides and piperacillin or other penicillins, resulting in reduced levels of the aminoglycoside, seems to occur in patients with renal impairment. In those cases where concurrent use is thought necessary, it has been recommended that the serum levels of both antibacterials are closely monitored.[1] However, note that antibacterial inactivation can continue in the assay sample, and one author[20] suggests that rapid assay is necessary, while others[11] note the importance of protecting samples against further inactivation. There would seem to be no reason for avoiding concurrent use in patients with normal renal function because no significant *in vivo* inactivation appears to occur. Moreover there is good clinical evidence that concurrent use is valuable, especially in the treatment of Pseudomonas infections.[2,21]

Evidence for an interaction between oral neomycin and penicillins seems limited to the report about phenoxymethylpenicillin, and its clinical significance is unclear. It seems possible that oral **kanamycin** and **paromomycin** might interact similarly, but this needs confirmation.

Aminoglycosides + Polygeline (*Haemaccel*)

The incidence of acute renal failure appears to be increased in cardiac surgical patients given polygeline (*Haemaccel*) with gentamicin.

Clinical evidence

The observation of a differing incidence of acute renal failure in patients undergoing coronary artery bypass surgery in two similar units, prompted a retrospective review of patient records. This showed that the only management differences were related to antibacterial prophylaxis and the bypass prime content (i.e. the solution used to prime the cardiopulmonary bypass circuit). Acute renal failure was defined as a more than 50% rise in serum creatinine on the first postoperative day in those patients whose creatinine was also greater than 120 micromol/L. Four groups of patients were identified, and the incidence of renal failure was as follows:

Group A: (polygeline plus **gentamicin** and flucloxacillin) 31% (28 of 91 patients);

Group B: (polygeline plus cefalotin)12% (9 of 72 patients);

Group C: (crystalloid plus **gentamicin** and flucloxacillin) 7% (4 of 57 patients);

Group D: (crystalloid plus cefalotin) 2% (1 of 47 patients).

Polygeline (*Haemaccel*) 1 litre, which is a urea linked gelatin colloid with a calcium concentration of 6.25 micromol/L, was used for groups A and B, with crystalloid - Hartmann's solution or Ringer's injection (calcium concentration 2 mmol/L) to make up the rest of the prime volume of 2 litres. Groups C and D received only crystalloid (no polygeline) in the prime. Albumin 100 mL was used in groups B and D.[1] However, the study has been criticised because other drugs that affect renal function (such as ACE inhibitors, cimetidine, NSAIDs or clonidine), which may have been taken by the patients were not considered.[2] This criticism has been refuted because of the large sample size involved.[3]

Mechanism

Not fully understood. It is thought that the relatively high calcium content of the polygeline may have potentiated gentamicin-associated nephrotoxicity. Hypercalcaemia has been shown in *animals* to increase aminoglycoside-induced nephrotoxicity.[4]

Importance and management

Information appears to be limited to this clinical study and *animal* studies, but the evidence available suggests that a clinically important adverse interaction occurs between these drugs. The incidence of acute renal failure in cardiac surgery patients is normally about 3 to 5%[5] which is low compared with the 31% shown by those given polygeline and gentamicin. The authors of the study advise avoidance of these two drugs. More study is needed.

Aminoglycosides + Vancomycin

The nephrotoxicity of the aminoglycosides appears to be potentiated by vancomycin.

Clinical evidence, mechanism, importance and management

A retrospective review of 105 patients who had received an aminoglycoside with vancomycin for at least 5 days found that nephrotoxicity occurred in 27% of the patients. Of these, 6 had no other identifiable cause for nephrotoxicity.[1] A study assessing the risks factors for nephrotoxicity with aminoglycosides (**tobramycin** and **gentamicin**) enrolled 1489 patients, 157 of whom developed clinical nephrotoxicity. Of these patients 118 had no immediately identifiable cause (such as acute renal failure) and further evaluation of other risk factors found that the concurrent use of vancomycin increased the risk of nephrotoxicity.[2]

A number of other studies,[3-9] including those where patients have had individualised pharmacokinetic monitoring,[3] and those using both once daily and multiple daily dosing,[4] have all found that vancomycin independently increases the risk of nephrotoxicity in patients receiving aminoglycosides. In one meta-analysis of 8 studies, the incidence of nephrotoxicity with the combination was 4.3% greater than with aminoglycosides alone and 13.3% greater than with vancomycin alone.[8]

Risk factors are said to include vancomycin peak and trough levels,[1,6] aminoglycoside trough levels,[1,3,6] decreased albumin concentrations,[2] male gender,[1-3] advanced age,[1-3] increased length of treatment,[1-3] liver disease or ascites,[1,2] as well as a large number of other disease states (such as leukaemia,[2] peritonitis[1] or neutropenia),[1] although their significance in practice has been questioned.[2]

The concurrent use of these antibacterials is therapeutically useful, but the risk of increased nephrotoxicity should be borne in mind. Therapeutic drug monitoring and regular assessment of renal function is warranted, as is recommended with the use of either drug alone.

Aminoglycosides + Verapamil

Verapamil appears to protect the kidney from damage caused by gentamicin.

Clinical evidence, mechanism, importance and management

In a comparative study, 9 healthy subjects were given **gentamicin** alone (2 mg/kg loading dose, followed by doses every 8 hours to achieve a peak concentration of 5.5 mg/L and a trough concentration of 0.5 mg/L), and 6 other subjects were given the same dose of **gentamicin** with sustained-release verapamil 180 mg twice daily. The **gentamicin** AUCs of the two groups were virtually the same but the 24-hour urinary excretion of alanine aminopeptidase (AAP) was modestly reduced, by 18%, in the group given verapamil. The reduction in AAP excretion was particularly marked during the first 6 days.[1] The significance of urinary AAP is that this enzyme is found primarily in the brush border membranes of the proximal renal tubules, and its excretion is an early and sensitive marker of renal damage. Thus it seems that verapamil may modestly protect the kidneys from damage by **gentamicin**, but using a drug as potentially toxic as verapamil to provide this protection, when the risks of renal toxicity can be minimised by carefully controlling the **gentamicin** dose, is unwarranted. Information about other aminoglycosides and other calcium-channel blockers seems to be lacking.

Aminoglycosides; Amikacin + Dopamine

Dopamine probably does not alter the clearance of amikacin in premature infants.

Clinical evidence, mechanism, importance and management

A retrospective review of the amikacin levels achieved in 240 premature infants found that the median amikacin clearance in infants given dopamine was lower than in infants who did not receive dopamine. However, when the birth weight, gestational age, or use of non-selective COX inhibitors was considered, the change in clearance caused by dopamine was no longer significant.[1] The requirement for dopamine may indicate other medical issues that also have an impact on the clearance of amikacin, and it is therefore essential that doses of amikacin for such infants are individualised.

1. Allegaert K, Debeer A, Cossey V, Rayyan M, Devlieger H. Dopamine is not an independent risk factor for reduced amikacin clearance in extremely low-birth-weight infants. *Pediatr Crit Care Med* (2006) 7, 143–6.

Aminoglycosides; Tobramycin + Sucralfate

An *in vitro* study with tobramycin found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut. This suggests that the efficacy of tobramycin in gut decontamination might be decreased.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, tobramycin 50 mg/mL was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the tobramycin concentration fell rapidly and progressively over 90 minutes to about 1%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of tobramycin, suggesting that the interaction was irreversible.[1] The reason for this change is not known, but the authors of the study suggest that sucralfate forms insoluble chelates with tobramycin.[1]

It is not known how important this interaction is likely to be in practice, but the efficacy of tobramycin in gut decontamination may be decreased. Separating the doses of tobramycin and sucralfate might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.[1] More study is needed to find out whether this interaction is clinically important, but in the meanwhile it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

Aminosalicylic acid + Antacids

An aluminium/magnesium hydroxide antacid had no significant effect on the pharmacokinetics of aminosalicylic acid in one study.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given a single 6-g dose of aminosalicylic acid with cycloserine, ethionamide and clofazimine, after an overnight fast, or with 15 mL of maximum strength ***Mylanta***, containing **aluminium/magnesium hydroxide** 400/400 mg and **simeticone** 40 mg/5 mL. The antacid had no significant effect on the pharmacokinetics of aminosalicylic acid.[1] No adjustments to the timing of dosing would therefore appear to be necessary if both drugs are given.

1. Peloquin CA, Zhu M, Adam RD, Singleton MD, Nix DE. Pharmacokinetics of para-aminosalicylic acid granules under four dosing conditions. *Ann Pharmacother* (2001) 35, 1332–8.

Aminosalicylic acid + Diphenhydramine

Diphenhydramine can cause a small reduction in the absorption of aminosalicylic acid from the gut.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects[1] found that diphenhydramine 50 mg given intramuscularly 10 minutes before a 2-g oral dose of aminosalicylic acid, reduced the mean peak serum aminosalicylic acid levels by about 15%. This effect may occur because diphenhydramine reduces peristalsis in the gut, which in some way reduces aminosalicylic acid absorption. The extent to which diphenhydramine or any other anticholinergic drug diminishes the therapeutic response to long-term treatment with aminosalicylic acid is uncertain, but it is probably small.

1. Lavigne J-G, Marchand C. Inhibition of the gastrointestinal absorption of p-aminosalicylate (PAS) in rats and humans by diphenhydramine. *Clin Pharmacol Ther* (1973) 14, 404–12.

Aminosalicylic acid + Food

A high-fat meal increases the extent of absorption of aminosalicylic acid. Orange juice appears to have no significant effect on the pharmacokinetics of aminosalicylic acid.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given a single 6-g dose of aminosalicylic acid with cycloserine, ethionamide and clofazimine, after an overnight fast, with **orange juice** or a high-fat meal. The high-fat meal increased the maximum aminosalicylic acid plasma level and AUC by 50% and 70%, respectively, when compared with an overnight fast, although there was wide inter-individual variation in the effects of the meal. **Orange juice** had no significant effect on the pharmacokinetics of aminosalicylic acid.[1]

1. Peloquin CA, Zhu M, Adam RD, Singleton MD, Nix DE. Pharmacokinetics of para-aminosalicylic acid granules under four dosing conditions. *Ann Pharmacother* (2001) 35, 1332–8.

Aminosalicylic acid + Probenecid

The plasma levels of aminosalicylic acid can be raised up to fourfold by probenecid.

Clinical evidence, mechanism, importance and management

In a study in 7 patients, probenecid 500 mg every 6 hours increased the plasma levels of aminosalicylic acid 4 g by as much as fourfold.[1] Similar results are described in three other reports.[2-4]

The reasons for this effect are uncertain but it seems probable that probenecid successfully competes with aminosalicylic acid for active excretion by the kidney tubules, which results in the increased aminosalicylic acid levels.

The documentation of this interaction is old but it appears to be established. Such large increases in plasma aminosalicylic acid levels would be expected to lead to toxicity. It also seems possible that the dose of aminosalicylic acid could be reduced without losing the required therapeutic response, but this needs confirmation. Monitoring aminosalicylic acid levels, where possible, would probably be useful. Concurrent use should be undertaken with caution.

Antibacterials + Immunoglobulins

One *animal* study found that for severe infections antibacterials were less effective in the presence of high-dose immunoglobulin, but this was not seen in less severe infections.

Clinical evidence, mechanism, importance and management

A study in an *animal* model of severe group B streptococcal infection found the following mortalities: 51% with **benzylpenicillin** 200 mg/kg alone, 88% with immunoglobulin and benzylpenicillin, and 100% with immunoglobulin 2 g/kg alone. A smaller dose of immunoglobulin 0.5 g/kg was not associated with an increase in mortality.[1] Roughly similar results were found when the penicillin was replaced by **ceftriaxone**.[1]

In another study using a 1000-fold smaller inoculum of group B streptococci, there was no difference in mortality between **benzylpenicillin** 200 mg/kg daily alone and **benzylpenicillin** with immunoglobulin 0.25 to 2 g/kg, and there was some evidence of a lower incidence of bacteraemia with the combination.[1,2]

Immunoglobulins are used with antibacterials in the successful prevention of infections in clinical practice, and no special precautions appear to be needed in this situation. However, their clinical use for treating established infection is unclear, and the above findings suggest that some caution is warranted.

2. Kim KS. Efficacy of human immunoglobulin and penicillin G in treatment of experimental group B streptococcal infection. *Pediatr Res* (1987) 21, 289–92.

Aztreonam + Other antibacterials

There appear to be no clinically significant pharmacokinetic interactions between aztreonam and amikacin, cefradine, clindamycin, gentamicin, metronidazole or nafcillin.

Clinical evidence, mechanism, importance and management

A study in healthy subjects given a single 1-g intravenous dose of aztreonam found that its maximum levels were reduced by 13% and 10% when it was given with **gentamicin** 80 mg and **metronidazole** 500 mg, respectively. Serum bound aztreonam fell by 5% when it was given with **nafcillin** 500 mg and increased by 5% when it was given with **cefradine** 1 g. When aztreonam 1 g and **clindamycin** 600 mg were given together, their renal excretion was increased by 5% and 11%, respectively. None of these changes was statistically significant.[1] Another study in healthy subjects found that the AUC of a 1-g intravenous dose of aztreonam was reduced by 22% by **amikacin** 500 mg, and the AUC of **amikacin** was increased by 27% by aztreonam.[2] These changes are modest and unlikely to be clinically significant in most patients.

Carbapenems + Probenecid

Probenecid increases the AUC of doripenem and meropenem, but does not appear to interact with ertapenem to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Doripenem

Probenecid increased the AUC of doripenem by 75% and prolonged its plasma elimination half-life by 53%. The manufacturer does not recommend the concurrent use of doripenem with probenecid.[1]

(b) Ertapenem

The use of probenecid with ertapenem is reported to decrease the renal clearance of unbound ertapenem by about 50%, probably because probenecid inhibits the renal tubular secretion of ertapenem. Probenecid slightly increased the elimination half-life and AUC of ertapenem and therefore concurrent use is considered unlikely to increase the effects of ertapenem.[2]

(c) Meropenem

In 6 healthy subjects probenecid 1 g given orally 2 hours before meropenem and 500 mg given orally 1.5 hours after meropenem, increased the AUC of meropenem 500 mg by 43%.[3] Another study in 6 healthy subjects found that probenecid 1.5 g in divided doses the day before meropenem and 500 mg one hour before meropenem increased the AUC of meropenem 1 g by up to 55% and increased its half-life by 33% (from 0.98 to 1.3 hours).[4] In both studies the serum levels of meropenem were modestly increased. This is possibly because meropenem and probenecid compete for active kidney tubular secretion.[5,6] The manufacturers say that because the potency and duration of meropenem are adequate without probenecid, they do not recommend concurrent use.[5,6]

Cephalosporins + Acetylcysteine

Acetylcysteine does not alter the pharmacokinetics of cefpodoxime or cefadroxil.

Clinical evidence, mechanism, importance and management

The pharmacokinetics of a single 200-mg dose of **cefpodoxime proxetil** are minimally affected by a single 200-mg dose of acetylcysteine.[1] Similarly, the pharmacokinetics of a single 1-g dose of **cefadroxil** are not significantly altered by acetylcysteine.[2] These interactions are unlikely to be of clinical importance.

1. Kees F, Wellenhofer M, Bröhl K, Grobecker H. Bioavailability of cefpodoxime proxetil with co-administered acetylcysteine. *Arzneimittelforschung* (1996) 46, 435–8.
2. Barkworth MF, Mangold B, Rehm KD, Schmieder G, Töberich H, Vinchenzo A, Weber J, Rübartsch C. Ermittlung der bioverfügbarkeit von cefadroxil bei gleichzeitiger gabe von N-acetylcystein. *Arzneimittelforschung* (1991) 41, 839–43.

Cephalosporins + Antacids

No clinically significant interactions appear to occur between an aluminium/magnesium hydroxide antacid and cefaclor AF, cefalexin, cefetamet pivoxil, cefixime or cefprozil; between *Alka-Seltzer* and cefixime; or between ceftibuten and *Mylanta*. In contrast, antacids reduce the bioavailability of cefpodoxime proxetil.

Clinical evidence, mechanism, importance and management

(a) Cefaclor

A study with cefaclor AF (a formulation with a slow rate of release) found that an **aluminium/magnesium hydroxide** antacid (*Maalox*) given one hour after the cefaclor AF to fed subjects reduced the AUC by 18%.[1] This reduction is small and unlikely to be clinically important.

(b) Cefalexin

An **aluminium/magnesium hydroxide** antacid (*Maalox*) given as 8 doses of 10 mL on day one and 2 doses of 10 mL on day 2, had only small and therapeutically unimportant effects on the pharmacokinetics of cefalexin 1 g.[2]

(c) Cefetamet pivoxil

Cefetamet pivoxil 1 g was given to 18 healthy subjects after breakfast with or without 80 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox 70*) given the evening before, 2 hours before, and after breakfast. The pharmacokinetics of the cefetamet were unaffected by the antacid.[3]

(d) Cefixime

An **aluminium/magnesium hydroxide** antacid (*Maalox*) and ***Alka-Seltzer*** (aspirin, calcium phosphate, citric acid and **sodium bicarbonate**) do not significantly affect the absorption of cefixime,[4,5]

(e) Cefpodoxime proxetil

A study in 10 healthy subjects found that 10 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox*) reduced the bioavailability of cefpodoxime proxetil by about 40%. This was considered to be due to reduced dissolution at increased gastric pH values.[6] These results confirm the findings of a previous study with **sodium bicarbonate** and **aluminium hydroxide**.[7] It has been recommended that cefpodoxime is given at least 2 hours after antacids.[6]

(f) Cefprozil

An **aluminium/magnesium hydroxide** antacid (*Maalox*) does not affect the bioavailability of cefprozil.[8]

(g) Ceftibuten

In 18 healthy subjects, 60 mL of an antacid containing **aluminium/magnesium hydroxide** plus **simeticone** (*Mylanta II*) was found not to affect the pharmacokinetics of ceftibuten 400 mg.[9]

Cephalosporins + Calcium-channel blockers

Nifedipine increases the levels of cefixime. The pharmacokinetics of cefpodoxime proxetil are not affected by nifedipine or diltiazem.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects the AUC and peak serum levels of a single 200-mg dose of **cefixime** were increased by about 70% and 50%, respectively, when **cefixime** was taken 30 minutes after a 20-mg dose of **nifedipine**. The rate of absorption was also increased. One suggested reason for this interaction is that the **nifedipine** increases the absorption of the **cefixime** by affecting the carrier system across the epithelial wall of the gut.[1] It seems doubtful if this increased **cefixime** bioavailability is clinically important (the combination was well-tolerated) and no particular precautions would seem to be necessary on concurrent use.

In 12 healthy subjects, the pharmacokinetics of a single 200-mg dose of **cefpodoxime proxetil** were found to be unchanged by single doses of either **diltiazem** 60 mg or **nifedipine** 20 mg.[2] No special precautions would seem necessary during concurrent use.

Information about other cephalosporins and calcium-channel blockers seems to be lacking, but there seems to be no particular reason to suspect an interaction.

Cephalosporins + Colestyramine

Colestyramine binds with cefadroxil and cefalexin in the gut, which delays their absorption.

Clinical evidence

In 4 subjects, the peak serum levels of a 500-mg oral dose of **cefadroxil** were reduced and delayed when it was taken with 10 g of colestyramine, but the total amount absorbed was not affected.[1] Similar results were found in a study involving **cefalexin** and colestyramine.[2]

Mechanism

Colestyramine is an ion-exchange resin, which binds with these two cephalosporins in the gut. This prevents the early and rapid absorption of the antibacterial, but as the colestyramine/cephalosporin complex passes along the gastrointestinal tract, the antibacterial is progressively released and eventually virtually all of it becomes available for absorption.[1]

Importance and management

Direct information seems to be limited to the studies cited. The clinical significance is uncertain, but as the total amount of antibacterial absorbed is not reduced this interaction is probably of little importance. Information about other cephalosporins seems to be lacking.

Cephalosporins + Food

The bioavailabilities of cefadroxil, cefalexin, cefdinir, cefixime, cefprozil, and cefradine are not affected by food. Cefaclor may be given without regard to food but absorption of an extended-release preparation may be increased by food. The bioavailabilities of cefetamet pivoxil and cefuroxime axetil may be increased by food.

Clinical evidence, mechanism, importance and management

(a) Cefaclor

A study in 18 healthy subjects, the bioavailability and AUC of a single 250-mg capsule of cefaclor was unchanged when it was given after an overnight fast or within 30 minutes of different meals. The rate of absorption and its maximum plasma levels were decreased: a low-fat vegetarian diet produced the smallest decrease in maximum plasma levels (26%) and a high-fat non-vegetarian diet produced the largest decrease (47%), when compared with the levels achieved after an overnight fast. However, therapeutic efficacy (measured by time levels were above MIC_{50}) was not significantly altered.[1] In a further study, healthy subjects were given a single 500-mg dose of cefaclor as an extended-release tablet. The rate of absorption was decreased by food but compared with the fasting state, the maximum levels were increased; by 52% for rice-based diets, by 33% for low-fat-vegetarian food, by 29% for high-fat non-vegetarian food, by 13% for high-fat-vegetarian food, and by 7% for low-fat non-vegetarian food. Compared with the fasting state, all the diets increased the time above MIC_{90}, with a significant increase of almost 42% with low-fat vegetarian (wheat-based) food.[2] The manufacturer of immediate-release cefaclor capsules states that total absorption is the same whether the drug is given with or without food,[3] but for the extended-release preparation, as absorption is enhanced by food, the manufacturer recommends that this preparation should be taken with meals.[4]

(b) Cefadroxil

The manufacturers of cefadroxil state that the bioavailability of cefadroxil is unaffected by food so it may be taken either with meals or on an empty stomach.[5]

(c) Cefalexin

The manufacturers of cefalexin state that it is acid stable and may be given without regard to meals.[6]

(d) Cefdinir

In 6 healthy subjects, the pharmacokinetics of a single 100-mg dose of cefdinir were unaltered by a normal-protein diet, a high-protein diet, or a normal-protein diet supplemented with L-phenylalanine 7.5 g/day for 12 days.[7]

(e) Cefetamet pivoxil

A study found that the bioavailability of cefetamet pivoxil was up to 25% higher when it was given 10 minutes after a standard breakfast rather than in the fasting state.[8,9] In another study, healthy subjects were given oral cefetamet pivoxil hydrochloride 1 g (equivalent to 693 mg of cefetamet free acid) either: 1 hour before food with 200 mL of water; with a standard breakfast and a cup of tea or coffee; or one hour after breakfast with 200 mL of water. The cefetamet maximum plasma levels were 5.5 micrograms/mL, 5.47 micrograms/mL and 6.57 micrograms/mL, respectively, and the AUCs, compared to the fasting state were decreased by 6% when taken with breakfast and increased by 13% when taken one hour

after breakfast. The time to reach maximum plasma levels was increased from 3.3 hours when given before food to 4.3 hours when given with food, and to 4.1 hours when given one hour after food.[10] It was thought possible that the amount of fluid taken with cefetamet may have affected absorption, but a study in which cefetamet 1 g was given under fasting conditions with either 250 or 450 mL of water found that increasing fluid intake did not affect absorption. Further, the absorption when taken with food, with or without 200 mL of water was similar. These changes are modest. Nevertheless, the authors recommended that cefetamet pivoxil should be taken within an hour of a meal to improve absorption. The delay in absorption was not considered to be of significance.[10]

(f) Cefixime

A study in healthy subjects given a single 400-mg dose of cefixime, either in the fasting state or immediately after a standard breakfast found that the time to peak serum levels was increased from about 3.8 hours to 4.8 hours when cefixime was given with food, probably because of delayed gastric emptying. The cefixime serum levels, AUC and 24-hour urinary recovery were similar for fasted and fed states.[11] Cefixime may be given without regard to meals.[11,12]

(g) Cefpodoxime proxetil

In a study in healthy subjects, cefpodoxime proxetil 400 mg tablets were given with 180 mL of water after an overnight fast, or either one hour before, with, or 2 hours after the start of a high-fat meal. Dosing one hour before the meal was similar to dosing in the fasting state. However, when cefpodoxime was taken with, or 2 hours after the meal its peak plasma levels were increased by about 45% and 46%, respectively, when compared with the peak levels achieved in the fasting state. The AUC was also increased, by 40%. The rate of cefpodoxime absorption was not greatly affected by food.[13] Studies with a 200-mg dose of cefpodoxime have also found that food increases the extent, but not the rate, of cefpodoxime absorption.[14] However, the extent of the food effect appears to be greater with the 400 mg dose. This is possibly because the bioavailability of the 400-mg tablets is less than that of the 200-mg tablets, so food may have a greater effect on the higher strength preparation.[13] In another study by the same authors the AUC and urinary excretion of cefpodoxime proxetil 200 mg given as a suspension were higher (11% and 14%, respectively) when taken with a high-fat meal rather than in the fasting state. Maximum plasma levels were not affected by a high-fat meal but the time to achieve maximum levels was prolonged.[15]

The manufacturers state that the bioavailability of cefpodoxime proxetil 100 mg tablets and suspension is increased by food.[16,17] The studies[13-15] suggest the increased bioavailability of the tablets, but possibly not that of the suspension, when given with food may be clinically significant.

(h) Cefprozil

A study in healthy subjects found that, although food caused slight changes in the rate of absorption of a 1-g dose of cefprozil its pharmacokinetics (including total absorption) were not significantly affected.[18]

(i) Cefradine

A study in healthy subjects given cefradine 500 mg in the fasting state or immediately after a meal found the time to peak levels was increased from 0.8 hours to 2 hours by food. Peak serum levels of cefradine were reduced by 45% when it was given after food. However, the half-life and AUC were not affected.[19] The manufacturer states that cefradine may be given without regard to meals.[20]

(j) Cefuroxime axetil

A study in healthy subjects given cefuroxime axetil 500 mg intravenously or oral doses of 125 mg to 1 g with or without food found that 36% and 52% of a 500-mg oral dose was absorbed in the fasting and fed states respectively.[21] In another study in healthy subjects, a single 1-g dose of cefuroxime axetil was given 2 hours before or 35 minutes after a standard cooked breakfast. The bioavailability of cefuroxime was markedly enhanced by food.[22] The manufacturer notes that optimum absorption of cefuroxime axetil occurs when it is given after a meal.[23] This is probably because of delayed gastric emptying and transit which allowed more complete dissolution and absorption.[22]

Cephalosporins + H_2-receptor antagonists

Ranitidine and famotidine reduce the bioavailability of cefpodoxime proxetil. Ranitidine with sodium bicarbonate reduces the bioavailability of cefuroxime axetil. No clinically significant pharmacokinetic interactions appear to occur between cefaclor AF and cimetidine, or between cefetamet pivoxil, cefalexin or ceftibuten and ranitidine.

Clinical evidence

(a) Cefaclor

A study using cefaclor AF (a formulation with a slow rate of release) found that **cimetidine** 800 mg taken the previous night reduced its maximum plasma concentration by 12%.[1]

(b) Cefalexin

Ranitidine 150 mg for 3 doses had only small and therapeutically unimportant effects on the pharmacokinetics of cefalexin 1 g.[2] In another study in healthy subjects, **ranitidine** 150 mg for 3 doses prolonged the time to attain peak serum levels of a single 500-mg dose of cefalexin from 1.19 hours to 1.48 hours. Other pharmacokinetic parameters were not significantly affected. Similar results were found when **omeprazole** was given instead of ranitidine.[3]

(c) Cefetamet pivoxil

In 18 healthy subjects, **ranitidine** 150 mg twice daily for 4 days did not affect the pharmacokinetics of cefetamet pivoxil 1 g given after breakfast.[4]

(d) Cefpodoxime proxetil

A study in 10 healthy fasted subjects found that **famotidine** 40 mg reduced the bioavailability of cefpodoxime proxetil by about 40%.[5] This confirms the findings of a previous study with **ranitidine**.[6]

(e) Ceftibuten

In 18 healthy subjects **ranitidine** 150 mg every 12 hours for 3 days raised the maximum plasma levels and AUC of ceftibuten by 23% and 16%, respectively. However these values lie within the normal ranges seen in healthy subjects.[7]

(f) Cefuroxime axetil

Ranitidine 300 mg with sodium bicarbonate 4 g reduced the AUC of cefuroxime axetil 1 g by 43% when the combination was given to fasted subjects. However, when cefuroxime was given after food, its bioavailability was higher, and minimally affected by **ranitidine** plus sodium bicarbonate (10% reduction in AUC) .[8]

Mechanism

The reduction in the bioavailability of some of the cephalosporins is thought to be due to reduced dissolution at increased gastric pH values.[5]

Importance and management

In most cases the interactions between the cephalosporins and H_2-receptor antagonists are not clinically significant. The clinical importance of the interaction with cefpodoxime has not been studied, but the manufacturer recommends that cefpodoxime is given at least 2 hours before H_2-receptor antagonists.[9] As it is thought that a change in gastric pH is responsible for this interaction it would seem likely that **proton pump inhibitors** will interact similarly.

As long as cefuroxime is taken with food (as is recommended[10]), any interaction is minimal. The bioavailability of cefetamet pivoxil,[4] and cefpodoxime proxetil,[5,6] are also enhanced by food so it is probable that any interaction with drugs that raise gastric pH may be similarly minimised.

Cephalosporins + Loop diuretics

The nephrotoxic effects of cefaloridine and possibly cefalotin or cefacetrile appear to be increased by furosemide. Cefradine brain levels are reduced by furosemide. No important interactions appear to occur between furosemide and cefoxitin, ceftazidime, ceftriaxone, or cefuroxime.

Clinical evidence

(a) Nephrotoxicity

Nine out of 36 patients who developed acute renal failure while taking **cefaloridine** had also been taking a diuretic: furosemide was used in 7 cases. Other factors such as patient age and drug dose may also have been involved. The authors of this report related their observations to previous *animal* studies, which showed that potent diuretics such as furosemide and etacrynic acid enhanced the incidence and extent of tubular necrosis.[1] Several other reports describe nephrotoxicity in patients given both **cefaloridine** and furosemide.[2-4] There is a possibility that this effect also occurs with **cefalotin** and **cefacetrile** because *animal* studies found an increase in nephrotoxicity,[5,6] and there is a single report describing nephrotoxicity in one patient taking **cefalotin** with furosemide.[2] **Cefoxitin** seems to be relatively free of nephrotoxicity alone or with furosemide.[7]

(b) Changes in serum levels and clearance

A clinical study[8] found that furosemide 80 mg increased the serum half-life of **cefaloridine** by 25%, and in another study **cefaloridine** clearance was reduced by furosemide.[9] A further study found that brain concentrations of **cefradine** are markedly reduced by furosemide.[10] In a study in 6 healthy subjects, furosemide 40 mg, given one hour before a 1-g intramuscular dose of **ceftazidime**, raised the serum **ceftazidime** levels by about 20 to 40% over 8 hours and increased its AUC by 28%. Furosemide given 3 hours before **ceftazidime** had much smaller effects.[11] The serum half-lives of intravenous **cefoxitin** and **cefuroxime** were not affected by oral furosemide.[12] **Ceftriaxone** does not appear to interfere with the diuretic effects of furosemide.[13]

Mechanism

Cefaloridine is nephrotoxic, but why this should be increased by furosemide is not understood. It may possibly be related to a reduction in its clearance.[9]

Importance and management

The interaction between cefaloridine and furosemide is not well-established, but there is enough evidence to suggest that concurrent use should be undertaken with care. Age and/or renal impairment may possibly be predisposing factors. Renal function should be checked frequently if both drugs are given. A pharmacokinetic study suggests that the development of this adverse interaction may possibly depend on the time relationship of drug use, and it has been recommended that furosemide should be avoided for 3 or 4 hours before the cefaloridine.[14] There seems to be no evidence about other loop diuretics, but it seems possible that they will interact similarly.

Although the manufacturers of ceftazidime issue a caution about the use of high doses of cephalosporins with other nephrotoxic drugs, they say that clinical experience has not shown this to be a problem with ceftazidime at the recommended doses.[15] The rest of the information about other cephalosporins and furosemide is fairly sparse. Most appear not to interact adversely, with a few possible exceptions, namely cefalotin (nephrotoxicity in a single case[2] and *animal* studies[5]) and cefacetrile (nephrotoxicity in *animal* studies[6]). Care is clearly prudent with these two cephalosporins.

Cephalosporins + Metoclopramide or Propantheline

The pharmacokinetics of cefprozil and cefpodoxime proxetil are minimally affected by propantheline and metoclopramide.

Clinical evidence, mechanism, importance and management

(a) Cefpodoxime

In 12 healthy subjects, the pharmacokinetics of a single 200-mg dose of cefpodoxime proxetil were not significantly altered when it was given 30 minutes after a single dose of metoclopramide 10 mg or propantheline 30 mg.[1]

(b) Cefprozil

A study in 15 healthy subjects who received a single 30-mg dose of metoclopramide or a single 30-mg dose of propantheline 30 minutes before a single 1 g dose of cefprozil, found that the pharmacokinetics of cefprozil were only minimally affected by these drugs.[2]

Cephalosporins + NSAIDs

The biliary excretion of ceftriaxone is increased by diclofenac. The clearance of ceftazidime is significantly reduced by indometacin in neonates Cefadroxil does not alter the pharmacokinetics of diclofenac.

Clinical evidence, mechanism, importance and management

(a) Diclofenac

The pharmacokinetics of diclofenac 100 mg daily were unaffected by either **cefadroxil** 2 g daily (8 patients) or doxycycline 100 mg daily (7 patients) for one week.[1] No special precautions are needed while taking either of these drugs and diclofenac.

A pharmacokinetic study in 8 patients who had undergone cholecystectomy and who had a T-drain in the common bile duct, found that diclofenac 50 mg every 12 hours increased the excretion of intravenous **ceftriaxone** 2 g in the bile by about fourfold and roughly halved the urinary excretion.[2] The clinical importance of this is uncertain, but probably small.

(b) Indometacin

A study found that the prenatal use of indometacin reduced the clearance of **ceftazidime** 25 mg/kg by 18% in 12 premature neonates (born at about 29 weeks) who were 10 days old. Further, in similar neonates who had not received indometacin, the clearance of **ceftazidime** increased over the first 10 days of life, but this was not seen when indometacin had been given.[3] A further study by the same authors intended to establish an appropriate dose of **ceftazidime** for premature neonates. This study found that in 25 subjects who had received indometacin prenatally, the clearance of **ceftazidime** was reduced by 31% and therefore the authors suggest that additional dose reductions are required. However, note that the effect of indometacin was cancelled out in neonates who had also received betamethasone prenatally.[4] *Animal* studies have shown that indometacin reduces **ceftazidime** excretion by decreasing its glomerular filtered load.[5]

The dose of **ceftazidime** in preterm infants in the first week of life is normally based on chronological age and glomerular filtration rate, although some have suggested that the gestational age should be taken into account.[4] Additional dose adjustments are recommended in preterm infants who are also given indometacin.[3,4]

Cephalosporins + Probenecid

The serum levels of many cephalosporins are raised by probenecid. Possible exceptions include ceforanide, ceftazidime, ceftriaxone and latamoxef. The rise in serum levels may possibly increase the risk of nephrotoxicity with some cephalosporins such as cefaloridine and cefalotin.

Clinical evidence

Ten healthy subjects given a single 500-mg oral dose of **cefradine** or **cefaclor** developed markedly raised serum antibacterial concentrations when they were also given probenecid (500 mg doses taken 25, 13 and 2 hours before the antibacterial). Peak serum levels of the antibacterial were very roughly doubled.[1] Similar results were obtained in another study in healthy subjects given **cefradine** orally or intramuscularly.[2]

Although some cephalosporins do not appear to interact with probenecid, in general, most have their clearance reduced, their serum levels raised and sometimes their half-lives prolonged by probenecid, see 'Table 10.2', (p.334).

Mechanism

Probenecid inhibits the excretion of most cephalosporins by the renal tubules by successfully competing for the excretory mechanisms. A fuller explanation of this mechanism is set out in 'Drug excretion interactions', (p.7). Thus the cephalosporin is retained in the body and its serum levels rise. The extent of the rise cannot always be fully accounted for by this mechanism alone and it is suggested that some change in tissue distribution may sometimes have a part to play.[1]

Importance and management

An extremely well-documented interaction. The serum levels of many (but not all) cephalosporins will be higher if probenecid is given, but no special precautions are normally needed. The interaction has been used clinically; however, elevated serum levels of some cephalosporins, in particular cefaloridine and cefalotin, might possibly increase the risk of nephrotoxicity.

Cephalosporins; Cefalexin + Pirenzepine

Pirenzepine (50 mg for 4 doses) had only small and therapeutically unimportant effects on the pharmacokinetics of a 1-g dose of cefalexin.[1]

Cephalosporins; Cefalotin + Colistin

Renal failure has been attributed to the concurrent use of cefalotin and colistin.

Clinical evidence, mechanism, importance and management

Four patients developed acute renal failure, which appeared to be reversible, during treatment with colistin. Three were given cefalotin concurrently and the fourth had previously been taking this antibacterial.[1] An increase in renal toxicity associated with the concurrent use of these drugs has been described in another report.[2] The reason for this reaction is not

Table 10.2 Effect of probenecid on the pharmacokinetics of the cephalosporins

Drug	*Route*	*Effect of probenecid*	*Refs*
Cefacetrile	Intramuscular	Mean serum half-life increased from 52 minutes to 90 minutes	1
Cefaclor	Oral	Serum level approximately doubled; renal excretion inhibited; renal excretion after 4 hours reduced by 61%	2,3
Cefadroxil	Oral	Probenecid 500 mg every 8 hours for 5 doses increased the half-life of cefadroxil from 1.13 hours to 1.63 hours and reduced its renal excretion by 58%; probenecid slightly increased and prolonged cefadroxil serum levels	4
Cefalexin	Oral	Reduced clearance	5
Cefaloglycin	Oral	Increased peak serum levels and duration of antibacterial activity	6
Cefaloridine	Intramuscular/Intravenous	Plasma levels increased by 20%. Clearance reduced by 24% (intravenous); increased serum levels; prolonged antibacterial activity (intramuscular)	7,8
Cefalotin	Intravenous	Plasma levels increased by 70%. Clearance reduced by 59%	7
Cefamandole	Intramuscular	Peak serum levels almost doubled; half-life prolonged from 1.1 hours to 2 hours	9
Cefazedone	Intravenous	AUC increased more than threefold; elimination half-life increased from 1.58 hours to 4.44 hours; total clearance reduced by 68%	10
Cefazolin	Intramuscular/Intravenous	At 6 hours serum levels of intramuscular dose doubled; after intravenous dose elimination half-life increased from 1.6 hours to 2.7 hours and mean serum level after 24 hours was increased from 1.1 mg/L to 2 mg/L; therapeutic levels at steady-state maintained by once daily rather than three times daily dose regimen	11-13
Cefditoren	Oral	Increased plasma half-life; decreased excretion and renal clearance	14
Cefmenoxime	Intravenous	Renal clearance of cefmenoxime reduced from 159 mL/minute to 66 mL/minute; AUC almost doubled	15
Cefmetazole	Intravenous	Mean AUC increased by about 58%; clearance reduced by about 36%; half-life increased from 1.5 hours to 2.27 hours	16
Cefonicid	Intramuscular	Probenecid 1 g increased the maximum levels of cefonicid 500 mg by 52%, increased the AUC twofold, increased the half-life from 3.5 hours to 7.5 hours, reduced elimination rates and decreased renal clearance	17
Ceforanide	Intramuscular	No significant effect	18
Cefotaxime	Intramuscular/Intravenous	Oral probenecid 500 mg every 6 hours for 24 hours before, and 1 g 30 minutes before, intravenous cefotaxime 1 g reduced renal clearance by about half and almost doubled its AUC. Delayed excretion and increased plasma levels due to effects on renal tubular transfer. Clearance of cefotaxime and also its metabolites decreased by probenecid	19-21
Cefoxitin	Intramuscular/Intravenous	Serum half-life increased from 39 minutes to 129 minutes and clearance halved (intravenous); greater increase in AUC when probenecid given 1 hour before rather than with cefoxitin (intravenous); increasing dose of probenecid from 1 to 2 g increased AUC of cefoxitin (intramuscular)	21-23
Cefprozil	Oral	Significant increase in half-life and maximum levels, AUC approximately doubled, and clearance decreased by about 60%	24
Cefradine	Oral/Intramuscular	Serum levels approximately doubled. Peak levels delayed (from 1 to 2 hours oral and from 1 to 1.5 hours intramuscular); half-lives prolonged	2,25
Ceftazidime	Intravenous	Probenecid 500 mg every 6 hours for 24 hours before and 1 g immediately before a single intravenous dose of ceftazidime 1 g did not significantly affect ceftazidime clearance. Pharmacokinetics of single 50-mg/kg dose of ceftazidime in patients with cystic fibrosis not affected by pre-treatment with probenecid 2 g	19,26
Ceftizoxime	Intramuscular/Intravenous	AUC increased by 49% (both routes); half-life increased from 1.7 hours to 2.3 hours (intravenous) and 1.9 hours to 2.8 hours (intramuscular)	27
Ceftriaxone	Intravenous	No significant effect	28
Cefuroxime	Intravenous	AUC increased by 44 to 50%; half-life prolonged by 63%; clearance decreased by 29%	29
Latamoxef	Intravenous	Probenecid 500 mg every 6 hours for 24 hours before and 1 g immediately before a single 1-g intravenous dose of latamoxef did not significantly affect latamoxef clearance	19

Cephalosporins; Cefdinir + Iron compounds

Ferrous sulfate markedly reduces the absorption of cefdinir.

Clinical evidence

When 6 healthy subjects were given **ferrous sulfate** (1050 mg of *Fero-Gradumet*, sustained release, equivalent to 210 mg of elemental iron) with cefdinir 200 mg the AUC of cefdinir was reduced by 93%. When **ferrous sulfate** was taken 3 hours after cefdinir, the absorption of cefdinir remained unchanged for 3 hours and then rapidly fell, the total AUC over 12 hours being reduced by 36%.[1] There have been a small number of reported cases of maroon or red stools in children who have taken cefdinir with iron supplements.[2,3] One of these cases occurred in a child who was receiving an iron-containing infant formula.[3]

Mechanism

It is believed that iron compounds chelate with cefdinir in the gut to produce a poorly absorbed complex, which may discolour the stools.

Importance and management

An established interaction of clinical importance. Avoid ferrous sulfate and other iron compounds while taking cefdinir. The manufacturer advises separating the administration of cefdinir and iron preparations by at least 2 hours, but notes that although iron-containing vitamin supplements may interact, iron-fortified infant formula may be taken with cefdinir.[4] Parents should be advised about the potential discoloration of the stools. There is no information to suggest that other cephalosporins interact in this way.

Cephalosporins; Cefotaxime + Penicillins

Azlocillin and mezlocillin may reduce the clearance of cefotaxime.

Clinical evidence, mechanism, importance and management

A patient with renal failure developed encephalopathy with focal motor status and generalised convulsions when given cefotaxime 2 g every 8 hours and **azlocillin** 5 g every 8 hours (high-dose).[1] In a study in subjects with either normal or impaired renal function, the clearance of a single dose of cefotaxime was reduced by 40 to 50% by **azlocillin** regardless of renal function.[2]

When 8 healthy subjects were given intravenous cefotaxime 30 mg/kg and **mezlocillin** 50 mg/kg together over 30 minutes the pharmacokinetics of the **mezlocillin** were unchanged but the clearance of the cefotaxime was reduced by about 40%. However, in a series of 5 patients with end-stage renal disease no significant decrease in cefotaxime clearance was seen when **mezlocillin** was given.[3]

Doses of cefotaxime may need to be reduced in the presence of either **azlocillin** or **mezlocillin**. One report suggests a dose reduction of cefotaxime is advisable if the glomerular filtration rate is 20 to 40 mL/minute and **azlocillin** is also given.[2]

There seems to be no information about other penicillins.

Cephalosporins; Cefotaxime + Phenobarbital

A 30-month study noted a very marked increase in drug-induced reactions in children in intensive care who were given high-dose phenobarbital and beta-lactam antibacterials (mainly cefotaxime). Twenty-four out of 49 children developed drug-induced reactions, which were mainly exanthematous skin reactions.[1] The reasons for this reaction are not known. It would seem prudent to consider this interaction in patients who develop skin reactions while taking both drugs.

1. Harder S, Schneider W, Bae ZU, Bock U, Zielen S. Unerwünschte Arzneimittelreaktionen bei gleichzeitiger Gabe von hochdosiertem Phenobarbital und Betalaktam-Antibiotika. *Klin Padiatr* (1990) 202, 404–7.

Chloramphenicol + Cimetidine

Isolated reports describe fatal aplastic anaemia in two patients given intravenous chloramphenicol and cimetidine.

Clinical evidence, mechanism, importance and management

Pancytopenia and aplastic anaemia developed in a man taking cimetidine 1.2 g daily, within 18 days of being given intravenous chloramphenicol 1 g every 6 hours. It proved to be fatal.[1] Another patient, similarly treated, developed fatal aplastic anaemia after 19 days.[2] A drug interaction with cimetidine was suspected because the onset of pancytopenia was more rapid than in previous cases where chloramphenicol alone induced aplastic anaemia. This effect may occur because the bone marrow depressant effects of the two drugs are additive. There are at least 8 other cases of aplastic anaemia following the use of parenteral chloramphenicol in the absence of cimetidine.[2] The general importance of these observations is uncertain, but the authors of one of the reports suggest that these drugs should be used together with caution.

Chloramphenicol + Dapsone

Dapsone does not significantly affect the pharmacokinetics of oral chloramphenicol.

Clinical evidence, mechanism, importance and management

A comparison of the pharmacokinetics of oral chloramphenicol in 8 healthy subjects and 8 patients with uncomplicated lepromatous leprosy found that the half-life of a single 500-mg dose of chloramphenicol was prolonged from 4.3 hours to 6.4 hours in patients with leprosy, possibly due to changes in liver function. The elimination half-life of chloramphenicol was further increased, to about 8 hours, when the subjects were also given dapsone 100 mg daily for 8 days. However, this latter increase was not statistically significant. Although there was no clinically significant interaction between dapsone and chloramphenicol, the disposition of chloramphenicol may be altered in leprosy.[1]

1. Garg SK, Kumar B, Shukla VK, Bakaya V, Lal R, Kaur S. Pharmacokinetics of aspirin and chloramphenicol in normal and leprotic patients before and after dapsone therapy. *Int J Clin Pharmacol* (1988) 26, 204–5.

Chloramphenicol + Other antibacterials

An old report suggests that the use of chloramphenicol may antagonise the effects of ampicillin in bacterial meningitis. In contrast, no antagonism and even additive antibacterial effects have been described in other infections. Chloramphenicol levels have been markedly lowered by rifampicin (rifampin) in a small number of children.

Clinical evidence

(a) Antibacterial antagonism

A study in 264 patients (adults, and children over 2 months old) with acute bacterial meningitis found that when they were given **ampicillin** 150 mg/kg daily alone, the case-fatality ratio was 4.3% compared with 10.5% in comparable subjects given a combination of **ampicillin**, chloramphenicol 100 mg/kg daily (up to 4 g), and **streptomycin** 40 mg/kg daily (up to 2 g). The neurological sequelae (hemiparesis, deafness, cranial nerve palsies) were also markedly increased by the combined use of these drugs.[1] Antibacterial antagonism was clearly seen in a 10-week-old infant with *Salmonella enteritidis* meningitis, who was given chloramphenicol and **ceftazidime**.[2]

However, in contrast a report claims that antibacterial antagonism was not seen in 65 of 66 patients given chloramphenicol and **benzylpenicillin** for bronchitis or bronchopneumonia.[3] **Ampicillin** with chloramphenicol is more effective than chloramphenicol alone in the treatment of typhoid,[4] and in a study of 700 patients, **procaine benzylpenicillin** with chloramphenicol was shown to be more effective than chloramphenicol alone in the treatment of gonorrhoea (failure rates of 1.8% compared with 8.5%).[5]

(b) Pharmacokinetic interactions

In a study in premature and full-term neonates, infants and small children, it was found that the presence of **penicillin** markedly raised chloramphenicol levels.[6]

Two children, aged 2 and 5 years, with *Haemophilus influenzae* meningitis, were given chloramphenicol 100 mg/kg daily in four divided doses by infusion over 30 minutes. Within 3 days of starting **rifampicin** (**rifampin**) 20 mg/kg daily their peak serum chloramphenicol levels were reduced by 86% and 64%, respectively, and only returned to the therapeutic range when the chloramphenicol dose was increased to 125 mg/kg daily.[7]

Two other children, of 5 and 18 months, with *Haemophilus influenzae* infections, are also reported to have shown reductions of 75% and 94%, respectively, in serum chloramphenicol levels when given **rifampicin** 20 mg/kg daily for 4 days. These reductions occurred despite 20 to 25% increases in the chloramphenicol dose.[8]

Mechanism

By no means fully understood. Chloramphenicol inhibits bacterial protein synthesis and can change an actively growing bacterial colony into a static one. Thus the effects of a bactericide, such as penicillin, which interferes with cell wall synthesis, are blunted, and the death of the organism occurs more slowly. This would seem to explain the antagonism seen with some organisms.

It is thought that rifampicin (rifampin), a potent enzyme inducer, markedly increases the metabolism of chloramphenicol by the liver, thereby lowering its serum levels.[7,8]

Importance and management

Proven cases of antibacterial antagonism of chloramphenicol by penicillins in patients seem to be few in number, and there is insufficient evidence to impose a general prohibition, because, depending on the organism, penicillins and chloramphenicol have been used together with clear advantage.

So far only four cases of an interaction between rifampicin (rifampin)

and chloramphenicol appear to have been reported. However, the evidence is of good quality and in line with the way rifampicin interacts with other drugs, so this interaction should be taken seriously. There is a risk that chloramphenicol levels will become subtherapeutic. The authors of the second report point out that raising the chloramphenicol dose may possibly expose the patient to a greater risk of bone marrow aplasia. They suggest delaying rifampicin prophylaxis in patients with invasive *Haemophilus influenzae* infections until the end of chloramphenicol treatment.

Chloramphenicol + Paracetamol (Acetaminophen)

Although there is limited evidence to suggest that paracetamol may affect chloramphenicol pharmacokinetics its validity has been criticised.

Clinical evidence, mechanism, importance and management

Three studies report alterations in the pharmacokinetics of chloramphenicol by paracetamol. The first was conducted in 6 adults in intensive care after an observation that the half-life of chloramphenicol was prolonged by paracetamol in children with kwashiorkor. The addition of 100 mg of intravenous paracetamol increased the half-life of chloramphenicol in the adults from 3.25 hours to 15 hours.[1] However, this study has been criticised because of potential errors in the method used to calculate the half-life,[2] the unusual doses used,[2,3] and because the pharmacokinetics of the chloramphenicol with and without paracetamol were calculated at different times after the administration of chloramphenicol.[4] It has also been pointed out that malnutrition (e.g. kwashiorkor) can increase the elimination rate and AUC of chloramphenicol independently of paracetamol.[2]

The second study demonstrated a different interaction, in that the clearance of chloramphenicol was *increased* and the half-life *reduced* by paracetamol.[5] This study has also been criticised as it does not account for the fact that chloramphenicol clearance increases over the duration of a treatment course, which suggests that the changes seen in the pharmacokinetics of chloramphenicol may be independent of the paracetamol.[6] The authors later admit this as a possibility.[7] The third study found no differences in the pharmacokinetics of chloramphenicol after the first dose, but at steady state, the AUC and peak serum levels of chloramphenicol were lower in children who also received paracetamol.[8]

Three other studies do not support the existence of a pharmacokinetic interaction between chloramphenicol and paracetamol.[2-4]

The clinical significance of these reports is unclear, and clinical evidence of toxicity or treatment failure of chloramphenicol appears to be lacking. It would seem prudent to remain aware of the potential for interaction, especially in malnourished patients, but routine monitoring would appear unnecessary without further evidence.

Chloramphenicol + Phenobarbital

Studies in children have found that phenobarbital can markedly reduce serum chloramphenicol levels. There is a single report, in one adult, of markedly increased serum phenobarbital levels caused by chloramphenicol.

Clinical evidence

(a) Effects on chloramphenicol

A study in a group of infants and children (aged one month to 12 years) given chloramphenicol 25 mg/kg every 6 hours found that 6 of them, also taking phenobarbital, had reduced serum chloramphenicol levels, when compared with 17 control patients. The peak levels were lowered by 34%, from 25.3 to 16.6 micrograms/mL, and the trough levels were lowered by 44%, from 13.4 to 7.5 micrograms/mL.[1] Two children aged 3 and 7 months were given chloramphenicol 100 mg/kg daily, initially intravenously, and later orally for *Haemophilus influenzae* meningitis. The chloramphenicol levels halved over the first 2 days of treatment, while the children were receiving phenobarbital 10 mg/kg daily to prevent convulsions. One child had serum chloramphenicol levels of only 5 micrograms/mL even though the initial doses used were expected to give levels of 15 to 25 micrograms/mL.[2]

Another study confirmed that this interaction occurred in 20 neonates, but no statistically significant effect was found in 40 infants.[3] Decreased chloramphenicol levels have been described in a single case report of a child who was also taking phenytoin and phenobarbital. The serum chloramphenicol levels were 35.1 micrograms/mL before the antiepileptics were started, 19.1 micrograms/mL after 2 days of phenytoin, and 13.2 micrograms/mL a month after the addition of phenobarbital.[4] For more information on the interaction of chloramphenicol with phenytoin see 'Phenytoin + Chloramphenicol', p.633.

(b) Effects on phenobarbital

A man admitted to hospital on numerous occasions for pulmonary complications associated with cystic fibrosis, had average serum phenobarbital levels of 33 micrograms/mL while taking phenobarbital 200 mg daily and oral chloramphenicol 600 mg every 6 hours. One week after the antibacterial was withdrawn, his serum phenobarbital levels were 24 micrograms/mL even though the phenobarbital dose was increased from 200 to 300 mg daily.[5]

Mechanism

Phenobarbital is a potent liver enzyme inducer, which can increase the metabolism and clearance of chloramphenicol (clearly demonstrated in *rats*[6]), so that its serum levels fall and its effects are reduced. Chloramphenicol inhibits the metabolism of the phenobarbital (also demonstrated in *animals*[7]) so that the effects of the barbiturate are increased.

Importance and management

This interaction appears to be established. The documentation is limited but what happened is consistent with the recognised enzyme-inducing actions of phenobarbital and the inhibitory actions of chloramphenicol. Concurrent use should be well monitored to ensure that chloramphenicol serum levels are adequate, and that phenobarbital levels do not become too high (indicators of toxicity include drowsiness, ataxia or dysarthria). Make appropriate dose adjustments as necessary.

Clindamycin or Lincomycin + Food

The serum levels of lincomycin are markedly reduced (by up to two-thirds) if taken in the presence of food, but clindamycin is not significantly affected. Cyclamate sweeteners can also reduce the absorption of lincomycin.

Clinical evidence

In a study in 10 healthy subjects the mean peak serum levels of a single 500-mg oral dose of lincomycin were about 3 micrograms/mL when taken 4 hours before **breakfast**, 2 micrograms/mL when taken 1 hour before breakfast, and less than 1 microgram/mL when taken after breakfast. The mean total amounts of lincomycin recovered from the urine were 40.4 mg, 23.8 mg, and 8.9 mg, respectively.[1]

Reduced serum lincomycin levels due to the presence of **food** have been described in other reports,[2,3] but the absorption of clindamycin is not affected.[3,4]

Sodium cyclamate, an artificial sweetener found in diet foods, drinks and some pharmaceuticals, can also markedly reduce the absorption of lincomycin. The AUC of lincomycin 500 mg was reduced by about 75% by 1 Molar equivalent of **sodium cyclamate** (said to be an amount equal to only part of a bottle of diet drink, but exact quantity not stated).[5]

Mechanism

Not understood.

Importance and management

The food interaction with lincomycin is well established and of clinical importance. Lincomycin should not be taken with food or within several hours of eating a meal if adequate serum levels are to be achieved. An alternative is clindamycin, a synthetic derivative of lincomycin, which has the same antibacterial spectrum but is not affected by food.

Clindamycin or Lincomycin + Kaolin

Kaolin-pectin can markedly reduce the absorption of lincomycin. The rate but not the extent of clindamycin absorption is altered by kaolin.

Clinical evidence

In 8 healthy subjects about 85 mL of *Kaopectate* (kaolin-pectin) reduced the absorption of lincomycin 500 mg by about 90%. Giving the *Kaopectate* 2 hours before the antibacterial had little or no effect on its absorption, whereas when *Kaopectate* was given 2 hours after lincomycin, the absorption was reduced by about 50%. The absorption rate of clindamycin is markedly prolonged by kaolin, but the extent of its absorption remains unaffected.[1]

Mechanism

It seems probable that the lincomycin becomes adsorbed onto the kaolin, thereby reducing its bioavailability. The kaolin also coats the lining of the gut and acts as a physical barrier to absorption.[2]

Importance and management

Information seems to be limited to this study, but the interaction between lincomycin and kaolin appears to be established and of clinical importance. For good absorption and a good antibacterial response separate their administration as much as possible, ideally giving the kaolin at least 2 hours before the antibacterial. Clindamycin appears to be a suitable alternative to lincomycin. However, note that marked diarrhoea is an indication that lincomycin or clindamycin should be stopped immediately. This is because it may be a sign of pseudomembranous colitis, which can be fatal.

Clofazimine + Miscellaneous

The bioavailability of a single dose of clofazimine is increased by a high-fat meal, and slightly decreased by orange juice and an aluminium/magnesium hydroxide antacid.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study healthy subjects received a single 200-mg dose of clofazimine after a 12 hour fast (13 subjects), with 240 mL of **orange juice** (15 subjects), with a high-fat meal (15 subjects) or with 15 mL of an **aluminium**/**magnesium hydroxide** and **simeticone**-containing antacid given 9 hours before the clofazimine, at the time of dosing, and four times daily for the subsequent day. The high-fat meal increased the AUC and maximum plasma levels of clofazimine by 98% and 146%, respectively. The **orange juice** reduced the AUC and maximum plasma levels of clofazimine by 13% and 7%, respectively, and the **antacid** reduced the AUC and maximum plasma levels of clofazimine by 16% and 35%, respectively. There was wide inter-individual variation in each of the study groups.[1]

The clinical significance of the findings of this single-dose study with food is unclear; clofazimine has a half-life after repeated doses of about 70 days. The manufacturer advises that clofazimine is taken with meals.[2] The changes in clofazimine levels caused by the **antacid** and **orange juice** are small, and unlikely to be clinically relevant.

Colistin + Sucralfate

An *in vitro* study with colistin sulfate found that it became markedly and irreversibly bound to sucralfate at the pH values found in the gut.

Clinical evidence, mechanism, importance and management

To simulate what might happen in the gut, colistin sulfate 50 mg/L was mixed with sucralfate 500 mg in 40 mL of water at pH 3.5 and allowed to stand for 90 minutes at 25°C. Analysis of the solution showed that the colistin concentration fell rapidly and progressively over 90 minutes to about 40%. When the pH of the mixture was then raised to 6.5 to 7 for 90 minutes, there was no change in the concentration of colistin, suggesting that the interaction was irreversible.[1] The reason for this change is not known, but the suggestion is that sucralfate forms insoluble chelates with colistin.[1]

It is not known how important this interaction is likely to be in practice, but the efficacy of colistin in gut decontamination and gut infections may be decreased. Separating the doses might not be effective in some postoperative patients because their gastric function may not return to normal for up to 5 days, and some sucralfate might still be present when the next dose is given.[1] More study is needed to find out whether this interaction is clinically important, but in the meanwhile it would seem prudent to monitor concurrent use carefully, being alert for any evidence of reduced effects.

Co-trimoxazole + Azithromycin

Azithromycin does not alter the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given co-trimoxazole (trimethoprim and sulfamethoxazole) 960 mg daily for 7 days found that a single 1.2-g dose of azithromycin given on day 7 did not alter the pharmacokinetics of either trimethoprim or sulfamethoxazole to a clinically relevant extent.[1]

1. Amsden GW, Foulds G, Thakker K. Pharmacokinetic study of azithromycin with fluconazole and cotrimoxazole (trimethoprim-sulfamethoxazole) in healthy volunteers. *Clin Drug Invest* (2000) 20, 135–42.

Co-trimoxazole + Azoles

Fluconazole, but not ketoconazole inhibits the metabolism of sulfamethoxazole to its hydroxylamine metabolite.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given co-trimoxazole (sulfamethoxazole 800 mg with trimethoprim 160 mg) either alone or one hour after either **fluconazole** 150 mg or **ketoconazole** 200 mg. **Ketoconazole** had no effect on the urinary recovery of sulfamethoxazole or its metabolites. However, **fluconazole** significantly inhibited the formation of sulfamethoxazole hydroxylamine and also inhibited the oxidation of sulfamethoxazole to its 5-methylhydroxy- and 5-methylhydroxy acetate metabolites. The amount of unchanged sulfamethoxazole or its *N*-acetyl or glucuronide metabolites were not affected by **fluconazole**.[1] Another study in HIV-positive patients given co-trimoxazole (sulfamethoxazole 800 mg with trimethoprim 160 mg daily) found that **fluconazole** 200 mg daily decreased the AUC, urinary recovery, and formation clearance of sulfamethoxazole hydroxylamine by 37%, 53% and 61% respectively.[2] As the hydroxylamine metabolite is possibly one of the causes of sulfamethoxazole toxicity, the concurrent use of **fluconazole** may be associated with reduced rates of sulfamethoxazole toxicity.[1,2]

Evidence about other azoles appears to be lacking, but they would, in general, be expected to interact similarly.

Co-trimoxazole + Cimetidine

Cimetidine has no significant effect on the pharmacokinetics of co-trimoxazole.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 6 healthy subjects were given cimetidine 400 mg every 6 hours for 6 days, with a single 960-mg dose of co-trimoxazole (trimethoprim with sulfamethoxazole) on day 6. Although trimethoprim levels were consistently higher in the presence of cimetidine, the slight difference was not statistically significant. Cimetidine had no effect on the pharmacokinetics of sulfamethoxazole.[1]

1. Rogers HJ, James CA, Morrison PJ, Bradbrook ID. Effect of cimetidine on oral absorption of ampicillin and co-trimoxazole. *J Antimicrob Chemother* (1980) 6, 297–300.

Co-trimoxazole + Kaolin-pectin

Kaolin-pectin can cause a small but probably clinically unimportant reduction in trimethoprim levels, and has no effect on sulfamethoxazole pharmacokinetics.

Clinical evidence, mechanism, importance and management

Co-trimoxazole suspension (trimethoprim 160 mg with sulfamethoxazole 800 mg) was given to 8 healthy subjects, with and without 20 mL of kaolin-pectin suspension. Kaolin-pectin reduced the AUC and the maximum serum levels of trimethoprim by about 12% and 20%, respectively. Changes in the sulfamethoxazole pharmacokinetics were not statistically significant.[1] The probable reason for this reduction in the trimethoprim AUC is that trimethoprim is adsorbed onto the kaolin-pectin, which reduces the amount available for absorption. However, the reduction is small and unlikely to be clinically relevant.

1. Gupta KC, Desai NK, Satoskar RS, Gupta C, Goswami SN. Effect of pectin and kaolin on bioavailability of co-trimoxazole suspension. *Int J Clin Pharmacol Ther Toxicol* (1987) 25, 320–1.

Co-trimoxazole + Prilocaine/Lidocaine cream

Methaemoglobinaemia developed in a baby treated with co-trimoxazole when *Emla* (prilocaine/lidocaine) cream was applied to his skin. Other drugs that cause methaemoglobinaemia are predicted to have similar effects.

Clinical evidence, mechanism, importance and management

A 12-week-old child, given co-trimoxazole for 2 months for pyelitis, was given 5 g of *Emla* cream (prilocaine 25 mg and lidocaine 25 mg per gram) applied to the back of his hands and the cubital regions. Unfortunately his operation was delayed, and 5 hours later, just before the operation began, his skin was noted to be pale and his lips had a brownish cyanotic colour. This was found to be due to the presence of 28% methaemoglobin (reference range less than 3%).[1] The authors of the report suggest that prilocaine together with sulfamethoxazole (both known to cause methaemoglobin formation) suppressed the activity of two enzymes (NADH-dehydrogenase and NADP-diaphorase), which normally keep blood levels of methaemoglobin to a minimum.[1] A study in 20 children[2] confirmed that *Emla* cream can increase methaemoglobin levels, although levels *decreased* in 6 of them. However, the maximum increase was 1.2% (from 0.7 to 1.9%), and the highest value was 2%, which was still within the reference range. Another study found similar small increases in methaemoglobin levels, and found that these remained elevated after 24 hours. The authors concluded that daily application of prilocaine with lidocaine may lead to accumulation, and a greater risk of toxicity.[3]

The case report appears to be unusual, but it has been suggested that there may be a special risk of methaemoglobinaemia with *Emla* in children with pre-existing anaemia, reduced renal excretion of the metabolites of prilocaine, or the concurrent use of sulfonamides.[3] It would seem prudent to keep *Emla* contact time to a minimum in these patients. Note that the UK and US manufacturers advise that *Emla* should not be applied to the skin of infants who are under the age of 12 months who are receiving treatment with methaemoglobin-inducing drugs. They specifically name the **sulfonamides**.[4] In addition, the manufacturers name a number of other drugs that they suggest may cause methaemoglobinaemia. This includes **aminosalicylic acid**, **benzocaine**, **chloroquine**, **dapsone**, **metoclopramide**, **nitrates**, **nitrofurantoin**, **nitroprusside**, **paracetamol** (**acetaminophen**), **phenacetin**, **phenobarbital**, **phenytoin**, and **primaquine**.[4,5]

Co-trimoxazole or Trimethoprim + Rifamycins

The pharmacokinetics of trimethoprim are not significantly affected by rifabutin, and probably not by rifampicin (rifampin). Trimethoprim does not affect the pharmacokinetics of rifampicin.

Rifabutin does not affect the pharmacokinetics of sulfamethoxazole, but significantly increases exposure to its hydroxylamine

metabolite and as a result may increase adverse reactions to sulfamethoxazole in HIV-positive patients.
A significant reduction in co-trimoxazole levels and a decrease in prophylactic efficacy has been seen in HIV-positive patients taking rifampicin. Limited evidence suggests that co-trimoxazole can increase rifampicin levels.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

Twelve HIV-positive patients taking co-trimoxazole (sulfamethoxazole and trimethoprim; strength not stated) twice daily for 7 days were also given rifabutin 300 mg daily for a further 14 days. The sulfamethoxazole component remained unaffected by rifabutin but the trimethoprim AUC was decreased by 22%. This small reduction is not expected to be clinically significant.[1] However, another study in HIV-positive patients given co-trimoxazole (sulfamethoxazole 800 mg with trimethoprim 160 mg daily) found that although rifabutin 300 mg daily had minimal effects on the disposition of sulfamethoxazole and its acetylated metabolite, it significantly increased the AUC, urinary recovery and formation clearance of its hydroxylamine metabolite by about 50%. As the hydroxylamine metabolite may be one of the factors associated with adverse reactions to sulfamethoxazole in HIV-positive patients, concurrent rifabutin may increase the rate of adverse reactions.[2]

(b) Rifampicin (Rifampin)

No significant pharmacokinetic interaction seems to occur when healthy subjects are given trimethoprim 240 mg daily with rifampicin 900 mg daily (both in divided doses). After 4 to 5 days, less trimethoprim is recovered in the urine, as more is metabolised before excretion due to the enzyme-inducing effects of rifampicin, but this does not appear to be of clinical importance.[3,4] Another study also notes that no clinically significant pharmacokinetic interaction occurs between trimethoprim and rifampicin.[5]

However, a case-control study of the efficacy of co-trimoxazole in preventing toxoplasmosis in HIV-positive patients found a link between rifampicin use and co-trimoxazole failure,[6] which prompted the authors to conduct a pharmacokinetic study. When rifampicin 600 mg daily was given to 10 HIV-positive patients with co-trimoxazole 960 mg daily, it was found that the AUCs of trimethoprim and sulfamethoxazole were reduced by 56% and 28%, respectively. These changes are sufficient to reduce the efficacy of co-trimoxazole treatment.[7] It would therefore seem prudent to consider this interaction when giving rifampicin to HIV-positive patients taking co-trimoxazole prophylaxis.

In one study, 15 patients with tuberculosis, who had taken rifampicin 450 mg daily for at least 15 days, were given co-trimoxazole (trimethoprim 320 mg and sulfamethoxazole 800 mg every 12 hours) for 5 to 10 days. Rifampicin levels were measured at five time points over 6 hours before and during co-trimoxazole treatment. At 4 and 6 hours, rifampicin levels were significantly higher (27% and 56%, respectively) during co-trimoxazole use, but peak levels were only increased by about 18%. Concurrent use did not result in any increase in adverse effects.[8]

Co-trimoxazole + Salbutamol (Albuterol)

Salbutamol reduces the rate but increases the extent of sulfamethoxazole absorption.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects, oral salbutamol 4 mg four times daily for 2 weeks had no effect on the pharmacokinetics of a single 400-mg oral dose of sulfamethoxazole (given as co-trimoxazole), although the absorption rate constant was reduced by about 40% and the extent of absorption over 72 hours was increased by 23%.[1] A possible reason for these effects is that salbutamol stimulates the beta receptors in the gut, causing relaxation, which allows an increased contact time, and therefore increased absorption of sulfamethoxazole.[1] The clinical significance of this interaction is unknown, but it seems unlikely to be of importance. No interaction would be expected with inhaled salbutamol.

Cycloserine + Ethionamide

Neurotoxic adverse effects may be potentiated by the concurrent use of cycloserine and ethionamide.

Clinical evidence, mechanism, importance and management

Three cases of encephalopathy have been reported in patients taking antimycobacterial regimens that included ethionamide (and in 2 cases, isoniazid): in one case symptoms occurred during the concurrent use of ethionamide and cycloserine. All 3 patients recovered after the withdrawal of either ethionamide (and isoniazid) or cycloserine, and treatment with nicotinamide and other vitamin B compounds.[1] The manufacturers note that the concurrent use of ethionamide can potentiate the neurotoxic adverse effects of cycloserine.[2,3] The US manufacturer of ethionamide notes that convulsions have been reported in patients also taking cycloserine and they recommend special care with treatment regimens that include both drugs.[4]

4. Trecator (Ethionamide). Wyeth Pharmaceuticals Inc. US Prescribing information, November 2007.

Cycloserine + Isoniazid

The adverse CNS effects of cycloserine are increased by isoniazid.

Clinical evidence, mechanism, importance and management

A report describes both an increase and a decrease in serum cycloserine levels in some subjects, which were apparently caused by isoniazid; however, the mean level of cycloserine was not significantly changed. Only one out of 11 patients taking cycloserine alone developed adverse effects (drowsiness, dizziness, unstable gait), but when isoniazid was added, 9 of the 11 developed these effects.[1] The manufacturers recommend monitoring for these adverse effects if both drugs are given and adjusting the doses as necessary to manage them.[2,3]

Cycloserine + Miscellaneous

Orange juice and an aluminium/magnesium hydroxide-containing antacid do not affect the pharmacokinetics of cycloserine, but a high-fat meal delays its absorption.

Clinical evidence, mechanism, importance and management

(a) Antacids

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not affected by 15 mL of an antacid containing **aluminium/magnesium hydroxide** and **simeticone** (*Mylanta*) was given 9 hours before the cycloserine, at the same time as the cycloser-

ine, immediately after meals, and at bedtime on both the dosing day and the following day.[1]

(b) Food

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of cycloserine was not significantly affected by 240 mL of **orange juice**.[1] When cycloserine 500 mg was given 15 minutes after the start of a high-fat meal, which was completed within 30 minutes, its AUC was not affected, but its maximum serum levels were reduced by about 16% and the time to maximum levels was increased from 45 minutes to 3.5 hours. The authors suggest that, in patients with relatively low plasma levels or patients receiving once rather than twice daily doses, it is possible that the delay in absorption could result in increased periods of sub-inhibitory levels.[1] However, there is no evidence to suggest that this is clinically significant.

Dapsone + Antacids

The absorption of dapsone is unaltered by an antacid containing aluminium/magnesium hydroxide and/or simeticone.

Clinical evidence, mechanism, importance and management

A study to see whether changes in gastric pH might affect the absorption of dapsone found that when a single 100-mg dose of dapsone was taken with the second of 11 doses of **aluminium/magnesium hydroxide** and **simeticone** (*Mylanta II*), given every hour, the absorption of the dapsone remained unchanged. The mean gastric pH rose from 2.3 before using the antacid, to 4.5 or higher while taking dapsone and the antacid.[1] In another study, 8 subjects were given a single 100-mg dose of dapsone as a liquid oral preparation followed immediately by 12.5 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox TC*). The peak plasma levels of dapsone were increased by about 11% and the time to peak levels was reduced from 1.9 hours to 1.3 hours. However, the dapsone AUC and elimination rate were not affected.[2] No special precautions would therefore seem to be needed if *Mylanta II*, *Maalox TC* or any other similar antacid is used with dapsone. See also 'NRTIs + Dapsone', p.946, for a discussion of the effects of the buffer in didanosine tablets on dapsone absorption.

Dapsone + Clarithromycin

Clarithromycin does not alter the metabolism of dapsone.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given single 100-mg doses of dapsone before and after taking clarithromycin 1 g twice daily for 10 days, found that the clearance of dapsone was unchanged. Of equal importance was finding that the AUC of the *N*-hydroxylation metabolite of dapsone, which appears to be responsible for its haematological toxicity (methaemoglobinaemia), was also unchanged.[1]

In another study, 11 HIV-positive patients were given dapsone 100 mg daily then clarithromycin 500 mg twice daily for 2 weeks. Clarithromycin had no effect on dapsone clearance or on the production of the hydroxylamine metabolite of dapsone.[2] These results suggest that the cytochrome P450 isoenzyme CYP3A4, which is inhibited by clarithromycin, is not involved in dapsone metabolism.[2]

Clarithromycin would not be expected to alter the toxicity of dapsone, and no special precautions are required during concurrent use.

Dapsone + Clofazimine

Dapsone can reduce the anti-inflammatory effects of clofazimine. Clofazimine does not affect the pharmacokinetics of dapsone.

Clinical evidence, mechanism, importance and management

Fourteen out of 16 patients with severe recurrent erythema nodosum leprosum (ENL) did not respond adequately when given dapsone and clofazimine and needed additional treatment with corticosteroids. When the dapsone was stopped the patients responded to clofazimine alone, and in some instances the ENL was controlled by smaller doses.[1] Further evidence of this interaction comes from a laboratory study, which suggests that the actions of clofazimine may be related to its ability to inhibit neutrophil migration (resulting in decreased numbers of neutrophils in areas of inflammation), whereas dapsone can have the opposite effect.[1] Although the information is very limited, it would seem prudent to avoid the concurrent use of dapsone and clofazimine in the treatment of ENL. The authors of this report[1] are at great pains to emphasise that what they describe only relates to the effects of dapsone on the anti-inflammatory effects of clofazimine, and not to the beneficial effects of concurrent use when treating drug-resistant *Mycobacterium leprae*.

A study in patients taking clofazimine and dapsone[2] and 4 other studies in patients also taking isoniazid or rifampicin suggest that clofazimine does not affect the pharmacokinetics of dapsone.[3-6] However, one earlier study[7] found that clofazimine transiently increased the renal excretion of dapsone in 9 of 17 patients with leprosy who had recently discontinued dapsone.

Dapsone + Drugs that affect gastric pH

Cimetidine raises serum dapsone levels, and may reduce methaemoglobinaemia due to the hydroxylamine metabolite of dapsone. Cimetidine, ranitidine and omeprazole do not appear to affect the outcome of dapsone prophylaxis against pneumocystis pneumonia. The absorption of dapsone does not appear to be altered by nizatidine-induced increases in gastric pH.

Clinical evidence, mechanism, importance and management

In 7 healthy subjects **cimetidine** 400 mg three times daily for 3 days increased the AUC of a single 100-mg dose of dapsone by 40%.[1] The probable reason for this effect is that the **cimetidine** (a known non-specific enzyme inhibitor) inhibits the metabolism of the dapsone by the liver. Although this might be expected to increase the risk of haematological adverse effects of dapsone by raising its serum levels, **cimetidine** also apparently markedly reduces the production of the hydroxylamine metabolite of dapsone (the AUC fell by more than half). Dapsone hydroxylamine appears to be responsible for the methaemoglobinaemia and haemolysis that may occur with dapsone.[1] These findings were later confirmed in 6 patients taking long-term dapsone 75 to 350 mg daily who were given **cimetidine** 1.2 g daily for 2 weeks. Steady-state serum dapsone levels rose by about 47%, accompanied by a fall in serum methaemoglobin levels from 7.1% to 5.2% (reference range less than 2%) in the first week.[2] Similar findings were reported in a further 3-month study in 8 patients.[3] However, a sustained decrease in methaemoglobin was not seen, with levels returning to baseline at week 12, despite the continued use of **cimetidine**.[3] Another report based on a small number of patients, comparing those given **cimetidine**, **ranitidine** or **omeprazole** with those not tak-

ing acid suppression, found no difference in the outcome of dapsone prophylaxis for pneumocystis pneumonia in HIV-positive patients.[4] A study in healthy subjects found that the increase in pH produced by **nizatidine** did not result in any clinically significant changes in the rate or extent of dapsone absorption.[5] It would therefore seem that no additional precautions are needed if H_2-receptor antagonists or proton pump inhibitors are given to patients taking dapsone. Dapsone + Fluconazole

Fluconazole decreases the production of the toxic metabolite of dapsone, and might therefore reduce the incidence of adverse reactions to dapsone.

Clinical evidence, mechanism, importance and management

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then in random order either fluconazole 200 mg daily, rifabutin 300 mg daily or fluconazole with rifabutin, each for 2 weeks. Dapsone pharmacokinetics were unaffected by fluconazole. However, fluconazole inhibited the production of the *N*-hydroxylamine metabolite of dapsone (AUC, urinary recovery, and formation clearance reduced by about 50%).[1]

Hydroxylamine is assumed to be responsible for the haematological toxicity of dapsone (methaemoglobinaemia). The findings of this study suggest that the production of this metabolite is mediated by the cytochrome P450 isoenzyme CYP2C9, which fluconazole inhibits.

On the basis of these results, fluconazole would not be expected to alter the efficacy of dapsone, but might reduce its toxicity. Further study is needed to assess this potential.

Dapsone + Probenecid

The serum levels of dapsone can be markedly raised by probenecid.

Clinical evidence

Twelve patients with quiescent tuberculoid leprosy were given dapsone 300 mg with probenecid 500 mg, and 5 hours later another 300-mg dose of dapsone. At 4 hours, the dapsone serum levels were raised by about 50%. The urinary excretion of dapsone and its metabolites were reduced.[1]

Mechanism

Not fully examined. It seems probable that the probenecid inhibits the renal excretion of dapsone by the kidney.

Importance and management

The documentation is very limited. It is likely that the probenecid will raise the serum levels of dapsone given long-term. The importance of this is uncertain, but the extent of the rise and evidence that the haematological toxicity of dapsone may be related to dapsone levels[2] suggests that it may well have some clinical importance. It would therefore seem prudent to monitor for dapsone adverse effects if probenecid is also given.

Dapsone + Proguanil

No pharmacokinetic interaction appears to occur between dapsone and proguanil, and they have been successfully used together for malaria prophylaxis.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that proguanil 200 mg daily had no effect on the pharmacokinetics of dapsone 10 mg daily, nor on its principal metabolite, monoacetyldapsone. The authors of this report are extremely cautious because, despite this lack of a pharmacokinetic interaction at these doses, they say that increased dapsone toxicity cannot be ruled out.[1] However, dapsone 25 mg was successfully used with proguanil 200 mg daily for malaria prophylaxis in the Vietnam war,[2] and the same regimen, but with the dapsone dose every third day was successful as prophylaxis against proguanil-resistant falciparum malaria in Papua New Guinea.[1] Moreover, a different dose (dapsone 4 or 12.5 mg with proguanil 200 mg daily), was well tolerated over a period of 80 days when used as malaria prophylaxis in Thailand.[3]

Dapsone + Pyrimethamine

Pyrimethamine does not significantly affect the pharmacokinetics of dapsone.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects given single doses of dapsone 100 mg, pyrimethamine 25 mg, or both drugs together found that the peak plasma levels of dapsone fell by 17%, its half-life was unchanged, and the apparent volume of distribution was increased by 26% (from 1.53 to 1.93 L/kg). The pharmacokinetics of pyrimethamine were not affected by dapsone.[1] In another study HIV-positive patients were given dapsone 200 mg weekly (the maximum tolerated dose) either alone or with pyrimethamine 25 mg weekly. In contrast to the earlier study, there was a *decrease* in the volume of distribution of dapsone when it was given with pyrimethamine, although dapsone levels were not significantly altered.[2] Furthermore, the tolerability of once-weekly dapsone with pyrimethamine was found to be similar to that of once-weekly dapsone alone.[2]

Dapsone + Rifamycins

Rifampicin (rifampin) increases the urinary excretion of dapsone, lowers its serum levels and increases the risk of toxicity (methaemoglobinaemia). Similarly, rifabutin increases the clearance of dapsone, and may also increase its toxicity.

Clinical evidence

(a) Rifabutin

Twelve HIV-positive patients were given dapsone 100 mg daily for 2 weeks and then, in random order, either rifabutin 300 mg daily, fluconazole 200 mg daily, or fluconazole with rifabutin, each for 2 weeks. Rifabutin alone increased the clearance of dapsone by 67%. When combined with fluconazole, rifabutin increased the clearance of dapsone by 38%, which shows that fluconazole (a known enzyme inhibitor) partially attenuates the enzyme-inducing effects of rifabutin. Rifabutin increased the formation clearance of dapsone by 92%, which was again attenuated by

fluconazole. Rifabutin did not affect the AUC of the hydroxylamine metabolite of dapsone, which is thought to be associated with dapsone toxicity.[1]

Similarly, in a population analysis of 60 HIV-positive children, 7 of whom were also receiving rifabutin, factors associated with increased dapsone clearance included rifabutin use. It was suggested that dapsone clearance was increased by 38 to 50% in these children.[2]

(b) Rifampicin (Rifampin)

A study in 7 patients with leprosy given single doses of dapsone 100 mg and rifampicin 600 mg, alone or together, found that while the pharmacokinetics of rifampicin were not significantly changed, the half-life of dapsone was roughly halved and the AUC was reduced by about 20%.[3] Other studies in patients given both drugs for several days, similarly found reduced dapsone serum levels and an increased urinary excretion.[4-8] Likewise, a study in HIV-positive adults also found lowered dapsone levels in the presence of rifampicin.[9] Another study in 12 healthy subjects given a single 100-mg dose of dapsone before and after taking rifampicin 600 mg daily for 10 days, found that the clearance of dapsone was increased more than 3.5-fold (from 2.01 to 7.17 L/hour). Of equal importance was the finding that the production of the hydroxylamine metabolite of dapsone, which appears to be responsible for the haematological toxicity (methaemoglobinaemia), was markedly increased. The 24-hour AUC of methaemoglobin was increased by more than 60%,[10] suggesting that this interaction increases dapsone toxicity.

Mechanism

Rifampicin and rifabutin increase the metabolism and clearance of dapsone. Rifampicin also increases the blood levels of the toxic hydroxylamine metabolite of dapsone. Similarly, rifabutin increased the formation of this metabolite, although increases in the AUC were not seen.

Importance and management

The interaction between dapsone and rifampicin is established but of uncertain clinical importance. Concurrent use should be well monitored to confirm that treatment is effective. It may be necessary to raise the dose of dapsone. It has been pointed out that there is the risk of treatment failures for pneumocystis pneumonia as well as for leprosy.[11] Also be alert for any evidence of methaemoglobinaemia.

Although there is less information, rifabutin appears to interact similarly to rifampicin. When dapsone is given with rifabutin, the dose of dapsone may need to be increased, but this may increase exposure to the potentially toxic hydroxylamine metabolite.[1]

Dapsone + Trimethoprim

The serum levels of both dapsone and trimethoprim are possibly raised by concurrent oral use. Both increased efficacy and dapsone toxicity have been seen. Topical dapsone levels are also raised by trimethoprim given as co-trimoxazole.

Clinical evidence

Eighteen patients with AIDS, treated for pneumocystis pneumonia and taking dapsone 100 mg daily, were compared with 30 other patients taking dapsone with trimethoprim 20 mg/kg daily. Trimethoprim raised dapsone levels by 40% (from 1.5 to 2.1 micrograms/mL), at 7 days (steady-state). Dapsone toxicity (methaemoglobinaemia) was also increased.[1] Trimethoprim plasma levels were 48% higher in the 30 patients also taking dapsone when compared with another group of 30 patients given co-trimoxazole (trimethoprim with sulfamethoxazole), but the incidence of toxicity was higher in the co-trimoxazole group.[1] However, a later study by the same authors in 8 asymptomatic HIV-positive patients given dapsone 100 mg daily and trimethoprim 200 mg every 12 hours found that the steady-state pharmacokinetics of each drug was unaffected by the other, although the single dose pharmacokinetics indicated higher serum levels than at steady state for both drugs.[2]

A study in 17 patients with acne vulgaris who applied dapsone 5% gel topically, and took co-trimoxazole (trimethoprim with sulfamethoxazole) 960 mg twice daily, found no significant change in the pharmacokinetics of either trimethoprim or sulfamethoxazole. In contrast, the AUC and maximum plasma level of dapsone were increased by 45% and 39%, respectively. Further, the AUC and maximum plasma level of dapsone hydroxylamine, the metabolite responsible for the haematological adverse effects, were increased by 145% and 113%, respectively. However, these parameters were still lower than would be expected after an oral dose of dapsone 100 mg.[3]

Mechanism

Not understood. Dapsone and trimethoprim appear to have mutually inhibitory effects on clearance.

Importance and management

Information is limited. The difference between the results of the two studies using oral dapsone may be because the first was in patients with AIDS and pneumocystis pneumonia and the second was in asymptomatic HIV-positive patients whose drug metabolism may possibly be different. Concurrent use appears to be an effective form of treatment, but be alert for evidence of increased dapsone toxicity (methaemoglobinaemia). No adverse effects would be expected if topical dapsone is given with oral trimethoprim or co-trimoxazole.

Dapsone + Ursodeoxycholic acid (Ursodiol)

A single case suggests that the effectiveness of dapsone in the treatment of dermatitis herpetiformis may be reduced by ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A 61-year-old man taking dapsone 50 mg daily for dermatitis herpetiformis started taking ursodeoxycholic acid 450 mg twice daily for cholecystitis. Two weeks later the dermatitis herpetiformis worsened and the dose of dapsone was increased to 150 mg daily. However, his condition did not improve, so ursodeoxycholic acid was stopped and, as his condition improved, the dapsone dose was reduced to 100 mg, and then 50 mg daily. Two months later ursodeoxycholic acid was restarted and there was again an exacerbation of the dermatitis herpetiformis.[1] This case appears to have also been published elsewhere.[2] The general importance of this isolated report is unknown, but consider the possibility of reduced dapsone effects if ursodeoxycholic acid is also given.

Daptomycin + Aminoglycosides

The pharmacokinetics of daptomycin are not altered by gentamicin or tobramycin. The pharmacokinetics of tobramycin are not altered by daptomycin.

Clinical evidence, mechanism, importance and management

(a) Gentamicin

In a crossover study in 11 healthy subjects who were given intravenous daptomycin 6 mg/kg daily for 3 days with 1 mg/kg gentamicin given every 8 hours starting after the second dose of daptomycin, there were no clinically significant changes in the pharmacokinetics of daptomycin.[1] No daptomycin dose adjustment therefore seems necessary on concurrent use.

(b) Tobramycin

In a crossover study, 6 healthy subjects were given daptomycin 2 mg/kg, tobramycin 1 mg/kg, or both drugs together. There was no change in the pharmacokinetics of either drug.[2] No dose adjustment of either drug would be expected to be necessary on concurrent use.

2. Woodworth JR, Nyhart EH, Wolny JD, Brier GL, Black HR. Tobramycin and daptomycin disposition when co-administered to healthy volunteers. *J Antimicrob Chemother* (1994) 33, 655–9.

Daptomycin + Miscellaneous

The use of statins, probably fibrates and possibly ciclosporin with daptomycin may increase the risk of muscle toxicity. Daptomycin does not appear to interact with warfarin, but its use may result in falsely elevated prothrombin times. NSAIDs may reduce daptomycin excretion and concurrent use may increase the risks of renal impairment. Probenecid and aztreonam do not appear to affect the pharmacokinetics of daptomycin.

Clinical evidence, mechanism, importance and management

(a) Drugs causing myopathy

The US manufacturers describe a study in 20 healthy subjects taking **simvastatin** 40 mg daily, in which the addition of daptomycin 4 mg/kg per day for 14 days did not result in an increase in adverse effects, when compared with subjects given placebo. In contrast, in a phase III study of patients with bacteraemia, 5 out of 22 patients who were currently, or had recently, been taking a **statin** developed raised creatinine phosphokinase levels.[1] Furthermore, a case report describes a patient who was given daptomycin 6.5 mg/kg daily, who developed muscle pain and a raised creatinine phosphokinase level (20 771 units/L). He had been taking **simvastatin**, but this had been discontinued when the daptomycin was started.[2] It is difficult to know whether this was a result of an interaction as another case of rhabdomyolysis (creatinine phosphokinase 21 243 units/L) was attributed to the use of daptomycin alone: the patient was taking no other drugs known to cause myopathy (fibrates and statins specifically mentioned).[3] A review of patients with Gram-positive complicated skin and skin structure infections found that musculoskeletal pain or myalgia occurred in up to 0.4% of patients. In patients with similar infections treated with daptomycin the incidence of myopathy was slightly higher, at 0.2 to 0.9%,[4] suggesting that daptomycin may modestly increase the risk of muscle toxicity.

The manufacturers note that experience of the concurrent use of daptomycin with statins is limited, and therefore the use of a statin should be suspended if daptomycin is given,[1,5] unless the benefits of concurrent use outweigh the risks, in which case the patient's creatine kinase should be monitored more frequently than weekly.[5] See also 'muscle toxicity', (p.1313), for further guidance on monitoring for statin-associated myopathy, and risk factors for muscle toxicity. The UK manufacturers give the same guidance for **fibrates** and **ciclosporin**, both of which have been associated with myopathy.[1]

(b) NSAIDs

The UK manufacturers note that NSAIDs (including coxibs) may reduce the renal excretion of daptomycin and have additive detrimental effects on renal function if used with daptomycin.[5] They advise caution on concurrent use, which in practice probably means keeping a close eye on renal function and monitoring for possible daptomycin adverse effects.

(c) Warfarin

The US manufacturers describe a study in 16 healthy subjects in which daptomycin 6 mg/kg daily for 5 days did not affect either the pharmacokinetics or the INR in response to a single 25-mg dose of warfarin. The pharmacokinetics of daptomycin were also unchanged.[1] However, as experience is limited the manufacturers advise monitoring the INR for the first few days of concurrent use. Note that daptomycin causes a concentration-dependent false prolongation of the prothrombin time.[1,5] This only appears to occur with recombinant thromboplastin reagents. Blood for INR testing should therefore be drawn during the daptomycin trough (i.e. immediately before the next dose). If a raised INR is found it is recommended that the INR should be re-tested, and alternative methods of monitoring should be considered.[1]

(d) Miscellaneous

The US manufacturers[1] briefly mention a small study in which daptomycin was given with **aztreonam** without any significant change in the pharmacokinetics of either drug. They also mention a study in which **probenecid** did not alter the pharmacokinetics of daptomycin.

Ethambutol + Antacids

Aluminium hydroxide and aluminium/magnesium hydroxide can cause a small reduction in the absorption of ethambutol in some patients.

Clinical evidence, mechanism, importance and management

A study in 13 patients with tuberculosis, given a single 50-mg/kg dose of ethambutol, found that when they were also given three 1.5-g doses of **aluminium hydroxide gel** (at the same time and 15 and 30 minutes later) their peak serum ethambutol levels were delayed and reduced. The average urinary excretion of ethambutol over a 10-hour period was reduced by about 15%, but there were marked variations between individual patients. In some patients there was no interaction, and the absorption of ethambutol was even increased in others.[1] No interaction was seen in 6 healthy subjects similarly treated.[1] A further study in 14 healthy subjects found that 30 mL of an **aluminium/magnesium hydroxide** antacid decreased the AUC and maximum serum levels of a 25-mg/kg dose of ethambutol by 10% and 29%, respectively.[2]

The reason for this interaction is not understood, but **aluminium hydroxide** can affect gastric emptying. The reduction in absorption is generally small and variable, and it seems doubtful if it will have a significant effect on the treatment of tuberculosis. However, the authors of the second study suggest avoiding giving antacids at the same time as ethambutol,[2] and the US manufacturer states that **aluminium hydroxide**-containing antacids should not be taken until 4 hours after a dose of ethambutol.[3]

1. Mattila MJ, Linnoila M, Seppälä T, Koskinen R. Effect of aluminium hydroxide and glycopyrrhonium on the absorption of ethambutol and alcohol in man. *Br J Clin Pharmacol* (1978) 5, 161–6.

3. Myambutol (Ethambutol). X-Gen Pharmaceuticals Inc. US Prescribing information, May 2007.

Ethambutol + Food

The pharmacokinetics of ethambutol given with a high-fat breakfast were only slightly different to its pharmacokinetics when it is

given in the fasting state.[1] Therefore ethambutol may be given without regard to meals.

1. Peloquin CA, Bulpitt AE, Jaresko GS, Jelliffe RW, Childs JM, Nix DE. Pharmacokinetics of ethambutol under fasting conditions, with food, and with antacids. *Antimicrob Agents Chemother* (1999) 43, 568–72.

Ethambutol + Rifabutin

Rifabutin does not appear to affect the pharmacokinetics of ethambutol.

Clinical evidence, mechanism, importance and management

Ten healthy subjects were given a single 1.2-g dose of ethambutol before and after taking rifabutin 300 mg daily for a week. No clinically relevant changes in the pharmacokinetics of ethambutol were seen.[1] Although 5 of the subjects experienced moderate to severe chills, and one had transient thrombocytopenia, these reactions are unlikely to have been due to an interaction. No special precautions would appear to be necessary during concurrent use.

Ethionamide + Isoniazid

Isoniazid may contribute to acute psychotic reactions associated with ethionamide, but evidence for this is limited.

Clinical evidence, mechanism, importance and management

Acute psychotic reactions occurring during treatment with either isoniazid or ethionamide are reported to be uncommon.[1] Acute mania occurred in a patient taking streptomycin, isoniazid and prednisolone for 4 months, and ethionamide and pyrazinamide for 27 days. It was thought that ethionamide was probably responsible for the psychotic reaction but that isoniazid and prednisolone may have potentiated the reaction.[2] In another patient, ethionamide was considered to be responsible for psychological changes, which resolved when the drug was stopped. However, the contribution of alcohol and other concurrent drugs such as isoniazid was not ruled out.[3] One study in patients found that ethionamide 750 mg increased the serum levels of a single 10-mg/kg dose of isoniazid at 4 hours but not at one or 10 hours, but this was not considered to be of therapeutic significance[4] and the toxic symptoms reported with the combination[5,6] were considered not to be due to increased isoniazid levels.[4]

A clinically significant interaction therefore seems unlikely, but as both drugs can, rarely, cause psychotic reactions these tentative reports cannot entirely be dismissed.

6. Trendelenburg F. Antibakterielle chemotherapie der tuberkulose. *Fortschr Arzneimittelforsch* (1964) 7, 193–303.

Ethionamide + Miscellaneous

A study in 12 healthy subjects found that the bioavailability of a single 500-mg dose of ethionamide was not significantly affected by food, orange juice or antacids, when compared with ethionamide bioavailability under fasting conditions. It was suggested that ethionamide may be given with food if tolerance is a problem.[1] The US manufacturer of ethionamide advises that it may be taken without regard to meals.[2]

2. Trecator (Ethionamide). Wyeth Pharmaceuticals Inc. US Prescribing information, November 2007.

Fosfomycin + Cimetidine

In a study in 9 healthy subjects, the pharmacokinetics of a 50-mg dose of fosfomycin were not significantly altered by two 400 mg doses of cimetidine, given the night before and 30 minutes before the fosfomycin.[1]

1. Bergan T, Mastropaolo G, Di Mario F, Naccarato R. Pharmacokinetics of fosfomycin and influence of cimetidine and metoclopramide on the bioavailability of fosfomycin trometamol. New Trends in Urinary Tract Infections (eds Neu and Williams) Int Symp Rome 1987, p 157–66. Published in 1988.

Fosfomycin + Metoclopramide

Metoclopramide reduces fosfomycin bioavailability.

Clinical evidence, mechanism, importance and management

Metoclopramide 20 mg given to 9 healthy subjects 30 minutes before fosfomycin 50 mg/kg reduced the peak serum levels of fosfomycin by 42% and reduced the AUC by 27%. These changes appear to occur because metoclopramide speeds the transit through the gut, so that less time is available for good absorption. However, despite these reductions, the urinary concentrations of fosfomycin remained above the minimum levels required for common urinary pathogens for at least 36 hours after the dose.[1] This suggests that the interaction is unlikely to be clinically important.

1. Bergan T, Mastropaolo G, Di Mario F, Naccarato R. Pharmacokinetics of fosfomycin and influence of cimetidine and metoclopramide on the bioavailability of fosfomycin trometamol. New Trends in Urinary Tract Infections (eds Neu and Williams) Int Symp Rome 1987, p 157–66. Published in 1988.

Fusidic acid + Colestyramine

***In vitro* studies have shown that colestyramine can bind with sodium fusidate in the gut, thereby reducing its activity,[1] and *in vivo animal* studies have shown peak fusidate levels are decreased by 33 to 77% by colestyramine,[2] but whether this also occurs clinically has not been confirmed. It is generally recommended that other drugs are given one hour before or 4 to 6 hours after colestyramine.**

Isoniazid + Aminosalicylic acid

Isoniazid levels are raised by aminosalicylic acid.

Clinical evidence, mechanism, importance and management

A study found that aminosalicylic acid significantly increased the plasma levels of isoniazid at 4 and 6 hours after administration by 32% and 114%, respectively in fast acetylators of isoniazid, and by 21% and 39%, respectively in slow acetylators of isoniazid. The half-life of isoniazid was increased from 1.32 hours to 2.89 hours in the fast acetylators and from 3.05 hours to 4.27 hours in the slow acetylators (see 'Genetic factors', (p.4), for more information about acetylator status). The effects were probably due to the inhibition of isoniazid metabolism by aminosalicylic acid.[1] There seem to be no reports of isoniazid toxicity arising from this interac-

tion, but the manufacturers of isoniazid warn that adverse effects are more likely in the presence of aminosalicylic acid.[2]

1. Hanngren Å, Borgå O, Sjöqvist F. Inactivation of isoniazid (INH) in Swedish tuberculous patients before and during treatment with para-aminosalicylic acid (PAS). *Scand J Respir Dis* (1970) 51, 61–9.
2. Isoniazid Tablets. UCB Pharma Ltd. UK Summary of product characteristics, July 2009.

Isoniazid + Antacids

The absorption of isoniazid from the gut is modestly reduced by aluminium hydroxide, slightly reduced by magaldrate, and not affected by aluminium/magnesium hydroxide tablets or didanosine chewable tablets.

Clinical evidence

Aluminium hydroxide (*Amphojel*) 45 mL was given to 10 patients with tuberculosis at 6 am, 7 am and 8 am, followed immediately by isoniazid and any other medication they were receiving. The plasma isoniazid levels at one hour were decreased, and peak plasma levels occurring between one and 2 hours after the dose were reduced by about 25%, when adjusted for different doses.[1] The effect of **magaldrate** (hydrated magnesium aluminate) was smaller,[1] and in another well-controlled study **aluminium/magnesium hydroxide** (*Mylanta*) had no effect on isoniazid plasma levels.[2]

Didanosine chewable tablets contain antacids (**aluminium/magnesium hydroxide**) in the formulation, but it has been shown that they do not affect the bioavailability of isoniazid.[3]

Mechanism

Aluminium hydroxide delays gastric emptying,[4,5] causing retention of the isoniazid in the stomach. As isoniazid is largely absorbed from the intestine, this explains the slight decrease in plasma isoniazid concentrations. Aluminium hydroxide also appears to inhibit the absorption of isoniazid.

Importance and management

Information on this interaction is limited, and it is not established. The clinical importance of the modest reductions in isoniazid levels with aluminium hydroxide in one study is uncertain, but likely to be small. Aluminium/magnesium hydroxide did not interact, and neither did didanosine chewable tablets.

5. Hava M, Hurwitz A. The relaxing effect of aluminium and lanthanum on rat and human gastric smooth muscle in vitro. *Eur J Pharmacol* (1973) 22, 156–61.

Isoniazid + Chlorpromazine

A study in 11 patients found that the half-life of isoniazid was increased by 41% when a single 300-mg dose of chlorpromazine was given one hour before a single 5 mg/kg intravenous dose of isoniazid.[1] The clinical relevance of this finding is unclear.

1. Matilla MJ, Takki S. Half-lives of isoniazid and salicylic acid in serum and their modification by different drugs in psychiatric patients. *Ann Med Exp Biol Fenn* (1969) 47, 124–8.

Isoniazid + Disulfiram

In most patients the concurrent use of isoniazid and disulfiram is uneventful, but difficulties in co-ordination, with changes in mental status, behaviour, and drowsiness have been reported in a small number of patients.

Clinical evidence

Seven patients with tuberculosis who had been taking isoniazid for at least 30 days, without problems, experienced adverse reactions within 2 to 8 days of starting to take disulfiram 500 mg daily. Among the symptoms were dizziness, disorientation, a staggering gait, insomnia, irritability and querulous behaviour, listlessness, and lethargy. One patient became hypomanic. Most of the patients were also taking chlordiazepoxide, and other drugs included aminosalicylic acid, streptomycin and phenobarbital. The adverse reactions decreased or disappeared when the disulfiram was either reduced to 250 or 125 mg daily, or withdrawn. These 7 patients represented less than one-third of those who received both drugs.[1] As disulfiram is known to inhibit the metabolism of chlordiazepoxide,[2] another 4 patients were given only isoniazid and disulfiram. Although their reaction was not as severe, all 4 developed drowsiness and depression.[1]

In contrast, another report describes the concurrent use of both drugs, without problems, in 200 patients.[3] A retrospective study in patients taking isoniazid-containing regimens for tuberculosis found no difference in the rate of toxicity in 13 patients taking disulfiram, when compared with a large group of patients not taking disulfiram. However, the small number of patients taking disulfiram in this study limits the strength of the negative finding.[4] Another patient taking disulfiram with isoniazid and rifampicin (rifampin) also did not experience any problems.[5]

Mechanism

Not understood. One idea is that some kind of synergy occurs between the two drugs because both can produce similar adverse effects if given in high doses. The authors of one report[1] speculate that isoniazid and disulfiram together inhibit two of three biochemical pathways concerned with the metabolism of dopamine. This leaves a third pathway open, catalysed by COMT (catechol-*O*-methyl transferase), which produces a number of methylated products of dopamine. These methylated products may possibly have been responsible for the mental and physical reactions seen.

Importance and management

Information about this interaction appears to be limited to the reports cited. Its incidence is uncertain but apparently quite small. Two-thirds of the patients in one study, and at least 200 other patients did not experience an interaction. It would therefore seem that concurrent use need not be avoided, but the response should be monitored. If marked changes in mental status occur, or there is unsteady gait, the manufacturers recommend that the disulfiram should be withdrawn.[6]

Isoniazid + Etanercept

A case report describes a patient who developed optic neuritis while taking isoniazid and etanercept.

Clinical evidence, mechanism, importance and management

A case report describes a patient with rheumatoid arthritis who developed latent tuberculosis, and was given isoniazid and pyridoxine. Five days after starting to take these drugs, he also started treatment with subcutaneous etanercept twice weekly. Approximately 2 months later he experienced a reduction in visual acuity, which was attributed to optic neuritis. After stopping treatment with etanercept and isoniazid, and starting a corticosteroid, his condition improved. The authors of the case report considered that the combination of isoniazid and etanercept were causative factors in his optic neuritis, although either drug alone may have caused this adverse

effect.[1] No particular precautions are warranted on the basis of this isolated case.

1. Noguera-Pons R, Borrás-Blasco J, Romero-Crespo I, Antón-Torres R, Navarro-Ruiz A, González-Ferrandez JA. Optic neuritis with concurrent etanercept and isoniazid therapy. *Ann Pharmacother* (2005) 39, 2131–5.

Isoniazid + Ethambutol

Ethambutol does not appear to affect isoniazid levels. However, it seems that the optic neuropathy caused by ethambutol may be increased by isoniazid.

Clinical evidence, mechanism, importance and management

In 10 patients with tuberculosis, the mean serum levels of a 300-mg dose of isoniazid were not significantly changed by a single 20-mg/kg dose of ethambutol.[1] The possible effects of concurrent use over a period of time were not studied. However, there is some evidence that the optic neuropathy caused by ethambutol may be increased by isoniazid, and any effects resolve more slowly after the use of isoniazid.[2-5] One group of authors recommends that both ethambutol and isoniazid should be stopped immediately if severe optic neuritis occurs. They further recommend that isoniazid should be stopped if less severe optic neuritis does not improve within 6 weeks after stopping ethambutol.[6]

6. Sivakumaran P, Harrison AC, Marschner J, Martin P. Ocular toxicity from ethambutol: a review of four cases and recommended precautions. *N Z Med J* (1998) 111, 428–30.

Isoniazid + Fluconazole

A double-blind, crossover study in 16 healthy subjects (8 fast and 8 slow acetylators of isoniazid) found that fluconazole 400 mg daily for a week had no clinically significant effect on the pharmacokinetics of isoniazid.[1] No special precautions would appear necessary during concurrent use.

1. Buss DC, Routledge PA, Hutchings A, Brammer KW, Thorpe JE. The effect of fluconazole on the acetylation of isoniazid. *Hum Exp Toxicol* (1991) 10, 85–6.

Isoniazid + Food

The absorption of isoniazid is reduced by food. See also 'Isoniazid + Food; Cheese or Fish', below, for toxic reactions between isoniazid and specific foods.

Clinical evidence

In 9 healthy subjects the mean peak serum levels of isoniazid 10 mg/kg were delayed, and reduced by 79%,when isoniazid was given with breakfast rather than when fasting. The AUC was reduced by 43%.[1] In another study in 14 healthy subjects given isoniazid with a full fat breakfast, the maximum serum levels of isoniazid were decreased by 51%, its absorption was delayed, and its AUC was decreased by 12%.[2] Similar results have been found in other studies.[3,4]

Mechanism

Uncertain. Food delays gastric emptying so that absorption further along the gut is also delayed, but the reduction in absorption is not understood.

Importance and management

Information is limited but the interaction seems to be established. For maximum absorption isoniazid should be taken without food, hence the manufacturer's guidance to take it at least 30 minutes before or 2 hours after food.[5]

5. Isoniazid Tablets. UCB Pharma Ltd. UK Summary of product characteristics, July 2009.

Isoniazid + Food; Cheese or Fish

Patients taking isoniazid who eat some foods, particularly fish from the scombroid family (tuna, mackerel, salmon) that are not fresh, may experience an exaggerated histamine poisoning reaction. Cheese has also been implicated in this reaction, but the adverse effects may be due to the weak MAOI effects of isoniazid rather than histamine poisoning.

Clinical evidence

Three months after starting to take isoniazid 300 mg daily, a woman experienced a series of unpleasant reactions 10 to 30 minutes after eating cheese. These reactions included chills, headache (sometimes severe), itching of the face and scalp, slight diarrhoea, flushing of the face (and on one occasion the whole body), variable and mild tachycardia, and a bursting sensation in the head. Blood pressure measurements showed only a modest rise (from her normal blood pressure of 95/65 mmHg to 110/80 mmHg). No physical or biochemical abnormalities were found.[1]

Headache, dizziness, blurred vision, tachycardia, flushing and itching of the skin, redness of the eyes, burning sensation of the body, difficulty in breathing, abdominal colic, diarrhoea, vomiting, sweating and wheezing have all been described after other patients taking isoniazid ate cheese.[2-6] Certain tropical fish, including **tuna** (**skipjack** or **bonito**; ***Katsuwanus pelamis***),[7-11] ***Sardinella (Amblygaster) sirm***,[12] ***Rastrigella kanagurta***,[13] **saury** (**skipper** or **bill-fish**)[14] and others[15] are also implicated. There are a few hundred cases of this reaction on record.

Mechanism

The reaction appears to be an exaggeration of the histamine poisoning that can occur after eating some foods, such as members of the scombroid family of fish (tuna, mackerel, salmon, etc), if they are not fresh and adequately refrigerated. These fish (and some cheeses) have a high histidine content and under poor storage circumstances the histidine is decarboxylated by bacteria to produce unusually large amounts of histamine. Normally this is inactivated by histaminase in the body, but isoniazid is a potent inhibitor of this enzyme, which means that the histamine is absorbed largely unchanged and histamine poisoning develops.[16] Histamine survives all but very prolonged cooking. Tuna fish can contain 180 to 500 mg histamine per 100 g, other types of fish may contain as little as 0.5 to 7.5 mg.[10]

Alternatively, it has been suggested that the cases of reactions to cheese are caused by tyramine content and the weak MAOI properties of isoniazid. See 'MAOIs or RIMAs + Tyramine-rich foods', p.1395, for more details of the mechanism of this interaction.

Importance and management

An established interaction of clinical importance. With the exception of one patient who appeared to have had a cerebrovascular accident,[9] the reactions experienced by the others were unpleasant and alarming but usually not serious or life-threatening. They required little or no treatment, although 'scombroid poisoning' in the absence of isoniazid is sometimes more serious. Two reports say that treatment with antihistamines can be effective.[10,15] Isoniazid has been in use since 1956 and there is little need to now introduce any general dietary restrictions, but if any of these reactions are experienced, examine the patient's diet and advise the avoidance of any probable offending foodstuffs. Very mature cheese and fish of the scombroid family (tuna, mackerel, salmon and other varieties of dark meat fish) that are not fresh are to be treated with suspicion, but the likely histamine or tyramine content of food cannot be assessed without undertak-

ing a detailed analysis. See 'Table 32.2', (p.1394), and 'Table 32.3', (p.1396), for a list of tyramine-rich foods and drinks.

Isoniazid + H_2-receptor antagonists

Cimetidine and ranitidine do not appear to affect the pharmacokinetics of isoniazid.

Clinical evidence, mechanism, importance and management

In 13 healthy subjects, **cimetidine** 400 mg or **ranitidine** 300 mg, three times daily, for 3 days had no effect on the pharmacokinetics of a single 10-mg/kg dose of isoniazid. The absorption and the metabolism of isoniazid were both unchanged.[1] No special precautions would appear to be necessary on concurrent use. Although data about other H_2-receptor antagonists appears to be lacking, based on this study, they would not be expected to interact with isoniazid.

Isoniazid + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest reduction in isoniazid absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on isoniazid absorption, healthy subjects were given 10 to 20 g of oral **sodium sulfate** or 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of isoniazid excreted in the urine, was decreased by 50% with **castor oil** and by 41% with **sodium sulfate** at 4 hours. However, serum levels of isoniazid were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.[1]

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Isoniazid + Pethidine (Meperidine)

An isolated case report describes hypotension and lethargy in a patient after he took isoniazid with pethidine.

Clinical evidence, mechanism, importance and management

A patient became lethargic and his blood pressure fell from 124/68 mmHg to 84/50 mmHg within 20 minutes of being given pethidine 75 mg intramuscularly. An hour before, he had been given isoniazid. There was no evidence of fever or cardiac arrhythmias, and his serum electrolytes, glucose levels and blood gases were normal. His blood pressure returned to normal over the next 3 hours. He had previously had both pethidine and isoniazid separately without incident. He was subsequently uneventfully given intravenous morphine sulfate 4 mg every 2 to 4 hours.[1] The authors of the report attribute this reaction to the MAO-inhibitory properties of the isoniazid and equate it with the severe and potentially fatal interaction between MAOIs and pethidine (see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381), but in reality this reaction was mild and lacked many of the characteristics of the more serious reaction. Moreover, isoniazid possesses only mild MAO-inhibitory properties and does not normally interact to the same extent as the non-selective MAOIs.

There is too little evidence to advise against concurrent use, but bear this interaction in mind in case of an unexpected response to treatment.

1. Gannon R, Pearsall W, Rowley R. Isoniazid, meperidine, and hypotension. *Ann Intern Med* (1983) 99, 415.

Isoniazid + Prednisolone

Prednisolone can lower isoniazid levels.

Clinical evidence, mechanism, importance and management

Isoniazid 10 mg/kg daily was given to 26 patients with tuberculosis. The 13 slow acetylators of isoniazid had a 23% fall in plasma isoniazid levels when they were given **prednisolone** 20 mg, while the 13 fast acetylators had a 38% fall over 8.5 hours (see 'Genetic factors', (p.4), for an explanation of acetylator status). The reasons for these changes are not understood but changes in the metabolism, and/or the excretion of the isoniazid by the kidney, are possibilities. Despite these changes the response to treatment was excellent.[1] In another group of 49 patients (including both slow and fast acetylators of isoniazid), rifampicin 12 mg/kg largely counteracted the isoniazid-lowering effects of **prednisolone**.[1]

None of these interactions were of clinical importance, but the authors point out that if the dose of isoniazid had been lower, its effects might have been reduced. Be aware of the possibility of a reduced response during concurrent use, and raise the isoniazid dose if necessary. There seems to be no information about other corticosteroids.

Isoniazid + Propranolol

Propranolol causes a small reduction in the clearance of isoniazid.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects, the clearance of a single 600-mg intravenous dose of isoniazid was reduced by 21%, from 16.4 to 13 L/hour, by propranolol 40 mg three times daily for 3 days.[1] It is suggested that propranolol reduces the clearance of isoniazid by inhibiting its metabolism (acetylation) by the liver.[1] However, as the increase in isoniazid levels is likely to be only modest this interaction is probably of little clinical importance.

1. Santoso B. Impairment of isoniazid clearance by propranolol. *Int J Clin Pharmacol Ther Toxicol* (1985) 23, 134–6.

Isoniazid + Pyrazinamide

A study in 19 patients with tuberculosis found that pyrazinamide did not affect serum levels of isoniazid.[1]

1. Levy D, Duysak S, Zylberberg B, Haapanen J, Russell WF, Middlebrook G. Effect of pyrazinamide on antimicrobially active serum isoniazid. *Dis Chest* (1960) 38, 148–51.

Isoniazid + Quinolones

Ciprofloxacin may cause a slight increase in the bioavailability of isoniazid, and pefloxacin may increase both the absorption and excretion of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

In a single-dose study, ciprofloxacin 500 mg was found to increase the absorption of isoniazid 300 mg by about 15%. The time to reach maximum plasma levels was increased from 3 hours to 4 hours. The rate of elimination and plasma half-life of isoniazid were not significantly affected.[1] In a very similar study, measurement of the salivary and urinary levels of isoniazid also found that ciprofloxacin increased the absorption of isoniazid, although the time to reach maximum salivary levels of isoniazid was shortened from 4 hours to 3 hours.[2] The urinary excretion was also increased by 38% in the presence of ciprofloxacin. The effects on isoniazid absorption may be due to inhibition of gastric motility and emptying by ciprofloxacin.[1] However, these effects are modest and unlikely to be clinically significant.

(b) Pefloxacin

In a study in 6 healthy subjects a single 400-mg dose of pefloxacin increased the maximum salivary levels and AUC of a single 300-mg dose of isoniazid almost twofold, indicating increased absorption. The time to reach maximum saliva concentrations was reduced from 5 hours to 4 hours. The excretion of isoniazid was also increased by 38%, as measured by an increased recovery from the urine.[3] The clinical relevance of the increased salivary levels of isoniazid is unclear. The authors suggest that concurrent use may lead to increased isoniazid toxicity. Therefore, until more is known, if patients develop isoniazid adverse effects (e.g. nausea, vomiting, constipation), while taking pefloxacin, consider this interaction as a possible cause.

Isoniazid + Rifamycins

The concurrent use of a rifamycin and isoniazid is common and therapeutically valuable, but there is evidence that the incidence of hepatotoxicity may be increased, particularly in slow acetylators of isoniazid. One study suggests the bioavailability of rifampicin may be reduced by isoniazid but other studies found no pharmacokinetic interaction. Rifabutin and rifampicin do not alter the pharmacokinetics of isoniazid.

Clinical evidence, mechanism, importance and management

(a) Rifabutin

In 6 healthy subjects, rifabutin 300 mg daily for 7 days, had no significant effect on the pharmacokinetics of a single 300-mg dose of isoniazid or its metabolite acetylisoniazid.[1] Two of the 6 subjects were rapid acetylators of isoniazid (see 'Genetic factors', (p.4), for more information about acetylator status).

Although both drugs have been effectively used together in the treatment of tuberculosis, it is not clear whether concurrent use increases the incidence of hepatotoxicity, as occurs with isoniazid and rifampicin (see below). However, as regular monitoring of liver function is required for both isoniazid and rifabutin, no additional monitoring seems necessary on concurrent use. The manufacturer of rifabutin notes that haematological reactions of rifabutin could be increased by isoniazid, but, again, as regular monitoring of white blood cell and platelet counts is advised,[2] no additional monitoring seems necessary.

(b) Rifampicin (Rifampin)

Most studies have shown that the serum levels and half-lives of isoniazid and rifampicin are not significantly affected by concurrent use,[3-6] even in those with hepatic impairment.[6] There was also no difference[4] between rapid and slow acetylators of isoniazid, (see 'Genetic factors', (p.4), for more information about acetylator status). One single-dose study in healthy subjects found that isoniazid 12 mg/kg reduced the AUC of rifampicin 10 mg/kg by about 25%.[7] There is some evidence that the incidence and severity of hepatotoxicity rises if both drugs are given together.[8] Reports from India suggest that the incidence can be as high as 8 to 10%, while much lower figures of 2 to 3% are reported in the US.[9] There is one case report that appears to prove that hepatotoxicity can arise rapidly from the use of both drugs. The patient tolerated both drugs individually, but hepatotoxicity reappeared on concurrent use.[10]

The reasons for the hepatotoxicity are not fully understood but rifampicin or isoniazid alone can cause liver damage by their own toxic action. One suggestion is that the rifampicin alters the metabolism of isoniazid, resulting in the formation of hydrazine, which has proven to be hepatotoxic.[9-11] Higher plasma levels of hydrazine are said to occur in slow acetylators of isoniazid,[9] but this effects was not found in one study.[12] There has been at least one fatality caused by this combination.[13] The manufacturers of rifampicin advise that caution is particularly needed in patients with impaired liver function, the elderly, malnourished patients, and children under 2 years of age. In patients with normal pre-treatment liver function, after baseline LFTs, further tests are only needed if fever, vomiting, or jaundice occur, or if the patient deteriorates.[14] However, one of the manufacturers of isoniazid suggests that liver function tests should be reviewed monthly in patients receiving both drugs.[15]

Isoniazid + Salicylates

Isoniazid prolongs the half-life of salicylate in patients given aspirin.

Clinical evidence, mechanism, importance and management

In 8 patients it was found that the half-life of isoniazid was reduced by 14% when a single 2-g dose of sodium salicylate was given one hour before a single 5 mg/kg intravenous dose of isoniazid. This is unlikely to be clinically relevant. Further analysis in 10 patients found that the half-life of salicylate was almost doubled when a 2 g dose of aspirin was given with isoniazid 600 mg. A further dose of isoniazid was given 4 hours later.[1] The clinical relevance of this increase in the half-life of salicylate is unclear, but it seems likely to be small, particularly with antiplatelet doses of aspirin.

1. Matilla MJ, Takki S. Half-lives of isoniazid and salicylic acid in serum and their modification by different drugs in psychiatric patients. *Ann Med Exp Biol Fenn* (1969) 47, 124–8.

Isoniazid + SSRIs and related antidepressants

A few reports suggest that no important interaction occurs between isoniazid and the SSRIs or nefazodone. However, adverse reactions have been seen during concurrent use and one report found an increased discontinuation rate in patients taking an SSRI with isoniazid.

Clinical evidence

Two HIV-positive patients taking **fluoxetine** 20 mg daily were also given isoniazid. One of them tolerated the use of both drugs, but the other developed vomiting and diarrhoea, and after 10 days the **fluoxetine** was stopped.[1]

A woman who had been hospitalised for serious depression was given **nefazodone** 300 mg daily. A few days later she began to take isoniazid 300 mg daily, and was later discharged on an increased **nefazodone** dose of 400 mg daily. She was reported to have had no problems while taking both drugs over a 5-month period.[2]

A woman with tuberculosis taking isoniazid 300 mg daily presented with depression, and was given **sertraline** 50 mg daily, later raised to 150 mg daily, without problems. She responded well and was reported to have taken both drugs together for 8 months without problems.[2]

A retrospective review of HIV-positive patients who were taking either an SSRI, isoniazid, or both, found that the rate of discontinuation of the SSRI was higher in those also taking isoniazid (7 of 10 patients) than in the group of patients taking an SSRI alone (2 of 14). It is unclear why this rate was increased; little mention is made of the influence of other drugs or medical conditions.[3]

Mechanism

In theory isoniazid could interact with the SSRIs[4] because it has some weak MAO inhibitory activity. However, isoniazid rarely interacts like the non-selective MAOIs. This is because isoniazid seems to lack activity on mitochondrial MAO even though it has activity on plasma MAO. Therefore no adverse interaction would usually be expected.

Importance and management

Direct information about the concurrent use of isoniazid and SSRIs seems to be limited, but the case reports cited here[1,2,4] would suggest that the concurrent use of isoniazid and these SSRIs is normally without problems. However, also be aware that one report suggests the possibility of an increase in adverse effects with the combination of SSRIs and isoniazid.[3]

Linezolid + Antacids

A study in healthy subjects found that *Maalox 70mVal* suspension 10 mL (aluminium/magnesium hydroxide) did not affect the pharmacokinetics of a single 600-mg dose of linezolid.[1]

1. Grunder G, Zysset-Aschmann Y, Vollenweider F, Maier T, Krähenbühl S, Drewe J. Lack of pharmacokinetic interaction between linezolid and antacid in healthy volunteers. *Antimicrob Agents Chemother* (2006) 50, 68–72.

Linezolid + Aztreonam

In a single-dose study in healthy subjects, the pharmacokinetics of intravenous aztreonam 1 g and intravenous linezolid 375 mg were not affected by concurrent use. Therefore dose alterations are unlikely to be needed if both drugs are given.[1]

1. Sisson TL, Jungbluth GL, Hopkins NK. A pharmacokinetic evaluation of concomitant administration of linezolid and aztreonam. *J Clin Pharmacol* (1999) 39, 1277–82.

Linezolid + Dextromethorphan

There is no important pharmacokinetic interaction between linezolid and dextromethorphan, but one case of concurrent use resulted in serotonin syndrome.

Clinical evidence, mechanism, importance and management

In a study in 14 healthy subjects, two 20-mg doses of dextromethorphan given 4 hours apart, before and during the use of linezolid 600 mg every 12 hours, had no effect on linezolid pharmacokinetics. The AUC and maximum level of the dextromethorphan metabolite, dextrorphan was decreased by 30%, but this was not considered sufficient to warrant any dosing alterations. There was no evidence of serotonin syndrome, as measured by changes in body temperature, alertness and mental performance.[1] However, the manufacturer describes one case where the concurrent use of linezolid and dextromethorphan resulted in serotonin syndrome.[2] Linezolid has mild reversible MAOI activity, and serotonin syndrome has been described when dextromethorphan was taken by patients also taking antidepressant MAOIs, see 'MAOIs or RIMAs + Dextromethorphan', p.1375. If the concurrent use of linezolid and dextromethorphan is considered necessary, it would seem prudent to monitor for symptoms of serotonin syndrome. See under 'Additive or synergistic interactions', (p.9), for more information about serotonin syndrome.

2. Zyvox (Linezolid). Pharmacia Ltd. UK Summary of product characteristics, September 2009.

Linezolid + Diphenhydramine

A single case report describes delirium in a patient receiving linezolid and diphenhydramine.

Clinical evidence

A case report describes a patient taking linezolid 600 mg twice daily, with metronidazole, aztreonam and diphenhydramine to treat a rash caused by previous antibacterials. The patient developed delirium, with aggression and hallucinations 2 days after starting to take the diphenhydramine. The symptoms of delirium resolved 2 to 3 days after the diphenhydramine was withdrawn. Metronidazole was also stopped at the same time.[1]

Mechanism

There are several factors that could account for the delirium seen in this patient. Linezolid may have enhanced the antimuscarinic action of diphenhydramine resulting in the symptoms seen. In addition, psychotic disorders including hallucinations are a very rare adverse effect of metronidazole,[2] and can also occur due to sepsis.

Importance and management

Evidence for an interaction between diphenhydramine and linezolid appears to be limited to this isolated case, the reasons for which are not established. As such, no general recommendations can be made.

2. Flagyl Tablets (Metronidazole). Winthrop Pharmaceuticals UK Ltd. UK Summary of product characteristics, August 2008.

Linezolid + Food

Linezolid modestly increases the blood pressure response to oral tyramine. The bioavailability of linezolid is not affected by enteral feeds or food.

Clinical evidence, mechanism, importance and management

(a) Enteral feeds

In a study, 9 patients receiving enteral feeds were given a single 600-mg dose of linezolid as a suspension via a nasogastric tube or gastric tube. The

rate and extent of linezolid absorption was not significantly different from that found in another 6 patients not receiving enteral feeds. No dose adjustments are therefore thought to be required if linezolid is given with enteral feeds.[1]

(b) Food

A study in healthy subjects found that the plasma levels following a single 375-mg oral dose of a linezolid tablet were 23% higher when given to fasted subjects than when it was taken immediately after a high-fat meal. However, the AUCs were not significantly different, indicating that the extent of absorption was not affected by food.[2] Another study in healthy subjects found that food delayed the rate but not the extent of absorption and distribution of linezolid into tissues.[3] The manufacturer of linezolid states that both the oral suspension and the film-coated tablets may be taken with or without food.[4]

(c) Tyramine-rich food

In a pharmacodynamic study in healthy subjects, the dose of oral tyramine required to raise the systolic blood pressure by 30 mmHg was decreased by a factor of about 3.5 (from a range of 300 to 600 mg without linezolid to 100 to 200 mg with linezolid) when the subjects were pretreated with linezolid 625 mg twice daily for 4 to 7 days. This increase in the pressor response to tyramine was similar to that seen with moclobemide 150 mg three times daily.[5] Further, another placebo-controlled study in healthy subjects found that single doses of linezolid 600 mg and moclobemide 300 mg also caused similar increases in the pressor response to intravenous tyramine, as measured by amount of tyramine required to raise the systolic blood pressure by 30 mmHg.[6]

Linezolid is a weak, non-selective inhibitor of MAO. As a consequence, it can inhibit the breakdown of tyramine by MAO in the gut, and can also potentiate the effect of tyramine at nerve endings, therefore causing an increase in blood pressure (see *Mechanism*, under 'MAOIs or RIMAs + Tyramine-rich foods', p.1395). However, the extent of this rise was similar to that for moclobemide, which is much less than that seen with antidepressant MAOIs.

The manufacturers of linezolid recommend that patients should avoid large amounts of tyramine-rich foods and drinks[4,7] and should not consume more than 100 mg of tyramine per meal.[7] For a list of the possible tyramine-content of various foods and drinks, see 'Table 32.2', (p.1394), 'Table 32.3', (p.1396) and 'Table 32.4', (p.1397), but note that these amounts are only a guide. The manufacturers advice is in line with the dietary restrictions recommended for RIMAs rather than the more stringent dietary recommendations required in patients taking non-selective MAOIs.

Linezolid + Mirtazapine

Serotonin syndrome has been reported in patients taking linezolid with mirtazapine.

Clinical evidence

A patient taking linezolid 600 mg twice daily developed delirium, confusion and visual hallucinations 2 weeks after starting to take mirtazapine 15 or 30 mg daily and gabapentin 300 mg at night. Gabapentin was stopped and the delirium resolved. About 4 weeks later the delirium recurred and then resolved when the patient discontinued mirtazapine. Mirtazapine was restarted without recurrence of delirium. The patient subsequently took mirtazapine 15 mg daily with linezolid 600 mg twice daily without adverse effects.[1] See 'Linezolid + SSRIs', p.353, for mention of a case of serotonin syndrome in a patient taking mirtazapine, citalopram and linezolid.

Mechanism

Not fully understood. Linezolid has weak MAOI effects, and serotonin syndrome is known to occur when MAOIs are given with 'tricyclics', (p.1391) and 'SSRIs', (p.1384), which are related to mirtazapine.

Importance and management

Information on the interaction between linezolid and mirtazapine appears to be limited, but it is in line with the way both drugs are known to interact. If linezolid is used with a drug with serotonergic actions, including mirtazapine it would seem prudent to monitor for symptoms of serotonin syndrome, which may take several weeks to manifest. See 'serotonin syndrome', (p.9), for further details on the development and management of this syndrome.

1. Aga VM, Barklage NE, Jefferson JW. Linezolid, a monoamine oxidase inhibiting antibiotic, and antidepressants. *J Clin Psychiatry* (2003) 64, 609–11.

Linezolid + Miscellaneous

Linezolid is predicted to interact with a number of drugs (e.g. salbutamol, buspirone, inotropes and vasopressors, triptans) in the same way as the MAOIs. The concurrent use of linezolid and gentamicin does not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

Linezolid is a weak, reversible, non-selective inhibitor of MAOI. It is therefore expected to share the interactions of the antidepressant MAOIs, although the magnitude of any interaction is likely to be smaller. The UK manufacturer of linezolid[1] contraindicates its use with a number of drugs, unless facilities are available for close observation and monitoring of blood pressure. Similarly, the US manufacturer advises that patients should only receive linezolid with these drugs if they are observed for signs of 'serotonin syndrome', (p.9).[2]

The drugs mentioned include:

- Beta agonist bronchodilators; consider 'MAOIs or RIMAs + Sympathomimetics; Beta-agonist bronchodilators', p.1387.
- Buspirone; consider 'MAOIs or RIMAs + Buspirone', p.1374.
- Inotropes and vasopressors (e.g. adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine, dobutamine); consider 'MAOIs or RIMAs + Sympathomimetics; Directly-acting', p.1388.
- Triptans; consider 'Triptans + MAOIs', p.688.

The manufacturers also contraindicate the concurrent use of linezolid with or within 2 weeks of taking any other drug that inhibits MAO-A or MAO-B.[1] They specifically name the non-selective MAOIs **isocarboxazid** and **phenelzine**.[1,2] The UK manufacturer includes the RIMA, moclobemide, and the MAO-B inhibitor, selegiline.[1] See 'MAOIs + MAOIs or RIMAs', p.1378, and see 'MAO-B inhibitors + MAOIs or RIMAs', p.807.

The US manufacturer of linezolid notes that the pharmacokinetics of neither linezolid or gentamicin are altered when the two drugs are given together.[2]

Linezolid + Nasal decongestants

In one study the use of linezolid with phenylpropanolamine or pseudoephedrine resulted in additive hypertensive effects.

Clinical evidence

In a placebo-controlled study, 14 healthy patients were given two 60-mg doses of **pseudoephedrine** or two 25-mg doses of **phenylpropanolamine** 4 hours apart, with and without linezolid. The mean maximum blood pressure rise was 11 mmHg with placebo, 15 mmHg with linezolid, 18 mmHg with **pseudoephedrine** and 14 mmHg with **phenylpropanolamine**. When the subjects were given linezolid with **pseudoephedrine** the rise was 32 mmHg, which was similar to the 38 mmHg rise seen with linezolid plus **phenylpropanolamine**. However, these rises were transient, resolving in about 2 hours. No effects were seen on linezolid pharmacokinetics.[1]

Mechanism

Linezolid acts as a weak MAO-inhibitor, which allows the accumulation of some noradrenaline at adrenergic nerve endings associated with arterial blood vessels. Pseudoephedrine and phenylpropanolamine, both indirectly-acting sympathomimetics, can release these above-normal amounts of noradrenaline resulting in blood vessel constriction and a rise in blood pressure.

Importance and management

Evidence for an interaction between linezolid and phenylpropanolamine or pseudoephedrine appears to be limited to this report, but given what is known about the way non-selective MAOIs interact with these drugs (see 'MAOIs or RIMAs + Sympathomimetics; Indirectly-acting', p.1388) an interaction appears to be established. However, it should be said that the evidence available indicates that blood pressure rises are unlikely to be of the proportions seen with the antidepressant MAOIs, which result in hypertensive crises. The manufacturers of linezolid[2,3] contraindicate the use of pseudoephedrine and phenylpropanolamine with linezolid unless there are facilities available for close observation of the patient and monitoring of blood pressure. The UK manufacturer additionally advises careful dose titration if concurrent use is undertaken.

Pseudoephedrine and phenylpropanolamine are present in some cough and cold remedies, which can be bought without prescription. Patients should be told to avoid these preparations while taking linezolid. There appears to be no direct information about **ephedrine**, but it would be expected to interact similarly.

Linezolid + Pethidine (Meperidine)

A single case report describes serotonin syndrome, which developed when a patient was given pethidine and linezolid.

Clinical evidence, mechanism, importance and management

A case report describes a 27-year old man who developed serotonin syndrome after receiving linezolid and pethidine. He developed myoclonus and paranoid ideations, with an elevated temperature, respiratory rate, heart rate and blood pressure 2 hours after receiving the third dose of linezolid, and half an hour after receiving pethidine for amphotericin-associated rigors. His neuropsychiatric symptoms resolved within 2 hours of stopping the pethidine.[1]

The UK manufacturer of linezolid[2] (a drug with weak, reversible, non-selective MAOI activity) contraindicates its use with pethidine, unless facilities are available for close observation and monitoring of blood pressure, because of the possibility of serious reactions, similar to those that have occurred with antidepressant MAOIs and pethidine, see 'MAOIs or RIMAs + Opioids; Pethidine (Meperidine)', p.1381. Similarly, the US manufacturer advises that patients should only receive linezolid with pethidine if they are observed for signs of 'serotonin syndrome', (p.9).[3]

Linezolid + Rifampicin (Rifampin)

The serum levels of intravenous linezolid are reduced by intravenous rifampicin.

Clinical evidence, mechanism, importance and management

A 31-year-old woman was given intravenous rifampicin 300 mg every 8 hours and linezolid 600 mg every 12 hours for an MRSA infection. During rifampicin treatment her linezolid peak and trough levels were 7.29 micrograms/mL and 2.04 micrograms/mL, respectively. However, when the rifampicin was stopped the linezolid peak and trough levels were higher, at 12.46 micrograms/mL and 5.03 micrograms/mL, respectively.[1]

In an earlier study, healthy subjects were given a single 600-mg dose of intravenous linezolid either alone or with a single 600-mg dose of intravenous rifampicin. This study also found that rifampicin reduced the serum levels of linezolid by 10%, 20% and 35% at 6 hours, 9 hours and 12 hours, respectively.[2]

The manufacturers of linezolid report the findings of a study in 16 healthy subjects who took linezolid 600 mg twice daily for 5 doses with or without rifampicin 600 mg daily for 8 days. There was a reduction in linezolid maximum plasma levels and AUC of 21% and 32%, respectively.[3,4]

Linezolid is not metabolised by the cytochrome P450 enzyme system so the reduction in levels is unlikely to be due to increased metabolism associated with rifampicin enzyme induction. The reduction in linezolid serum levels may be attributable to the induction of P-glycoprotein by rifampicin, resulting in increased excretion of linezolid.[1,2]

The clinical significance of this interaction is unclear and the concurrent use of rifampicin and linezolid is not established. The available evidence suggests that, where possible, linezolid levels should be monitored if both drugs are given. If this is not possible it would seem prudent to monitor concurrent use closely to ensure that the antibacterial treatment is effective.

Linezolid + SNRIs

Serotonin syndrome has been reported in patients taking linezolid with venlafaxine or duloxetine.

Clinical evidence

(a) Duloxetine

A case report describes a 55-year old woman taking duloxetine 60 mg daily who developed changes in her mental status including confusion, restlessness and abnormal movements 3 hours after receiving linezolid 600 mg. She was also tachycardic, with a low grade fever, hyperreflexic and unable to stay awake. Serotonin syndrome was suspected, and duloxetine was withheld. Her symptoms improved over the subsequent 12 hours.[1]

(b) Venlafaxine

An 85-year-old man taking venlafaxine 150 mg daily was given ciprofloxacin, rifampicin and linezolid 600 mg twice daily for a hip prosthesis infection. After 20 days he was found to be confused and disorientated, and 4 days later he was also drowsy, and suffering myoclonic jerks. Linezolid and venlafaxine were stopped and the symptoms resolved over 2 days.[2] Other cases of serotonin syndrome in patients taking venlafaxine and linezolid have also been reported,[3,4] including a case in which the patient continued to take venlafaxine, but at half the original dose.[3] A further case report describes a 7-year-old boy taking venlafaxine and methylphenidate who was given linezolid for osteomyelitis. He took all three drugs (doses not stated) for several days without any alterations in vital signs or evidence of serotonin syndrome.[5]

Mechanism

Not fully understood. Linezolid has weak MAOI effects, and serotonin syndrome is known to occur when MAOIs are given with 'venlafaxine', (p.1383).

Importance and management

Information on the interaction between linezolid and duloxetine or venlafaxine appears to be limited, but it is in line with the way both drugs are known to interact. If linezolid is used with a drug with serotonergic actions, including duloxetine and venlafaxine it would seem prudent to monitor for symptoms of serotonin syndrome, which may take several weeks to manifest. See 'serotonin syndrome', (p.9), for further details on the development and management of this syndrome.

Linezolid + SSRIs

Serotonin syndrome has been reported in patients taking linezolid with SSRIs.

Clinical evidence

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibacterials) when either were used with drugs known to interact with MAOIs, including unnamed SSRIs.[1,2] However, a number of case reports describe serotonin syndrome in patients given linezolid and an SSRI. These are described in the sections below.

(a) Citalopram

A case report describes an 85-year-old woman taking citalopram who developed tremor, confusion, dysarthria, hyperreflexia, agitation, and restlessness after linezolid was started. Citalopram was stopped and the symptoms resolved over 72 hours.[3] There are several other similar case reports of this interaction between linezolid and citalopram,[4-8] including one patient who was given citalopram 40 mg daily and mirtazapine 30 mg daily, whose symptoms resolved 2 days after stopping linezolid,[6] and one patient who received citalopram 40 mg daily and continued to show signs of serotonin syndrome 10 days after the end of a 12 day course of linezolid, which were partially resolved by cyproheptadine.[8]

(b) Escitalopram

A patient taking escitalopram 10 mg daily was also given intravenous linezolid 600 mg twice daily. After 3 days of concurrent therapy, she experienced two seizures. She also demonstrated mental status changes, agitation, and diarrhoea. Other causes of the seizures could not be ruled out, but the authors consider this case was highly suggestive of serotonin syndrome.[8]

(c) Fluoxetine

One patient taking fluoxetine had a transient episode of asymptomatic hypertension after one dose of linezolid, but since this patient had no other symptoms of serotonin syndrome, it was not considered an interaction.[2] However, a 4-year-old girl given fluoxetine 5 mg daily developed symptoms of serotonin syndrome 2 days after starting linezolid 140 mg every 12 hours, and after a procedure for which she was given fentanyl 200 micrograms. Fentanyl may have been a contributing factor.[9]

A further case report describes a 23-year old patient who received 6 doses of linezolid 600 mg whilst also taking fluoxetine 80 mg daily and developed abdominal pain, and unsteady gait. His symptoms were attributed to serotonin syndrome, and improved after the linezolid was stopped.[10]

A woman who was given linezolid 18 days after stopping fluoxetine developed serotonin syndrome, and required treatment with cyproheptadine.[11]

(d) Paroxetine

Paroxetine has also been implicated in the development of serotonin syndrome.[12,13] In one case paroxetine was stopped 3 days before linezolid was started.[12] In the other case, an elderly patient was given linezolid 600 mg every 12 hours, 21 days after amitriptyline 10 mg daily, paroxetine 20 mg daily and alprazolam 500 micrograms daily were started.[13]

(e) Sertraline

A woman taking sertraline 100 mg daily developed serotonin syndrome (incoordination, confusion and hypertension) 4 days after starting to take linezolid 600 mg twice daily. Her symptoms subsided 4 days after linezolid was withdrawn. She then required a further course of linezolid, and, despite stopping sertraline on day one, she again exhibited symptoms likely to be those of serotonin syndrome on day 9. The linezolid was stopped and cyproheptadine was given, and her symptoms resolved.[14] Other cases have also been published:[5,15,16] in one case symptoms resolved within one day of discontinuing linezolid and sertraline.[5]

Mechanism

Not fully understood. Linezolid has weak MAOI effects, and serotonin syndrome is known to occur when MAOIs are given with 'SSRIs', (p.1384). In the case of the patient taking linezolid with amitriptyline and paroxetine, it is possible that an interaction between amitriptyline and paroxetine contributed to the development of serotonin syndrome.

Importance and management

Information on the interaction between linezolid and the SSRIs, appears to be limited, but what is known suggests that the interaction is probably rare. The manufacturers of linezolid say that concurrent use of SSRIs should be avoided unless patients are closely observed[17] (for serotonin syndrome[18]) and have their blood pressure monitored.[17] If linezolid is used with a drug with serotonergic actions it would seem prudent to monitor for symptoms of serotonin syndrome, which may take several weeks to manifest. Note that in some cases, serotonin syndrome has occurred several days after stopping the SSRI. Consideration should be given to allowing a washout period after stopping the SSRI if clinically appropriate. See 'serotonin syndrome', (p.9), for further details on the development and management of this syndrome.

Linezolid + Tricyclic antidepressants

Serotonin syndrome has been reported in a patient taking linezolid with amitriptyline and paroxetine and is also predicted to occur if linezolid is given with any tricyclic antidepressant.

Clinical evidence, mechanism, importance and management

In an analysis of phase III studies, changes in vital signs did not differ between patients given linezolid and comparator drugs (i.e. antibacterials) when either were used with drugs known to interact with MAOIs, including unnamed cyclic antidepressants.[1,2] A case report describes serotonin syndrome in an elderly patient taking linezolid 600 mg every 12 hours, 21 days after amitriptyline 10 mg daily, paroxetine 20 mg daily and alprazolam 500 micrograms daily were started.[3] However, it seems possible that an interaction between amitriptyline and paroxetine, or between paroxetine and linezolid contributed to the development of serotonin syndrome in this case.

Information on an interaction between linezolid and the tricyclics is limited and inconclusive. However, both drugs have caused serotonin syndrome when given with other serotonergic drugs. The manufacturers of linezolid say that concurrent use of tricyclic antidepressants should be

avoided unless patients are closely observed[4] (for serotonin syndrome[5]) and have their blood pressure monitored.[4] If linezolid is used with a drug with serotonergic actions it would seem prudent to monitor for symptoms of serotonin syndrome, which may take several weeks to manifest. See 'serotonin syndrome', (p.9), for further details on the development and management of this syndrome.

5. Zyvox (Linezolid). Pharmacia & Upjohn. US Prescribing information, July 2008.

Linezolid + Vitamins

The pharmacokinetics of linezolid are not affected by either vitamin C or vitamin E.

Clinical evidence, mechanism, importance and management

In a study, healthy subjects were given vitamin C 1 g daily or vitamin E 800 units daily for 8 days with a single 600-mg dose of linezolid on day 6. As *in vitro* studies have indicated that endogenous reactive oxygen species (ROS) may affect linezolid clearance, it was considered possible that antioxidant supplements may affect the balance of ROS and linezolid clearance. However, the study found that antioxidants (vitamins C and E) given in doses far higher than the recommended daily intake did not affect linezolid pharmacokinetics. Therefore no dose adjustments are considered necessary during concurrent use.[1]

1. Gordi T, Tan LH, Hong C, Hopkins NJ, Francom SF, Slatter JG, Antal EJ. The pharmacokinetics of linezolid are not affected by concomitant intake of the antioxidant vitamins C and E. *J Clin Pharmacol* (2003) 43, 1161–7.

Loracarbef + Acetylcysteine

A study in healthy subjects found that acetylcysteine 200 mg had no effect on the absorption of loracarbef 400 mg.[1]

1. Roller S, Lode H, Stelzer I, Deppermann KM, Boeckh M, Koeppe P. Pharmacokinetics of loracarbef and interaction with acetylcysteine. *Eur J Clin Microbiol Infect Dis* (1992) 11, 851–5.

Loracarbef + Food

Food reduces the maximum plasma levels of loracarbef, but does not alter its bioavailability.

Clinical evidence, mechanism, importance and management

Loracarbef 400 mg was given to 12 healthy subjects either in a fasting state or following a standard breakfast. Food slowed the rate of absorption, but not the total bioavailability of loracarbef.[1] In another study, food was found to decrease the maximum plasma levels of a single 200-mg dose of loracarbef and increase the time to achieve maximum levels but the AUC of loracarbef was not significantly affected by food.[2] In a crossover study 24 healthy subjects received a single 200-mg dose of loracarbef after an overnight fast, a vegetarian low-fat breakfast, a vegetarian high-fat breakfast, a non-vegetarian low-fat breakfast, and a non-vegetarian high-fat breakfast. There was no significant difference between the pharmacokinetics of loracarbef observed after each of the four different meals. There was, however, a significant decrease in the maximum plasma level of loracarbef between the fed state and the fasted state, ranging from a 43% decrease with a high-fat vegetarian meal, to a 59% decrease with a low-fat non-vegetarian meal.[3] Loracarbef should be taken one hour before or 2 hours after food.[4]

Macrolides + Antacids

Aluminium/magnesium hydroxide antacids may reduce the peak levels of azithromycin, and aluminium/magnesium hydroxide (with simeticone) can prolong the absorption of erythromycin. Aluminium/magnesium hydroxide antacids do not appear to significantly alter the pharmacokinetics of clarithromycin, roxithromycin or telithromycin.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the peak serum levels, but not the total absorption, of **azithromycin** was reduced by 30 mL of *Maalox* (**aluminium**/**magnesium hydroxide**).[1] It is suggested therefore that **azithromycin** should not be given at the same time as antacids, but should be taken at least one hour before or 2 hours after.[2,3]

In 8 healthy subjects 30 mL of *Mylanta* (**aluminium**/**magnesium hydroxide** and [**simeticone**]) had no significant effect on the AUC, peak serum concentration, or time to peak serum concentration of **erythromycin stearate** 500 mg, but the mean elimination rate constant was more than doubled. It was suggested that the effect on elimination may be due to a possible prolonging of absorption, although the reason for this effect is unclear.[4] However, an *in vitro* study has suggested that the release and absorption of **erythromycin stearate** may be slowed in the presence of some antacids, including **aluminium** and **magnesium hydroxides**, **aluminium** and **magnesium trisilicates**, and **simeticone** because of adsorption of **erythromycin** by the antacids.[5] The clinical relevance of this is uncertain, but likely to be small.

Aluminium/magnesium hydroxide antacids are reported not to affect the pharmacokinetics of **clarithromycin**,[6] **roxithromycin**,[7] or **telithromycin**.[8,9]

Macrolides + Azoles

Moderate pharmacokinetic interactions appear to occur between several of the azoles and macrolides but many of these are unlikely to be of clinical significance. However, clarithromycin may almost double itraconazole levels, and ketoconazole may almost double telithromycin levels.

Clinical evidence, mechanism, importance and management

(a) Azithromycin

1. Fluconazole. Single doses of fluconazole 800 mg and azithromycin 1.2 g were given to 18 healthy subjects alone and together without any significant change in the pharmacokinetics of either drug.[1]

2. Voriconazole. In healthy subjects, azithromycin 500 mg daily for 3 days had no significant effect on the AUC and maximum plasma levels of voriconazole 200 mg twice daily.[2]

(b) Clarithromycin

1. Fluconazole. Twenty healthy subjects were given clarithromycin 500 mg twice daily for 8 days. Fluconazole 400 mg daily was added on day 5, followed by 200 mg daily on days 6 to 8. The fluconazole increased the minimum plasma levels of the clarithromycin by 33% and the $AUC_{0\text{-}12}$ by 18%.[3] These relatively small changes in the pharmacokinetics of clarithromycin are almost certainly of little or no clinical importance.

2. Itraconazole. A study in 8 patients with AIDS, taking itraconazole 200 mg daily, found that when clarithromycin 500 mg twice daily for 14 days was also given, the maximum serum levels and the AUC of the itraconazole were increased by 90% and 92%, respectively.[4] A report of 3 patients who took clarithromycin with itraconazole describes clarithromycin and itraconazole levels above the expected values in each of the patients. In one patient the clarithromycin plasma level was more than double the expected upper level, and the itraconazole level was almost ninefold the expected level.[5] Both clarithromycin and itraconazole are known to be metabolised by the hepatic cytochrome P450 isoenzyme CYP3A4 and it is therefore probable that competition for metabolism leads to a reduction in the clearance of itraconazole. The first report does not comment on the outcome of this almost twofold increase in itraconazole levels, but none of the three patients in the second report experienced signs or symptoms of either clarithromycin or itraconazole toxicity.[5] However, it would seem prudent to be alert for the need to reduce its dosage. More study is needed.

3. Posaconazole. The manufacturer of posaconazole notes that it is metabolised by UDP glucuronidation, and is a substrate for P-glycoprotein, and suggests that inhibitors of these pathways, (they name clarithromycin) may increase posaconazole plasma levels.[6] The clinical relevance of any interaction has not been established.

(c) Erythromycin

1. Itraconazole. The manufacturer of itraconazole notes that the peak plasma levels and AUC of a single 200-mg dose of itraconazole were increased by 44% and 36%, respectively, by a single 1-g dose of erythromycin ethyl succinate.[7] However, no dose adjustments are recommended.

2. Posaconazole. The manufacturer of posaconazole notes that it is metabolised by glucuronidation, and is a substrate for P-glycoprotein, and suggests that inhibitors of these pathways, (they name erythromycin) may increase posaconazole plasma levels.[6] The clinical relevance of any interaction has not been established.

3. Voriconazole. In healthy subjects, erythromycin 1 g twice daily for 7 days had no significant effect on the AUC and maximum plasma levels of voriconazole 200 mg twice daily.[2]

(d) Telithromycin

In a study in which healthy subjects were given either telithromycin 800 mg daily, **ketoconazole** 800 mg daily or both drugs together, it was found that the AUC and peak plasma levels of telithromycin were increased by 95% and 51%, respectively. It may be prudent to monitor for telithromycin adverse effects on concurrent use. In a further related study, healthy subjects were given **itraconazole** 200 mg daily, telithromycin 800 mg daily, or both drugs together. **Itraconazole** was found to increase the AUC and peak plasma levels of telithromycin by 54% and 22%, respectively. No serious adverse effects were reported in either study and telithromycin did not increase the QTc intervals observed with either **ketoconazole** or **itraconazole** alone.[8,9] Another study[10] by the same authors, in subjects aged 60 years or older and with a creatinine clearance of 30 mL/minute or more, found that, when **ketoconazole** was given, levels of telithromycin were increased but were only slightly higher than those found in younger healthy subjects[8] in the earlier study.

Macrolides + Food

Food appears to halve the absorption of azithromycin from the capsule formulation, but does not alter the AUC of azithromycin tablets or suspension. The pharmacokinetics of telithromycin are not altered by food.

Clinical evidence, mechanism, importance and management

(a) Azithromycin

A review by the manufacturers briefly mentions that food reduced the absorption of azithromycin by about half.[1] It is suggested therefore that azithromycin *capsules* should not be given at the same time as food, but should be taken at least one hour before or 2 hours after a meal.[1,2] However, the US manufacturers note that a high-fat meal increased the maximum levels of azithromycin *tablets* by 23%, and had no effect on the AUC.[3] Similarly, food increased the maximum levels of azithromycin *suspension* by 56%, without altering the AUC.[3] Azithromycin suspension[2,3] and tablets[3] may therefore be taken without regard to food.

(b) Telithromycin

In a crossover study, 18 healthy subjects were given a single 800-mg dose of telithromycin after an overnight fast, or at the end of a high-fat breakfast. There was no clinically significant change in the pharmacokinetics of telithromycin when taken with food.[4] Telithromycin can therefore be taken alone, or with food.[5]

Macrolides + Grapefruit juice

Grapefruit juice modestly increases the bioavailability of erythromycin, but does not affect the bioavailability of clarithromycin or telithromycin.

Clinical evidence

(a) Clarithromycin

In a study, 12 healthy subjects were given a single 500-mg dose of clarithromycin and 240 mL of either water or freshly squeezed grapefruit juice with and 2 hours after clarithromycin. Grapefruit juice increased the time to peak levels of both clarithromycin and its metabolite, 14-hydroxyclarithromycin, from about 82 minutes to 148 minutes and from about 85 minutes to 172 minutes, respectively, but it did not affect the extent of clarithromycin absorption and had no significant effects on any other pharmacokinetic parameters.[1]

(b) Erythromycin

A study in 6 healthy subjects given a single 400-mg dose of erythromycin with either water or grapefruit juice found that grapefruit juice increased the AUC and maximum plasma level of erythromycin by about 49% and

52%, respectively. The time to achieve maximum levels and the half-life of erythromycin were not affected.[2]

(c) Telithromycin

A study in 16 healthy subjects given telithromycin 800 mg daily found that grapefruit juice did not affect telithromycin pharmacokinetics.[3]

Mechanism

Some components of grapefruit juice, possibly flavonoids such as naringenin, or a psoralen, dihydroxybergamottin, may inhibit the activity of the cytochrome P450 isoenzyme CYP3A4 in the gut.[1] The levels of drugs metabolised by CYP3A4, such as the macrolides, may therefore be raised by grapefruit juice. Erythromycin levels, but not those of clarithromycin or telithromycin appear to be affected by grapefruit juice. It has been suggested that a drug with low or variable bioavailability may be more likely to have its levels increased by grapefruit juice and it has been suggested that this may partly explain why the pharmacokinetics of clarithromycin (bioavailability of about 55%) and telithromycin (bioavailability of about 60%) are not significantly affected.[1]

Importance and management

Information is very limited but it would appear that there is unlikely to be a clinically significant interaction between grapefruit juice and either clarithromycin or telithromycin. The increased bioavailability of erythromycin was found in a single-dose study and it has been suggested that more prolonged administration of erythromycin with grapefruit juice could increase levels further and potentially increase the risk of adverse effects.[4] More study is needed to establish this.

Macrolides + H_2-receptor antagonists

Cimetidine doubled the levels of erythromycin in one single-dose study, and a single case report describes reversible deafness, which was attributed to this interaction. No clinically significant interaction appears to occur when cimetidine is given with azithromycin or clarithromycin, or when ranitidine is given with clarithromycin, roxithromycin, or telithromycin.

Clinical evidence

(a) Cimetidine

A 64-year-old woman was admitted to hospital with cough, dyspnoea and pleuritic pain and was found to have an atypical pneumonia and renal impairment. All her antihypertensive treatment (methyldopa, propranolol, co-amilofruse) was stopped, due to hypotension, and her treatment for duodenal ulcer was changed from ranitidine 150 mg twice daily to cimetidine 400 mg at night. She was then given amoxicillin 500 mg three times daily and **erythromycin** stearate 1 g four times daily. Two days later she complained of 'fuzzy hearing' and audiometry showed a bilateral hearing loss. The **erythromycin** was stopped and her hearing returned to normal after 5 days.[1] This prompted a study of this possible interaction in 8 healthy subjects, which found that cimetidine 400 mg twice daily increased the AUC of a single 250-mg dose of **erythromycin** by 73%. Maximum serum **erythromycin** levels were doubled.[1]

The pharmacokinetics of **azithromycin** were not affected by a single 800-mg dose of cimetidine in one study,[2] and although cimetidine prolongs the absorption of **clarithromycin**, this is unlikely to be of clinical significance.[3]

(b) Ranitidine

The pharmacokinetics of **clarithromycin**,[4] **roxithromycin**[5] and **telithromycin**[6,7] are reported to be unaffected by ranitidine.

Mechanism

Cimetidine is known to inhibit the *N*-demethylation of erythromycin so that it is metabolised and cleared from the body more slowly and its serum levels rise. Deafness is known to be one of the adverse effects of erythromycin,[1] which usually occurs with high-doses or intravenous use, and was probably exacerbated by renal impairment[4] in the patient described above.

Importance and management

Clinical information about an interaction between cimetidine and erythromycin seems to be limited to this case and the associated single-dose study. The manufacturers note that, with erythromycin alone, reversible hearing loss has been reported, usually in patients with renal impairment and those receiving high doses[8] (greater than 4 g daily[9]) and usually when given by the intravenous route.[9] If deafness were to occur, the management would seem to be similar (withdraw the erythromycin) regardless of whether or not cimetidine was present, so no additional precautions seem necessary.

There is evidence that azithromycin and clarithromycin do not interact with cimetidine, and ranitidine does not interact with clarithromycin, roxithromycin or telithromycin. No interaction would be expected between the macrolides and other non-enzyme inducing H_2-receptor antagonists.

Macrolides + Penicillins

Although there is *in vitro* evidence of antagonism between erythromycin and penicillins, this combination has been used successfully to treat community-acquired pneumonia.

Clinical evidence, mechanism, importance and management

Some *in vitro* evidence suggests that antagonism may occur between erythromycin (a bacteriostatic drug) and penicillins (bactericidal drugs) when they are used against staphylococci[1] and *Streptococcus pneumoniae*.[2] However, another study has suggested that this *in vitro* antagonism against *S. pneumoniae* between 'penicillin' and erythromycin is minimal and dependent on the interpretative criteria applied.[3] Clinical evidence for this interaction is apparently lacking, and the combination is generally used successfully for pneumonia.[4] In the UK, the combination of amoxicillin and erythromycin or another macrolide (e.g. azithromycin or clarithromycin) has been recommended by the British Thoracic Society (BTS) for adult patients with non-severe community-acquired pneumonia who require hospital admission.[5] In addition, the BTS has recommended an intravenous combination of a beta-lactamase stable antibacterial such as co-amoxiclav (amoxicillin with clavulanic acid) with a macrolide (erythromycin or clarithromycin) for severe community-acquired pneumonia in hospitalised patients.[6]

Macrolides + Rifamycins

The concurrent use of rifabutin and azithromycin does not appear to affect the levels of either drug, but a very high incidence of neutropenia was seen in one study of the combination. Both rifabutin and rifampicin markedly reduce clarithromycin levels. Clarithromycin increases the levels of rifabutin and the combination is associated with an increased risk of uveitis and neutropenia. Rifampicin (rifampin) greatly reduces telithromycin levels and concurrent use is not recommended.

Clinical evidence

(a) Rifabutin

1. Neutropenia. A study in 12 healthy subjects was designed to investigate the safety and possible interactions between rifabutin 300 mg daily, and **azithromycin** 250 mg daily or **clarithromycin** 500 mg twice daily, over 14 days. The subjects were matched against 18 healthy controls who received either of the macrolides or rifabutin alone. The study had to be abandoned after 10 days because 14 patients developed neutropenia; 2 taking rifabutin alone, and all 12 of those taking rifabutin with a macrolide. Eight subjects developed a fever, 5 required colony simulating factors, and 3 required hospitalisation.[1]

2. Pharmacokinetics. In a randomised study[2] investigating a possible regimen for the prophylaxis of *Mycobacterium avium* complex (MAC) disease, 12 HIV-positive patients were given **clarithromycin** 500 mg daily, to which rifabutin 300 mg daily was added on day 15. By day 42 the **clarithromycin** AUC had fallen by 44%, and the levels of the metabolite, 14-hydroxyclarithromycin, had risen by 57%. A further 14 patients were given rifabutin 300 mg daily with **clarithromycin** 500 mg every 12 hours from day 15. After 28 days the AUC of the rifabutin had increased by 99%, and the AUC of the active metabolite, 25-*O*-desacetyl-rifabutin, had increased by 375%. Another group of patients with lung disease due to MAC were given **clarithromycin** 500 mg twice daily. When rifabutin 600 mg was added the **clarithromycin** levels fell by 63% (from 5.4 to 2 micrograms/mL).[3] Limited information from a randomised study in healthy subjects suggested similar results.[1] Fluconazole appears to further increase the effects of clarithromycin on rifabutin.[4] One study suggests that there is no pharmacokinetic interaction between **azithromycin** and rifabutin.[1]

3. Uveitis or arthralgias. Uveitis, and in some cases pseudojaundice, aphthous stomatitis and an arthralgia syndrome have been described in patients taking both **clarithromycin** 1 to 2 g daily and rifabutin 300 to 600 mg daily.[5-8] The authors of a study in which patients with pulmonary *Mycobacterium avium* complex disease were given rifabutin 600 mg daily with clarithromycin 500 mg twice daily (15 patients) or azithromycin 600 mg daily (11 patients) considered that overall there was a high incidence of adverse events, which included 2 patients in the clarithromycin group who developed uveitis requiring discontinuation of both drugs.[9]
Reports suggest that uveitis develops between 27 to 370 days after taking the combination.[6,7] The reaction appears to be dose-dependent. In patients taking rifabutin 600 mg with clarithromycin the incidence of uveitis was 14% in patients weighing more than 65 kg, 45% in those weighing between 55 and 65 kg and 64% in those weighing less than 55 kg. The risk of developing uveitis was reduced from a mean of 43% to 13% when the dose of rifabutin was reduced to 300 mg daily.[10] The presence of fluconazole does not appear to affect the development of uveitis in patients taking clarithromycin with rifabutin,[6,7,10] but it has been suggested that this was because only small doses (50 mg) were used.[7]
Uveitis did not develop in 8 patients taking rifabutin and **azithromycin** 500 mg daily,[7] although cases of uveitis have been reported in patients taking rifabutin, fluconazole, and **azithromycin** 1.2 g weekly but they have been attributed to an interaction between rifabutin and fluconazole.[11]
See 'Azoles + Rifabutin', p.247.

(b) Rifampicin (Rifampin)

Patients with lung disease due to MAC were given **clarithromycin** 500 mg twice daily. When rifampicin 600 mg daily was added, the mean serum levels of **clarithromycin** fell by almost 90% (from 5.4 to 0.7 micrograms/mL).[3] Similar results are reported in two further studies.[12,13]

The manufacturer of **telithromycin** notes that rifampicin reduces its AUC and maximum serum levels by 86% and 79%, respectively.[14]

Two cases of cholestatic jaundice have been reported in patients taking rifampicin with **troleandomycin**.[15,16]

Mechanism

Both rifabutin and rifampicin (rifampin) are known enzyme inducers, which can increase the metabolism of other drugs by the liver, thereby reducing their serum levels. Rifampicin is recognised as being the more potent inducer. Rifabutin is also a substrate for the cytochrome P450 isoenzyme CYP3A4. Both clarithromycin and fluconazole are inhibitors of CYP3A4 and it is probable that clarithromycin and fluconazole exert additive effects resulting in greater inhibition of rifabutin metabolism than occurs with either drug alone.[4]

The reason for the uveitis is not known, but based on *animal* studies it has been suggested that it is associated with effective treatment of MAC and is due to release of a mycobacterial protein, rather than a toxic effect of the drugs.[17] It has been suggested that lower body-weight and concurrent clarithromycin may result in toxic rifabutin serum levels, although concurrent fluconazole, which increases rifabutin levels, does not appear to be a factor.[10] The hepatotoxicity seen with rifampicin and troleandomycin is probably due to additive effects as both drugs are known to be hepatotoxic.

Importance and management

(a) Rifabutin and Rifampicin: Pharmacokinetics

Direct information appears to be limited to the reports cited but the interactions would appear to be established. What is not entirely clear is whether these interactions result in treatment failures because of the potentially subtherapeutic clarithromycin serum levels. Because of the lack of information, be alert for evidence of reduced efficacy if clarithromycin and rifampicin are used.

Although rifabutin can lower clarithromycin levels, the efficacy of this combination for MAC infection is established, although not without risk, see *Uveitis*, below. Clarithromycin raises rifabutin levels and therefore increases the risks of adverse effects. Concurrent use may therefore be desirable, but monitoring for adverse effects is necessary.

Due to a pharmacokinetic interaction the UK manufacturers recommend that telithromycin should not be given during and for 2 weeks after the use of rifampicin.[14]

(b) Rifabutin: Neutropenia

Information regarding neutropenia with macrolides and rifamycins is very limited but what is known suggests that white cell counts should be monitored closely if rifabutin is given with azithromycin or clarithromycin. Rifabutin is known to cause polyarthritis on rare occasions, but in conjunction with clarithromycin it appears to happen at much lower doses.[8] Careful monitoring is necessary.

(c) Rifabutin: Uveitis

The CSM in the UK has warned about the need to be aware of the increased risk of uveitis with clarithromycin and rifabutin. If uveitis occurs the CSM recommends that rifabutin should be stopped and the patient should be referred to an ophthalmologist. Because of the increased risk of uveitis they also say that consideration should be given to reducing the dose of rifabutin to 300 mg daily in the presence of macrolides.[18] A review and a case-control study also suggest that this dose is associated with a reduced risk of uveitis and maintains efficacy.[10,19] A similar suggestion has been made by others.[9]

Macrolides; Azithromycin + Ceftriaxone

A study in healthy subjects found that there did not appear to be a pharmacokinetic interaction between steady-state intravenous azithromycin and ceftriaxone: the combination was well-tolerated.[1]

1. Chiu LM, Menhinick AM, Johnson PW, Amsden GW. Pharmacokinetics of intravenous azithromycin and ceftriaxone when administered alone and concurrently to healthy volunteers. *J Antimicrob Chemother* (2002) 50, 1075–9.

Macrolides; Azithromycin + Chloroquine

A study in which healthy subjects were given azithromycin 1 g daily for 3 days either alone or with chloroquine base 600 mg daily on days 1 and 2, and 300 mg on day 3, found no pharmacokinetic interaction.[1]

1. Cook JA, Randinitis EJ, Bramson CR, Wesche DL. Lack of a pharmacokinetic interaction between azithromycin and chloroquine. *Am J Trop Med Hyg* (2006) 74, 407–12.

Macrolides; Clarithromycin + Disulfiram

Fatal toxic epidermal necrolysis and fulminant hepatitis occurred in a patient taking disulfiram and clarithromycin.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had taken disulfiram 250 mg daily for about a month, with clarithromycin 500 mg twice daily and paracetamol 500 mg three times daily for one week, developed fatal toxic epidermal necrolysis and fulminant hepatitis. He had not drunk alcohol for several weeks and although he was taking paracetamol, the dose was below the toxic range and therefore an interaction between disulfiram and clarithromycin was considered probable.[1]

Disulfiram alone may cause hepatic toxicity, possibly as the result of hypersensitivity or toxic metabolites. It was suggested that inhibition of the cytochrome P450 isoenzyme CYP3A4 by clarithromycin could have resulted in the accumulation of toxic metabolites of disulfiram. Hepatocellular damage is uncommon in patients receiving clarithromycin alone, but may occur in patients with underlying disease. Both clarithromycin and disulfiram alone may cause adverse skin reactions, but neither has been reported to cause toxic epidermal necrolysis. The reason why this should occur on concurrent use is not understood.[1] Information seems to be limited to this single report, so no general conclusions can be drawn.

Macrolides; Erythromycin + Carbimazole

An isolated case describes torsade de pointes in an elderly patient taking carbimazole and oral erythromycin.

Clinical evidence

A 75-year-old woman with known mild mitral stenosis taking digoxin, furosemide, warfarin and carbimazole was given oral erythromycin 250 mg four times daily for a urinary tract infection. Three days later she experienced presyncopal episodes, and 4 days later she was admitted to hospital with syncope and self-terminating episodes of torsade de pointes. She completed the 7-day course of erythromycin on the day before admission. Five days after admission, when the QT interval was back to normal, she was inadvertently rechallenged with erythromycin, given as prophylaxis before permanent pacemaker insertion. After two doses of erythromycin 500 mg given at an interval of 6 hours, she developed torsade de pointes associated with a prolonged QT interval (QTc 612 milliseconds). The QT interval returned to normal 4 days after erythromycin was discontinued.[1]

Mechanism

QT prolongation and torsade de pointes are rare with oral erythromycin. Carbimazole is rapidly metabolised to thiamazole which is the active form of the drug. Thiamazole inhibits cytochrome P450 isoenzymes including CYP3A4 and it may therefore have inhibited the metabolism of erythromycin resulting in higher than normal levels. In addition, hypothyroidism can cause torsade de pointes, and therefore mild hypothyroidism induced by carbimazole could have contributed.[1] Furthermore, bradycardia (heart rate less than 60 bpm) may also have contributed to the development of torsade de pointes.

Importance and management

It was suggested that the combination of oral erythromycin and carbimazole could lead to torsade de pointes in susceptible individuals. In this case, female sex, presence of valvular heart disease, bradycardia, hypokalaemia, and hypothyroidism may all have been contributory factors.[1] See also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Macrolides; Erythromycin + Sucralfate

Sucralfate does not appear to affect the pharmacokinetics of erythromycin.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects the pharmacokinetics (elimination rate constant, half-life, AUC) of a single 400-mg dose of erythromycin ethylsuccinate were not significantly altered by a single 1-g dose of sucralfate. It was concluded that the therapeutic effects of erythromycin are unlikely to be affected by concurrent use.[1]

1. Miller LG, Prichard JG, White CA, Vytla B, Feldman S, Bowman RC. Effect of concurrent sucralfate administration on the absorption of erythromycin. *J Clin Pharmacol* (1990) 30, 39–44.

Macrolides; Erythromycin + Urinary acidifiers or alkalinisers

In the treatment of urinary tract infections, the antibacterial activity of erythromycin is maximal in alkaline urine and minimal in acidic urine.

Clinical evidence

Urine taken from 7 subjects receiving erythromycin 1 g every 8 hours, was tested against 5 genera of Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Pseudomonas aeruginosa* and *Serratia* sp.) both before and after treatment with **acetazolamide** or **sodium bicarbonate**, given to alkalinise the urine. A direct correlation was found between the activity of the antibacterial and the pH of the urine. In general, acidic urine had little or no antibacterial activity, whereas alkalinised urine had activity.[1]

Clinical studies have confirmed the increased antibacterial effectiveness of erythromycin in the treatment of bacteriuria when the urine is made alkaline.[2,3]

Mechanism

The pH of the urine does not apparently affect the way the kidney handles erythromycin (most of it is excreted actively rather than passively) but it does have a direct influence on the way the antibacterial affects the microorganisms. Mechanisms suggested include effects on bacterial cell receptors, the induction of active transport mechanisms on bacterial cell walls, and changes in ionisation of the antibacterial, which enables it to enter the bacterial cell more effectively.

Importance and management

An established interaction, which can be exploited. Should erythromycin be used to treat urinary tract infections its efficacy can be maximised by making the urine alkaline (for example with acetazolamide or sodium bicarbonate). Treatment with urinary acidifiers will minimise the activity of the erythromycin for urinary tract infections and should be avoided. There is no evidence that the efficacy of erythromycin in other infections is affected by urinary acidifiers or alkalinisers.

Methenamine + Urinary acidifiers or alkalinisers

Urinary alkalinisers (e.g. potassium or sodium citrate) and those antacids that can raise the urinary pH above 5.5 inhibit its activation of methenamine.

Clinical evidence, mechanism, importance and management

Methenamine and methenamine mandelate are only effective as urinary antiseptics if the pH is about 5.5 or lower, when formaldehyde is released. This is normally achieved by giving urinary acidifiers such as ammonium chloride, ascorbic acid,[1,2] or sodium acid phosphate. In the case of methenamine hippurate, the acidification of the urine is achieved by the presence of hippuric acid. The concurrent use of substances that raise the urinary pH such as **acetazolamide**, **sodium bicarbonate**, **potassium** or **sodium citrate** is clearly contraindicated. **Potassium citrate mixture BPC** has been shown to raise the pH by more than 1 at normal therapeutic doses, thereby making the urine sufficiently alkaline to interfere with the activation of methenamine to formaldehyde.[3] Some **antacids** (containing magnesium, aluminium or calcium as well as sodium bicarbonate, as mentioned above) can also cause a significant rise in the pH of the urine.[4]

Metronidazole + Barbiturates

Phenobarbital markedly increases the metabolism of metronidazole and treatment failure has been reported in both adults and children.

Clinical evidence

A woman with vaginal trichomoniasis was given metronidazole on several occasions over the course of a year, but the infection flared up again as soon as it was stopped. When it was realised that she was also taking **phenobarbital** 100 mg daily, the metronidazole dose was doubled to 500 mg three times daily, and she was cured after a 7-day course.[1] A pharmacokinetic study found that the clearance of metronidazole was increased by **phenobarbital** (half-life 3.5 hours compared with the normal half-life of 8 to 9 hours).[1]

A retrospective study in children who had not responded to metronidazole for giardiasis or amoebiasis found that 80% of them had been taking long-term **phenobarbital**. In a prospective study in 36 children the normal recommended metronidazole dose had to be increased about threefold to 60 mg/kg to achieve a cure. The half-life of metronidazole in 15 other children taking **phenobarbital** was found to be 3.5 hours, compared with the normal half-life of 8 to 9 hours.[2]

Other studies in patients with Crohn's disease and healthy subjects have found that **phenobarbital** reduces the AUC of metronidazole by about one-third,[3] and increases the clearance of metronidazole by 50%.[4]

Mechanism

Phenobarbital is a known, potent liver-enzyme inducer, which increases the metabolism and clearance of metronidazole from the body.

Importance and management

An established and clinically important interaction. Monitor the effects of concurrent use and anticipate the need to increase the metronidazole dose two to threefold if phenobarbital is given. All of the barbiturates are potent liver enzyme inducers and would therefore be expected to interact similarly.

Metronidazole + Chloroquine

An isolated report describes acute dystonia in one patient, which was attributed to an interaction between metronidazole and chloroquine.

Clinical evidence, mechanism, importance and management

A patient was given a 7-day course of metronidazole and ampicillin, following a laparoscopic investigation. She developed acute dystonic reactions (facial grimacing, coarse tremors, and an inability to maintain posture) on day 6, within 10 minutes of being given chloroquine phosphate (equivalent to 200 mg of base) and intramuscular promethazine 25 mg. The dystonic symptoms started to subside within 15 minutes of being given diazepam 5 mg intravenously, and had completely resolved within 2 hours.[1]

The authors of the report attribute the dystonia to an interaction between metronidazole and chloroquine as she had taken both drugs alone without

adverse effect. However, they do not fully assess the possible contribution of **promethazine**, which is known to cause dystonias. It is therefore possible that the reaction seen was an adverse effect of the **promethazine**, or perhaps even an interaction between **promethazine** and chloroquine, which, very rarely, has been associated with movement disorders. No general recommendations can therefore be made from this single report.

1. Achumba JI, Ette EI, Thomas WOA, Essien EE. Chloroquine-induced acute dystonic reactions in the presence of metronidazole. *Drug Intell Clin Pharm* (1988) 22, 308–10.

Metronidazole and related drugs + Cimetidine

Cimetidine reduces the metabolism of tinidazole, and possibly also metronidazole.

Clinical evidence

(a) Metronidazole

In 6 healthy subjects, the half-life of a 400-mg intravenous dose of metronidazole was increased from 6.2 hours to 7.9 hours by cimetidine 400 mg twice daily for 6 days. The total plasma clearance of metronidazole was reduced by almost 30%.[1] However, in another study in 6 patients with Crohn's disease, cimetidine 600 mg twice daily for 7 days was found not to affect either the AUC or the half-life of metronidazole,[2] and no evidence of an interaction was found in a further study in 6 healthy subjects.[3]

(b) Tinidazole

In a study in 6 healthy subjects, cimetidine 400 mg twice daily for 7 days raised the peak serum levels of a single 600-mg dose of tinidazole by 21%, increased the 24-hour AUC by 40% and increased the half-life by 47%, from 7.66 to 11.23 hours.[4]

Mechanism

Cimetidine is a well known enzyme inhibitor, which probably inhibits the metabolism of the metronidazole and tinidazole by the liver.

Importance and management

Evidence for an interaction between metronidazole or tinidazole and cimetidine appears to be limited to these studies. With metronidazole, only one study found an interaction, but the effects were modest, and unlikely to be clinically relevant. Similarly the effects of cimetidine on tinidazole are small, and probably not of any clinical importance.

4. Patel RB, Shah GF, Raval JD, Gandhi TP, Gilbert RN. The effect of cimetidine and rifampicin on tinidazole kinetics in healthy human volunteers. *Indian Drugs* (1986) 23, 338–41.

Metronidazole + Diosmin

Diosmin reduces the metabolism of metronidazole to some extent.

Clinical evidence, mechanism, importance and management

A single 800-mg dose of metronidazole was given to 12 healthy subjects following 9 days of treatment with diosmin 500 mg daily. The metronidazole AUC and maximum plasma concentrations were raised by 27% and 25%, respectively.[1] This interaction is thought to occur because of an inhibitory effect of diosmin on metronidazole metabolism by hepatic enzymes, and inhibition of P-glycoprotein. The increase in metronidazole levels is similar to that seen with other drugs (e.g. 'cimetidine', (above)), and are not considered to be clinically significant. Therefore no clinically significant pharmacokinetic interaction is likely to occur if metronidazole is given with diosmin.

1. Rajnarayana K, Reddy MS, Krishna DR. Diosmin pretreatment affects bioavailability of metronidazole. *Eur J Clin Pharmacol* (2003) 58, 803–807.

Metronidazole + Disulfiram

Acute psychoses and confusion can be caused by the concurrent use of metronidazole and disulfiram.

Clinical evidence, mechanism, importance and management

In a double-blind study in 58 hospitalised chronic alcoholics taking disulfiram, 29 patients were also given metronidazole 750 mg daily for a month, then 250 mg daily thereafter. Six of the 29 subjects in the group receiving metronidazole developed acute psychoses or confusion. Five of the 6 had paranoid delusions and in 3 visual and auditory hallucinations were also seen. The symptoms persisted for 2 to 3 days after the drugs were withdrawn, but had disappeared after about 2 weeks and did not reappear when disulfiram alone was restarted.[1] Similar reactions have been described in two other reports.[2,3]

The reason for this interaction is not understood, but it appears to be established. Concurrent use should be avoided or very well monitored. Withdrawing the drugs appears to resolve any adverse effects.

Metronidazole + Mebendazole

A case-control study identified the concurrent use of metronidazole and mebendazole as a risk factor in an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Clinical evidence, mechanism, importance and management

A case control study was conducted in an attempt to identify risk factors associated with an outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis that occurred amongst Filipino workers in Taiwan. The risk of developing this serious condition was significantly higher in workers who had taken both metronidazole and mebendazole sometime in the preceding 6 weeks (odds ratio of 9.5). In addition, there was an increase in risk with higher doses of metronidazole.[1]

The information is limited to this report, which does not establish an interaction. However, Stevens-Johnson syndrome/toxic epidermal necrolysis is a serious condition, and therefore, the manufacturer of mebendazole states that the concurrent use of mebendazole and metronidazole should be avoided.[2] Caution would certainly seem appropriate if both drugs are considered essential.

1. Chen K-T, Twu S-J, Chang H-J, Lin R-S. Outbreak of Stevens-Johnson syndrome/toxic epidermal necrolysis associated with mebendazole and metronidazole use among Filipino laborers in Taiwan. *Am J Public Health* (2003) 93, 489–92.
2. Vermox (Mebendazole). Janssen-Cilag Ltd. UK Summary of product characteristics, May 2009.

Metronidazole + Miscellaneous

The absorption of metronidazole is unaffected by kaolin-pectin, but it is slightly reduced by an aluminium hydroxide antacid and colestyramine.

Clinical evidence, mechanism, importance and management

In 5 healthy subjects, the bioavailability of a single 500-mg dose of metronidazole was not significantly changed by 30 mL of a **kaolin-pectin** antidiarrhoeal mixture. However, a 15% reduction in metronidazole bioavailability occurred with 30 mL of an **aluminium hydroxide**/**simeticone** suspension, and a 21% reduction occurred with a single 4-g dose of

colestyramine.[1] The clinical importance of these reductions is small, and no special precautions seem necessary on concurrent use.

1. Molokhia AM, Al-Rahman S. Effect of concomitant oral administration of some adsorbing drugs on the bioavailability of metronidazole. *Drug Dev Ind Pharm* (1987) 13, 1229–37.

Metronidazole + Prednisone

Prednisone modestly decreases the AUC of metronidazole.

Clinical evidence, mechanism, importance and management

In 6 patients with Crohn's disease the AUC of metronidazole 250 mg twice daily was reduced by 31% by prednisone 10 mg twice daily for 6 days. It was suggested that this occurred because prednisone induces the metabolism of metronidazole by liver enzymes.[1]

Information appears to be limited to this report and the interaction is probably of only limited clinical importance. Information about other corticosteroids is lacking.

1. Eradiri O, Jamali F, Thomson ABR. Interaction of metronidazole with phenobarbital, cimetidine, prednisone, and sulfasalazine in Crohn's disease. *Biopharm Drug Dispos* (1988) 9, 219–27.

Metronidazole and related drugs + Rifampicin (Rifampin)

Rifampicin modestly increases the clearance of metronidazole and tinidazole.

Clinical evidence

(a) Metronidazole

Intravenous metronidazole 500 mg or 1 g was given to 10 healthy subjects before and after they took rifampicin 450 mg daily for 7 days. Rifampicin reduced the AUC of metronidazole by 33% and increased its clearance by 44%. Results were the same with both metronidazole doses.[1]

(b) Tinidazole

In a study in 6 healthy subjects, rifampicin 600 mg daily for 7 days reduced the peak serum levels of a single 600-mg dose of tinidazole by 22%, reduced its $AUC_{0\text{-}24}$ by 30% and reduced its half-life by 27% (from 7.66 to 5.6 hours).[2]

Mechanism

This interaction almost certainly occurs because rifampicin (a well-recognised and potent enzyme inducer) increases the metabolism of metronidazole and tinidazole by the liver.

Importance and management

The clinical significance of these interactions appear not to have been studied. A 30% reduction in metronidazole exposure would not be expected to be of much clinical significance and there do not appear to be any reports of an interaction in practice. The effect of rifampicin on tinidazole is smaller, and a clinically relevant reduction in the effects of tinidazole seems unlikely.

1. Djojosaputro M, Mustofa SS, Donatus IA, Santoso B. The effects of doses and pre-treatment with rifampicin on the elimination kinetics of metronidazole. *Eur J Pharmacol* (1990) 183, 1870–1.
2. Patel RB, Shah GF, Raval JD, Gandhi TP, Gilbert RN. The effect of cimetidine and rifampicin on tinidazole kinetics in healthy human volunteers. *Indian Drugs* (1986) 23, 338–41.

Metronidazole + Sucralfate

Sucralfate does not alter the pharmacokinetics of metronidazole.

Clinical evidence, mechanism, importance and management

Because oral triple therapy to eradicate *Helicobacter pylori* using sucralfate instead of bismuth has yielded inconsistent results, a 5-day study was undertaken in 14 healthy subjects to investigate whether sucralfate interacts with metronidazole. It was found that sucralfate 2 g twice daily had no effect on the pharmacokinetics of a single 400-mg dose of metronidazole.[1] Sucralfate would therefore not be expected to alter the effects of metronidazole.

1. Amaral Moraes ME, De Almeida Pierossi M, Moraes MO, Bezerra FF, Ferreira De Silva CM, Dias HB, Muscará MN, De Nucci G, Pedrazzoli J. Short-term sucralfate administration does not alter the absorption of metronidazole in healthy male volunteers. *Int J Clin Pharmacol Ther* (1996) 34, 433–7.

Nitrofurantoin + Antacids

Magnesium trisilicate reduces the absorption of nitrofurantoin. Aluminium hydroxide is reported not to interact with nitrofurantoin. Whether other antacids interact adversely is uncertain.

Clinical evidence

In 6 healthy subjects, **magnesium trisilicate** 5 g in 150 mL of water reduced the absorption of a single 100-mg oral dose of nitrofurantoin by more than 50%. The time during which the concentration of nitrofurantoin in the urine was at, or above 32 micrograms/mL (a level stated to be the minimum inhibitory concentration) was also reduced.[1] The amounts of nitrofurantoin adsorbed by other antacids during *in vitro* tests were as follows: **magnesium trisilicate** and **charcoal** 99%, **bismuth subcarbonate** and **talc** 50 to 53%, **kaolin** 31%, **magnesium oxide** 27%, **aluminium hydroxide** 2.5% and **calcium carbonate** 0%.[1]

A crossover study in 6 healthy subjects confirmed that **aluminium hydroxide gel** does not affect the absorption of nitrofurantoin from the gut (as measured by its excretion into the urine).[2] Another study, in 10 healthy subjects, found that an antacid containing **aluminium/magnesium hydroxide** and **magnesium carbonate** reduced the absorption of nitrofurantoin by 22%.[3]

Mechanism

Antacids can, to a greater or lesser extent, adsorb nitrofurantoin onto their surfaces, as a result less is available for absorption by the gut and for excretion into the urine.

Importance and management

Information appears to be limited to these reports. There seems to be nothing in the literature confirming that a clinically important interaction occurs between nitrofurantoin and antacids. One reviewer offers the opinion that common antacid preparations are unlikely to interact with nitrofurantoin.[4]

It is not yet known whether magnesium trisilicate significantly reduces the antibacterial effectiveness of nitrofurantoin but the response should be monitored. While it is known that the antibacterial action of nitrofurantoin is increased by drugs that acidify the urine (so that reduced actions would be expected if the urine were made more alkaline by antacids) this again does not seem to have been confirmed. The results of the *in vitro* studies suggest that the possible effects of the other antacids are quite small, and aluminium hydroxide is reported not to interact.

Nitrofurantoin + Antigout drugs

On theoretical grounds the toxicity of nitrofurantoin may possibly be increased, and its efficacy in urinary tract infections decreased, by probenecid and sulfinpyrazone.

Clinical evidence, mechanism, importance and management

A study of the way the kidneys handle nitrofurantoin found that intravenous **sulfinpyrazone** 2.5 mg/kg reduced the secretion of nitrofurantoin by the renal tubules by about 50%.[1] This reduction would be expected to reduce its urinary antibacterial efficacy, and the higher serum levels might lead to increased systemic toxicity, but there do not seem to be any reports

suggesting that this represents a real problem in practice. The same situation would also seem likely with **probenecid**, but there do not appear to be any reports confirming this interaction.

The clinical importance of both of these interactions is therefore uncertain, but it would seem prudent to be alert for any evidence of reduced antibacterial efficacy and increased systemic toxicity if either **sulfinpyrazone** or **probenecid** is used with nitrofurantoin.

Nitrofurantoin + Antimuscarinics or Diphenoxylate

Diphenoxylate and antimuscarinic drugs such as propantheline can double the absorption of nitrofurantoin in some patients.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects **propantheline** 30 mg given 45 minutes before nitrofurantoin approximately doubled the absorption of nitrofurantoin 100 mg (as measured by the urinary excretion).[1] In another study, **diphenoxylate** 200 mg daily for 3 days nearly doubled nitrofurantoin absorption in 2 out of 6 men.[2] **Atropine** 500 micrograms given subcutaneously 30 minutes before a single 100-mg dose of nitrofurantoin had little effect on the bioavailability of nitrofurantoin, but the absorption and excretion into the urine was delayed.[3]

It was suggested that the reduced gut motility caused by these drugs allows the nitrofurantoin to dissolve more completely so that it is absorbed by the gut more easily. Whether this is of any clinical importance is uncertain but it could possibly increase the incidence of dose-related adverse reactions. So far there appear to be no reports of any problems arising from concurrent use.

Nitrofurantoin + Azoles

In an isolated case hepatic and pulmonary toxicity occurred when nitrofurantoin was given with fluconazole, but not with itraconazole.

Clinical evidence, mechanism, importance and management

A 73-year-old man who had taken nitrofurantoin 50 mg daily for 5 years was given **fluconazole** 150 mg weekly for onychomycosis. At the start of treatment with **fluconazole** his hepatic enzyme levels were slightly raised, and 3 weeks later they were increased more than twofold. Two months after starting **fluconazole** the patient's hepatic enzyme levels had increased fivefold and he had fatigue, dyspnoea on exertion, pleuritic pain, burning tracheal pain, and a cough. Bilateral pulmonary disease was confirmed by chest X-rays, and pulmonary function tests suggested nitrofurantoin toxicity. Both **fluconazole** and nitrofurantoin were discontinued, and hepatic and lung function gradually improved.[1]

Either **fluconazole** or nitrofurantoin could have caused the liver toxicity. However, it was considered that both the lung and liver toxicity may have been due to an interaction between nitrofurantoin and **fluconazole**, possibly due to increased nitrofurantoin concentrations resulting from competition with **fluconazole** for renal tubular secretion.

Some 2 years earlier the patient had received pulse **itraconazole** (less than 1% excreted in the urine as active drug) with nitrofurantoin without raised liver enzymes or any other adverse effects.[1]

Information appears to be limited to this report, but bear it in mind in the event of increased nitrofurantoin adverse effects. More study is needed.

1. Linnebur SA, Parnes BL. Pulmonary and hepatic toxicity due to nitrofurantoin and fluconazole treatment. *Ann Pharmacother* (2004) 38, 612–16.

Nitrofurantoin + Metoclopramide

Metoclopramide reduces the absorption of nitrofurantoin.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects the urinary excretion of a 100-mg dose of nitrofurantoin was approximately halved by pretreatment with a 10-mg intramuscular dose of metoclopramide and a 10-mg oral dose of metoclopramide given 30 minutes before the nitrofurantoin.[1]

It is thought that metoclopramide increases the gastric emptying rate, thus decreasing nitrofurantoin absorption. The practical importance of this is uncertain, and there seem to be no reports of an interaction in practice.

1. Männistö P. The effect of crystal size, gastric content and emptying rate on the absorption of nitrofurantoin in healthy human volunteers. *Int J Clin Pharmacol Biopharm* (1978) 16, 223–8.

Nitrofurantoin + Pyridoxine (Vitamin B_6)

Paraesthesias occurred in an elderly woman who had taken pyridoxine for several years and several courses of nitrofurantoin over a 10-year period.

Clinical evidence, mechanism, importance and management

A 73-year-old woman with a 10-year history of recurrent urinary-tract infections treated with nitrofurantoin 100 mg twice daily for 3 to 10 days, two to three times each year and who also took conjugated oestrogens, calcium and magnesium, and a vitamin B complex (including pyridoxine 100 mg for 5 years), reported tingling and burning sensation of the distal lower extremity and alternate sensations of hot and cold in both feet 3 weeks after taking a 6-day course of nitrofurantoin. She also had abdominal discomfort. Her pyridoxine levels were 88.6 nanograms/mL (reference range 2 to 26 nanograms/mL). No evidence of peripheral sensory motor neuropathy, lower motor neurone dysfunction, myopathic dysfunction, or abdominal problems was found, but one year after symptoms developed she still had paraesthesias of the distal lower extremity.[1]

Nitrofurantoin may cause neuropathy after both short- or long-term treatment and occurs more frequently in women and the elderly. Pyridoxine, particularly in high doses may cause sensory neuropathy. Either drug could have caused the paraesthesias. However, it has been suggested that concurrent use of nitrofurantoin with other neurotoxic medications may increase the potential for neurotoxicity. The reason for the elevated pyridoxine levels is unclear, but they may have contributed to the neuropathy.

Information appears to be limited to this report, but bear it in mind in the event of unexpected toxicity.

Nitroxoline + Antacids

The antibacterial effects of nitroxoline have been found to be reduced *in vitro* by magnesium and calcium ions because they form chelates with the nitroxoline.[1] In the absence of any direct clinical information it would seem prudent to monitor concurrent use for any evidence that its antibacterial effects are reduced. In many interactions with antacids, separating administration by 2 to 3 hours is effective in minimising the extent of the effects.

1. Pelletier C, Prognon P, Bourlioux P. Roles of divalent cations and pH in mechanism of action of nitroxoline against *Escherichia coli* strains. *Antimicrob Agents Chemother* (1995) 707–13.

Novobiocin + Rifampicin (Rifampin)

Rifampicin reduces the half-life of novobiocin.

Clinical evidence, mechanism, importance and management

When 10 healthy subjects were given novobiocin 1 g daily for 13 days with rifampicin 600 mg daily, the novobiocin half-life was reduced from

5.85 hours to 2.66 hours and its AUC was reduced by almost 50%. There were no significant changes to the half-life or AUC of rifampicin. The serum novobiocin and rifampicin levels were not significantly altered and the trough serum levels of both antibacterials when given alone or concurrently remained in excess of the MIC for 90% of the strains of MRSA tested.[1] No special precautions would therefore seem to be necessary during concurrent use.

1. Drusano GL, Townsend RJ, Walsh TJ, Forrest A, Antal EJ, Standiford HC. Steady-state serum pharmacokinetics of novobiocin and rifampin alone and in combination. *Antimicrob Agents Chemother* (1986) 30, 42–5.

Penicillins + Acacia or Guar gum

The absorption of amoxicillin may be significantly reduced when given with or 2 hours after acacia. Guar gum causes a small reduction in the absorption of phenoxymethylpenicillin.

Clinical evidence, mechanism, importance and management

(a) Acacia

In healthy subjects the maximum serum levels and AUC of a single 500-mg dose of **amoxicillin** were reduced by 73% and 79%, respectively, when given with acacia (gum arabic: amount not stated) and by 56% and 49%, respectively, when given 2 hours after acacia. The pharmacokinetics of **amoxicillin** were not significantly affected when it was given 4 hours after acacia. Acacia is used in pharmaceutical preparations as a suspending, demulcent and emulsifying agent. Concurrent administration with **amoxicillin** could result in subtherapeutic levels of the antibacterial, but whether or not this would occur with the amount of acacia in a dose of a preparation containing it as an excipient is not known. In some countries acacia is given to patients with chronic renal failure. The authors suggest that if **amoxicillin** is used to treat urinary tract infections in patients also treated with acacia, it should be given 4 hours before or after the acacia.[1]

(b) Guar gum

In 10 healthy subjects, guar gum 5 g (*Guarem*, 95% guar gum) reduced the absorption of a single 1980-mg dose of **phenoxymethylpenicillin** (penicillin V). Peak serum penicillin levels were reduced by 25% and the AUC_{0-6} was reduced by 28%.[2] The reasons are not understood. The clinical significance of this interaction is uncertain, but the reduction in serum levels is only small. It would clearly only be important if the reduced amount of penicillin absorbed was inadequate to control infection The effect of guar gum on other penicillins seems not to have been studied.

Penicillins + Allopurinol

The incidence of skin rashes in patients taking either ampicillin or amoxicillin is increased by allopurinol.

Clinical evidence

A retrospective search through the records of 1324 patients, 67 of whom were taking allopurinol and **ampicillin**, found that 15 of them (22%) developed a skin rash compared with 94 (8%) of the patients not taking allopurinol.[1] The types of rash were not defined. Another study found that 35 out of 252 patients (14%) taking allopurinol and **ampicillin** developed a rash, compared with 251 out of 4434 (6%) taking **ampicillin** alone.[2] A parallel study revealed that 8 out of 36 patients (22%) taking **amoxicillin** and allopurinol developed a rash, whereas only 52 out of 887 (6%) did so when taking **amoxicillin** alone.[2]

A case report describes a patient who developed erythema multiforme shortly after starting **amoxicillin** and allopurinol and who was found to have both allopurinol hypersensitivity and type IV amoxicillin hypersensitivity.[3]

In contrast, one study did not find that the incidence of penicillin-related rashes was increased by allopurinol, and the authors suggested that this contrasting finding may be because exposure to penicillins was shorter in their study.[4]

Mechanism

Not understood. One suggestion is that the hyperuricaemia was responsible.[1] Another is that hyperuricaemic individuals may possibly have an altered immunological reactivity.[5]

Importance and management

An established interaction of limited importance. There would seem to be no strong reason for avoiding concurrent use, but prescribers should recognise that the development of a rash is by no means unusual. Whether this also occurs with penicillins other than ampicillin or amoxicillin is uncertain, and does not seem to have been reported.

Penicillins + Antacids

Aluminium/magnesium hydroxide and aluminium hydroxide do not significantly affect the bioavailability of amoxicillin or amoxicillin with clavulanic acid (co-amoxiclav). Antacids may reduce the absorption of the hydrochloride salt of pivampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin or Co-amoxiclav

The pharmacokinetics of amoxicillin 1 g, and both amoxicillin and clavulanic acid (given as co-amoxiclav 625 mg), were not significantly altered by 10 doses of **aluminium/magnesium hydroxide** (*Maalox*) 10 mL, with the last dose given 30 minutes before amoxicillin.[1] Another study found that four 40-mg doses of **aluminium hydroxide** (*Aludrox*) given at 20 minute intervals had no effect on the pharmacokinetics of either amoxicillin or clavulanic acid (given as co-amoxiclav 750 mg with the second dose of antacid).[2]

There would seem to be no reason for avoiding the concurrent use of antacids and amoxicillin or co-amoxiclav.

(b) Pivampicillin

The UK manufacturers of pivampicillin[3] used to recommend that, because antacids may decrease pivampicillin absorption, concurrent use should be avoided. This warning relates to a hydrochloride salt formulation, which needs acidic conditions for optimal absorption, whereas the basic salt formulation should not be affected by any pH change.[4]

Penicillins + Catha (Khat)

Chewing khat reduces the absorption of ampicillin and, to a lesser extent, amoxicillin, but the effects are minimal 2 hours after khat chewing stops.

Clinical evidence, mechanism, importance and management

A study in 8 healthy Yemeni male subjects found that chewing khat reduced the absorption of oral **ampicillin** from the gut.[1] When **ampicillin** 500 mg was taken with 250 mL water 2 hours before, just before khat chewing started, or midway through a 4-hour chewing session, the amounts of unchanged **ampicillin** in the urine fell by 46%, 41% and 49%, respectively. Even when **ampicillin** was taken 2 hours after a chewing

session had stopped, the amount of drug excreted unchanged in the urine fell by 12%. A parallel series of studies with **amoxicillin** 500 mg found much smaller reductions. The equivalent reductions were 14%, 9%, 22% and 13%. A similar study found that chewing khat resulted in variable reduction in the bioavailability of **amoxicillin** 500 mg, which was maximal (22%) when it was given midway during the 4-hour chewing period.[2]

The reasons for this interaction are not known, but the authors of the reports suggest that tannins from the khat might form insoluble and non-absorbable complexes with these penicillins, and possibly also directly reduce the way the gut absorbs them.[1]

Khat (the leaves and stem tips of *Catha edulis*) is chewed in some African and Arabian countries for its stimulatory properties. The authors of one of the studies concluded that both **ampicillin** and **amoxicillin** should be taken 2 hours after khat chewing to ensure that maximum absorption occurs.[1]

Penicillins + Chloroquine

Chloroquine reduces the absorption of ampicillin, but does not affect the absorption of ampicillin from bacampicillin.

Clinical evidence

In 7 healthy subjects, chloroquine 1 g reduced the absorption (as measured by excretion in the urine) of a single 1-g dose of oral **ampicillin** by about one-third (from 29 to 19%).[1] Another study by the same author demonstrated that the absorption of **ampicillin** from **bacampicillin** tablets was unaffected by chloroquine.[2]

Mechanism

A possible reason for the reduction in absorption is that the chloroquine irritates the gut so that the ampicillin is moved through more quickly, thereby reducing the time for absorption.

Importance and management

Information appears to be limited to the studies cited, which used large doses of chloroquine (1 g) when compared with those usually used for malarial prophylaxis (300 mg base weekly) or for rheumatic diseases (150 mg daily). The reduction in the ampicillin absorption is also only moderate. The general clinical importance of this interaction therefore seems likely to be small. However, one report suggests separating the dosing by not less than 2 hours.[1] An alternative would be to use bacampicillin (an ampicillin pro-drug), which does not appear to interact with chloroquine.[2] More study is needed to confirm and evaluate the importance of this interaction.

2. Ali HM. The effect of Sudanese food and chloroquine on the bioavailability of ampicillin from bacampicillin tablets. *Int J Pharmaceutics* (1981) 9, 185–90.

Penicillins + Food

The absorption of many penicillins is not significantly affected by food. The exceptions are ampicillin (food may reduce its levels by up to 50%), cloxacillin, and possibly pivampicillin and phenoxymethylpenicillin.

Clinical evidence, mechanism, importance and management

(a) Dietary fibre

In 10 healthy subjects the AUC of a single 500-mg oral dose of **amoxicillin** was found to be 12.17 micrograms/mL per hour when the subjects consumed a low-fibre diet (7.8 g of insoluble fibre daily) but only 9.65 micrograms/mL per hour when the subjects consumed a high-fibre diet (36.2 g of insoluble fibre daily); a difference of about 20%. Peak serum levels were the same and occurred at 3 hours.[1] The clinical relevance of these changes is likely to be minimal.

(b) Enteral and parenteral feeds

A single 250-mg intravenous dose of **ampicillin** was given to 7 healthy subjects 2 hours into a 12-hour infusion of parenteral nutrition or 4 hours after an enteral meal. The parenteral nutrition was of two types, one with and one without amino acids, calcium and phosphorus, both without lipids, and of similar calorific content and volume to the enteral feed. None of the three regimens altered the pharmacokinetics of intravenous **ampicillin**.[2] Note that the **ampicillin** was given in a separate limb to the parenteral nutrition.

(c) Food

1. Amoxicillin and Co-amoxiclav. When amoxicillin was taken after food, its serum levels were reduced by about 50% and its urinary excretion was reduced, when compared with the fasted state.[3] However, in another study in 16 healthy subjects, a standard breakfast had no effect on the AUC of a single 500-mg dose of amoxicillin.[4] Similarly, a crossover study in 18 healthy subjects given co-amoxiclav (amoxicillin 500 mg with **clavulanic acid** 250 mg), either 2 hours before or with a fried breakfast, found that the breakfast had no significant effect on the pharmacokinetics of amoxicillin or **clavulanic acid**. Moreover, a further study in 43 healthy subjects found that taking co-amoxiclav with food tended to minimise the incidence (but not the severity) of gastrointestinal adverse effects (watery stools, nausea and vomiting).[5] It would therefore be beneficial to take co-amoxiclav with a meal.

2. Ampicillin. When a single 500-mg dose of ampicillin was taken immediately after food, its serum levels were reduced by about 50% and its urinary excretion was reduced.[3] In 16 healthy subjects, a standard breakfast reduced the AUC of a single 500-mg dose of ampicillin by 31%.[4] Another study found ampicillin absorption was delayed and the total absorption reduced when it was taken with food. Urinary excretion of ampicillin was about 30% of a dose when given on an empty stomach and about 20% when given with food.[6] It is recommended that ampicillin is taken one hour before food or on an empty stomach to optimise absorption.

3. Bacampicillin. When 6 healthy subjects took a 1.6-g dose of bacampicillin either 35 minutes after breakfast or 2 hours before breakfast, its AUC was 26% lower with the post-breakfast dose, but this difference was not statistically significant.[7] On the basis of other work that also suggests that no important interaction occurs with food,[8,9] the manufacturers say that bacampicillin can be given without regard to the time of food intake.

4. Flucloxacillin. A study in children given flucloxacillin 12.5 mg/kg as either tablets or mixture found that while the absorption depended on both the formulation and age of the child, there was no difference in levels achieved when given to a subject when fasting or with a breakfast.[10] However, it is recommended that flucloxacillin is taken one hour before food or on an empty stomach to optimise absorption. The presence of food is reported to reduce the rate and extent of absorption of the related drug **cloxacillin**,[11] and therefore it may be prudent to follow the advice given for flucloxacillin.

5. Pivampicillin. A study in healthy subjects found the absorption of pivampicillin was delayed when it was given with food, but the amount absorbed was not affected. The urinary excretion of ampicillin following pivampicillin was about 60% of the dose when taken with or without food.[6] However, another study in which pivampicillin 350 mg was given in the fasting state or with a standardised cooked breakfast found that food both delayed and reduced the absorption of pivampicillin by almost 50%.[12]

6. Pivmecillinam. The manufacturer of pivmecillinam states that the tablets should preferably be taken with or immediately after a meal.[13]

(d) Milk

The peak levels and the AUCs of oral **phenoxymethylpenicillin** and *oral* **benzylpenicillin** were reduced by 40 to 60% in infants and children when they were given with milk.[14] It is recommended that **phenoxymethylpenicillin** is taken one hour before food or on an empty stomach to optimise absorption.

Co-amoxiclav (**amoxicillin** 500 mg with **clavulanic acid** 250 mg) was given to 16 healthy subjects at the same time as the second of four 200-mL glasses of milk (taken at 20 minute intervals). Although the bioavailability of the **amoxicillin** and **clavulanic acid** tended to be decreased, and the time to peak levels delayed, the changes did not reach statistical significance.[15] No special precautions would seem to be necessary.

Penicillins + H_2-receptor antagonists

Cimetidine does not adversely affect the bioavailability of ampicillin or co-amoxiclav, but the bioavailability of oral benzylpenicillin may be increased in some subjects. Ranitidine does not affect the pharmacokinetics of amoxicillin, but may possibly reduce the bioavailability of bacampicillin.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin and Co-amoxiclav

Cimetidine 200 mg, given three times daily the day before and with a single 200-mg dose of co-amoxiclav (amoxicillin with clavulanic acid), had no significant effect on the bioavailability of amoxicillin or clavulanic acid.[1] Another study found that **ranitidine** (300 mg given the day before and 150 mg given with the antibacterial) had no effect on the pharmacokinetics of a single 1-g dose of amoxicillin.[2]

(b) Ampicillin

In a placebo-controlled study in 6 healthy subjects, **cimetidine** 400 mg every 6 hours for 6 days had no effect on the pharmacokinetics of a single 500-mg dose of ampicillin given on day 6.[3]

(c) Bacampicillin

One small study suggested that when bacampicillin was given with **ranitidine** 300 mg and **sodium bicarbonate** 4 g, the AUC was reduced by 78% when the drugs were given with breakfast and by 55% when the drugs were given without food.[4] However, these results have been criticised because the study only included 6 subjects and because of differences in methodology between the compared groups.[5] The findings remain unconfirmed, and their clinical significance is uncertain.

(d) Benzylpenicillin

A study using a 600-mg *oral* dose of benzylpenicillin found that **cimetidine** raised the benzylpenicillin serum levels by about threefold in one subject, but did not significantly affect benzylpenicillin levels in another 4 subjects.[5] The clinical significance of these findings is unclear, especially as benzylpenicillin is more usually given parenterally.

Penicillins + Miscellaneous

Aspirin, indometacin, phenylbutazone, sulfaphenazole and sulfinpyrazone prolong the half-life of benzylpenicillin. Some sulfonamides reduce oxacillin blood levels. Pirenzepine does not affect the pharmacokinetics of amoxicillin, and chlorothiazide, sulfamethizole and sulfamethoxypyridazine do not affect the half-life of benzylpenicillin.

Clinical evidence, mechanism, importance and management

Studies in patients given different drugs for 5 to 7 days showed the following increases in the half-life of **benzylpenicillin**: **aspirin** 63%, **indometacin** 22%, **phenylbutazone** 139%, **sulfaphenazole** 44% and **sulfinpyrazone** 65%. It seems likely that competition between these drugs and **benzylpenicillin** for excretion by the kidney tubules caused these increases.[1] Changes in the half-life of benzylpenicillin with **chlorothiazide**, **sulfamethizole** and **sulfamethoxypyridazine** were not significant.[1]

In healthy subjects, **sulfamethoxypyridazine** 3 g given 8 hours before a 1-g dose of oral **oxacillin** reduced the 6-hour urinary recovery by 55%. **Sulfaethidole** 3.9 g given 3 hours before the **oxacillin** reduced the 6-hour urinary recovery by 42%.[2]

Pirenzepine 50 mg given three times daily on the day before and with a single 1-g dose of **amoxicillin** had no significant effect on the pharmacokinetics of the antibacterial.[3]

None of the interactions listed appears to be adverse, and no particular precautions would seem necessary during concurrent use of these drugs and the penicillins. The importance of the interaction between **oxacillin** and the sulfonamides is uncertain, but it can easily be avoided by choosing alternative drugs.

Penicillins + Nifedipine

Nifedipine increases the absorption of amoxicillin from the gut. Nafcillin increases the clearance of nifedipine.

Clinical evidence, mechanism, importance and management

(a) Amoxicillin

In 8 healthy subjects when amoxicillin 1 g was given 30 minutes after a 20-mg nifedipine capsule, the peak serum amoxicillin levels were raised by 33%, the bioavailability was raised by 21% and the absorption rate was raised by 70%.[1] The authors speculate that the uptake of amoxicillin through the gut wall is increased by nifedipine in some way.[1] There would seem to be no good reason for avoiding concurrent use as overall the bioavailability was not significantly altered.

(b) Nafcillin

In a randomised, placebo-controlled study, 9 healthy subjects were given a single 10-mg nifedipine capsule after a 5-day course of nafcillin 500 mg four times daily. The nifedipine AUC was decreased by 63% and its clearance was increased by 145%, but the effect of these changes on nifedipine pharmacodynamics was not assessed. It was suggested that nafcillin is an inducer of cytochrome P450 isoenzymes, and increased the metabolism of nifedipine.[2] The clinical significance of these changes is unclear, but it may be prudent to be alert for any decrease in the efficacy of nifedipine.

Penicillins + Probenecid

Probenecid reduces the excretion of the penicillins.

Clinical evidence

(a) Amoxicillin

In 10 healthy subjects a single 3-g dose of amoxicillin was given with or without probenecid 1 g. Two hours after administration, the serum levels of amoxicillin taken with probenecid were 55% higher than those with amoxicillin alone, and they remained higher for up to 18 hours.[1] Similar results were found in another study.[2] Amoxicillin 3 g twice daily plus placebo, amoxicillin 1 g twice daily plus probenecid 1 g twice daily, and amoxicillin 1 g twice daily plus probenecid 500 mg four times daily were given to 6 patients to treat bronchiectasis. The maximum serum concentration and half-life of both high- and low-dose amoxicillin were similar, but in the regimens containing probenecid the clearance of amoxicillin was reduced by two-thirds, when compared with amoxicillin given alone.[3]

(b) Amoxicillin with clavulanic acid

A crossover study in 16 healthy subjects found that probenecid, 1 g given 12 hours and one hour before a single 500-mg dose of amoxicillin, with or without 250 mg of clavulanic acid, had no significant effects on the pharmacokinetics of clavulanic acid. However, the AUC of amoxicillin was increased by 89% and 77% when given with clavulanic acid and alone, respectively, and the maximum plasma level of amoxicillin was increased by 54% and 29% when given with clavulanic acid and alone, respectively.[4]

(c) Benzylpenicillin

Four healthy subjects were given infusions of benzylpenicillin at three different rates, either alone or with probenecid (as a separate infusion), at rates to provide low and high plasma levels. An infusion rate of probenecid 83 mg/hour, corresponding to a daily dose of 2 g was found to produce about 90% inhibition of the tubular excretion of benzylpenicillin (at plasma levels of 25 mg/L). Doses of probenecid above 2 g daily did not have a significantly greater effect.[5]

(d) Mezlocillin

A study in healthy subjects found that probenecid 1 g, given one hour before an intramuscular injection of mezlocillin, increased the peak serum levels and AUC of mezlocillin by 65% and decreased the total clearance, renal clearance and apparent volume of distribution by 38%, 52%, and 35%, respectively.[6]

(e) Nafcillin

A study in 5 healthy subjects given 500 mg of intravenous nafcillin sodium with probenecid, 1 g given orally the previous night and 2 hours before the antibacterial, found that the urinary recovery of nafcillin was reduced from 30% to 17%, and its AUC was approximately doubled.[7]

(f) Piperacillin with Tazobactam

In 10 healthy subjects probenecid 1 g given one hour before a single infusion of piperacillin 3 g with tazobactam 375 mg caused a decrease of about 25% in the clearance of both components. The half-life of tazobactam was increased by 72%.[8] A study in 8 healthy subjects found that oral probenecid 1 g, given one hour before an intramuscular injection of piperacillin 1 g, increased both the peak plasma level and terminal half-life of piperacillin by 30% and increased its AUC by 60%. The apparent volume of distribution of piperacillin was reduced by 20% and renal clearance was reduced by 40%.[9]

(g) Pivampicillin

In a crossover study, healthy subjects were given either pivampicillin 350 mg every 8 hours or a tablet of MK-356 (approximately 350 mg of pivampicillin with 200 mg of probenecid). Peak ampicillin levels of 4 to 5 micrograms/mL were found about one hour after administration of the first and last dose of both treatments suggesting that probenecid did not affect the elimination of the ampicillin metabolite of pivampicillin. Administration of MK-356 (pivampicillin 700 mg with probenecid 400 mg) twice daily indicated that peak serum levels of ampicillin were increased and elimination rate slowed following successive doses.[10]

(h) Procaine benzylpenicillin

A study in patients given intramuscular procaine benzylpenicillin 2.4 or 4.8 g with or without probenecid 2 g found the peak serum levels were higher in patients given probenecid, but because of wide interpatient variation, possibly associated with differences in the release of penicillin from the injection sites; the exact potentiating effect of probenecid could not be determined.[11] However, another study in men and women given procaine benzylpenicillin 2.4 g and 4.8 g, respectively (for uncomplicated gonorrhoea), found treatment failure after one week in 15.4% of men and 10.4% of women. Failure rates were reduced to 1.8% and 3.7%, respectively, when oral probenecid 1 g was given with the penicillin.[12]

(i) Ticarcillin

Probenecid, either 500 mg twice daily, 1 g daily, or 2 g daily was added to ticarcillin 3 g every 4 hours, which was being given to treat infections in adult cystic fibrosis patients. In all cases the clearance of ticarcillin was reduced: by about 27% with the 500-mg dose regimen, by about 32% with the 1-g dose regimen and by about 43% with the 2-g dose regimen.[13]

Mechanism

In each case the penicillin competes with the probenecid for excretion by the renal tubules, although with nafcillin, non-renal clearance may also play a part.

Importance and management

In the case of amoxicillin, benzylpenicillin, nafcillin and ticarcillin the effects of probenecid are of clinical significance. The presence of clavulanic acid does not alter the interaction of amoxicillin with probenecid. In the case of the ticarcillin study the authors suggest that a 12-hourly dosing regimen could be used if probenecid is given concurrently, which has implications for home treatment. When piperacillin with tazobactam is given with probenecid the changes are not thought to provide any benefit in terms of dose reduction or alteration of the dose interval. Note that this is generally considered to be a beneficial interaction, but bear in mind that, in some cases, such as in renal impairment, the increase in penicillin levels may be undesirably large.

Penicillins + Tetracyclines

Data from the 1950s suggested that the tetracyclines can reduce the effectiveness of penicillins in the treatment of pneumococcal meningitis and probably scarlet fever. It is uncertain whether a similar interaction occurs with other infections. This interaction may possibly be important only with those infections where a rapid kill is essential.

Clinical evidence

When **chlortetracycline** originally became available it was tested as a potential treatment for meningitis. In patients with pneumococcal meningitis it was found that intramuscular **benzylpenicillin** 600 mg every 2 hours was more effective than the same regimen of penicillin with intravenous **chlortetracycline** 500 mg every 6 hours. Out of 43 patients given penicil-

lin alone, 70% recovered, compared with only 20% in another group of 14 essentially similar patients who had received both antibacterials.[1]

Another report about the treatment of pneumococcal meningitis with intramuscular or intravenous **penicillin** and intravenous tetracyclines (**chlortetracycline**, **oxytetracycline**, **tetracycline**) confirmed that the mortality was much lower in those given only penicillin, rather than the combination of penicillin and a tetracycline.[2] In the treatment of scarlet fever (Group A beta-haemolytic streptococci), no difference was seen in the initial response to treatment with penicillin (oral **procaine benzylpenicillin**) and **chlortetracycline** or the penicillin alone, but spontaneous reinfection occurred more frequently in those who had received both antibacterials.[3]

Mechanism

The generally accepted explanation is that bactericides such as the penicillins, which inhibit bacterial cell wall synthesis, require cells to be actively growing and dividing to be maximally effective, a situation that will not occur in the presence of bacteriostatic antibacterials, such as the tetracyclines.

Importance and management

Documentation is limited, but this is an apparently important interaction when treating pneumococcal meningitis and probably scarlet fever. However, the use of these antibacterials for such severe infections has largely been superseded. It has not been shown to occur when treating pneumococcal pneumonia.[4] It has been suggested that antagonism, if it occurs, may only be significant when it is essential to kill bacteria rapidly,[4] i.e. in serious infections such as meningitis or in neutropenic patients. Any penicillin and any tetracycline would be expected to behave in this way. The manufacturers of some tetracyclines (including doxycycline and oxytetracycline) advise that their use with penicillins should be avoided.[5-7]

Note that, the macrolides, which are also bacteriostatic would be expected to attenuate the action of penicillins, but this does not seem to occur in practice. See 'Macrolides + Penicillins', p.356.

Penicillins + Valproate

An isolated report describes hyperammonaemic encephalopathy in an elderly patient during treatment with valproate and pivmecillinam.

Clinical evidence, mechanism, importance and management

There is a report of hyperammonaemic encephalopathy which developed in a 72-year-old woman taking valproate monotherapy for partial epilepsy after she started treatment with **pivmecillinam** 600 mg daily. She recovered after discontinuation of valproate and use of cefuroxime instead of **pivmecillinam**.[1] Valproate may reduce serum carnitine,[1] for reasons that are not well understood.[2] Valproate-induced hyperammonaemic encephalopathy may be due to reduced carnitine levels.[1]

Pivmecillinam and **pivampicillin** are hydrolysed to release mecillinam or ampicillin, respectively, as well as pivalic acid and formaldehyde. One of the potential problems of these drugs is that the pivalic acid can react with carnitine to form pivaloyl-carnitine, which is excreted in the urine, and so the body can become depleted of carnitine. Carnitine deficiency also manifests as muscle weakness and cardiomyopathy.

The risks of carnitine deficiency due to **pivmecillinam** or **pivampicillin** seem to be small in healthy adults, but the manufacturer of **pivmecillinam** issues a warning about long-term or frequently repeated treatment.[3]

The authors of the report advise caution if **pivmecillinam** is added to treatment with valproate.[1] Although this appears to be the only report of an adverse effect due to the combined effects of **pivmecillinam** and valproate on carnitine levels, the manufacturer of **pivmecillinam** advises its avoidance with valproic acid or valproate.[3] **Pivampicillin** is likely to have a similar effect and should therefore probably also be avoided.

Penicillins; Amoxicillin + Amiloride

Amiloride can cause a small reduction in the absorption of amoxicillin.

Clinical evidence, mechanism, importance and management

When 8 healthy subjects were given amiloride 10 mg followed 2 hours later by a single 1-g oral dose of amoxicillin, the bioavailability and maximum serum levels of amoxicillin were reduced by 27% and 25%, respectively, and the time to reach maximum levels was delayed from 1 hour to 1.56 hours. When amoxicillin was given intravenously its bioavailability was unchanged by amiloride.[1] A second study in which amiloride and amoxicillin were delivered directly to the jejunum found that amiloride had no effect on the jejunal permeability of amoxicillin.[2]

It is thought that the absorption of beta lactams like amoxicillin depends on a dipeptide carrier system in the cells lining the intestine (brush border membrane). This system depends on the existence of a pH gradient between the outside and inside of the cells, which is maintained by a Na-H exchanger. As this exchanger is inhibited by amiloride the reduced absorption seen in the first study would seem to be explained.

This reported reduction in the absorption of the amoxicillin is only small and unlikely to have very much clinical relevance. There seems to be no information about other penicillins.

Penicillins; Cloxacillin + Proguanil

Proguanil may reduce the bioavailability of cloxacillin.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in healthy subjects given cloxacillin 500 mg with or without proguanil 200 mg found that the total amount of cloxacillin excreted in the urine over 12 hours was reduced by up to 48% by proguanil. The time to maximum excretion and the half-life of cloxacillin were increased by 23% and 34%, respectively. The reasons why cloxacillin absorption is reduced by proguanil are not known, but it has been suggested that it may be due to adsorption of cloxacillin on to proguanil in the gut, formation of a drug-complex, increased gastric motility or increased beta-lactam ring hydrolysis leading to reduced cloxacillin bioavailability.[1] The clinical implications of the interaction are unknown.

1. Babalola CP, Iwheye GB, Olaniyi AA. Effect of proguanil interaction on bioavailability of cloxacillin. *J Clin Pharm Ther* (2002) 27, 461–4.

Penicillins; Dicloxacillin + Rifampicin (Rifampin)

Rifampicin increases the oral clearance of dicloxacillin and reduces its plasma levels.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that rifampicin 600 mg daily for 10 days decreased the maximum plasma level of a single 1-g dose of dicloxacillin by 27% and increased its mean oral clearance by 26%. The

mean absorption time increased from 0.71 hours to 1.34 hours. Rifampicin increased the formation clearance, maximum level and AUC of the 5-hydroxymetabolite of dicloxacillin by 135%, 119%, and 59%, respectively. Dicloxacillin is a substrate of P-glycoprotein and it was suggested that the effects of rifampicin on dicloxacillin were due to induction of both intestinal P-glycoprotein and dicloxacillin metabolism.[1] The changes in the levels of dicloxacillin are modest, and unlikely to be clinically relevant.

1. Putnam WS, Woo JM, Huang Y, Benet LZ. Effect of the *MDR1* C3435T variant and P-glycoprotein induction on dicloxacillin pharmacokinetics. *J Clin Pharmacol* (2005) 45, 411–21.

Penicillins; Flucloxacillin + Paracetamol (Acetaminophen)

A case report describes severe acidosis in a critically ill patient receiving paracetamol and flucloxacillin.

Clinical evidence, mechanism, importance and management

A case report describes a patient with sepsis and renal impairment who was admitted to an intensive care unit with a high anion gap (42 mmol/L) metabolic acidosis which was tentatively attributed to treatment with flucloxacillin and paracetamol. He had received 8 g of paracetamol and 16 g of flucloxacillin over the 4 days before admission. The patient was diagnosed with pyroglutamic acidaemia, which is defined as a high anion gap acidosis resulting from excess production of 5-oxoproline. It was suggested that the depletion of glutathione by paracetamol, and further inhibition of the production of glutathione from 5-oxoproline by flucloxacillin had contributed to this patients condition. Note that this patient was also receiving carbamazepine, phenobarbital and phenytoin, which the authors suggest may also have reduced glutathione stores.[1]

This is not an unusual combination of drugs, and the clinical significance of this case, in a patient with serious medical problems, to other patients is unclear.

1. Peter JV, Rogers N, Murty S, Gerace R, Mackay R, Peake SL. An unusual cause of severe metabolic acidosis. *Med J Aust* (2006) 185, 223–5.

Penicillins; Piperacillin with Tazobactam + Vancomycin

Vancomycin does not interact to a clinically relevant extent with piperacillin and tazobactam.

Clinical evidence, mechanism, importance and management

A randomised, crossover study in 9 healthy subjects found that infusions of vancomycin 500 mg and piperacillin 3 g with tazobactam 375 mg had little or no effect on the pharmacokinetics of any of the antibacterials, except that the piperacillin AUC was slightly raised, by about 7%. It was concluded that no dose adjustments are needed if these drugs are given together.[1]

1. Vechlekar D, Sia L, Lanc R, Kuye O, Yacobi A, Faulkner R. Pharmacokinetics of piperacillin/tazobactam (Pip/Taz) IV with and without vancomycin IV in healthy adult male volunteers. *Pharm Res* (1992) 9 (10 Suppl), S-322.

Protionamide + Other antimycobacterials

Protionamide appears to be very hepatotoxic and this effect is possibly increased by the concurrent use of rifampicin (rifampin) or rifandin. Protionamide does not affect the pharmacokinetics of either dapsone or rifampicin.

Clinical evidence

In a study of 39 patients with leprosy, 39% became jaundiced after treatment for 24 to 120 days with **dapsone** 100 mg daily, protionamide 300 mg daily and **rifandin** [isopiperazinylrifamycin SV] 300 to 600 mg monthly. Laboratory evidence of liver damage occurred in 56% of patients, and despite the withdrawal of the drugs from all the patients, 2 of them died.[1] All the patients except two had previously taken **dapsone** alone for 3 to 227 months without reported problems.[1] In another group of patients with leprosy, 22% (11 of 50) had liver damage after treatment with **dapsone** 100 mg and protionamide 300 mg given daily, and **rifampicin** (rifampin) 900 mg, protionamide 500 mg and **clofazimine** 300 mg given monthly over a period of 30 to 50 days. One patient died.[1] Most of the patients recovered within 30 to 60 days after withdrawing the treatment. Jaundice, liver damage and deaths have occurred in other patients with leprosy given **rifampicin** and protionamide or **ethionamide**.[2-4]

Protionamide does not affect the pharmacokinetics of either **dapsone** or **rifampicin**.[5]

Mechanism

Although not certain, it seems probable that the liver damage was primarily caused by the protionamide, and possibly exacerbated by the rifampicin (rifampin) or the rifandin.

Importance and management

This serious and potentially life-threatening hepatotoxic reaction to protionamide is established, but the part played by the other drugs, particularly the rifampicin (rifampin), is uncertain. Strictly speaking this may not be an interaction. If protionamide is given the liver function should be very closely monitored in order to detect toxicity as soon as possible. This monitoring is probably sufficient to detect any adverse interaction.

Pyrazinamide + Antacids

In 14 healthy subjects, 30 mL of *Mylanta* (aluminium/magnesium hydroxide) given 9 hours before, with, and after a single 30-mg/kg dose of pyrazinamide decreased the time to peak absorption by 17%, but had no effect on other pharmacokinetic parameters.[1] This change is not clinically important.

1. Peloquin CA, Bulpitt AE, Jaresko GS, Jelliffe RW, James GT, Nix DE. Pharmacokinetics of pyrazinamide under fasting conditions, with food, and with antacids. *Pharmacotherapy* (1998) 18, 1205–11.

Pyrazinamide + Antigout drugs

Pyrazinamide commonly causes hyperuricaemia and may therefore reduce the uricosuric effect of benzbromarone and probenecid, however benzbromarone may have modest efficacy in reducing the hyperuricaemia caused by pyrazinamide. Allopurinol is unlikely to be effective against pyrazinamide-induced hyperuricaemia, and may exacerbate the situation.

Clinical evidence and mechanism

(a) Allopurinol

It is thought that pyrazinamide is hydrolysed in the body to pyrazinoic acid, which appears to be responsible for its hyperuricaemic effect. Pyrazinoic acid is oxidised by the enzyme xanthine oxidase to 5-hydroxypyrazoic acid.[1] As allopurinol is an inhibitor of xanthine oxidase, its presence increases pyrazinoic acid concentrations[2] thereby probably worsening pyrazinamide-induced hyperuricaemia.[3]

(b) Benzbromarone

In 5 subjects with hyperuricaemia and gout a single dose of pyrazinamide completely abolished the uricosuric effect of a single 160-mg dose of benzbromarone.[4] Other authors also briefly mention the same finding.[5] However in another study, when 10 patients taking pyrazinamide 35 mg/kg daily for tuberculosis were given benzbromarone 50 mg daily for 8 to

10 days, uric acid levels were reduced by an average of 24%, and returned to normal in 4 patients.[6] It is unclear from these studies whether or not pyrazinamide abolishes the uricosuric effects of benzbromarone.

(c) Probenecid

The interactions of probenecid and pyrazinamide and their effects on the excretion of uric acid are complex and intertwined. Probenecid increases the secretion of uric acid into the urine, apparently by inhibiting its reabsorption from the kidney tubules.[7] Pyrazinamide on the other hand decreases the secretion of uric acid into the urine by one-third to one-half,[8] resulting in a rise in the serum levels of urate in the blood, thereby causing hyperuricaemia.[8,9] The result of using probenecid and pyrazinamide together is not however merely the simple sum of these two effects. This is because pyrazinamide additionally decreases the metabolism of the probenecid and prolongs its uricosuric effects, and the effect of pyrazinamide is reduced. Also, probenecid inhibits the secretion of pyrazinamide, increasing its effects.[10]

Importance and management

Pyrazinamide commonly causes hyperuricaemia, and would be expected to antagonise the effects of uricosuric drugs such as benzbromarone. Benzbromarone may have modest efficacy in reducing hyperuricaemia caused by pyrazinamide, but further study is necessary to establish this.

If probenecid were to be used to treat the hyperuricaemia caused by pyrazinamide, the normal uricosuric effects of probenecid would be diminished, and larger doses would be required. Allopurinol would appear to be unsuitable for treating pyrazinamide-induced hyperuricaemia as it potentially exacerbates the situation.

Note that pyrazinamide should be used with caution[11] or is contraindicated[12] in patients with a history of gout. Baseline serum uric acid levels should be established in all patients given pyrazinamide.[12] If hyperuricaemia accompanied by gouty arthritis occurs (without liver dysfunction[12]), pyrazinamide should be stopped.[11,12]

Pyrazinamide + Food

In 14 subjects a high-fat breakfast approximately doubled the time to peak absorption of a single 30-mg/kg dose of pyrazinamide but had no effect on other pharmacokinetic parameters.[1] It would therefore seem that pyrazinamide may be taken without regard to meals.

Quinolones + Antacids or Calcium compounds

The serum levels of many of the quinolone antibacterials can be reduced by aluminium and magnesium antacids. Calcium compounds interact to a lesser extent, and bismuth compounds interact only minimally.

Clinical evidence

There is a wealth of information about the interaction between quinolones and antacids and for simplicity this is summarised in 'Table 10.3', (p.370). This table shows what happens to the maximum serum levels (C_{max}) and the relative bioavailabilities (%) when the quinolones listed have been given at the same time as antacids, and when separated by time intervals (e.g. –2 h; two hours before the antacid).

Mechanism

It is believed that certain of the quinolone functional groups (3-carboxyl and 4-oxo) form insoluble chelates with aluminium and magnesium ions within the gut, which reduces their absorption.[1-3] The stability of the chelate formed seems to be an important factor in determining the degree of interaction.[3] It has been suggested from *animal* studies that adsorption of quinolones by aluminium hydroxide re-precipitated in the small intestine may be a factor in the reduced bioavailability of quinolones.[4] See also 'Quinolones + Iron or Zinc compounds', p.378.

Importance and management

The interactions between quinolones and antacids are generally well documented, well established and, depending on the particular quinolone and antacid concerned, of clinical importance. The risk is that the serum levels of the antibacterial may fall below minimum inhibitory concentrations (i.e. become subtherapeutic, particularly against organisms such as staphylococci and *Pseudomonas aeruginosa*[5]), resulting in treatment failures.[6] From a review of the use of levofloxacin, it has been suggested that the low levels of quinolones which occur as a result of this interaction may contribute to the development of resistance.[7] The overall picture is that the aluminium/magnesium antacids interact to a greater extent than the calcium compounds, and bismuth compounds hardly at all.

Possible alternatives to the antacids, which do not appear to interact with the quinolones, include the 'H_2-receptor antagonists', (p.377) and 'omeprazole', (p.380).

(a) Aluminium/magnesium antacids

'Table 10.3', (p.370) shows that the aluminium/magnesium antacids can greatly reduce the bioavailabilities of the quinolones. Separating their administration to reduce the admixture of the two drugs in the gut minimises the interaction, a very broad rule-of-thumb being that the quinolones should be taken at least 2 hours before and not less than 4 to 6 hours after the antacid.[1,8-14] The only obvious exception is **fleroxacin**, which appears to interact minimally.

(b) Bismuth compounds

As can be seen from 'Table 10.3', (p.370), bismuth compounds have little or no effect on the bioavailability of **ciprofloxacin**. Information about other quinolones appears to be lacking. However, using **ciprofloxacin** as a guide it would seem that any interaction is likely only to be of minimal clinical importance, and no action appears to be necessary.

(c) Calcium compounds

Information about the interactions with calcium carbonate is more limited than with the aluminium/magnesium antacids, but 'Table 10.3', (p.370) shows that the bioavailabilities of **ciprofloxacin**, **norfloxacin**, and to a lesser extent **gemifloxacin**, can be reduced. Other calcium compounds, for example those used as phosphate binders, are likely to interact similarly. These reductions are less than those seen with the aluminium/magnesium antacids, but using **ciprofloxacin** as a guide a very broad rule-of-thumb would be to separate the drug administration by about 2 hours to minimise this interaction.[15,16] This is clearly not necessary with **levofloxacin**,[17] **lomefloxacin**,[18] **moxifloxacin**[19] or **ofloxacin**,[20] nor probably with some of the other quinolones that have yet to be studied, but in the absence of direct information a 2-hour separation errs on the side of caution.

(d) Sodium antacids

Sodium bicarbonate does not interact significantly with **norfloxacin**[21] but information about other quinolones appears to be lacking. However, bear in mind that in the case of **ciprofloxacin** an excessive rise in urinary pH

Quinolones + Antineoplastics

The absorption of ciprofloxacin and ofloxacin can be reduced by some cytotoxic antineoplastics. Production of the active metabolite of cyclophosphamide may be reduced by ciprofloxacin.

Clinical evidence

(a) Ciprofloxacin

Six patients with newly diagnosed haematological malignancies (5 with acute myeloid leukaemia and one with non-Hodgkin's lymphoma) were given ciprofloxacin 500 mg twice daily to control possible neutropenic infections. It was found that, after 13 days of chemotherapy, their mean maximum serum ciprofloxacin levels had fallen by 46% (from 3.7 to 2 mg/L) and the $AUC_{0\text{-}4}$ was reduced by 47%. There were large individual differences between the patients. The antineoplastics used were **cyclophosphamide**, **cytarabine**, **daunorubicin**, **doxorubicin**, **mitoxantrone** and **vincristine**.[1]

A study in 8 patients who received a course of CHOP (**cyclophosphamide**, **doxorubicin**, prednisolone and **vincristine**) found that oral ciprofloxacin, 1 g given in the evening and 500 mg given on the morning before intravenous **cyclophosphamide** was given, reduced the AUC of the active metabolite of **cyclophosphamide** by 32%.[2]

For mention that methotrexate toxicity has occurred in 2 patients during treatment with ciprofloxacin, see 'Methotrexate + Antibacterials; Ciprofloxacin', p.745.

(b) Ofloxacin

Ten patients with non-Hodgkin's lymphoma, hairy cell leukaemia or acute myeloid leukaemia were given ofloxacin 400 mg at breakfast time for antibacterial prophylaxis during neutropenia. Blood samples were taken 3 days before chemotherapy began and then at 2 to 3 days, 5 to 7 days, and 8 to 10 days. The maximum serum ofloxacin levels were reduced by 18% two to three days after the chemotherapy but none of the other pharmacokinetic measurements were changed by the antineoplastic treatment. The serum levels had returned to normal by 5 to 7 days. At all times serum levels exceeded the expected MICs of the gram-negative potential pathogens. The antineoplastics used were **cyclophosphamide**, **cytarabine**, **doxorubicin**, **etoposide**, **ifosfamide** (with mesna), **vincristine**.[3]

Mechanism

Uncertain. The reduction in serum levels seems to result from a reduction in the absorption of the quinolones by the small intestine, possibly related to the damaging effect cytotoxic antineoplastics have on the rapidly divid-

ing cells of the intestinal mucosa. It was suggested that the production of the active metabolite of cyclophosphamide may have been inhibited by ciprofloxacin.

Importance and management

Direct information is limited, but the reports of reduced serum levels are consistent with the way cytotoxic antineoplastics can reduce the absorption of some other drugs; however, the authors suggest that these changes are probably clinically unimportant, because the serum levels achieved are likely to be sufficient to treat most infections. If the suggested mechanism of interaction is correct, no interaction should occur if quinolones are given parenterally. Nothing appears to be documented about any of the other quinolones.

The significance of the reduction in the active metabolite of cyclophosphamide seen in one study is unclear; however the authors suggest that a reduction in the therapeutic efficacy of cyclophosphamide may result and this combination should therefore be avoided. It has also been suggested that this interaction was a high-risk factor for relapse in patients undergoing bone marrow transplantation when ciprofloxacin was given as prophylaxis during cyclophosphamide use.[4]

Quinolones + Chinese herbal medicines

Sho-saiko-to, Rikkunshi-to and Sairei-to do not interact with ofloxacin, and Hotyu-ekki-to, Rikkunshi-to and Juzen-taiho-to do not interact with levofloxacin.

Clinical evidence, mechanism, importance and management

The bioavailability and urinary recovery of a single 200-mg oral dose of **ofloxacin** were not significantly altered in 7 healthy subjects by three Chinese herbal medicines (**Sho-saiko-to**, **Rikkunshi-to** or **Sairei-to**).[1] The bioavailability and renal excretion of a single 200-mg oral dose of **levofloxacin** was not affected in 8 healthy subjects given single 2.5-g doses of **Hotyu-ekki-to**, **Rikkunshi-to** or **Juzen-taiho-to**.[2] There would therefore seem to be no reason for avoiding concurrent use. Information about other quinolones is lacking. The ingredients of these herbal medicines are detailed in 'Table 10.4', (p.375).

Quinolones + Dairy products

Dairy products reduce the bioavailability of ciprofloxacin and norfloxacin, and to a minor extent, gatifloxacin, but not enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably not fleroxacin.

Clinical evidence

(a) Ciprofloxacin

A study in 7 healthy subjects found that 300 mL of **milk** or **yoghurt** reduced the peak plasma levels of a single 500-mg dose of ciprofloxacin by 36% and 47%, respectively, and reduced its AUC by 33% and 36%, respectively.[1] In another study 300 mL of **milk** reduced the AUC of ciprofloxacin 500 mg by about 30%.[2]

(b) Enoxacin

A study found that **milk** and a standard breakfast had no effect on enoxacin absorption.[3]

(c) Fleroxacin

In a study, a fat and liquid calcium meal had no clinically significant effect on the pharmacokinetics of fleroxacin.[4] In another study, **milk** had no effect on fleroxacin pharmacokinetics.[2]

(d) Gatifloxacin

In one study 200 mL of **milk** reduced the AUC of gatifloxacin 200 mg by about 15%.[5]

(e) Lomefloxacin

Milk had no effect on the pharmacokinetics of lomefloxacin.[6]

(f) Moxifloxacin

A study found that the rate of absorption of a single 400-mg dose of moxifloxacin was slightly delayed by 250 g of **yoghurt**. The maximum plasma level of moxifloxacin was reduced by about 15%, but its bioavailability was unaffected.[7]

(g) Norfloxacin

A study found that 300 mL of **milk** or **yoghurt** reduced the absorption and the peak plasma levels of a single 200-mg dose of norfloxacin by roughly 50%.[8]

(h) Ofloxacin

A study in 21 healthy subjects found that 8 oz (about 250 mL) of **milk** had no clinically significant effects on the absorption of 300 mg of ofloxacin.[9] Another study confirmed the lack of a significant interaction between ofloxacin and both **milk** and **yoghurt**.[10]

Mechanism

The proposed reason for these changes is that the calcium in milk and yoghurt or other dairy products combines with the ciprofloxacin and norfloxacin to produce insoluble chelates. Compare also 'Quinolones + Antacids or Calcium compounds', p.369.

Importance and management

The effect of these changes to ciprofloxacin and norfloxacin pharmacokinetics on the control of infection is uncertain but until the situation is clear patients should be advised not to take these dairy products within one to 2 hours of either ciprofloxacin or norfloxacin to prevent admixture in the gut. The slight reduction in gatifloxacin levels is probably not clinically relevant.

Enoxacin, lomefloxacin, moxifloxacin, ofloxacin and probably fleroxacin do not appear to interact with dairy products to a clinically relevant extent, and they may therefore provide a useful alternative to the interacting quinolones.

Quinolones + Didanosine

An extremely marked reduction in the serum levels of ciprofloxacin occurs if it is given at the same time as didanosine tablets, because of an interaction with the antacid buffers in the didanos-

ine formulation. Other quinolones are expected to interact similarly. Didanosine enteric-coated capsules do not interact with ciprofloxacin.

Clinical evidence

When 12 healthy subjects were given **ciprofloxacin** 750 mg with two didanosine placebo tablets (i.e. all of the antacid additives but no didanosine), the **ciprofloxacin** AUC and maximum serum levels were reduced by 98% and 93%, respectively.[1] The antacids in this formulation were dihydroxyaluminium sodium carbonate and magnesium hydroxide.

Other studies have looked at whether separating administration affects this interaction. When 16 HIV-positive patients were given **ciprofloxacin** 1.5 g daily 2 hours before didanosine tablets, the AUC of **ciprofloxacin** was reduced by only 26%.[2] Another study in just one subject found that when **ciprofloxacin** 500 mg was given 2 hours after taking two didanosine placebo tablets the **ciprofloxacin** serum levels were reduced below minimal inhibitory concentrations, but giving the **ciprofloxacin** 2 hours before the didanosine placebo tablets resulted in normal blood levels.[3]

The enteric-coated capsule formulation of didanosine (which does not contain antacids) does not interact with **ciprofloxacin**.[4]

Mechanism

Didanosine is extremely acid labile at pH values below 3, so one of the formulations contains buffering agents (dihydroxyaluminium sodium carbonate and magnesium hydroxide) to keep the pH as high as possible to minimise the acid-induced hydrolysis. Ciprofloxacin forms insoluble non-absorbable chelates with these metallic ions in the buffer so that its bioavailability is markedly reduced. See also 'Quinolones + Antacids or Calcium compounds', p.369.

Importance and management

Direct information is limited to these reports but the interaction between buffered didanosine and ciprofloxacin appears to be clinically important. Such drastic reductions in serum ciprofloxacin levels mean that minimal inhibitory concentrations are unlikely to be achieved. Ciprofloxacin should be given at least 2 hours before or 6 hours after didanosine tablets (see 'Quinolones + Antacids or Calcium compounds', p.369). Other quinolone antibacterials that interact with antacids are also expected to interact with didanosine tablets, but so far reports are lacking. Didanosine enteric-coated capsules do not interact.

Quinolones + Enteral feeds or Food

The absorption of ciprofloxacin can be reduced by enteral feeds. Moxifloxacin and ofloxacin are similarly affected, but the extent of the interaction is smaller. No interaction is seen with garenoxacin or gatifloxacin and enteral feeds.
Apart from dairy products most foods delay but do not reduce the absorption of ciprofloxacin, enoxacin, gemifloxacin, lomefloxacin, ofloxacin or sparfloxacin. A high-fat/high-calcium breakfast did not reduce ciprofloxacin levels. Calcium-fortified orange juice significantly reduces the absorption of ciprofloxacin, but not gatifloxacin or levofloxacin.

Clinical evidence

A. Enteral feeds

(a) Ciprofloxacin

When ciprofloxacin 750 mg was given to 13 fasted subjects with *Ensure* its oral bioavailability was reduced by 28% and its mean maximum serum levels were reduced by 48%. In this study the subjects were given 120 mL of the study liquid (*Ensure* or water) and this was repeated at 30-minute intervals for 5 doses. The ciprofloxacin was crushed and mixed with the second dose of the study liquid and the cup rinsed with another 60 mL of the study liquid.[1]

Other enteral feeds given orally (*Osmolite*, *Pulmocare*, and *Resource*) similarly reduced the bioavailability and maximum serum levels of ciprofloxacin by about one-quarter to one-third in two other studies.[2,3] One comparative study found that *Ensure* reduced the AUC of ciprofloxacin by 40% in men but by only 15% in women.[4]

In a study of 26 hospitalised patients, ciprofloxacin bioavailability was reduced by 53% and 67% by *Jevity* or *Sustacal*, respectively, when given via gastrostomy or jejunostomy tubes. Despite this, the serum levels achieved with gastrostomy tubes were roughly equivalent to those seen in subjects taking tablets orally.[5] In another study in patients given *Jevity* or *Osmolite*, the 4 patients with a nasoduodenal tube achieved a ciprofloxacin AUC that was about double that seen in the 3 patients with a nasogastric tube or a gastrostomy tube.[6] In contrast, in another study in healthy subjects, there was no difference in the bioavailability of ciprofloxacin when it was given alone or when it was given with *Osmolite* via a nasogastric tube.[7]

The bioavailability of ciprofloxacin 750 mg every 12 hours in 5 patients with severe gram-negative intra-abdominal infections was reduced by 47% when it was added to enteral feeding with *Nutrison* or *Nutrison E+* and given via nasogastric or nasoduodenal tubes. The serum levels were similar to those found in another 7 patients given ciprofloxacin with these enteral feeds and also to those found when the 5 original patients were given intravenous ciprofloxacin 400 mg every 12 hours.[8] In another study, in 12 intensive care patients, the AUC of ciprofloxacin 400 mg given by intravenous infusion was similar to that found after a dose of 750 mg given via nasogastric tube during enteral feeding with *Normo-Réal fibres*.[9]

(b) Garenoxacin

In a randomised crossover study, 18 healthy subjects received a single 600-mg dose of garenoxacin via a nasogastric tube, alone or 2 hours after the start of a 6-hour nasogastric feed of *Osmolite*. The pharmacokinetics of garenoxacin were not altered by the enteral feed.[10]

(c) Gatifloxacin

In a crossover study, 12 healthy subjects were given a single 400-mg dose of gatifloxacin alone, or with *Ensure* 120 mL given every 30 minutes for 5 doses, starting 30 minutes before the gatifloxacin. The AUC and maximum plasma levels of gatifloxacin were reduced by 26% and 45%, respectively, in the presence of *Ensure*.[11]

A randomised study in critically ill patients found no significant difference in the bioavailability of gatifloxacin given as a single 400-mg dose either nasogastrically or intravenously with two enteral feed schedules. Seven patients received continuous enteral feeds, and 8 patients received feeds interrupted for 2 hours before and after the administration of the gatifloxacin. In this study 5 different enteral feeds were given (*Glucerna*, *Impact*, *Jevity*, *Promote*, *and Pulmocare*) at rates ranging from 30 mL/hour to 75 mL/hour. There was significant variation in the bioavailability of gatifloxacin, most likely due to the critical illnesses of the patients.[12]

(d) Moxifloxacin

In a study in 12 healthy subjects, the oral bioavailability of a single 400-mg dose of moxifloxacin was decreased by 9% when it was given to as a suspension of a crushed tablet via a nasogastric tube with either water or *Isosource Energy*. This decrease was in comparison with oral administration of an uncrushed tablet with water. Maximum plasma levels were decreased by 5% and 12% after nasogastric administration with water and *Isosource Energy*, respectively.[13]

(e) Ofloxacin

The oral bioavailability of ofloxacin 400 mg was reduced by 10% when it was given to 13 healthy subjects with *Ensure*. The mean maximum serum ofloxacin levels were reduced by 36%. In this study the subjects were given 120 mL of the study liquid (*Ensure* or water) and this was repeated at 30-minute intervals for 5 doses. The ofloxacin was crushed and mixed with the second dose of the study liquid and the cup rinsed with another 60 mL of the study liquid.[1] Only small reductions in the AUCs of ofloxacin were seen in another study (11% in men, 13% in women) with *Ensure*.[4]

B. Food

Food delayed the absorption of **ciprofloxacin** and **ofloxacin** in 10 subjects, but their bioavailabilities remained unchanged.[14] A study in 12 healthy subjects found that standard or high-fat breakfasts did not affect the absorption of **ciprofloxacin**.[15] Another study in healthy subjects found that a standard breakfast reduced the bioavailability of a single 300-mg dose of **ofloxacin** by about 18%, but this was not considered clinically significant.[16] Other studies suggest that food delays the absorption of **ofloxacin**[17] and **lomefloxacin**[18] but the bioavailability is unchanged. Food also has no effect on the absorption of **enoxacin**, but high-carbohydrate meals delayed the peak serum levels by almost an hour.[19] The pharmacokinetics of **gemifloxacin** 320 mg or 640 mg[20] or **sparfloxacin** 200 mg[21] were not significantly affected when they were given to healthy subjects with high-fat or standard meals, although the absorption of **sparfloxacin** was slightly delayed.

C. Calcium-fortified foods

Calcium-fortified orange juice decreased the AUC of **ciprofloxacin** by 38% and decreased its maximum plasma level by 41%, when compared with water.[22] However, in another study, a high-fat/high-calcium breakfast did not affect the absorption of **ciprofloxacin**.[15]

The AUC of **gatifloxacin** was reduced by only 12% by calcium-fortified orange juice.[23] Similarly, in two studies, orange juice, calcium-fortified orange juice,[24] or a breakfast of calcium-fortified orange juice and cereal with or without milk[25] were found to decrease the bioavailability of **levofloxacin**. However, the **levofloxacin** AUC was decreased by less than 16%, an amount that rarely proves to be clinically significant.

Mechanism

Not fully understood. The quinolone antibacterials can form insoluble chelates with divalent ions, which reduces their absorption from the gut. Enteral feeds such as those used above contain at least two divalent ions, calcium and magnesium. However, an *in vitro* study found no evidence of chelate formation with ciprofloxacin, **levofloxacin** or ofloxacin and calcium or magnesium, and therefore suggested that either other divalent cations may be involved, or that the quinolones may be adsorbed onto other metal ions, proteins or fat in the enteral feed.[26]

It has also been suggested that alteration in pH as well as the presence of cations are required to form chelates with ciprofloxacin and while this helps explain the lack of effect of high calcium in a high-fat breakfast,[15] it does not explain the significant effect with enteral feeds or calcium-fortified orange juice. The differences seen in men and women are possibly due to a slower gastric emptying rate in men, which increases the exposure of the quinolone to the enteral feed.[4]

Importance and management

The interaction between ciprofloxacin and enteral feeds is established. No treatment failures have been reported but it may be clinically important. For example, if patients receiving enteral feeds were to be switched from parenteral to oral ciprofloxacin, there could be a significant reduction in serum ciprofloxacin levels. The authors of one study recommend that in patients with severe infections, such a switch from parenteral to nasogastric administration of ciprofloxacin should be restricted to those whose plasma ciprofloxacin levels can be routinely monitored. However, some have found the reduced levels with enteral feeding still provide adequate antibacterial levels,[8,27] but be alert for any evidence that ciprofloxacin is less effective and raise the dose as necessary. Use of enteral feeds with lower concentrations of divalent ions or even stopping tube feeding for a short period of time have been suggested as methods to try to improve ciprofloxacin absorption.[27] The authors of one *in vitro* study suggest that *Ensure* should be given at least 2 hours before or after fluoroquinolones.[26]

The interaction between ofloxacin or moxifloxacin and enteral feeds is much smaller and probably not clinically important but this needs confirmation. Garenoxacin and gatifloxacin appear not to interact. There are no specific reports about other quinolones but be alert for this interaction with any of them.

Apart from ‘dairy products’ (p.374), quinolones can be given with food

without any decrease in levels. However, calcium-fortified foods may cause significant interactions with ciprofloxacin.

Quinolones + H_2-receptor antagonists

Cimetidine can increase the serum levels of some quinolones (intravenous enoxacin or fleroxacin and oral clinafloxacin or pefloxacin). Famotidine can reduce the serum levels of norfloxacin, and ranitidine can reduce the absorption of enoxacin.

Clinical evidence and mechanism

(a) Ciprofloxacin

Neither **cimetidine**[1,2] nor **ranitidine**[3,4] appear to have a clinically important effect on the pharmacokinetics of ciprofloxacin.

(b) Clinafloxacin

Cimetidine 300 mg four times daily for 4 days increased the maximum serum levels of clinafloxacin by 15% and increased its AUC by 44%.[5]

(c) Enoxacin

The plasma levels of a 400-mg intravenous dose of enoxacin were higher when **cimetidine** 300 mg four times daily was given concurrently. Renal clearance and systemic clearance were reduced by 26% and 20%, respectively, and the elimination half-life was increased by 30%.[6]

In one study, **ranitidine** 150 mg twice daily did not affect the pharmacokinetics of a single 400-mg intravenous dose of enoxacin.[6] However, in another study, **ranitidine** 50 mg given intravenously 2 hours before a single 400-mg oral dose of enoxacin reduced the absorption of the enoxacin by 26 to 40%,[7,8] which seemed to be related to changes in gastric pH caused by **ranitidine**.[8]

(d) Fleroxacin

Cimetidine decreases the total clearance of fleroxacin by about 25%, without much effect on renal clearance, and increases its elimination half-life by 32%.[9]

(e) Gatifloxacin

Cimetidine does not alter the pharmacokinetics of gatifloxacin.[10]

(f) Levofloxacin

Cimetidine reduces the clearance of levofloxacin by about 25% and increased its AUC by almost 30%,[11] whereas **ranitidine** does not affect the pharmacokinetics of levofloxacin.[12]

(g) Lomefloxacin

Ranitidine does not affect the pharmacokinetics of lomefloxacin.[13,14]

(h) Moxifloxacin

Ranitidine does not affect the pharmacokinetics of moxifloxacin.[15]

(i) Norfloxacin

Famotidine given 8 hours before norfloxacin significantly reduced its maximum serum concentrations in 6 healthy subjects, but the AUC and urinary recovery rate were unchanged.[16]

(j) Ofloxacin

Cimetidine does not alter the pharmacokinetics of ofloxacin.[17]

(k) Pefloxacin

Cimetidine increases the AUC of intravenous pefloxacin by about 40%. It increases the half-life from 10.3 hours to 15.3 hours and the clearance of pefloxacin was reduced by almost 30%.[18]

(l) Sparfloxacin

Cimetidine does not alter the pharmacokinetics of sparfloxacin.[19]

(m) Tosufloxacin

Famotidine does not alter the pharmacokinetics of tosufloxacin.[20]

(n) Trovafloxacin

Cimetidine does not alter the pharmacokinetics of trovafloxacin.[21]

Importance and management

Although the pharmacokinetic changes seen in some of these studies are moderate, none has been shown to affect the outcome of treatment and they are probably only of minor clinical relevance.

Quinolones + Iron or Zinc compounds

Ferrous fumarate, ferrous gluconate, ferrous sulfate and other iron compounds can reduce the absorption of ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin from the gut. Serum levels of the antibacterial may become subtherapeutic as a result. Limited evidence suggests that fleroxacin is not affected, lomefloxacin is only minimally affected and gemifloxacin is not affected when dosing is separated. Zinc appears to interact like the iron compounds. No interaction appears to occur with iron-ovotransferrin.

Clinical evidence

(a) Ciprofloxacin

The absorption of ciprofloxacin is markedly reduced by iron and zinc compounds. Several studies have clearly demonstrated reductions in the AUC and maximum serum levels of 30 to 90% with **ferrous fumarate**,[1] **ferrous gluconate**,[2] **ferrous sulfate**,[2-5] **iron-glycine sulfate**,[6] ***Centrum Forte***[2] (a multi-mineral preparation containing iron, magnesium, zinc, calcium, copper and manganese) and with ***Stresstabs 600-with-zinc***[4] (a multivitamin-with-zinc preparation). However **iron-ovotransferrin** has been found to have no significant effect on the absorption of ciprofloxacin.[7]

(b) Fleroxacin

A study in 12 subjects found that **ferrous sulfate** (equivalent to 100 mg of elemental iron) had no significant effect on the pharmacokinetics of fleroxacin.[8]

(c) Gatifloxacin

A study in 6 healthy subjects found that **ferrous sulfate** 160 mg given with gatifloxacin 200 mg decreased the maximum serum levels and AUC of gatifloxacin by 49% and 29%, respectively.[9]

A case report describes a woman who did not respond to treatment with gatifloxacin for hospital acquired pneumonia when it was given at the same time as a multivitamin preparation containing iron, magnesium and **zinc**. When administration was separated by 6 hours her clinical signs improved.[10]

(d) Gemifloxacin

In a study in 27 healthy subjects, gemifloxacin 320 mg was given either 3 hours before or 2 hours after **ferrous sulfate** 325 mg. The pharmacokinetics of gemifloxacin were not significantly altered in either case.[11]

(e) Levofloxacin

Ferrous sulfate has been found to reduce the bioavailability of levofloxacin by 79%.[12]

(f) Lomefloxacin

When lomefloxacin 400 mg was given with **ferrous sulfate** (equivalent to 100 mg of elemental iron), the lomefloxacin maximum serum levels were reduced by about 28% and the AUC was reduced by about 14%.[13]

(g) Moxifloxacin

In 12 healthy subjects **ferrous sulfate** (equivalent to 100 mg of elemental iron) reduced the AUC and maximum plasma levels of a single 400-mg dose of moxifloxacin by 39% and 59%, respectively. The rate of absorption was reduced (time to maximum plasma level increased from a mean of one hour to 2.79 hours).[14]

(h) Norfloxacin

In 8 healthy subjects **ferrous sulfate** reduced the AUC and maximum serum levels of a single 400-mg dose of norfloxacin by 73% and 75%, respectively.[5] **Ferrous sulfate** caused a 51% reduction in the AUC of norfloxacin in another study,[15,16] and a 97% reduction in bioavailability in a further single-dose study.[17] The same authors also found that both **ferrous sulfate** and **zinc sulfate** reduced the urinary recovery of norfloxacin by 55% and 56%, respectively.[18]

(i) Ofloxacin

In 8 healthy subjects **ferrous sulfate** (equivalent to 100 mg of elemental iron) reduced the AUC and maximum serum levels of a single 400-mg dose of ofloxacin by 25% and 36%, respectively.[5] In 9 healthy subjects **ferrous sulfate** 1050 mg decreased the absorption of ofloxacin 200 mg by 11%.[19] In 12 healthy subjects elemental iron 200 mg (in the form of an **iron-glycine-sulfate** complex) reduced the bioavailability of ofloxacin 400 mg by 36%.[6]

(j) Sparfloxacin

In a single-dose study in 6 subjects, **ferrous sulfate** 525 mg (equivalent to 170 mg of elemental iron) reduced the AUC of sparfloxacin 200 mg by 27%.[15,16]

Mechanism

It is believed that the quinolones form a complex with iron and zinc (by chelation between the metal ion and the 4-oxo and adjacent carboxyl groups), which is less easily absorbed by the gut. However, a study in *rats* using oral iron and intravenous ciprofloxacin suggested that the interaction may not be entirely confined to the gut.[20] This needs further study. Iron-ovotransferrin differs from other iron preparations in being able to combine directly with the transferrin receptors of intestinal cells, and appears to release little iron into the gut to interact with the quinolones.

Importance and management

The interactions between the quinolones and iron compounds are established and would appear to be of clinical importance because the serum antibacterial levels can become subtherapeutic. In descending order the extent of the interaction appears to be: norfloxacin, levofloxacin, ciprofloxacin, moxifloxacin, gatifloxacin, ofloxacin/sparfloxacin, then least affected, lomefloxacin.

None of these quinolones should be taken at the same time as any iron preparation that contains substantial amounts of iron (e.g. ferrous sulfate, ferrous gluconate, ferrous fumarate, iron-glycine sulfate). As the quinolones are rapidly absorbed, taking them 2 hours before the iron should minimise the risk of admixture in the gut and largely avoid this interaction. Information about other quinolones seems to be lacking but the same precautions should be taken with all of them except fleroxacin, which appears not to interact, and lomefloxacin, which seems to interact only minimally.

Iron-ovotransferrin does not interact with ciprofloxacin and is not expected to interact with any of the quinolones (see 'Mechanism') but this awaits confirmation.

There seems to be very little data about the interactions between zinc compounds and quinolones, but zinc appears to interact like iron and therefore the same precautions suggested for iron should be followed.

Quinolones + NSAIDs

A number of cases of convulsions have been seen in Japanese patients given fenbufen with enoxacin, and there is also one possible case involving ofloxacin. Normally no interaction seems to occur with most quinolones and NSAIDs, except where there is a predisposition to convulsive episodes. Isolated cases of convulsions, other neurological toxicity or skin eruptions have been seen when ciprofloxacin was given with indometacin, mefenamic acid or naproxen. These appear to be very rare events.

Clinical evidence

(a) Ciprofloxacin

As of 1995 the manufacturer of ciprofloxacin had, on record, two confirmed spontaneous reports of convulsions in patients taking ciprofloxacin and an NSAID; one with **mefenamic acid** and the other with **naproxen**.[1] These appear to be the only medically validated reports of an interaction between ciprofloxacin and an NSAID by 1995.[1]

A woman taking chloroquine 250 mg and **naproxen** 1 g daily developed dizziness, anxiety and tremors within a week of starting to take ciprofloxacin 1 g daily. The symptoms largely resolved when the chloroquine was stopped; it was not known if she also stopped the naproxen. Two months after chloroquine was discontinued, and while she was still taking ciprofloxacin, **indometacin** was started. This time she developed pain in her feet and became extremely tired. The pain partially subsided and the fatigue vanished when the ciprofloxacin was stopped. Later she was found to have some axonal demyelination, compatible with drug-induced polyneuropathy.[2]

A study in 8 healthy subjects found that the pharmacokinetics of ciprofloxacin were unaffected by treatment with **fenbufen** for 3 days.[3] Another study, in 12 healthy subjects, found that the concurrent use of single doses of ciprofloxacin and **fenbufen** produced no evidence, using EEG recordings, of increased CNS excitatory effects.[4]

(b) Enoxacin

A total of 17 Japanese patients have been identified, with apparently no previous history of seizures, who in the 1986 to 1987 period developed convulsions when given **fenbufen** 400 mg to 1.2 g daily with enoxacin 200 to 800 mg.[5] Two case reports of this interaction have been published.[6,7] An 87-year-old Japanese woman taking enoxacin 200 mg also had convulsions after receiving a single 50-mg intravenous dose of **flurbiprofen**.[8]

(c) Levofloxacin

A study in 24 healthy subjects found plasma levels of single 125-mg and 500-mg doses of levofloxacin were increased by about 13%, 6.5 hours after they were given **fenbufen** 600 mg. No changes in CNS activity were found.[9]

(d) Ofloxacin

One patient taking **fenbufen** 800 mg had involuntary movements of the neck and upper extremities after taking ofloxacin 600 mg.[5] In 10 healthy subjects the pharmacokinetics of ofloxacin 200 mg twice daily were unchanged by **ketoprofen** 100 mg daily for 3 days.[10] The incidence of psychotic adverse effects (euphoria, hysteria, psychosis) in 151 patients taking ofloxacin were not increased by the concurrent use of NSAIDs (**aspirin**, **diclofenac**, **indometacin**, **dipyrone**).[11]

(e) Pefloxacin

In 10 healthy subjects the pharmacokinetics of pefloxacin 400 mg twice daily were not affected by **ketoprofen** 100 mg daily for 3 days.[10]

(f) Sparfloxacin

A 62-year-old woman developed drug eruptions (erythematous papules), which were attributed to sparfloxacin hypersensitivity induced by **mefenamic acid**.[12]

Mechanism

Not fully understood. Convulsions have occurred in a few patients taking quinolones alone, some of whom had epilepsy and some of whom did not, see 'Antiepileptics + Quinolones', p.598. Experiments in *mice* have shown that quinolones competitively inhibit the binding of GABA to its receptors.[13] GABA is an inhibitory transmitter in the CNS, which is believed to be involved in the control of convulsive activity. Enoxacin and fenbufen are known to affect the GABA receptor site in the hippocampus and frontal cortex of *mice*, which is associated with convulsive activity.[14] It could be that, if and when an interaction occurs, the NSAID simply lowers the amount of quinolone needed to precipitate convulsions in already susceptible individuals.

Importance and management

The interaction between enoxacin and fenbufen is established, but it seems to be uncommon. Nevertheless, it would seem prudent to avoid fenbufen with enoxacin. There are very many alternatives.

Reports of adverse interactions between other quinolones and NSAIDs are extremely rare. The general warning about convulsions with quinolones and NSAIDs issued by the CSM in the UK[15] seems to be an extrapolation from the interaction between enoxacin and fenbufen, and from some *animal* experiments. In addition to the data cited above, an epidemiological study of 856 users of quinolones (ciprofloxacin, enoxacin, nalidixic acid) and a range of NSAIDs found no cases of convulsions.[16] The overall picture would therefore seem to be that although a potential for interaction exists, the risk is very small indeed and normally there would seem to be little reason for most patients taking quinolones to avoid NSAIDs. Patients with epilepsy are a possible exception and it would seem prudent to avoid quinolones and NSAIDs wherever possible in these patients.

Quinolones + Omeprazole

Omeprazole has no clinically important effect on the pharmacokinetics of ciprofloxacin, garenoxacin, gemifloxacin, lomefloxacin, ofloxacin or trovafloxacin.

Clinical evidence, mechanism, importance and management

A single-dose study found that omeprazole 20 or 80 mg had no significant effect on the pharmacokinetics of single doses of **ofloxacin** 400 mg, **ciprofloxacin** 500 mg or **lomefloxacin** 250 or 400 mg.[1] Another study in 27 subjects found that omeprazole 40 mg daily for 3 days did not affect the pharmacokinetics of a single 1-g dose of an extended-release formulation of **ciprofloxacin** (*Depomed*).[2] Omeprazole 40 mg caused an 18% reduction in the AUC of a single 300-mg dose of **trovafloxacin** and a 32% reduction in the maximum serum levels, but this was considered not to be of clinical significance.[3] A randomised, crossover study in 12 healthy subjects found that the maximum serum levels and AUC of a single 320-mg dose of **gemifloxacin** were increased by 11% and 10%, respectively, by omeprazole 40 mg daily for 4 days. The confidence intervals indicated that the respective increases were unlikely to exceed 36% and 43%, and it was concluded that these two drugs could be given together without any need for dose adjustments.[4] In a study in 12 healthy subjects, slow-release omeprazole 40 mg daily did not affect the pharmacokinetics of a single 600-mg dose of **garenoxacin** and concurrent use did not increase adverse effects.[5]

Quinolones + Opioids

Morphine modestly reduces the AUC of trovafloxacin, but this is not considered to be clinically significant. Trovafloxacin did not alter the effects or pharmacokinetics of morphine. Oxycodone does not appear to significantly affect the pharmacokinetics of either levofloxacin or gatifloxacin. It has been suggested that opiates decrease oral ciprofloxacin levels, but good evidence for this appears to be lacking.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

In one non-randomised study[1] the levels of oral ciprofloxacin were only 1.3 mg/L in the presence of intramuscular **papaveretum**, compared to 3.22 mg/L in a control group not receiving **papaveretum**. The authors say that this means the peak ciprofloxacin levels in the **papaveretum** group would not reach the MIC of a number of gut pathogens. They name *Bacteroides fragilis* (but it should be noted that the levels of the control group also did not reach the MIC of this organism), and *Enterococcus faecalis*, many strains of which are only moderately susceptible to ciprofloxacin anyway. Further, the **papaveretum** group in this study had only 4 patients, and, as the authors note, the control group was not matched.[1] Based on this rather slim evidence, some have suggested that the concurrent use of opioids and ciprofloxacin as pre-medication should be avoided.[2-4]

(b) Gatifloxacin

In 12 healthy subjects, the pharmacokinetics of gatifloxacin 400 mg were not significantly altered by **oxycodone** 5 mg every 4 hours.[5]

(c) Levofloxacin

In 8 healthy subjects, the pharmacokinetics of oral levofloxacin 500 mg were not significantly altered by **oxycodone** 5 mg every 4 hours.[6]

(d) Trovafloxacin

An intravenous infusion of **morphine** 150 micrograms/kg given with oral trovafloxacin 200 mg to 18 healthy subjects caused a 36% reduction in the trovafloxacin AUC and a 46% reduction in the maximum serum levels. These levels were considered sufficient for prophylaxis of infection, and remained above the MICs of the most likely organisms to cause post-surgical infections. The bioavailability and effects of **morphine** were not significantly changed by trovafloxacin.[7]

Quinolones + Opioids; Methadone

An isolated case describes sedation, confusion and respiratory depression, which was attributed to the inhibition of methadone metabolism by ciprofloxacin.

Clinical evidence

A woman taking methadone 140 mg daily for 6 years, to manage pain due to chronic intestinal pseudo-obstruction, was admitted to hospital because of a urinary tract infection and given ciprofloxacin 750 mg twice daily. Two days later she became sedated and confused. Ciprofloxacin was replaced with co-trimoxazole and the patient recovered within 48 hours. She was treated with ciprofloxacin for recurrent urinary-tract infections a further three times and on each occasion the patient became sedated, with her normal alertness regained on discontinuing ciprofloxacin. On the last occasion, when the venlafaxine that she had also been taking was replaced by fluoxetine, she also developed respiratory depression, which was reversed with naloxone.[1]

Mechanism

The cytochrome P450 isoenzymes CYP1A2, CYP2D6 and CYP3A4 are involved in the metabolism of methadone. Ciprofloxacin is a potent inhibitor of CYP1A2 and possibly has some effect on CYP3A4. It is therefore probable that the confusion and sedation seen in the patient were due to the inhibition of methadone metabolism. The use of 'fluoxetine', (p.1489), and the fact that the patient was a smoker, may also have contributed.

Importance and management

This seems to be the only report of this interaction but it would appear to be of clinical importance. Care is needed if ciprofloxacin and methadone are given concurrently, especially if there are other factors present, such as smoking or the use of other enzyme inhibitors, which may also contribute to the interaction. Be alert for the need to change the methadone dose. Consider also 'Quinolones + Opioids', above.

1. Herrlin K, Segerdahl M, Gustafsson LL, Kalso E. Methadone, ciprofloxacin, and adverse drug reactions. *Lancet* (2000) 356, 2069–70.

Quinolones + Other antibacterials

There appear to be few documented cases of clinically relevant interactions between the quinolones and other antibacterials. How-

ever, note that clindamycin may antagonise the effects of ciprofloxacin on *Staphylococcus aureus*. Further, *in vitro* studies have demonstrated antagonistic antibacterial effects when nitrofurantoin and nalidixic acid are used together, and other quinolones are also said to antagonise the effects of nitrofurantoin.

Clinical evidence, mechanism, importance and management

(a) Aminoglycosides

A study found that a single 100-mg intravenous dose of **tobramycin** had no effect on the pharmacokinetics of **pefloxacin**, and **pefloxacin** did not affect the pharmacokinetics of **tobramycin**.[1] Similarly no pharmacokinetic interaction was found between **pefloxacin** and **amikacin**.[2]

(b) Cephalosporins

A study found that a single 2-g intravenous dose of **ceftazidime** had no effect on the pharmacokinetics of **pefloxacin**, and **pefloxacin** did not affect the pharmacokinetics of **ceftazidime**.[1]

In a study in 11 healthy subjects, the pharmacokinetics of **cefotaxime** and **ofloxacin** were similar, whether given alone or in combination, and the antimicrobial effect of the combination was additive for *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Enterobacter cloacae* and *Klebsiella pneumoniae*, but not for *Pseudomonas aeruginosa*.[3]

(c) Clindamycin

One study found that the pharmacokinetics of intravenous **ciprofloxacin** 200 mg were not affected by intravenous clindamycin 600 mg and there is evidence that combined use may possibly enhance the antibacterial activity, particularly against *Staphylococcus aureus* and *Streptococcus pneumoniae*.[4] However, another study found that the serum bactericidal activity of **ciprofloxacin** against *Staphylococcus aureus* was completely antagonised by clindamycin, if the strains were susceptible to the latter.[5]

(d) Macrolides

A study designed to assess the potential interaction between **trovafloxacin** and **azithromycin** found no significant alteration in the pharmacokinetics of either drug.[6]

(e) Metronidazole

A study found that a single 400-mg oral dose of metronidazole had no effect on the pharmacokinetics of **pefloxacin**, and similarly **pefloxacin** did not affect the pharmacokinetics of metronidazole.[1] In other studies no interaction was found between **ciprofloxacin** or **ofloxacin** (both 200 mg intravenously) and metronidazole 500 mg intravenously;[7] and metronidazole with **ciprofloxacin** orally.[8]

A further study, investigating the use of metronidazole 500 mg intravenously and **ciprofloxacin** 200 mg intravenously, also did not find any significant pharmacokinetic changes, although metronidazole reduced the **ciprofloxacin** volume of distribution by 20%.[4] This is not expected to be clinically significant.

(f) Nitrofurantoin

The antibacterial activity of **nalidixic acid** can be attenuated by sub-inhibitory concentrations of nitrofurantoin. In 44 out of 53 strains of *Escherichia coli*, *Salmonella* and *Proteus*, antagonism was shown.[9] Another study confirmed these findings.[10] Whether this similarly occurs if both antibacterials are given to patients is uncertain, but the advice that concurrent use should be avoided when treating urinary tract infections seems sound.[9] Active division of bacteria is required for the bactericidal activity of quinolones such as nalidixic acid, and the presence of a bacteriostatic drug such as nitrofurantoin may inhibit its action.[11] Other quinolone antibacterials (not named) and nitrofurantoin have been found to be antagonistic *in vitro*, although the clinical significance of this is unknown.[12,13]

(g) Penicillins

A single-dose study in 6 healthy subjects found that intravenous **azlocillin** 60 mg/kg reduced the clearance of intravenous **ciprofloxacin** 4 mg/kg by 35%. The pharmacokinetics of **azlocillin** were not affected.[14] Another study found that when a single 4-g intravenous dose of **piperacillin** was given with **pefloxacin** 400 mg the pharmacokinetics of both drugs were unchanged.[1] In 6 healthy subjects the absorption of **ofloxacin** 400 mg was not altered by **amoxicillin** 3 g.[15]

In another study, in 12 healthy subjects, the serum bacterial activity of **ciprofloxacin** with **piperacillin** against a variety of organisms was found to be additive, rather than antagonistic or synergistic despite the fact that the clearance of **ciprofloxacin** was reduced by 24%.[16]

(h) Rifampicin (Rifampin)

1. Ciprofloxacin. A single-dose study in 5 healthy subjects found that ciprofloxacin 500 mg decreased the peak serum levels of rifampicin 600 mg by 12%, and prolonged its half-life from 3.5 hours to 3.8 hours.[17] In a further study, ciprofloxacin did not affect the percentage of rifampicin recovered in the urine, but it did increase its initial rate of excretion.[18] In 12 elderly patients (aged 67 to 95 years), ciprofloxacin 750 mg and rifampicin 300 mg, both given every 12 hours for 2 weeks, did not significantly affect the pharmacokinetics of either drug.[19] This is confirmed by other pharmacokinetic studies, one of which also reported that combined use provided excellent serum bactericidal activity against *Staphylococcus aureus* strains, although activity was modestly lower than rifampicin alone.[5,20,21] No special precautions would seem necessary if rifampicin is given with ciprofloxacin.

2. Fleroxacin. A study in 13 healthy subjects found that rifampicin 600 mg daily for a week increased the clearance of fleroxacin 400 mg daily by 15%. However, the fleroxacin levels remained above the MIC_{90} of methicillin-sensitive strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* for at least 24 hours.[22]

3. Gatifloxacin. A study in 22 healthy subjects who took a single 400-mg dose of gatifloxacin alone, or with a combined preparation containing rifampicin 400 mg, isoniazid 300 mg and pyrazinamide 1.6 g, found that the AUC of gatifloxacin was increased by 10% when taken with the combined preparation. In addition, the AUC and maximum plasma concentration of rifampicin were reduced by 14% and 27%, respectively, by gatifloxacin.[23] The effect of these changes on the efficacy of treatment is unclear, but it seems likely to be small.

4. Moxifloxacin. A study in 19 patients who were nearing the end of treatment for tuberculosis with rifampicin 450 mg daily and isoniazid 600 mg daily found that the maximum plasma levels and AUC of moxifloxacin 400 mg daily for 5 days were reduced by 32% and 31%, respectively, when it was taken with the antimycobacterials, compared with when it was taken alone. It was also noted that the MIC of moxifloxacin against fast growing bacilli was achieved in only one patient taking moxifloxacin with the antimycobacterials, compared with 9 of 19 patients taking moxifloxacin alone.[24]Another study in healthy subjects found that the AUC of moxifloxacin 400 mg daily, given for 4 days alone, and then with rifampicin 600 mg daily for 10 days was reduced by 27% by rifampicin. There was no significant difference between the maximum plasma moxifloxacin levels achieved in each treatment period.[25] The clinical significance of these findings is unclear, but it seems likely to be small.

5. Pefloxacin. A study in 8 healthy subjects found that rifampicin 900 mg daily for 10 days decreased the half-life and $AUC_{0\text{-}12}$ of pefloxacin 400 mg twice daily by about 30%, due to a 35% increase in total plasma clearance.[26] Despite these changes the serum pefloxacin levels still remained well above the MIC (0.5 mg/L) for 90% of strains of methicillin-sensitive *Staphylococcus aureus* and *Staphylococcus epidermidis*.[26] A single-dose study in 5 healthy subjects found that pefloxacin 500 mg increased the AUC of a single 600-mg dose of rifampicin about twofold.[27] In a further study the urinary recovery of rifampicin was increased from 16% of the dose to 20% by pefloxacin.[28] No special precautions would seem necessary if rifampicin is given with pefloxacin.

Quinolones + Phosphate binders

The bioavailability of ciprofloxacin is markedly reduced by lanthanum. Other quinolones are likely to interact similarly. Sevelamer reduced the bioavailability of ciprofloxacin by 48% in one study.

Clinical evidence, mechanism, importance and management

(a) Lanthanum

In a randomised, crossover study, 12 healthy subjects received a single 750-mg dose of oral **ciprofloxacin** alone, or on the second day of a 2-day course of lanthanum 1 g three times daily. Lanthanum reduced the AUC and maximum plasma levels of **ciprofloxacin** by 54% and 56%, respectively.[1] It seems likely that **ciprofloxacin** forms an insoluble chelate with lanthanum within the gut, which reduces its absorption. Such a reduction in bioavailability may lead to subtherapeutic levels and hence reduced efficacy. It is therefore recommended that quinolones are not taken within 2 hours of lanthanum.[2]

(b) Sevelamer

In a crossover study in 15 healthy subjects, the AUC of **ciprofloxacin** was reduced by 39% and its relative oral bioavailability was reduced by 48% when a single 750-mg dose of **ciprofloxacin** was taken with sevelamer 2.8 g. The reduction was variable.[3] The mechanism of the interaction is unknown. Based on the results of this study, sevelamer should not be given at the same time as **ciprofloxacin** because the efficacy of **ciprofloxacin** might be reduced in some patients. Note that the manufacturers of sevelamer suggest that, when giving any other oral drug for which a reduction in the bioavailability could have a clinically significant effect on safety or efficacy, the drug should be given at least one hour before or 3 hours after sevelamer.[4,5] Until more is known it would seem prudent to apply this advice to all quinolones.

Quinolones + Pirenzepine

In 10 healthy subjects, four doses of pirenzepine 50 mg delayed the absorption of ciprofloxacin and ofloxacin, but their bioavailabilities remained unchanged.[1] The delayed absorption is unlikely to be of clinical significance.

1. Höffken G, Lode H, Wiley R, Glatzel TD, Sievers D, Olschewski T, Borner K, Koeppe T. Pharmacokinetics and bioavailability of ciprofloxacin and ofloxacin: effect of food and antacid intake. *Rev Infect Dis* (1988) 10 (Suppl 1), S138–S139.

Quinolones + Probenecid

Probenecid increases the serum levels and/or decreases the urinary excretion of cinoxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, levofloxacin, nalidixic acid and norfloxacin. Moxifloxacin, sparfloxacin, and probably ofloxacin, appear not to interact with probenecid.

Clinical evidence

(a) Cinoxacin

A study in 6 healthy subjects found that probenecid 500 mg three times daily roughly doubled the serum levels of a 3-hour intravenous infusion of cinoxacin. The renal clearance of cinoxacin was also reduced from 68% to 46% during and for the 4 hours after the infusion.[1]

(b) Ciprofloxacin

In one study, probenecid 1 g, given 30 minutes before ciprofloxacin 500 mg, was found to reduce the renal clearance of ciprofloxacin by up to 50%. Other pharmacokinetic parameters (maximum serum levels, AUC) were unchanged and no accumulation of ciprofloxacin appeared to occur, probably due to an increase in extra-renal elimination.[2]

Another study found that the renal clearance of ciprofloxacin was reduced by 64% by probenecid. However, in contrast to the other study cited, the AUC of ciprofloxacin was increased by 74% and the AUC of its 2-aminoethylamino metabolite was increased by 234%. As a consequence, levels of ciprofloxacin in tears, sweat and saliva were also increased, but probenecid had no direct effect on ciprofloxacin distribution into these fluids.[3]

(c) Clinafloxacin

Probenecid 1 g, given one hour before a single 400-mg dose of clinafloxacin, reduced the total and renal clearance of clinafloxacin by 24% and 36%, respectively, raised its AUC by 32%, and increased its elimination half-life from 6.3 hours to 7 hours.[4]

(d) Enoxacin

In one subject, the renal clearance of enoxacin 600 mg was approximately halved, and the half-life increased from 3.5 hours to 4.5 hours by a single 2.5-g dose of probenecid.[5]

(e) Fleroxacin

A study in 6 healthy subjects given a single 200-mg dose of fleroxacin, followed by 500 mg of probenecid 30 minutes, 12 hours, 24 hours and 36 hours later, found that the AUC of fleroxacin was increased by 37% and its urinary excretion was decreased by 22%.[6] Another study found that probenecid increased the AUC of fleroxacin 400 mg by 26% (not statistically significant), and had no effect on fleroxacin urinary excretion.[7]

(f) Levofloxacin

A study in 12 healthy subjects found that although probenecid reduced the renal clearance of a single 500-mg oral dose of levofloxacin by about one-third and increased its AUC and half-life by similar amounts, the 72-hour urinary levofloxacin excretion was unaltered.[8]

(g) Moxifloxacin

A study in 12 healthy subjects found that probenecid had no clinically significant effects on the pharmacokinetics of a single 400-mg dose of moxifloxacin.[9]

(h) Nalidixic acid

Two subjects, acting as their own controls, took nalidixic acid 500 mg with and without probenecid 500 mg. The peak serum levels of nalidixic

acid were unaffected at 2 hours, but at 8 hours the levels were increased threefold by probenecid.[10]

Another study in 5 women with urinary tract infections treated with nalidixic acid found that probenecid increased the maximum serum nalidixic acid levels and AUC by 43% and 74%, respectively.[11]

(i) Norfloxacin

In 5 subjects the mean 12-hour urinary recovery of norfloxacin 200 mg was reduced by about half when they were given probenecid 1 g. Norfloxacin serum concentrations were unaffected.[12]

(j) Ofloxacin

A study in 8 healthy subjects found that probenecid 500 mg increased the AUC of a single 200-mg dose of ofloxacin by 16% and decreased the total body clearance by 14%. Other pharmacokinetic parameters were not significantly affected.[13]

(k) Sparfloxacin

In 6 healthy subjects, probenecid 1.5 g did not significantly affect the clearance, the AUC or the half-life of sparfloxacin 200 mg.[14]

Mechanism

The likely explanation for this interaction is that probenecid successfully competes with some quinolones for tubular excretion, so that their renal elimination is reduced. Some quinolones are more dependent on glomerular filtration than tubular excretion for elimination, and thus are unaffected by competition for tubular excretion.[7]

Importance and management

Established interactions, but their clinical importance seems not to have been assessed. The increased levels and decreased renal excretion of clinafloxacin caused by probenecid are not considered large enough to warrant dose adjustment,[4] and most of the changes seen with the other quinolones were of a similar magnitude. However, caution has been advised if probenecid is given with quinolones to patients with impaired renal function, or in the presence of other drugs that may also compete for renal excretion (such as some penicillins or cephalosporins).[3,4] Moxifloxacin, sparfloxacin, and probably ofloxacin, appear not to interact, and so may be useful alternatives in some situations.

Quinolones + Sucralfate

Sucralfate causes a marked reduction in the absorption of ciprofloxacin, enoxacin, gemifloxacin, lomefloxacin, moxifloxacin, ofloxacin, norfloxacin and sparfloxacin, but causes only a modest reduction in fleroxacin levels.

Clinical evidence

(a) Ciprofloxacin

In a study in 8 healthy subjects sucralfate 1 g four times daily reduced the AUC and maximum serum concentration of ciprofloxacin 500 mg by 88% and 90%, respectively.[1] A study in 12 healthy subjects found that a 1-g dose of sucralfate given 6 hours and 2 hours before a single 750-mg dose of ciprofloxacin, reduced the ciprofloxacin AUC by about 30%. In 3 subjects there were little or no changes in the AUC of ciprofloxacin but a decrease of more than 50% was seen in 4 others.[2] A related study in 12 healthy subjects found that the bioavailability of ciprofloxacin 750 mg was reduced by 7%, 20%, and 95%, respectively, when sucralfate was given 6 hours before, 2 hours before, or at the same time as, the ciprofloxacin.[3]

A patient given sucralfate 1 g four times daily had serum ciprofloxacin levels that were 85 to 90% lower than 5 other patients who were not taking sucralfate.[4] A single dose study found a 96% reduction in the AUC of ciprofloxacin following a 2-g dose of sucralfate.[5] Oral sucralfate does not alter the effects of ciprofloxacin on aerobic bacteria in the gut.[6]

(b) Enoxacin

In 8 healthy subjects when sucralfate 1 g was given 2 hours before or with enoxacin 400 mg the bioavailability of the enoxacin was reduced by 54% and 88%, respectively,. When sucralfate was given 2 hours after enoxacin its bioavailability was not affected.[7]

(c) Fleroxacin

In 20 healthy subjects, sucralfate 1 g every 6 hours reduced the bioavailability of fleroxacin 400 mg by 24%.[8]

(d) Gemifloxacin

In a study in 27 healthy subjects, gemifloxacin 320 mg was given either 3 hours before or 2 hours after sucralfate 2 g. The pharmacokinetics of gemifloxacin were not significantly altered when sucralfate was given after the gemifloxacin, probably due to its rapid absorption. However, when sucralfate was given 3 hours before gemifloxacin, its AUC and maximum plasma levels were decreased by 53% and 69%, respectively.[9]

(e) Levofloxacin

The pharmacokinetics of levofloxacin are unaffected by sucralfate taken 2 hours after the quinolone.[10]

(f) Lomefloxacin

A study in 12 subjects found that when lomefloxacin 400 mg was given 2 hours after sucralfate 1 g the lomefloxacin AUC and maximum serum concentration were reduced by about 25% and 30%, respectively.[11] Another study in 8 healthy subjects found that when lomefloxacin 400 mg was given with sucralfate 1 g, the lomefloxacin AUC was reduced by 51%.[12]

(g) Moxifloxacin

In 12 healthy subjects, a total of five doses of sucralfate 1 g, given at the same time as a single 400-mg dose of moxifloxacin and then 5, 10, 15, and 24 hours after the dose, reduced the AUC and maximum serum concentration of moxifloxacin by 40% and 29%, respectively.[13]

(h) Norfloxacin

A study in 8 healthy subjects found that sucralfate 1 g four times daily reduced the AUC of a single 400-mg dose of norfloxacin by 98%, when taken with the sucralfate, and by 42% when taken 2 hours after the sucralfate.[14] Another study found a reduction of 91% in the AUC of norfloxacin 400 mg when it was taken with sucralfate 1 g, but no reduction when norfloxacin was taken 2 hours before sucralfate.[15]

(i) Ofloxacin

A single-dose study found that sucralfate (dose not stated) reduced the maximum serum levels and AUC of a single 200-mg dose of ofloxacin by about two-thirds.[16] Another study found a reduction in the maximum serum levels and the AUC of ofloxacin of 70% and 61%, respectively, when ofloxacin 400 mg was taken with sucralfate 1 g, but no reduction when the ofloxacin was taken 2 hours before sucralfate.[15] Food reduced the extent of the interaction but it was still marked.[17]

(j) Sparfloxacin

In a study in 15 healthy subjects, sucralfate 1 g four times daily reduced the maximum serum levels, the AUC and the relative bioavailability of sparfloxacin 400 mg daily by 39%, 47%, and 44%, respectively.[18] In a study assessing staggered dosing of sucralfate 1.5 g on the pharmacokinet-

ics of sparfloxacin 300 mg, the AUC of sparfloxacin was unaffected when sucralfate was given 4 hours after the quinolone, but was decreased by 34% when sucralfate was given 2 hours after the quinolone, and by 51% when sucralfate was given at the same time as the quinolone.[19]

Mechanism

The aluminium hydroxide component of sucralfate (about 200 mg in each gram) forms an insoluble chelate between the cation and the 4-keto and 3-carboxyl groups of the quinolone, which reduces its absorption. See 'Quinolones + Antacids or Calcium compounds', p.369, for more on this mechanism.

Importance and management

Established and clinically important interactions. Because it seems probable that serum ciprofloxacin, enoxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, ofloxacin, norfloxacin and sparfloxacin levels will be reduced to subtherapeutic concentrations if given with sucralfate, separate the doses as much as possible (by 2 hours or more), giving the quinolone first. The manufacturer of ciprofloxacin advises that it should be given one to 2 hours before, or 4 hours after, sucralfate.[20] The study with moxifloxacin suggested that sucralfate should not be given for 2 hours before or 4 hours after the quinolone, but more study is needed to confirm both these findings and the effectiveness of separating the doses; however, the UK manufacturer of moxifloxacin advises separating administration by 6 hours,[21] whereas the US manufacturer of moxifloxacin recommends that it is taken at least 4 hours before or 8 hours after sucralfate.[22] The interaction with fleroxacin is only modest (bioavailability reduced by 24%) and probably not clinically important, but some separation of the doses may reduce the interaction further. This needs confirmation. **Pefloxacin** interacts with antacids containing aluminium hydroxide (see 'Quinolones + Antacids or Calcium compounds', p.369) and is therefore likely to interact with sucralfate.

The 'H_2-receptor antagonists', (p.377) and 'omeprazole', (p.380) do not interact with the quinolones and may therefore be alternatives to sucralfate in some situations.

Quinolones; Ciprofloxacin + Chloroquine

Chloroquine may modestly reduce ciprofloxacin levels.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects who were given a single 500-mg dose of ciprofloxacin alone, or with a single 600-mg dose of chloroquine found that the maximum plasma level of ciprofloxacin was reduced by 18% by chloroquine, and was below the minimum inhibitory concentration for *Plasmodium falciparum*.[1] The same or a very similar study is reported elsewhere.[2] The authors of these reports suggest that the reduction in ciprofloxacin bioavailability may have implications for the management of infections resistant to chloroquine. More study is needed to establish the clinical relevance of this small decrease in ciprofloxacin levels.

For details of a possible interaction between a NSAID and ciprofloxacin in a patient also taking chloroquine, see 'Quinolones + NSAIDs', p.379.

Quinolones; Ciprofloxacin + Pancreatic enzymes

The pharmacokinetics of ciprofloxacin are not affected by pancreatic enzyme supplements.

Clinical evidence, mechanism, importance and management

Six patients with cystic fibrosis, chronically infected with *Pseudomonas aeruginosa* and who had received a range of drugs including ceftazidime, tobramycin, ticarcillin and salbutamol, demonstrated no significant changes in the pharmacokinetics of a single 250-mg dose of ciprofloxacin when it was given with standard doses of pancreatic enzymes (seven *Pancrease* capsules).[1] Another study in 12 patients with cystic fibrosis found that giving pancreatic enzyme supplements 30 minutes before a single 750-mg dose of ciprofloxacin did not alter the pharmacokinetics of ciprofloxacin.[2] No special precautions would seem to be necessary during concurrent use.

2. Reed MD, Stern RC, Myers CM, Yamashita TS, Blumer JL. Lack of unique pharmacokinetic characteristics in patients with cystic fibrosis. *J Clin Pharmacol* (1988) 28, 691–9.

Quinolones; Ciprofloxacin + Paracetamol (Acetaminophen)

Paracetamol does not alter the pharmacokinetics of ciprofloxacin, but ciprofloxacin may delay and reduce maximum paracetamol levels.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, a single 500-mg dose of paracetamol had no effect on the pharmacokinetics of a single 500-mg dose of ciprofloxacin.[1] The maximum salivary concentration of a single 1-g dose of paracetamol was reduced by 30% by a single 500-mg dose of ciprofloxacin, and the time to reach maximum salivary levels was delayed from 0.7 hours to 1.43 hours. However, there was no significant change in the AUC of paracetamol in salivary samples. The authors of one study suggest that administration of ciprofloxacin and paracetamol should be separated to avoid a delayed onset of action of paracetamol.[2] However, unless analge-

sia is urgently required, this interaction seems unlikely to be clinically relevant, as the exposure to paracetamol did not appear to be affected.

1. Issa MM, Nejem RM, El-Abadla NS, El-Naby MK, Roshdy AA, Kheiralla ZA. Effects of paracetamol on the pharmacokinetics of ciprofloxacin in plasma using a microbiological assay. *Clin Drug Invest* (2007) 27, 463–7.
2. Issa MM, Nejem RM, El-Abadla NS. Oral ciprofloxacin affects the pharmacokinetics of paracetamol in saliva. *Clin Drug Invest* (2006) 26, 223–6.

Quinolones; Ciprofloxacin + Phenazopyridine

Phenazopyridine appears to increase the bioavailability of ciprofloxacin.

Clinical evidence, mechanism, importance and management

A study in 23 healthy subjects given a single 500-mg dose of ciprofloxacin either alone or with phenazopyridine 200 mg found that phenazopyridine increased the AUC and mean residence time of ciprofloxacin by about 30%. The time to achieve maximum plasma levels was increased from 1 hours to 1.5 hours.[1] If anything, this seems likely to be a beneficial, rather than adverse, interaction.

1. Marcelín-Jiménez G, Ángeles AP, Martínez-Rossier L, Fernández A. Ciprofloxacin bioavailability is enhanced by oral co-administration with phenazopyridine: a pharmacokinetic study in a Mexican population. *Clin Drug Invest* (2006) 26, 323–8.

Quinolones; Ciprofloxacin + Ursodeoxycholic acid (Ursodiol)

An isolated report describes a reduction in serum ciprofloxacin levels in a patient taking ursodeoxycholic acid.

Clinical evidence, mechanism, importance and management

A man with metastatic colon cancer had unusually low serum levels of ciprofloxacin following oral dosing; his only other medication was ursodeoxycholic acid 300 mg twice daily for gallstones. Despite the low antibacterial serum levels the bacteraemia cleared. Several months later, when he was readmitted to hospital, both drugs were again given, initially staggered, and then later together. When taken together the AUC of ciprofloxacin was reduced by 50% by ursodeoxycholic acid.[1] The reason for this interaction is not understood.

This seems to be the first and only report of an interaction between a quinolone and ursodeoxycholic acid and its importance is uncertain. More study is needed to establish this interaction, its importance, and its mechanism.

Quinolones; Levofloxacin + Antiretrovirals

There appears to be no clinically important pharmacokinetic interaction between levofloxacin and efavirenz, nelfinavir or zidovudine.

Clinical evidence, mechanism, importance and management

A study in HIV-positive patients who were taking zidovudine and lamivudine with either **efavirenz** or **nelfinavir**, found that levofloxacin 500 mg daily for 4 days did not affect the steady-state pharmacokinetics of either **efavirenz** 600 mg daily or **nelfinavir** 750 mg three times daily. The pharmacokinetics of levofloxacin during the concurrent use of **efavirenz** or **nelfinavir** were unaffected, except for the time to reach maximum levels, which was increased from a range of 0.9 to 1.7 hours in control subjects, to 3.3 hours with **efavirenz**. This may have occurred as a result of delayed gastric emptying caused by the **efavirenz**. A clinically important interaction between levofloxacin and either **efavirenz** or **nelfinavir** is unlikely.[1]

A double-blind study in 16 HIV-positive patients taking **zidovudine** with levofloxacin 350 mg every 8 hours or placebo, did not find any changes in the pharmacokinetics of either drug.[2] No dose adjustments would therefore be expected to be necessary if both drugs are given.

Quinolones; Lomefloxacin + Furosemide

Furosemide causes a small rise in the serum levels of lomefloxacin. The pharmacokinetics and diuretic effects of furosemide are not changed by lomefloxacin.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that when a single 200-mg dose of lomefloxacin was taken with furosemide 40 mg, the AUC of lomefloxacin was increased by 12%. The maximum serum levels and the half-life of lomefloxacin were also increased, but not to a statistically significant extent.[1] The suggested reason for the interaction is that there is some competition between the two drugs for excretion by the renal tubules. No significant changes were seen in the pharmacokinetics of furosemide nor in its diuretic effects.[1] The small rise in the serum levels of lomefloxacin is almost certainly too small to be important and there would seem to be no reason for avoiding concurrent use. Information about other quinolone antibacterials appears to be lacking.

Quinolones; Moxifloxacin + Itraconazole

A study in healthy subjects found that itraconazole 200 mg daily for 9 days did not affect the pharmacokinetics of a single 200-mg dose of moxifloxacin given on day 7. No clinically relevant changes were found in the pharmacokinetics of itraconazole.[1] No dose adjustments would seem to be necessary during concurrent use.

Quinolones; Ofloxacin + Cetraxate

A single-dose study found that cetraxate (dose not stated) did not affect the pharmacokinetics of a single 200-mg dose of ofloxacin.[1] No dose adjustments would seem to be necessary on concurrent use.

Quinupristin/Dalfopristin + Miscellaneous

Quinupristin/dalfopristin modestly increases the levels of intravenous midazolam, a substrate for CYP3A4. The manufacturers therefore predict that quinupristin/dalfopristin will raise the levels of a number of other CYP3A4 substrates.

Clinical evidence, mechanism, importance and management

The manufacturers report a study in which quinupristin/dalfopristin raised the levels of an intravenous bolus dose of midazolam by 33 to 38%.[1,2] These effects are relatively modest, but oral doses of midazolam may be increased to a greater extent. Be alert for increased and/or prolonged sedation when both drugs are given. This study also suggests that quinupristin/dalfopristin is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4, and this is supported by other studies in which the levels of

CYP3A4 substrates were raised by quinupristin/dalfopristin (consider also, 'Calcium-channel blockers + Quinupristin/Dalfopristin', p.1042). The manufacturers therefore predict that quinupristin/dalfopristin will raise the levels of other drugs metabolised by CYP3A4, including some antiarrhythmics (**disopyramide**, **lidocaine**, **quinidine**), antiretrovirals (such as **delavirdine**, **indinavir**, **nevirapine**, **ritonavir**), **astemizole**, **carbamazepine**, **cisapride**, **methylprednisolone**, **paclitaxel**, and **vinca alkaloids** (the US manufacturer specifically mentions **vinblastine**).[1] It would therefore be prudent to be alert for increased adverse effects when these drugs are given with quinupristin/dalfopristin. However, the manufacturers also advise that the concurrent use of quinupristin/dalfopristin with drugs that are metabolised by CYP3A4 and which may prolong the QTc interval should be avoided.[1,2] This would be expected to include **astemizole** and **cisapride**.

The manufacturers also name **diazepam** and the **statins** (the US manufacturer specifically mentions **lovastatin**) in their list of drugs that may have their levels raised by quinupristin/dalfopristin.[1,2] However, note that diazepam is not usually affected by CYP3A4 inhibitors, and the statins are not all metabolised by this route, see 'Lipid-regulating drugs', (p.1313). For a further list of CYP3A4 substrates, see 'Table 1.4', (p.6).

The manufacturers also note that when healthy subjects were given **rifampicin** and quinupristin/dalfopristin the pharmacokinetics of both drugs were unchanged. However, the AUC of the sum of quinupristin and its active metabolites was increased by 43%.[2] The clinical relevance of this finding is unclear.

Retapamulin + Azoles

Ketoconazole increases the plasma levels and AUC of topical retapamulin. Other azoles may interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturers note that the AUC and maximum plasma level of topical retapamulin ointment 1% applied to the abraded skin of healthy subjects was increased by 81% when they also took ketoconazole 200 mg twice daily.[1,2] However, this interaction is not expected to be clinically significant, and no dose adjustment of retapamulin is recommended due to its low systemic exposure following topical application.[1,2] Other azoles would be expected to interact similarly, or to a lesser extent.

Rifampicin (Rifampin) + Aminosalicylic acid

The serum levels of rifampicin are approximately halved if aminosalicylic acid granules containing bentonite are given.

Clinical evidence

In 30 patients with tuberculosis, the serum levels of rifampicin 10 mg/kg were reduced by more than 50% at 2 hours (from 6.06 to 2.91 micrograms/mL) by aminosalicylate.[1,2] Later studies in 6 healthy subjects found that this interaction was not due to the aminosalicylic acid itself but to the **bentonite**, which was the main excipient of the granules.[3] The rifampicin AUC was statistically unchanged in the presence of sodium aminosalicylate tablets (no **bentonite**), whereas it was reduced by more than 37% in the presence of **bentonite** from aminosalicylate granules.[3]

Other studies confirm this marked reduction in serum rifampicin levels in the presence of **bentonite** in aminosalicylic acid granules.[4]

Mechanism

The bentonite excipient in the aminosalicylic acid granules adsorbs the rifampicin onto its surface so that much less is available for absorption, which results in reduced serum levels.[3] Bentonite is a naturally occurring mineral (montmorillonite) consisting largely of hydrate aluminium silicate, and is similar to kaolin.

Importance and management

A well documented and clinically important interaction. Separating the administration of the two drugs by 8 to 12 hours to prevent their mixing in the gut has been suggested as an effective way to prevent this interaction.[1] Based on this interaction with rifampicin, one UK manufacturer of **rifabutin** gives the same administration advice.[5] An alternative is to give aminosalicylic acid preparations that do not contain bentonite.

Rifampicin (Rifampin) + Antacids

The absorption of rifampicin can be reduced by up to about one-third by antacids.

Clinical evidence

When 5 healthy subjects took a single 600-mg dose of rifampicin with various antacids the absorption of rifampicin was reduced. The antacids caused a fall in the urinary excretion of rifampicin as follows:

- 15 or 30 mL of **aluminium hydroxide gel** 29 to 31%;
- 2 or 4 g of **magnesium trisilicate** 31 to 36%;
- 2 g of **sodium bicarbonate** 21%.[1]

Three groups of 15 patients with tuberculosis were given a single oral dose of rifampicin 10 to 12 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg either alone or with about 20 mL of antacid. A 'significant number' of patients had peak rifampicin concentrations below 6.5 micrograms/mL (serum level quoted as necessary to achieve adequate lung concentrations) in the group receiving *Aludrox* (**aluminium hydroxide**), but no significant effect was noted in the group receiving *Gelusil* (**aluminium hydroxide** with **magnesium trisilicate**).[2] However, in a further study in 14 healthy subjects, 30 mL of *Mylanta* (**aluminium**/**magnesium hydroxide**) given 9 hours before, with and after rifampicin had no effect on rifampicin pharmacokinetics.[3]

Mechanism

It has been suggested that the rise in stomach pH caused by these antacids reduces the dissolution of the rifampicin and thereby inhibits its absorption. In addition, aluminium ions may form less soluble chelates with rifampicin, and magnesium trisilicate can adsorb rifampicin, both of which would also be expected to reduce bioavailability.[1]

Importance and management

Direct information seems to be limited to these reports. The effects of 20 to 35% reductions in rifampicin absorption do not appear to have been assessed, but if antacids are given it would be prudent to be alert for any evidence that treatment is less effective than expected. The US manufacturers of rifampicin advise giving rifampicin one hour before antacids.[4]

Rifampicin (Rifampin) + Barbiturates

Phenobarbital possibly modestly increases the clearance of rifampicin. The effect of rifampicin on phenobarbital levels is

unknown, but rifampicin markedly increases the clearance of another barbiturate hexobarbital.

Clinical evidence, mechanism, importance and management

In one study, the serum levels of rifampicin were reduced by 20 to 40% in 12 of 15 patients taking **phenobarbital** 100 mg daily.[1] In another study, although **phenobarbital** 100 mg daily for 7 days reduced the mean half-life of a single 600-mg dose of rifampicin by 15%, this was not statistically significant. However, in a further 5 patients with cirrhosis of the liver, **phenobarbital** reduced the half-life of rifampicin by a mean of 2.2 hours.[2]

The effect of rifampicin on **phenobarbital** levels does not appear to have been studied, but rifampicin markedly increased the clearance of another barbiturate **hexobarbital**, which is used as a marker of drug metabolism.[3-6]

The evidence for an interaction between rifampicin and the barbiturates is limited. Both rifampicin and the barbiturates are potent liver enzyme inducers. The outcome of their effects when combined is not clear from the available data, but a reduction in the levels of both drugs seems possible. Concurrent use need not be avoided, but be alert for a reduced response to both the barbiturate and rifampicin.

Rifampicin (Rifampin) + Clofazimine

Clofazimine does not affect the pharmacokinetics of rifampicin and rifampicin does not affect the bioavailability of clofazimine.

Clinical evidence, mechanism, importance and management

Clofazimine 100 mg daily, given to 15 patients with leprosy taking rifampicin 600 mg daily and dapsone 100 mg daily, had no effect on the pharmacokinetics of rifampicin.[1] A single-dose study found that the bioavailability of clofazimine remained unaltered when rifampicin was given, although a reduction in the rate of absorption was seen.[2] No special precautions would seem to be necessary on concurrent use.

Rifampicin (Rifampin) + Food

Food delays and reduces the absorption of rifampicin from the gut.

Clinical evidence

The absorption of a single 10-mg/kg dose of rifampicin was reduced when it was given to 6 healthy subjects with a standard Indian breakfast (125 g wheat, 10 g visible fat, 350 g vegetables). The AUC after 8 hours was reduced by 26% and the peak plasma levels were delayed, and reduced by about 30% (from 11.84 micrograms/mL at 2 hours to 8.35 micrograms/mL at 4 hours).[1] In another study, a high-fat breakfast reduced the maximum serum level of rifampicin 600 mg by 36% and delayed the absorption, but the AUC was not significantly altered.[2]

Mechanism

Not understood.

Importance and management

An established interaction. Rifampicin should be taken on an empty stomach (at least 30 minutes before a meal, or 2 hours after a meal) to ensure rapid and complete absorption.

Rifampicin (Rifampin) + Probenecid

Probenecid increased rifampicin levels in one study, but not in another.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects given probenecid 2 g, before and after a single 300-mg dose of rifampicin, found that probenecid increased the mean peak serum rifampicin levels by 86%. At 4, 6, and 9 hours after the dose the increases were 118%, 90%, and 102%, respectively.[1] However, subsequent studies in patients taking either rifampicin 600 mg daily, or rifampicin 300 mg daily given 30 minutes after a 2-g dose of probenecid, found that the probenecid group achieved serum rifampicin levels that were only about half of those achieved in patients taking rifampicin 600 mg alone, suggesting that no interaction occurred.[2] The reasons for these discordant results are not understood, although it has been suggested that erratic rifampicin absorption may have played a part.[2] The interaction is not proven, but it seems possible that some patients will experience a rise in rifampicin levels. Consider this interaction as a possible cause if rifampicin adverse effects are troublesome.

Sulfonamides + Local anaesthetics

Para-aminobenzoic acid, derived from certain local anaesthetics, can reduce the effects of the sulfonamides and allow the development of local and even generalised infections. However, it should be noted that the limited evidence for this interaction is from the 1940s.

Clinical evidence

Four patients taking sulfonamides developed local infections in areas where **procaine** had been injected before diagnostic taps for meningitis, or draining procedures in empyema. Extensive cellulitis of the lumbar region occurred in one case, and abscesses appeared at the puncture sites in another. However, it should be noted that lumbar punctures were being done at least daily and up to four times a day in the 3 patients with meningitis.[1]

An *in vitro* study demonstrated that the amount of **procaine** in the pleural fluid after anaesthesia for thoracentesis was sufficient to inhibit the antibacterial activity of 0.005% **sulfapyridine** against type III pneumococci.[2] Another *in vitro* study found that some local anaesthetics derived from para-aminobenzoic acid (PABA) inhibited the bacteriostatic activity of **sulfapyridine** and **sulfathiazole** but some other local anaesthetics not derived from PABA did not affect the antibacterial activity of these sulfonamides.[3] Other studies in *animals* confirm that both *in vitro*[4-6] and *in vivo*[7] antagonism can occur between sulfonamides and local anaesthetics that are hydrolysed to **PABA**.

Mechanism

The ester type of local anaesthetic is hydrolysed within the body to produce para-aminobenzoic acid (PABA). Sulfonamides work by inhibiting bacterial DNA synthesis by competitively inhibiting folate production. The PABA competes with the sulfonamides, so higher PABA concentrations effectively dilute the effects of the sulfonamides.

Importance and management

Clinical examples of this interaction seem to be few and of poor quality (note that the patients were given repeated lumbar punctures, up to four times daily in some instances). It should also be noted that the supporting evidence (human, *animal* and *in vitro* studies) dates back to the mid-1940s with nothing more recent apparently on record. Local anaesthetics of the ester type that are hydrolysed to para-aminobenzoic acid (e.g. tetracaine, procaine, benzocaine) present the greatest risk of a reaction, whereas those of the amide type (bupivacaine, cinchocaine, lidocaine, mepivacaine and prilocaine) would not be expected to interact adversely. The evidence seems to be too slim to preclude concurrent use of these drugs, but it is perhaps worth considering this interaction if high or repeated doses of the local anaesthetic are used. However, note that high doses or prolonged use of these ester-type anaesthetics are best avoided given their toxicity when used in this manner.

Sulfonamides; Sulfafurazole (Sulfisoxazole) + Laxatives

Sodium sulfate and castor oil used as laxatives can cause a modest reduction in sulfafurazole absorption.

Clinical evidence, mechanism, importance and management

In an experimental study of the possible effects of laxatives on the absorption of sulfafurazole, healthy subjects were given 10 to 20 g of oral **sodium sulfate** or 20 g of **castor oil** (doses sufficient to provoke diarrhoea). Absorption, measured by the amount of sulfafurazole excreted in the urine, was decreased by 50% with **castor oil**, and by 33% with **sodium sulfate** at 4 hours. However, serum levels of the drugs were relatively unchanged. The overall picture was that while these laxatives can alter the pattern of absorption, they do not seriously impair the total amount of drug absorbed.[1]

1. Mattila MJ, Takki S, Jussila J. Effect of sodium sulphate and castor oil on drug absorption from the human intestine. *Ann Clin Res* (1974) 6, 19–24.

Tetracyclines + Antacids

The serum levels and therefore the therapeutic effectiveness of the tetracyclines can be markedly reduced or even abolished by antacids containing aluminium, bismuth, calcium or magnesium. Other antacids, such as sodium bicarbonate, may also reduce the bioavailability of some tetracyclines. Even intravenous doxycycline levels can be reduced by antacids.

Clinical evidence

(a) Aluminium-containing antacids

A study in 5 patients and 6 healthy subjects found that within 48 hours of starting to take about 10 mL of aluminium hydroxide gel (*Amphogel*) every 6 hours with **chlortetracycline** 500 mg the serum levels of the antibacterial were reduced by 80 to 90%. One patient had a recurrence of her urinary tract infection, which only subsided when the antacid was withdrawn, and one patient maintained **chlortetracycline** levels despite antacid use.[1] Similar results were obtained in other studies.[2,3]

Further studies have found similar interactions with other tetracyclines:

- 30 mL of aluminium hydroxide reduced **oxytetracycline** serum levels by more than 50%,[3]
- 20 mL of aluminium hydroxide caused a 75% reduction in **demeclocycline** serum levels,[4]
- 15 mL of aluminium hydroxide caused a 100% reduction in serum **doxycycline** levels,[5,6]
- 30 mL of aluminium/magnesium hydroxide (*Maalox*) caused a 90% reduction in **tetracycline** serum levels.[7]

Intravenous doxycycline also appears to be affected. The mean serum levels of an intravenous dose of **doxycycline** were found to be reduced by 36% when 30 mL of aluminium hydroxide was taken four times daily, for 2 days before and after the antibacterial.[8]

(b) Bismuth-containing antacids

Bismuth subsalicylate reduces the absorption of **tetracycline** by 34%[9] and reduces the maximum serum levels of **doxycycline** by 50%.[10] It has been suggested the excipient *Veegum* (magnesium aluminium silicate) in some bismuth subsalicylate formulations enhances this effect.[11] Bismuth carbonate similarly interacts with the tetracyclines *in vitro*.[12] An observation that patients given metronidazole, with bismuth and **tetracycline** taken at the same time, experienced a *Helicobacter pylori* eradication rate greater than that achieved with metronidazole and bismuth has led to the suggestion that the reduced absorption of **tetracycline** may not be as clinically relevant in the treatment of this disorder.[13]

(c) Calcium-containing antacids

There seem to be no direct clinical studies with calcium-containing antacids, but a clinically important interaction seems almost a certainty, based on *in vitro* studies with calcium carbonate,[12] calcium in milk, (see 'Tetracyclines + Food', p.390), dicalcium phosphate,[14] and calcium as an excipient in tetracycline capsules.[15]

(d) Magnesium-containing antacids

Magnesium sulfate certainly interacts with **tetracycline**, but in the only clinical study available[16] the amount of magnesium was much higher than would normally be found in the usual dose of antacid. It has been suggested the excipient *Veegum* (magnesium aluminium silicate) enhances the effect of some bismuth subsalicylate formulations on **tetracycline** absorption,[11] and in one study, 30 mL of aluminium/magnesium hydroxide (*Maalox*) caused a 90% reduction in **tetracycline** serum levels.[7]

(e) Sodium-containing antacids

In 8 subjects, sodium bicarbonate 2 g reduced the absorption of a 250-mg capsule of **tetracycline** by 50%. However, if the **tetracycline** was dissolved before administration, the absorption was unaffected by sodium bicarbonate.[17] Another study stated that sodium bicarbonate 2 g had an insignificant effect on **tetracycline** absorption.[7]

Mechanism

The tetracyclines bind with aluminium, bismuth, calcium, magnesium and other metallic ions to form compounds (chelates), which are much less soluble and therefore much less readily absorbed by the gut.[18] Because doxycycline undergoes enterohepatic recirculation, even intravenous doxycycline is affected, although less so than oral. It has also been suggested that the antacids reduce gastric acidity and thereby decrease the absorption of tetracyclines,[17] but studies demonstrating the lack of a significant interaction with 'H_2-receptor antagonists', (p.390), suggest that this is not the case. The reduced absorption with bismuth compounds may be because they adsorb tetracyclines.[9] The interaction of some tetracycline preparations with sodium bicarbonate is unexplained.

Importance and management

Extremely well-documented, and well-established interactions. Their clinical importance depends on how much the serum tetracycline levels are lowered, but with normal antacid doses the reductions cited above (50 to 100%) are large enough to mean that many organisms will not be exposed to minimum inhibitory concentrations (MIC) of antibacterial. As a general rule none of the aluminium, bismuth, calcium or magnesium-containing antacids should be given at the same time as the tetracycline antibacterials. If they must be used, separate the doses by 2 to 3 hours or more to prevent their admixture in the gut. This also applies to **quinapril** formulations containing substantial quantities of magnesium (such as *Accupro*), although the interaction is less pronounced (see 'Tetracyclines + Quinapril', p.392), and to **didanosine** tablets that are formulated with antacid.[19] The enteric-coated capsule formulation (which does not contain antacids) is not expected to interact.[20]

Patients should be warned about taking any antacids and indigestion preparations at the same time as tetracyclines. Instead of using antacids to minimise the gastric irritant effects of the tetracyclines it is usually recommended that tetracyclines are taken after food; however, it is not entirely clear how much this affects their absorption (see 'Tetracyclines + Food', p.390). H_2-receptor antagonists may be suitable non-interacting alternatives to antacids in some situations, see 'Tetracyclines + H_2-receptor antagonists', p.390.

Tetracyclines + Antiepileptics; Enzyme-inducing

The serum levels of doxycycline are reduced and may fall below the accepted minimum inhibitory concentration in patients receiving long-term treatment with barbiturates, phenytoin or carbamazepine. Other tetracyclines do not appear to be affected.

Clinical evidence

A study in 14 patients taking **phenytoin** 200 to 500 mg daily, **carbamazepine** 300 mg to 1 g daily, or both, found that the half-life of **doxycycline** was approximately halved from 15.1 hours in patients not taking antiepileptics, to 7.2 hours in patients taking **phenytoin**, 8.4 hours in patients taking **carbamazepine**, and 7.4 hours in patients taking both drugs.[1]

Similar results were found in 16 other patients taking various combinations of **phenytoin**, **carbamazepine**, **primidone** or **phenobarbital**. The serum **doxycycline** levels of almost all of them fell below 0.5 micrograms/mL during the 12- to 24-hour period following their last dose of **doxycycline** 100 mg.[2] Other studies confirm this interaction between some **barbiturates** (**amobarbital**, **pentobarbital**, **phenobarbital**) and **doxycycline**.[3,4]

Tetracycline, **methacycline**, **oxytetracycline**, **demeclocycline** and **chlortetracycline** levels were not significantly affected by various combinations of **phenytoin**, **carbamazepine**, **primidone** or **phenobarbital**.[2]

Mechanism

Uncertain. These antiepileptics and barbiturates are known enzyme inducers and it seems probable that they increase the metabolism of the doxycycline by the liver, thereby increasing its clearance from the body.

Importance and management

The interactions between doxycycline and the enzyme-inducing antiepileptics are established, but the clinical significance of the reduction in levels does not seem to have been studied. Serum doxycycline levels below 0.5 micrograms/mL are less than the minimum inhibitory concentration (MIC) quoted by the authors, so that it seems likely that the antibacterial will be less effective. To accommodate this potential problem it has been suggested that the doxycycline dose could be doubled.[2] Alternatively any of the tetracyclines that are reported not to be affected by these antiepileptics (tetracycline, methacycline, oxytetracycline, demeclocycline and chlortetracycline) may provide a suitable alternative.[2]

Tetracyclines + Colestipol

Colestipol can reduce the absorption of tetracycline by about a half. Information about other tetracyclines is lacking but it seems likely that they will interact similarly.

Clinical evidence

In 9 healthy subjects, colestipol 30 g taken either in 180 mL of water or orange juice reduced the absorption of a single 500-mg dose of oral **tetracycline** by about 55%, as measured by recovery in the urine.[1]

Mechanism

Colestipol binds to bile acids in the gut and can also bind with some drugs, thereby reducing their availability for absorption. An *in vitro* study found a 30% binding with tetracycline.[2] The presence of citrate ions in the orange juice, which can also bind to colestipol, appears not to have a marked effect on the binding of the tetracycline.

Importance and management

An established interaction. Direct information seems to be limited to the report cited, but it is consistent with the way colestipol interacts with other drugs. In practice up to 30 g of colestipol is given daily in single or twice daily, in divided doses, and tetracycline 250 to 500-mg is given every 6 hours. As other drugs need to be given one hour before or 4 hours after colestipol it may be difficult to avoid some mixing in the gut. It seems very probable that a clinically important interaction will occur, but the extent to which the efficacy of tetracycline is affected seems not to have been determined. Advise patients to separate the doses as much as possible. Monitor the outcome well. Information about other tetracyclines is lacking but it also seems likely that they will interact similarly, but those that can be given less often may prove easier to administer, although note that doxycycline undergoes enterohepatic recirculation and therefore separating doses may not be completely effective.

Tetracyclines + Diuretics

It has been recommended by some that the concurrent use of tetracyclines and diuretics should be avoided because of their association with rises in blood urea nitrogen levels.

Clinical evidence, mechanism, importance and management

A retrospective study of patient records as part of the Boston Collaborative Drug Surveillance Program showed that an association existed between tetracycline use with diuretics (not named) and rises in blood urea nitrogen (BUN) levels.[1] It was suggested that tetracyclines should be avoided in patients taking diuretics when alternative antibacterials could be substitut-

ed.[1] However, the results of this study have been much criticised as the authors could not exclude physician bias,[1,2] they did not define what was meant by 'clinically significant rise in BUN',[2] they did not state whether or not this rise affected patient outcomes,[2] they did not measure creatinine levels,[3] they did not specify which diuretics were involved,[2] and they did not adequately consider the fact that diuretics are known to cause rises in BUN.[4] The patients most affected also had the highest levels of BUN before starting tetracyclines. Tetracyclines alone are known to cause rises in BUN, especially where a degree of renal impairment exists, although it has been suggested that **doxycycline** is less prone to this effect.[4] It would seem that tetracyclines and diuretics may be used together safely, although it would be wise to give thought to the patient's renal function.

Tetracyclines + Food

The calcium in food can complex with tetracycline to reduce its absorption. This is particularly notable with dairy products, which can reduce the absorption of the tetracyclines by up to 80%, thereby reducing or even abolishing their therapeutic effects. Doxycycline and minocycline are less affected by dairy products (25 to 30% reduction) and lymecycline is not affected by milk. Orange juice and coffee do not interact with tetracycline.

Clinical evidence

(a) Dairy products

1. Demeclocycline. In 4 subjects given dairy products the serum levels of a 300-mg dose of demeclocycline were 70 to 80% lower, when compared with subjects who took demeclocycline with a meal containing no dairy products. The dairy products used were either 8 oz (about 250 mL) of **fresh pasteurized milk**, 8 oz of **buttermilk** or 4 oz of **cottage cheese**.[1]

2. Doxycycline. The plasma doxycycline levels were reduced by 20%, from 1.79 micrograms/mL to 1.45 micrograms/mL, 2 hours after a single 100-mg oral dose was taken with 240 mL of **milk**.[2] Another study, in 9 healthy subjects, found a 30% reduction in the absorption of doxycycline 200 mg, and a 24% reduction in its peak serum levels when it was taken with 300 mL of **fresh milk**.[3] However, two other studies suggest that the absorption of doxycycline 200 mg is unaffected by milk,[4,5] although in one study the half-life was almost halved and its clearance increased.[5]

3. Lymecycline. In 10 healthy subjects the absorption of lymecycline 300 mg twice daily has not been shown to be significantly affected by 300 g of **milk**.[6]

4. Methacycline. In one study 300 mL of **milk** reduced the absorption of methacycline 300 mg by about 63%.[4]

5. Minocycline. In one study about 180 mL (6 oz) of **homogenised milk** reduced the absorption of minocycline 100 mg by 27%.[7]

6. Oxytetracycline. In one study 300 mL of **milk** reduced the absorption of oxytetracycline 500 mg by about 64%.[4]

7. Tetracycline. In one study about 180 mL (6 oz) of **homogenised milk** reduced the absorption of tetracycline hydrochloride 250 mg by 65%.[7] In another study the absorption of tetracycline 500 mg was reduced by about 50% by 300 mL of **milk**.[4] The addition of 16 mL **evaporated milk** to tea and coffee reduced the bioavailability of a single 250-mg dose of tetracycline by about 40 to 50%.[8]

(b) Other calcium-containing foods or drinks

A study in 9 healthy subjects found that 200 mL of **orange juice** or **coffee** (milk content, if any, unstated) did not significantly affect the bioavailability of a single 250-mg dose of **tetracycline**. This is despite the fact that **orange juice** contains 35 to 70 mg calcium per 100 mL.[9]

Tetracycline 250 mg was given to 9 healthy subjects with 200 mL of water on an empty stomach. The **tetracycline** bioavailability was compared with its administration after a standard meal (two slices of bread, ham, tomato, and water, containing 145 mg calcium) and a Mexican meal (two tortillas, beans, two eggs, tomato and water, containing 235 mg calcium). The cumulative amounts of tetracycline excreted in the urine at 72 hours were about 151 mg (fasting), 90 mg (standard meal) and 68 mg (Mexican meal).[10] Another study in 23 healthy subjects also found a reduction in the maximum **tetracycline** plasma levels and AUC when it was taken with food.[11] A brief report describes a 14% reduction in the bioavailability of **minocycline** when 12 healthy subjects took **minocycline** with a standard meal, although there was wide inter-individual variation in the findings.[12] The absorption of a 300-mg dose of **demeclocycline** was not affected when it was given with a meal not containing dairy products,[1] and **doxycycline** seems to be minimally affected by food not containing dairy products.[2]

Mechanism

The tetracyclines have a strong affinity for the calcium ions that are found in abundance in dairy products and some foodstuffs. The tetracycline/calcium chelates formed are much less readily absorbed from the gastrointestinal tract and as a result the serum tetracycline levels achieved are much lower. Some tetracyclines have a lesser tendency to form chelates, which explains why their serum levels are reduced to a smaller extent.[13]

Orange juice appears not to interact, despite its calcium content, because at the relevant pH values in the gut, the calcium is bound to components within the orange juice (citric, tartaric and ascorbic acids) and is not free to combine with the tetracycline.[9]

Importance and management

Well documented and very well established interactions of clinical importance. Reductions in serum tetracycline levels of 50 to 80% caused by calcium-rich foods are sufficiently large to reduce or even abolish their antibacterial effects. For this reason tetracyclines should not be taken with milk or dairy products such as yoghurt or cheese. Separate the ingestion of these foods and tetracycline as much as possible. In the case of iron, which interacts by the same mechanism, 2 to 3 hours is enough. Doxycycline[3,14] and minocycline[7] are not affected as much by dairy products (reductions of about 25 to 30%), and lymecycline appears unaffected, and in this respect they may have some advantages over the other tetracyclines.

It is usual to recommend that tetracyclines are taken one hour before or 2 hours after food (which would be expected to contain at least some calcium), to minimise admixture in the gut and thereby reduce the effects of the interaction. The separation is something of a compromise, because food can help to minimise the gastric irritant effects of the tetracyclines.

Tetracyclines + H_2-receptor antagonists

Cimetidine reduces the absorption of tetracycline but does not appear to affect its serum levels. Ranitidine does not appear to affect the bioavailability of doxycycline. Information about other tetra-

cyclines and H_2-receptor antagonists is lacking, but there would seem to be no reason to suspect that they will interact.

Clinical evidence, mechanism, importance and management

A study in 5 subjects found that **cimetidine** 200 mg three times daily and 400 mg at bedtime for 3 days reduced the absorption of a single 500-mg dose of a **tetracycline** capsule by about 30%, but had no effect on absorption when the **tetracycline** was given as a solution.[1] However, when **tetracycline** as either a tablet or a suspension was given to 6 subjects with **cimetidine** 1.6 g daily for 6 days, no changes in the plasma levels of **tetracycline** were seen.[2] Similar results were found in another study.[3]

In 10 healthy subjects, the bioavailability of **doxycycline** 200 mg was not altered by three 150-mg doses of **ranitidine**.[4]

No special precautions would seem necessary with either combination. Information about other tetracyclines seems to be lacking, but there would seem to be no reason to suspect that they will interact.

Tetracyclines + Iron compounds

The absorption of both the tetracyclines and iron compounds is markedly reduced by concurrent use, leading to reduced serum levels of the tetracyclines. Their therapeutic effectiveness may be reduced or even abolished.

Clinical evidence

(a) Effect on tetracyclines

An investigation in 10 healthy subjects given single oral doses of tetracyclines found that **ferrous sulfate** 200 mg decreased the serum antibacterial levels as follows: **doxycycline** 200 mg, 80 to 90%; **methacycline** 300 mg, 80 to 85%; **oxytetracycline** 500 mg, 50 to 60% and **tetracycline** 500 mg, 40 to 50%.[1] Another study in two groups of 8 healthy subjects found that **ferrous sulfate** 300 mg reduced the absorption of **tetracycline** and **minocycline** by 81% and 77%, respectively.[2]

Other studies found that in some instances iron caused the tetracycline serum levels to fall below minimum bacterial inhibitory concentrations.[3,4] If the iron was given 3 hours before or 2 hours after most tetracyclines the serum levels were not significantly reduced.[3-5] However, even when the iron was given up to 11 hours after **doxycycline**, serum concentrations were still lowered by 20 to 45%.[5] In contrast to this, another study found that four doses of **ferrous sulfate** (each equivalent to 80 mg of elemental iron) starting 11.5 hours after doxycycline did not affect the absorption of a 200-mg dose of **doxycycline**, and only reduced the AUC of a 100-mg dose of **doxycycline** by 17%.[6]

In 22 patients, an **iron polymaltose** complex, equivalent to 100 mg elemental iron, had no clinically significant effect on the pharmacokinetics of a single 500-mg dose of **tetracycline**.[7]

(b) Effect on iron

When **ferrous sulfate** 250 mg (equivalent to 50 mg of elemental iron) was given with **tetracycline** 500 mg, the absorption of iron was reduced by up to 78% in healthy subjects, and up to 65% in those with depleted iron stores.[8,9]

There was no change in the iron uptake into erythrocytes in 22 patients when an **iron polymaltose** complex, equivalent to 100 mg elemental iron, was given with a single 500-mg dose of **tetracycline**.[10]

Mechanism

The tetracyclines have a strong affinity for iron and form poorly soluble tetracycline/iron chelates, which are much less readily absorbed by the gut, and as a result the serum tetracycline levels achieved are much lower.[11,12] There is also less free iron available for absorption. Separating the administration of the two prevents their admixture.[3,4] However, doxycycline undergoes enterohepatic recycling, which could affect any attempt to keep the iron and antibacterial apart, although the significance of the enterohepatic recycling has been said to be minimal.[6] Even when given intravenously the half-life of doxycycline is reduced.[5] The different extent to which iron compounds interact with the tetracyclines appears to be a reflection of their ability to liberate ferrous and ferric ions, which are free to combine with the tetracycline.[13]

Importance and management

The interactions between the tetracyclines and iron compounds are well-documented, well-established, and of clinical importance. The 30 to 90% reductions in serum tetracycline levels that are caused by iron are so large that tetracycline levels may fall below the MIC.[4] However, the extent of the reductions depends on a number of factors.

- *the particular tetracycline used:* tetracycline and oxytetracycline in the study cited above were the least affected.[1]
- *the time-interval between the administration of the two drugs:* giving the iron 3 hours before or 2 to 3 hours after the antibacterial is satisfactory with tetracycline itself,[3] but one study found that even 11 hours was inadequate for doxycycline.
- *the particular iron preparation used:* with tetracycline the reduction in serum levels with ferrous sulfate was 80 to 90%, with **ferrous fumarate**, **succinate** and **gluconate**, 70 to 80%; with **ferrous tartrate**, 50%; and with **ferrous sodium edetate**, 30%. This was with doses containing equivalent amounts of elemental iron.[13] The small studies with **iron polymaltose** indicate that this preparation may have minimal interaction with tetracycline.

The interaction can therefore be accommodated by separating the doses as much as possible. It would also seem logical to choose one of the iron preparations causing minimal interference, but it seems unlikely that there will be a clinically significant difference between those that are commonly available (i.e. sulfate, fumarate and gluconate).

Only tetracycline, oxytetracycline, methacycline, minocycline and doxycycline have been shown to interact with iron, but it seems reasonable to expect that the other tetracyclines will behave in a similar way.

Tetracyclines + Kaolin-pectin

Kaolin-pectin reduces the absorption of tetracycline by about 50%.

Clinical evidence, mechanism, importance and management

Healthy subjects were given **tetracycline** 250 mg as a solution or as a capsule, with and without 30 mL of kaolin-pectin (*Kaopectate*). The absorption of both formulations was reduced by about 50% by the kaolin-pectin. Even when the kaolin-pectin was given 2 hours before or after the **tetracycline**, the drug absorption was still reduced by about 20%.[1] The likely reason for this interaction is that **tetracycline** becomes adsorbed onto the kaolin-pectin so that less is available for absorption.

If these two drugs are given together, consider separating the doses by at least 2 hours to minimise admixture in the gut. It may even then be necessary to increase the **tetracycline** dose. Information about other tetracyclines is lacking, but be aware that they may interact similarly.

1. Gouda MW. Effect of an antidiarrhoeal mixture on the bioavailability of tetracycline. *Int J Pharmaceutics* (1993) 89, 75–7.

Tetracyclines + Lanthanum

The bioavailability of tetracyclines is expected to be reduced by lanthanum, as concurrent use may result in the formation of insoluble chelates (as with other polyvalent cations). As a result, it is recommended that tetracyclines (the manufacturer names tetracycline and doxycycline) are not taken within 2 hours of a dose of lanthanum.[1]

1. Fosrenol (Lanthanum carbonate hydrate). Shire Pharmaceuticals Ltd. UK Summary of product characteristics, July 2008.

Tetracyclines + Metoclopramide

In 4 patients, metoclopramide 20 mg was found to double the rate of absorption and slightly reduce the maximum serum levels of a single 500-mg dose of tetracycline.[1] This appears to be of little clinical importance.

1. Nimmo J. The influence of metoclopramide on drug absorption. *Postgrad Med J* (1973) 49 (July Suppl), 25–8.

Tetracyclines + Quinapril

The absorption of tetracycline is reduced by the magnesium carbonate excipient in some quinapril formulations.

Clinical evidence

Quinapril, formulated as *Accupro*, contains **magnesium carbonate** as an excipient (250 mg in a 40 mg quinapril capsule, 47 mg in a 5 mg capsule). A pharmacokinetic study in 12 healthy subjects investigating the potential interaction between the **magnesium carbonate** in these capsules and **tetracycline** found that single doses of both strengths of *Accupro* capsules markedly reduced the absorption of **tetracycline**. The 5 mg and 40 mg *Accupro* capsules reduced the **tetracycline** AUC by 28% and 37%, respectively, and the maximum serum levels were reduced by 25% and 34%, respectively.[1]

Mechanism

The reason for these reductions in tetracycline levels is that the magnesium carbonate and the tetracycline form a less soluble chelate in the gut which is less well absorbed (see 'Tetracyclines + Antacids', p.388).

Importance and management

An established interaction but the extent of the reduction is only moderate and its clinical importance is uncertain. However, the authors of the study and the manufacturers[2] recommend that the concurrent use of *Accupro* and tetracycline should be avoided.[1] Other tetracyclines would be expected to behave similarly. One possible way to accommodate this interaction (as with the antacid interaction) is to separate the doses as much as possible (by about 2 to 3 hours) to minimise admixture in the gut.

Quinapril, formulated as *Quinil* tablets, contains **magnesium oxide**, and, based on the interaction with magnesium carbonate, the manufacturer advises that *Quinil* tablets should not be taken with tetracycline.[3]

3. Quinil (Quinapril hydrochloride). Tillomed Laboratories Ltd. UK Summary of product characteristics, May 2004.

Tetracyclines + Sucralfate

On theoretical grounds the absorption of tetracycline may possibly be reduced by sucralfate, but clinical confirmation of this appears to be lacking.

Clinical evidence, mechanism, importance and management

The manufacturers of sucralfate point out that it may reduce the bioavailability of **tetracycline**, probably because the two become bound together in the gut, thereby reducing absorption. It is suggested that they should be given 2 hours apart to minimise their admixture in the gut.[1] There do not appear to be any clinical reports in the literature confirming this potential interaction.

However, the formation of a **tetracycline**-sucralfate acid complex has been investigated in *animal* and *in vitro* studies and this indicates that the interaction may be clinically useful for *Helicobacter pylori* eradication because of direct delivery of **tetracycline** to the gastric mucosa for extended periods of time.[2-5]

Tetracyclines + Thiomersal

Patients taking tetracyclines who use contact lens solutions containing thiomersal may experience an inflammatory ocular reaction.

Clinical evidence, mechanism, importance and management

The observation that 2 patients had ocular reactions (red eye, irritation, blepharitis) when they used a 0.004% thiomersal-containing contact lens solution while taking a tetracycline, prompted further study of this interaction. A questionnaire revealed another 9 similar cases that suddenly began shortly after patients who had used thiomersal-containing solutions for 6 months without problem started to take a tetracycline. In each case the reaction cleared when the thiomersal or the tetracycline was stopped. The same reaction was also clearly demonstrated in *rabbits*.[1] The reasons are not understood. It would seem prudent to avoid the concurrent use of these compounds.

1. Crook TG, Freeman JJ. Reactions induced by the concurrent use of thimerosal and tetracycline. *Am J Optom Physiol Opt* (1983) 60, 759–61.

Tetracyclines + Zinc compounds

The absorption of tetracycline can be reduced by as much as 50% by zinc sulphate. Doxycycline interacts minimally with zinc.

Clinical evidence

When **tetracycline** 500 mg was given to 7 subjects either alone or with zinc sulfate 200 mg (equivalent to 45 mg of elemental zinc) the **tetracycline** serum concentrations and AUC were reduced by about 30 to 40%.[1] This study was repeated with **doxycycline** 200 mg and zinc, but **doxycycline** absorption was not affected.[1] A reduction in **tetracycline** absorption

of more than 50% has been seen in other studies when zinc was given concurrently.[2,3]

Tetracycline appears to cause minimal reductions in zinc concentrations.[2]

Mechanism

Zinc (like iron, calcium, magnesium and aluminium) forms a relatively stable and poorly absorbed chelate with tetracycline in the gut, which results in a reduction in the amount of antibacterial available for absorption.[4,5]

Importance and management

An established and moderately well documented interaction of clinical importance. Separate the administration of tetracycline and zinc compounds as much as possible to minimise admixture in the gut. In the case of 'iron', (p.391), which interacts by the same mechanism, 2 to 3 hours is usually enough. Alternatively it would seem that doxycycline is less affected, so it may be a useful alternative.[1] Other tetracyclines would be expected to interact like tetracycline itself, but this needs confirmation. The small reduction in serum zinc concentrations is likely to be of little practical importance.[2]

Tetracyclines; Doxycycline + Rifampicin (Rifampin)

Rifampicin may cause a marked reduction in doxycycline levels, which has led to treatment failures in some cases.

Clinical evidence

In 7 patients, rifampicin 10 mg/kg daily caused a considerable reduction in the serum levels of doxycycline 200 mg daily. The reduction was very marked in 4 patients but not significant in the other 3 patients. The AUC of doxycycline was reduced by 54%, its clearance was approximately doubled, and its half-life was reduced from about 14 hours to 9 hours.[1,2]

Five patients with brucellosis taking doxycycline 200 mg daily had a reduction in the doxycycline half-life from about 14.5 hours to 8 hours when they took rifampicin 200 mg daily.[3] Another study, in 20 patients treated for brucellosis, found that the mean AUC of doxycycline was nearly 60% lower in the presence of rifampicin, when compared with streptomycin. There were no treatment failures in the patients taking doxycycline and streptomycin, but two treatment failures occurred in the 10 patients taking doxycycline and rifampicin.[4]

A meta-analysis of 6 studies involving 544 patients with brucellosis found a significantly higher numbers of relapses and lower numbers of initial cures if doxycycline was given with rifampicin rather than streptomycin.[5]

Mechanism

Not established, but it seems almost certain that the rifampicin (a known potent enzyme inducer) increases the metabolism of the doxycycline thereby reducing its levels.

Importance and management

The interaction between doxycycline and rifampicin is established and of clinical importance. Monitor the effects of concurrent use and increase the doxycycline dose as necessary. No clinically important adverse interaction appears to occur between doxycycline and streptomycin.

Tetracyclines; Doxycycline + Simeticone

A study in 8 healthy subjects found that [simeticone] 2.25 g did not alter the bioavailability of a single 200-mg dose of doxycycline.[1]

1. Bistue C, Perez P, Becquart D, Vinçon G, Albin H. Effet du diméticone sur la biodisponibilité de la doxycycline. *Therapie* (1987) 42, 13–16.

Tetracyclines; Minocycline + Ethinylestradiol

There is some evidence that ethinylestradiol may accentuate the facial pigmentation that can be caused by minocycline.

Clinical evidence

Two teenage sisters with severe acne vulgaris, taking minocycline 50 mg four times daily for 14 days then 50 mg twice daily thereafter, developed dark-brown pigmentation in their acne scars when they took *Dianette* (cyproterone acetate and ethinylestradiol) for about 15 months.[1] The type of pigmentation was not identified because they both declined to have a biopsy, but in other cases it has been found to consist of haemosiderin, iron, melanin and a metabolic degradation product of minocycline.[1] Two other reports describe facial pigmentation in patients taking minocycline, two of whom were taking oral hormonal contraceptives containing ethinylestradiol.[2,3] Other young women who have developed minocycline pigmentation may also have been taking oral hormonal contraceptives because they fall into the right age-group, but this is not specifically stated in any of the reports.

Mechanism

Not understood. It seems possible that the facial pigmentation (melasma, chloasma) that can occur with hormonal contraceptives may have been additive with the effects of the minocycline.[1]

Importance and management

Evidence is very limited but it has been suggested that all patients given long-term minocycline treatment should be well screened for the development of pigmentation, particularly if they are taking other drugs such as the hormonal contraceptives that are known to induce hyperpigmentation.[1] Remember also that very rarely contraceptive failure has been associated with the use of minocycline and other tetracyclines, see 'Combined hormonal contraceptives + Antibacterials; Tetracyclines', p.1173.

Tetracyclines; Minocycline + Phenothiazines

An isolated report describes black galactorrhoea, which was attributed to an interaction between minocycline and perphenazine.

Clinical evidence, mechanism, importance and management

A woman taking minocycline 100 mg twice daily for 4 years to control pustulocystic acne, and also taking **perphenazine**, amitriptyline and diphenhydramine, developed irregular darkly pigmented macules in the areas of acne scarring and later began to produce droplets of darkly col-

oured milk. The milk was found to contain macrophages filled with positive iron-staining particles, assumed to be haemosiderin. The situation resolved when the drugs were withdrawn: the galactorrhoea within a week and the skin staining over 6 months.[1] Galactorrhoea is a known adverse effect of the phenothiazines and is due to an elevation of serum prolactin levels caused by the blockade of dopamine receptors in the hypothalamus. The dark colour appeared to be an adverse effect of the **minocycline**, which can cause haemosiderin to be deposited in cells, and in this instance to be scavenged by the macrophages that were then secreted in the milk. The general significance of this isolated case is unknown, but it seems likely to be small.

1. Basler RSW, Lynch PJ. Black galactorrhea as a consequence of minocycline and phenothiazine therapy. *Arch Dermatol* (1985) 121, 417–18.

Tetracyclines; Oxytetracycline + Pyridostigmine

When oxytetracycline 500 mg every 8 hours was given with pyridostigmine 30 mg every 8 hours the pharmacokinetics of both drugs were unchanged. There was an increase in erythrocyte cholinesterase activity when pyridostigmine was given with oxytetracycline, but the clinical significance of this finding is unclear.[1] It would appear that no dose adjustments are necessary on concurrent use.

1. Johnston A, Hedges A, Turner P. A study of the interaction between oxytetracycline and pyridostigmine. *Hum Toxicol* (1988) 7, 263–6.

Trimethoprim + Food or Guar gum

Guar gum and food can modestly reduce the absorption of trimethoprim suspension.

Clinical evidence, mechanism, importance and management

In a study over a 24-hour period, 12 healthy subjects were given a single 3-mg/kg oral dose of a trimethoprim suspension with food, with or without guar gum. The mean peak serum levels were reduced by food and by food given with 5 g of guar gum by 21% and 15%, respectively. Food, both with guar gum and alone, reduced the AUC of trimethoprim by about 22%.[1] The greatest individual reductions in peak serum levels and AUC were 44% and 36%, respectively with food, and 48% and 38%, respectively, with food and guar gum.[1] The reasons are not understood but it may be due to adsorption of the trimethoprim onto the food and guar gum.

The clinical importance of this interaction is uncertain but a modest reduction in absorption can occur in some individuals. However, trimethoprim is generally taken without regard to food, so this interaction would not appear to be significant in most patients.

Vancomycin + Colestyramine

Colestyramine may bind with vancomycin in the gut.

Clinical evidence, mechanism, importance and management

Colestyramine binds with vancomycin within the gut, thereby reducing its biological activity (about tenfold according to *in vitro* studies). The combination of vancomycin and colestyramine used to be used in antibacterial-associated colitis (now no longer recommended) and to overcome this interaction it was suggested that a vancomycin dose of 2 g daily should be used, and that administration of vancomycin and colestyramine should be separated as much as possible to minimise their admixture in the gut.[1] It is usually recommended that other drugs should be taken one hour before or 4 to 6 hours after colestyramine.

1. Taylor NS, Bartlett JG. Binding of *Clostridium difficile* cytotoxin and vancomycin by anion-exchange resins. *J Infect Dis* (1980) 141, 92–7.

Vancomycin + Indometacin

Indometacin reduces the renal clearance of vancomycin in premature neonates. This interaction does not appear to have been studied in adults.

Clinical evidence, mechanism, importance and management

In 6 premature neonates with patent ductus arteriosus given indometacin, the half-life of vancomycin 15 to 20 mg/kg given intravenously over one hour was found to be 24.6 hours, compared with only 7 hours in 5 other premature neonates without patent ductus arteriosus who were not given indometacin.[1] A second study, which included 4 premature infants who received vancomycin within 2 weeks of receiving indometacin for patent ductus arteriosus, suggested that only one of these infants had reduced vancomycin clearance as a result of indometacin use. This infant had received indometacin 4 days before starting vancomycin, and a 36-hour interval was required between doses to attain target vancomycin levels.[2] The reason for this effect is uncertain but it seems possible that the indometacin reduces the renal clearance of vancomycin. The authors of the first report suggest that the usual vancomycin maintenance dose should be halved if indometacin is also being used. If vancomycin therapeutic drug monitoring is possible it would be advisable to take levels and adjust the vancomycin dose and/or dosing interval accordingly. It is not known whether indometacin has the same effect on vancomycin in adults.

Vancomycin + Miscellaneous

The risk of nephrotoxicity and ototoxicity with vancomycin may possibly be increased if it is given with other drugs with similar toxic effects. There is some evidence to suggest that dobutamine, dopamine and furosemide can markedly reduce vancomycin serum levels following cardiac surgery.

Clinical evidence, mechanism, importance and management

A retrospective evaluation of the records of 18 critically ill patients in intensive care units following cardiac surgery, suggested that drugs with important haemodynamic effects (**dopamine**, **dobutamine**, **furosemide**) may lower the serum levels of vancomycin. It was noted that withdrawal of the interacting drugs was followed by an increase in the minimum steady-state serum levels of vancomycin, from 8.79 mg/L to 13.3 mg/L, despite no major changes in body-weight or estimated renal clearance. This resulted in a mean dose reduction of 4.26 mg/kg per day.

It is suggested that this interaction occurs because these drugs increase cardiac output, which increases the renal clearance of vancomycin, and therefore reduces its serum levels.[1] The clinical implication is that in this particular situation creatinine clearance is not as good a predictor of vancomycin clearance and consequently dose. Good therapeutic drug monitoring is needed to ensure that serum vancomycin levels are optimal. More confirmatory study is needed.

In addition, vancomycin is both potentially nephrotoxic and ototoxic, and its manufacturer therefore advises that it should be avoided with other drugs that have nephrotoxic potential, because the effects could be additive. They list **amphotericin B**, **aminoglycosides**, **bacitracin**, **colistin**, **polymyxin B** and **cisplatin**. They also list **etacrynic acid** and **furosemide** as potentially aggravating ototoxicity.[2] However, a review of 494 patients receiving **amphotericin B**, 57% of whom also received treatment with vancomycin, did not identify this combination as a risk factor for the development of nephrotoxicity.[3] In contrast, there is some evidence to suggest that additive nephrotoxicity can occur with the **aminoglycosides** (see 'Aminoglycosides + Vancomycin', p.327). The general warning issued by

the manufacturers to monitor carefully therefore seems a reasonable precaution.

3. Harbarth S, Pestotnik SL, Lloyd JF, Burke JP, Samore MH. The epidemiology of nephrotoxicity associated with conventional amphotericin B therapy. *Am J Med* (2001) 111, 528–34.

Vancomycin + Theophylline

Theophylline appears not to interact with vancomycin in premature infants.

Clinical evidence, mechanism, importance and management

Five premature infants (mean gestational age of 25 weeks and weighing 1.1 kg) were given theophylline (serum levels of 6.6 mg/L) for apnoea of prematurity. It was found that the pharmacokinetics of vancomycin 20 mg/kg given every 12 to 18 hours for suspected sepsis were unchanged by the presence of the theophylline, when compared with previously published data on the pharmacokinetics of vancomycin in neonates.[1] There seems to be no other clinical reports about vancomycin with theophylline or aminophylline (which is metabolised to theophylline), and nothing to suggest that vancomycin has any effect on the serum levels of theophylline.

1. Ilagan NB, MacDonald JL, Liang K-C, Womack SJ. Vancomycin pharmacokinetics in low birth weight preterm neonates on therapeutic doses of theophylline. *Pediatr Res* (1996) 39, 74A.

11

Anticholinesterases

The anticholinesterase drugs (or cholinesterase inhibitors) can be classified as **centrally-acting, reversible inhibitors** such as donepezil (used in the treatment of Alzheimer's disease), **reversible inhibitors with poor CNS penetration**, such as neostigmine (used in the treatment of myasthenia gravis), or **irreversible inhibitors**, such as ecothiopate and metrifonate. Note that organophosphorus insecticides are also potent cholinesterase inhibitors.

The centrally-acting anticholinesterases and the reversible anticholinesterases form the basis of this section, and these are listed in 'Table 11.1', (see below). Interactions where the anticholinesterases are affecting other drugs are covered elsewhere in the publication.

Centrally-acting anticholinesterases share a number of common pharmacodynamic interactions. The effects of anticholinesterases are expected to be additive with other cholinergic drugs or depolarising neuromuscular blockers, such as suxamethonium (succinylcholine) and antagonistic with antimuscarinic drugs or competitive (non-depolarising) neuromuscular blockers, such as tubocurarine, see 'Anticholinesterases; Centrally acting + Other drugs that affect acetylcholine', p.401. The concurrent use of anticholinesterases and drugs that slow the heart rate, such as beta blockers, some calcium-channel blockers and some antiarrhythmics may increase the risk of bradycardia, arrhythmias or syncope. Anticholinesterases may have the potential to exacerbate or induce extrapyramidal symptoms and so may possibly increase the risk of adverse effects with antipsychotics (see 'Anticholinesterases; Centrally acting + Antipsychotics', p.397).

Due to their differing pharmacokinetic characteristics, the centrally-acting anticholinesterases have slightly different interaction profiles. Tacrine is metabolised by the cytochrome P450 isoenzyme CYP1A2, and so interacts with fluvoxamine, a potent inhibitor of this isoenzyme (see 'Anticholinesterases; Centrally acting + SSRIs', p.402), whereas there is no evidence to suggest the other centrally acting anticholinesterases do. On the other hand, donepezil and galantamine are metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2D6, and so they may interact with ketoconazole (see 'Anticholinesterases; Centrally acting + CYP3A4 inducers or inhibitors', p.400) and quinidine (see 'Anticholinesterases; Centrally acting + Quinidine', p.402), respectively, whereas tacrine would not be expected to do so. Rivastigmine, which is metabolised by conjugation, seems relatively free of *pharmacokinetic* interactions. Consideration of concurrent drug use would therefore seem to be an important factor in the choice of a centrally-acting anticholinesterase.

Table 11.1 Anticholinesterase drugs; reversible

Centrally-acting inhibitors used principally for Alzheimer's disease	*Inhibitors with poor CNS penetration used principally for myasthenia gravis*
Donepezil	Ambenonium
Galantamine	Distigmine
Rivastigmine	Edrophonium (mainly used diagnostically)
Tacrine	Neostigmine
	Physostigmine
	Pyridostigmine (also used for glaucoma)

Anticholinesterases + Miscellaneous

A number of drugs can affect myasthenia gravis, often by increasing muscular weakness. This is, strictly speaking, a drug-disease interaction, but such effects may be expected to oppose the actions of the drugs used to treat myasthenia gravis. A number of drugs (e.g. chlorpromazine, methocarbamol, and propafenone) are clearly contraindicated in patients with myasthenia, and, as this is not strictly a drug interaction, they are not dealt with here. A number of case reports (see 'Table 11.2', (p.398)) describe the worsening or unmasking of myasthenia gravis with a range of different drugs. The evidence for many of these interactions is very sparse indeed, and in some instances they are simply rare and isolated cases. It would therefore be wrong to exaggerate their importance, but it would nevertheless be prudent to be alert for any evidence of worsening myasthenia if any of the drugs listed are added to established treatment.

Anticholinesterases + Ranitidine

In 10 patients with myasthenia gravis receiving long-term pyridostigmine, ranitidine 150 mg slightly reduced the renal clearance of pyridostigmine, but this was not statistically significant. Pyridostigmine plasma levels were unchanged.[1]

1. Eiermann, Sommer N, Winne D, Schumm F, Maier U, Breyer-Pfaff U. Renal clearance of pyridostigmine in myasthenic patients and volunteers under the influence of ranitidine and pirenzepine. *Xenobiotica* (1993) 23, 1263–75.

Anticholinesterases; Centrally acting + Amiodarone

The risk of adverse effects, including bradycardia, may be increased if a centrally-acting anticholinesterase is given with amiodarone.

Clinical evidence, mechanism, importance and management

An analysis of the French Pharmacovigilance Database for adverse drug reactions involving centrally-acting cholinesterases (**donepezil**, **galantamine** and **rivastigmine**) up to March 2006 found 45 potential drug interactions between centrally-acting anticholinesterases and amiodarone. Eleven of these interactions were thought to have caused adverse reactions [probably bradycardia]. Inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as amiodarone, were also involved in pharmacokinetic interactions with **donepezil** and **galantamine**, which are substrates of this isoenzyme. However, the extent to which the plasma concentrations of donepezil and galantamine were raised is unknown.[1]

It would appear that the effects of these centrally-acting anticholinesterases on heart rate can be additive with those of amiodarone. Be alert for bradycardia if amiodarone is given with **donepezil**, **galantamine** or **rivastigmine**. The effects of **tacrine** do not appear to have been studied, but it would also be expected to slow the heart rate, and therefore may have additive effects with amiodarone.

1. Tavassoli N, Sommet A, Lapeyre-Mestre M, Bagheri H, Montrastruc J-L. Drug interactions with cholinesterase inhibitors: an analysis of the French Pharmacovigilance Database and a comparison of two national drug formularies (Vidal, British National Formulary). *Drug Safety* (2007) 30, 1063–71.

Anticholinesterases; Centrally acting + Antipsychotics

No pharmacokinetic interaction appears to occur between risperidone and donepezil or galantamine, and the pharmacokinetics of thioridazine are not affected by donepezil. However, adverse effects such as movement disorders and neuroleptic malignant syndrome have occurred in patients given centrally-acting anticholinesterases with antipsychotics.

Clinical evidence, mechanism, importance and management

(a) Donepezil

1. Olanzapine. A 78-year-old man who had been taking olanzapine for 10 years experienced fatigue, progressive weakness, confusion, lethargy and severe muscle stiffness within a week of starting to take donepezil. He was diagnosed as having a variant of neuroleptic malignant syndrome secondary to an interaction between the two drugs.[1]

2. Risperidone. In a randomised, crossover study, 24 healthy subjects were given risperidone 500 micrograms twice daily with donepezil 5 mg daily. Although donepezil caused slight changes in the levels of risperidone and its metabolite, 9-hydroxyrisperidone, they were not considered clinically relevant. Concurrent use did not increase adverse effects.[2] In one study, 16 patients with schizophrenia taking risperidone were given donepezil 5 mg daily for 7 days without any alteration in their risperidone and 9-hydroxyrisperidone levels. The pharmacokinetics of donepezil were similar in the risperidone-treated patients and healthy controls taking donepezil alone.[3] However, a case report describes the emergence of parkinsonian symptoms in an 80-year-old woman after she was given donepezil 5 mg daily, with risperidone 1 mg daily added 12 days later. Risperidone was discontinued and she recovered without treatment.[4] Another report describes extrapyramidal adverse effects in a 79-year-old woman taking donepezil and risperidone.[5]

3. Thioridazine. In a crossover study, 11 healthy subjects were given donepezil 5 mg daily for 16 days, with a single 50-mg dose of thioridazine on the final day. Although donepezil did not affect the pharmacokinetics of thioridazine or its effects on the QT interval, thioridazine, either alone or in combination with donepezil, was poorly tolerated, and resulted in postural hypotension and increases in heart rate.[6] It would therefore seem prudent to use an alternative antipsychotic wherever possible.

4. Tiapride. Severe parkinsonism developed in a 79-year-old woman taking tiapride 25 mg twice daily and donepezil 3 mg daily, after the dose of donepezil was increased to 5 mg daily. Both tiapride and donepezil were discontinued and, on the following day, her gait disturbance began to improve: in 10 days, she could walk without assistance and the rigidity had disappeared. It was suggested that the two drugs had caused an acetylcholine/dopamine imbalance in the striatum resulting in the symptoms.[7]

(b) Galantamine

In a randomised, crossover study, 16 patients over 60 years of age were given a 14-day dose escalation of galantamine, after which they were given galantamine 12 mg twice daily with **risperidone** 500 micrograms twice daily, both for 13 doses. Although galantamine caused slight changes in the levels of **risperidone** and its metabolite, 9-hydroxyrisperidone, their combined level (the active moiety) was unchanged. The combination was well tolerated so no additional precautions would seem to be necessary on concurrent use.[8]

(c) Rivastigmine

A 58-year-old man receiving low-dose **olanzapine** and rivastigmine developed neuroleptic malignant syndrome 4 months after starting olanzapine and 6 weeks after his dose of rivastigmine was doubled to 6 mg twice daily. The patient fully recovered once the **olanzapine** was discontinued. **Olanzapine** was considered to be the probable cause of the patient's neuroleptic malignant syndrome, but it was suggested that rivastigmine might have contributed, possibly due to an acetylcholine/dopamine imbalance.[9]

In a study in 65 patients with Alzheimer's disease, 10 vascular dementia patients, and 15 mixed dementia patients, the patients were randomised to receive rivastigmine, **risperidone**, or both drugs together, for 20 weeks. No significant adverse events were reported on concurrent use.[10] However, a patient taking multiple drugs including **quetiapine**, **risperidone** and rivastigmine experienced acute dystonia, which resolved over the next 48 hours after rivastigmine was discontinued and benzatropine given. Three days later, rivastigmine was restarted and the dystonia-like symptoms returned within 2 hours of her morning dose.[11]

(d) Tacrine

An isolated report describes an 87-year-old man with dementia, who started taking **haloperidol** 5 mg daily for symptoms of agitation and paranoia. Doses of greater than 5 mg were noted to cause extrapyramidal symptoms. After 10 days, tacrine 10 mg four times daily was added. Within 72 hours he developed severe parkinsonian symptoms, which

Table 11.2 Case reports of drugs aggravating or unmasking myasthenia gravis

Drug	*Effect seen*	*Refs*
Acetazolamide 500 mg intravenously	Aggravation of muscular weakness in patients with myasthenia gravis taking unnamed anticholinesterases.	1
Ampicillin up to 1.5 g daily	Aggravation of myasthenic symptoms in 2 patients taking pyridostigmine.	2
Aspirin	Mild aggravation of myasthenic symptoms in a patient taking neostigmine.	3
Beta blockers	See Beta blockers + Anticholinesterases.	
Chloroquine	Persisting myasthenic symptoms, including muscular weakness, attributed to prior chloroquine use. Development of myasthenic symptoms in 3 patients, one who took chloroquine in overdose.	4-7
Ciprofloxacin	Aggravation of myasthenic symptoms in a patient taking pyridostigmine, and unmasking of myasthenia in one patient.	8, 9
Dipyridamole* 75 mg three times daily	Aggravation of myasthenic symptoms in a patient taking distigmine.	10
Erythromycin 500 mg intravenously	Precipitation of a myasthenic crisis in an undiagnosed 15-year-old girl.	11
Imipenem/cilastatin 500 mg four times daily	Aggravation of myasthenic symptoms in a patient taking pyridostigmine.	12
Interferons	Development of myasthenia gravis in patients given interferon-alfa (4 patients), interferon-beta (2 patients) and peginterferon-alfa 2a (1 patient), and aggravation of myasthenic symptoms in 1 patient given interferon- beta.	13-19
Ketoprofen 50 mg daily	Aggravation of myasthenic symptoms in a patient taking neostigmine.	3
Lithium carbonate 600 mg daily	Unmasking of myasthenia in one patient.	20
Norfloxacin*	Aggravation of myasthenic symptoms in a patient taking pyridostigmine.	21
Oxytetracycline	Transient aggravation of myasthenic symptoms in one patient taking pyridostigmine.	22, 23
Penicillamine	Aggravation of myasthenic symptoms in numerous patients taking anticholinesterases. Amitriptyline and imipramine also implicated in 2 cases.	24-27
Phenytoin 100 mg three times daily	Aggravation of myasthenic symptoms in an untreated patient.	28
Procainamide* 250 mg	Serious aggravation of myasthenic symptoms in a patient taking pyridostigmine. Two other less severe cases also reported.	29, 30
Quinidine* up to 970 mg daily	Mild aggravation of myasthenic symptoms in one patient taking pyridostigmine and another taking neostigmine. Development of myasthenic symptoms in 2 undiagnosed patients.	30-32
Rolitetracycline	Aggravation of myasthenic symptoms in 4 patients, two patients taking various anticholinesterases (cases originally reported elsewhere).	22, 23, 33

resolved within 8 hours of stopping both drugs.[12] Another isolated report describes a woman taking **haloperidol** 10 mg daily who similarly developed a disabling parkinsonian syndrome within one week of starting tacrine 10 mg four times daily.[13] One possible reason is that the haloperidol blocked the dopamine receptors in striatum, thereby increasing striatal acetylcholine activity, which was further increased by the tacrine.[2] It is not clear whether patients given other dopamine receptor blocking drugs and tacrine would similarly show this reaction.

Anticholinesterases; Centrally acting + Azoles

Ketoconazole modestly increases the levels of donepezil. Galantamine levels are also increased by ketoconazole. Other azoles may interact similarly.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Donepezil 5 mg daily was given to 18 healthy subjects with **ketoconazole** 200 mg daily, which is a specific and potent inhibitor of the cytochrome P450 isoenzyme CYP3A4. After one week of concurrent use, the maximum plasma levels and AUC of donepezil were increased by about 36%. Donepezil had no effect on the pharmacokinetics of **ketoconazole**.[1] None of the increases in donepezil levels were considered to be clinically relevant, and the authors suggest that no dose modifications will be required with **ketoconazole** or other CYP3A4 inhibitors.[1] Despite this, the UK manufacturer recommends that donepezil should be used with care with CYP3A4 inhibitors (which, to a greater or lesser extent, would be expected to include all azoles) and they specifically name **itraconazole**.[2]

(b) Galantamine

The manufacturers of galantamine note that **ketoconazole** increased the bioavailability of galantamine by 30%, probably by inhibiting the cytochrome P450 isoenzyme CYP3A4, by which galantamine is metabolised.[3,4] The UK manufacturer therefore predicts that **ketoconazole** may increase the incidence of nausea and vomiting with galantamine, and suggests that, based on tolerability, a reduction in the maintenance dose can be considered.[3] Note that, all azoles, to a greater or lesser extent, inhibit this isoenzyme, and therefore, until more is known, similar caution would seem prudent.

Anticholinesterases; Centrally acting + Calcium-channel blockers

The risk of adverse effects, including bradycardia, may be increased if donepezil, galantamine or rivastigmine are given concurrently with calcium-channel blockers.

Clinical evidence, mechanism, importance and management

An analysis of the French Pharmacovigilance Database for adverse drug reactions involving centrally-acting anticholinesterases (**donepezil**, **galantamine** and **rivastigmine**) up to March 2006 found 40 potential drug interactions between centrally-acting anticholinesterases and calcium-channel blockers. Fifteen of these were thought to have caused adverse reactions [probably bradycardia]. CYP3A4 inhibitors such as **diltiazem** and **verapamil** were also involved in pharmacokinetic drug interactions with **donepezil** and **galantamine**, which are substrates of this isoenzyme. The extent to which the plasma concentrations of donepezil and galantamine were raised is unknown.[1] However, as the effects of the potent CYP3A4 inhibitor ketoconazole was only modest (see 'Anticholinesterases; Centrally acting + Azoles', p.399) the effects of the modest CYP3A4 inhibitors **diltiazem** and **verapamil** would not be expected to be clinically relevant.

It would appear that the effects of these centrally-acting anticholinesterases on heart rate can be additive with those of the calcium-channel blockers. Although not stated in the report, only the calcium-channel blockers that have effects on heart rate (that is, **diltiazem** and **verapamil**) would be expected to be implicated. Be alert for bradycardia if either of these calcium-channel blockers is given with **donepezil**, **galantamine** or **rivastigmine**. The effects of **tacrine** do not appear to have been studied, but it would also be expected to slow the heart rate, and therefore may have additive effects with amiodarone.

Anticholinesterases; Centrally acting + CYP3A4 inducers or inhibitors

Potent inhibitors of CYP3A4 may raise donepezil levels and inducers of CYP3A4 may lower donepezil levels. Galantamine levels are also predicted to be increased by potent CYP3A4 inhibitors such as ritonavir, but the moderate CYP3A4 inhibitor, erythromycin, only slightly increased the bioavailability of galantamine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Ketoconazole, a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, modestly increases donepezil levels, see 'Anticholinesterases; Centrally acting + Azoles', p.399, but this was not considered to be clinically relevant. Despite this, the UK manufacturer suggests that CYP3A4 inhibitors (they specifically name **erythromycin**) could inhibit the metabolism of donepezil and should be used with care. Furthermore, both the US and UK manufacturers suggest that inducers of CYP3A4 (including **carbamazepine**, **dexamethasone**, **phenobarbital**, **phenytoin** and **rifampicin**) may lower donepezil levels.[1,2] The UK manufacturer says, that as the magnitude of the effect is unknown, such drug combinations should be used with care.[1] Note that, dexamethasone does not usually cause clinically relevant interactions as a result of this effect.

(b) Galantamine

Based on the interaction of ketoconazole, a potent CYP3A4 inhibitor, and galantamine (see 'Anticholinesterases; Centrally acting + Azoles', p.399), the manufacturers of galantamine predict that other potent CYP3A4 inhibitors (the UK manufacturers name **ritonavir**) may increase the AUC of galantamine.[3,4] As a consequence patients may experience an increased incidence of nausea and vomiting, and, based on tolerability, it is suggested that a decrease in the galantamine maintenance dose could be considered.[4] Until the extent of the interaction with ritonavir is known, this seems prudent.

Erythromycin, a moderate CYP3A4 inhibitor, only increased galantamine bioavailability by about 10%,[3,4] and so a clinically significant interaction would not be expected.

4. Reminyl Tablets (Galantamine hydrobromide). Shire Pharmaceuticals Ltd. UK Summary of product characteristics, September 2009.

Anticholinesterases; Centrally acting + Diazepam

Rivastigmine and tacrine do not appear to affect the pharmacokinetics of diazepam.

Clinical evidence, mechanism, importance and management

In a small study, **tacrine** 20 mg every 6 hours did not affect the pharmacokinetics of a single 2-mg dose of diazepam, when compared with diazepam alone.[1] Similarly the manufacturers of **rivastigmine** say that no pharmacokinetic interaction has been seen with diazepam in healthy subjects.[2,3] No diazepam dose adjustments would seem necessary if **tacrine** or **rivastigmine** are also given.

1. deVries TM, Siedlik P, Smithers JA, Brown RR, Reece PA, Posvar EL, Sedman AJ, Koup JR, Forgue ST. Effect of multiple-dose tacrine administration on single-dose pharmacokinetics of digoxin, diazepam, and theophylline. *Pharm Res* (1993) 10 (10 Suppl), S-333.
2. Exelon (Rivastigmine hydrogen tartrate). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, November 2009.
3. Exelon (Rivastigmine tartrate). Novartis Pharmaceuticals Corp. US Prescribing information, June 2006.

Anticholinesterases; Centrally acting + H_2-receptor antagonists

Cimetidine possibly increases the effects of tacrine. Cimetidine does not appear to significantly affect the pharmacokinetics of donepezil or galantamine, and ranitidine does not affect the bioavailability of galantamine.

Clinical evidence, mechanism, importance and management

Centrally-acting anticholinesterases may be expected to increase gastric acid secretion due to increased cholinergic activity, but it is not clear whether this would oppose the actions of the H_2-receptor antagonists.

(a) Donepezil

In a crossover study, donepezil 5 mg daily was given to 18 healthy subjects with **cimetidine** 800 mg daily. It was found that after one week of concurrent use the maximum plasma levels and AUC of donepezil were increased by 13% and 10%, respectively. Donepezil had no effect on the pharmacokinetics of **cimetidine**.[1] The changes in the pharmacokinetics of donepezil were not considered to be clinically relevant.[1]

(b) Galantamine

When a single 4-mg dose of galantamine was given on day 2 of a 3-day course of **cimetidine** 800 mg daily, the bioavailability of galantamine was increased by about 16%,[2] which would not be expected to be clinically significant. **Ranitidine** 300 mg daily had no effect on galantamine bioavailability.[2]

(c) Tacrine

In a study in 10 healthy, elderly subjects, **cimetidine** 300 mg four times daily for 2 days decreased the clearance of a single 40-mg dose of tacrine by 30%, and increased its AUC and maximum plasma level by 39% and 35%, respectively.[3] The manufacturer of tacrine says that **cimetidine** increased the AUC and the maximum plasma level of tacrine by about 64% and 54%, respectively.[4] The reason for these changes is not established, but it seems probable that **cimetidine** (a well-recognised liver enzyme inhibitor) reduces the metabolism of tacrine by the cytochrome P450 isoenzyme CYP1A2. An increase in both the beneficial effects and possibly adverse effects of tacrine (nausea, vomiting, diarrhoea) seems possible: one patient had to be withdrawn from the study mentioned above due to nausea and vomiting.[3] If the suggested mechanism of interaction is correct, the other H_2-receptor antagonists would not be expected to interact in this way.

4. Cognex (Tacrine hydrochloride). Sciele Pharma, Inc. US Prescribing information, June 2006.

Anticholinesterases; Centrally acting + HRT

A small study suggests that HRT can almost double the plasma levels of tacrine. Limited evidence suggests that oestrogens do not affect rivastigmine pharmacokinetics.

Clinical evidence, mechanism, importance and management

Observational results from a multicentre study of women with Alzheimer's disease receiving **tacrine** or placebo suggested that women receiving HRT (**conjugated oestrogens**, **estradiol** or **estrone sulfate**) and tacrine performed better on both cognitive and clinical assessments than women receiving tacrine alone or placebo. However, the subgroup of patients receiving HRT was not randomised and these patients were somewhat younger and better educated.[1] Following these observations, a randomised, crossover, placebo-controlled study was undertaken in 10 healthy women who were given HRT (**estradiol** 2 mg with **levonorgestrel** 250 micrograms daily) with a single 40-mg dose of **tacrine** on day 10. The HRT increased the mean **tacrine** AUC by 60%, increased the mean peak plasma level of tacrine by 46% and reduced the tacrine clearance by 31%. The AUC of one individual was increased threefold. These pharmacoki-

netic changes are thought to occur because HRT reduces the metabolism of **tacrine** to its main metabolite (1-hydroxytacrine) by the cytochrome P450 isoenzyme CYP1A2.[2] The importance of this interaction is uncertain, but increased **tacrine** levels would be expected to increase its adverse effects. Therefore it would seem prudent to be alert for the need to use a smaller **tacrine** dose in patients given HRT. More study of this interaction is needed.

In contrast, HRT did not enhance the response to **rivastigmine** in menopausal women with Alzheimer's disease.[3] **Rivastigmine** metabolism is minimally affected by the major cytochrome P450 isoenzymes and analysis of population data from 70 subjects found that oestrogens did not affect **rivastigmine** pharmacokinetics.[4]

Anticholinesterases; Centrally acting + Memantine

Memantine does not appear to attenuate the anticholinesterase effects of donepezil, galantamine, rivastigmine or tacrine, nor affect the pharmacokinetics of donepezil, galantamine or rivastigmine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In a study, 19 healthy subjects were given memantine 10 mg before and on the last day of taking donepezil (5 mg daily for 7 days then 10 mg daily for 22 days). The pharmacokinetics of both drugs were not significantly affected by concurrent use, and the effects of donepezil on anticholinesterase were also unaffected.[1] Furthermore, a one-year efficacy and safety study reported that the combination is well tolerated and beneficial.[2]

(b) Galantamine

A study in 15 healthy subjects found that the concurrent use of extended-release galantamine 16 mg daily with memantine 10 mg twice daily for 12 days did not affect the pharmacokinetics of galantamine and generally did not increase the incidence of adverse effects, although dizziness may have been more common.[3] Furthermore, a review of efficacy studies suggested that the effects of galantamine on anticholinesterase are unaffected by memantine, and that the combination is safe and generally well tolerated.[4]

(c) Rivastigmine

In vitro and *in vivo* studies demonstrate that the inhibition of cholinesterase by rivastigmine is not affected by the concurrent use of memantine.[5] A study in 16 patients with mild to moderate Alzheimer's disease taking rivastigmine 1.5 to 6 mg twice daily for 2 months or more found that memantine, increased in a gradual step-up approach to 10 mg twice daily, did not affect the pharmacokinetics of rivastigmine. The combination was well tolerated with adverse events being mild to moderate.[6]

(d) Tacrine

An *in vitro* study in *rats* suggested that memantine does not attenuate the anticholinesterase effects of tacrine at therapeutic concentrations.[7] Note that this study also found a lack of attenuation with donepezil and galantamine, which has subsequently been proven in clinical use.

Anticholinesterases; Centrally acting + Other drugs that affect acetylcholine

The effects of centrally-acting anticholinesterases (e.g. donepezil) are expected to be additive with those of other anticholinesterases (e.g. neostigmine) and cholinergics (e.g. pilocarpine). The effects of centrally-acting anticholinesterases and drugs with antimuscarinic effects are expected to be antagonistic, but case reports have described the opposite effect.

Clinical evidence, mechanism, importance and management

Anticholinesterases raise acetylcholine levels: some are more selective for raising acetylcholine levels in the brain (e.g. **donepezil**), whereas others (e.g. **neostigmine**, **pyridostigmine**) have a more generalised effect, see 'Table 11.1', (p.396). Therefore, if both drugs are given together their effects may be expected to be additive. Similarly, additive effects may be expected if anticholinesterases are given with cholinergic drugs, such as **bethanechol** or **pilocarpine**, which mimic the effects of acetylcholine, and depolarising neuromuscular blockers such as **suxamethonium** (**succinylcholine**), which act like acetylcholine to cause depolarisation. In contrast, competitive (non-depolarising) neuromuscular blockers (e.g. **tubocurarine**) compete with acetylcholine for receptors on the motor endplate of the neuromuscular junction and anticholinesterases such as neostigmine can oppose or reverse this blockade. See 'Neuromuscular blockers + Anticholinesterases', p.128, for reports of these interactions.

Drugs with **antimuscarinic** (anticholinergic) effects, which block the actions of acetylcholine, such as **atropine**, would be expected to oppose the actions of the anticholinesterases, and the findings of one long-term study suggested that concurrent use of these centrally-acting anticholinesterases and antimuscarinics may cause a greater rate of decline in cognitive function in patients with Alzheimer's disease.[1] Similar effects were found in another study in which urinary antimuscarinics (**oxybutynin**, **tolterodine**) were taken with **donepezil**, **rivastigmine**, **galantamine** or **tacrine**, although those with the lowest initial functional ability did not demonstrate any decline.[2] In another study, no decline in mental status was seen in patients taking centrally-acting anticholinesterases and antimuscarinics.[3]

In addition, an analysis of the French Pharmacovigilance Database for adverse drug reactions involving centrally-acting anticholinesterases (**donepezil**, **galantamine** and **rivastigmine**) up to March 2006 found 118 potential drug-drug interactions with antimuscarinic drugs. Of these, 24 were thought to have caused adverse drug reactions,[4] although the exact nature of the adverse effects due to antimuscarinic drugs was not stated.

Case reports also describe an interaction between centrally-acting anticholinesterases and antimuscarinics. Two patients taking **donepezil** and one taking **rivastigmine** were given **tolterodine** (a urinary antimuscarinic). One patient (taking **donepezil**) developed confusion, while the other two developed delusional states. This is the opposite effect to the predicted interaction (where the anticholinesterase may be expected to oppose the antimuscarinic effects of **tolterodine**). The authors suggest that the combination causes 'cholinergic neurogenic hypersensitivity' similar to that seen as a withdrawal reaction to anticholinesterases.[5] In contrast, a case report describes the successful use of **tolterodine** 6 mg daily in a patient taking **donepezil** 10 mg daily. The authors of this report suggest that, despite the predictions of an interaction, a trial of an **antimuscarinic** for urinary incontinence may be worthwhile in patients taking centrally-acting anticholinesterases.[6]

Seizures have occurred in 2 patients taking the irreversible anticholinesterase, **metrifonate**, after antimuscarinics were started and then abruptly discontinued. One patient took **hyoscyamine** for about 10 days and then experienced a generalised tonic-clonic seizure approximately 36 hours after the hyoscyamine was stopped. Another patient taking metrifonate 60 mg daily for 6 weeks experienced seizures after she was prescribed **doxepin** cream for pruritus, which was applied liberally for 5 days.[7]

The authors suggested that, in both cases, excess cholinergic stimulation

resulting in seizures was due to the abrupt discontinuation of the antimuscarinic and continued use of metrifonate.[7] It would therefore appear that the outcome of concurrent use is uncertain, but it would certainly be prudent to monitor the concurrent use of **donepezil**, **galantamine**, **rivastigmine** or **tacrine** and any cholinergic or antimuscarinic drug.

Anticholinesterases; Centrally acting + Quinidine

Quinidine inhibits the metabolism of galantamine and is predicted to inhibit the metabolism of donepezil. Quinidine does not affect the metabolism of tacrine.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In vitro study has shown that quinidine (an inhibitor of the cytochrome P450 isoenzyme CYP2D6) inhibits donepezil metabolism[1,2] and, as no clinical information is available, the manufacturer suggests care with the combination:[1] increased donepezil levels and adverse effects are theoretically possible.

(b) Galantamine

A study in 8 healthy subjects given a single 10-mg dose of galantamine found that almost 20% of a dose of galantamine is excreted in the urine as *O*-demethylgalantamine glucuronide. Four of the 8 subjects were then given quinidine 250 mg twice daily for 2 days, with a single 15-mg dose of galantamine on day 2. Quinidine abolished the excretion of *O*-demethylgalantamine glucuronide in 3 subjects, and substantially reduced it in the fourth. The cumulative urinary recovery of unchanged galantamine increased by 60% in the presence of quinidine.[3] Quinidine is a known potent inhibitor of the cytochrome P450 isoenzyme CYP2D6, by which galantamine is metabolised. Concurrent use therefore decreases the metabolism of galantamine. This would be expected to result in raised levels of galantamine, but this does not appear to have been assessed in this study. A population pharmacokinetic analysis of a database of 852 patients with Alzheimer's disease, showed that the clearance of galantamine was decreased by about 25 to 33% by CYP2D6 inhibitors including 7 patients receiving quinidine.[4] Consequently the UK manufacturer of galantamine suggests that the concurrent use of quinidine may result in increased adverse effects (mainly nausea and vomiting), and, if this occurs, a reduction in the maintenance dose of galantamine should be considered.[5] This seems prudent.

(c) Tacrine

In a study in 11 healthy subjects, quinidine 83 mg every 8 hours did not affect the clearance of a single 40-mg dose of tacrine.[6] As quinidine inhibits the cytochrome P450 isoenzyme CYP2D6 in the liver, it was concluded that CYP2D6 does not have an important role to play in the metabolism of tacrine. No tacrine dose adjustments would be expected to be necessary if quinidine is also given.

Anticholinesterases; Centrally acting + SSRIs

Fluvoxamine markedly increases the levels of tacrine, and increases its adverse effects. Paroxetine and fluoxetine may increase donepezil and galantamine levels. Sertraline does not appear to have a pharmacokinetic interaction with donepezil, and concurrent use seems generally well tolerated, although there may be an increase in gastrointestinal adverse effects, and one report describes hepatotoxicity. Rivastigmine and fluoxetine appear not to interact.

Clinical evidence, mechanism, importance and management

(a) Donepezil

Two case reports suggest that donepezil and **paroxetine** may interact, in one case with an increase in gastrointestinal adverse effects, and the other with increased CNS effects. These adverse effects were thought to occur because **paroxetine** may inhibit donepezil metabolism by the cytochrome P450 isoenzyme CYP2D6.[1] A further report describes a patient taking **paroxetine** for 6 months who developed hypertonic limbs and severe gait disorders when donepezil 5 to 10 mg daily was also given.[2] The manufacturer of donepezil logically predicts that **fluoxetine** could also inhibit the metabolism of donepezil, and until more information is available, they suggest care should be taken on the concurrent use of donepezil and CYP2D6 inhibitors.[3]

In a crossover study, 16 healthy subjects were given **sertraline** (50 mg daily increasing after 5 days to 100 mg daily) with donepezil 5 mg daily for 15 days. The pharmacokinetics of both drugs were not significantly altered by concurrent use, and, although there was some indication that gastrointestinal adverse effects may have been increased, overall adverse effects were not changed.[4] Another study similarly found that the concurrent use of donepezil and **sertraline** was well tolerated with a relatively low incidence of adverse effects, although diarrhoea was significantly more common with concurrent use than with donepezil alone.[5] A case report describes an 83-year-old woman taking **sertraline** 200 mg daily, who developed drug-induced cholestatic jaundice within 10 days of starting donepezil 5 mg daily. The authors suggest that although this reaction could have been in response to either drug, it may also have been precipitated by their concurrent use. The general significance of this report is unclear.[6]

(b) Galantamine

The manufacturers[7,8] note that an interaction study found that **paroxetine** 20 mg daily for 16 days increased the bioavailability of galantamine by about 40%, by inhibiting galantamine metabolism by the cytochrome P450 isoenzyme CYP2D6. The UK manufacturer warns about the increased risk of galantamine adverse effects (in particular nausea and vomiting) if **paroxetine** is added, and suggests a reduction in the galantamine dose, based on tolerability.[7] They also predict that other SSRIs that are potent inhibitors of CYP2D6 e.g. **fluoxetine** may interact similarly.[7] A population pharmacokinetic analysis of a database of 852 patients with Alzheimer's disease showed that the clearance of galantamine was decreased by about 25 to 33% by the concurrent use of CYP2D6 inhibitors including **fluoxetine** (48 patients) and **fluvoxamine** (14 patients),[8] although it should be noted that **fluvoxamine** is only a weak inhibitor of CYP2D6. Thus far there appear to be no reports of adverse reactions with any of these drugs.

(c) Rivastigmine

The manufacturers of rivastigmine report that in studies in healthy subjects no pharmacokinetic interaction was seen between rivastigmine and **fluoxetine**.[9,10] No dose adjustment of either drug would appear necessary with concurrent use.

(d) Tacrine

Fluvoxamine is an inhibitor of cytochrome P450 isoenzyme CYP1A2, the main isoenzyme involved in the metabolism of tacrine. An *in vitro* study showed that **fluvoxamine** is a potent inhibitor of tacrine metabolism, and it was therefore predicted that **fluvoxamine** may dramatically increase ta-

crine plasma levels in patients.[11] This prediction was confirmed in a placebo-controlled study in 13 healthy subjects who had an eightfold increase in the mean AUC of a single 40-mg dose of tacrine after taking **fluvoxamine** 100 mg for 6 days. A very large increase in the AUC of the hydroxylated metabolites of tacrine, and an eightfold fall in the clearance of tacrine were also seen. No subjects had any adverse effects when they took tacrine after placebo, but 5 had adverse effects (nausea, vomiting, sweating, and diarrhoea) when they took tacrine after **fluvoxamine**.[12] Another pilot study in one individual found that the total clearance of tacrine was reduced about tenfold and its half-life increased tenfold by **fluvoxamine** 100 mg daily.[13] A further study by the same authors, in 18 healthy subjects, found that the clearance of tacrine was reduced by about 85% by **fluvoxamine** 50 or 100 mg.[14] It is likely that standard tacrine doses will be poorly tolerated in the presence of **fluvoxamine** because of cholinergic adverse effects, and a decrease in tacrine dose is probably necessary.[14] Other SSRIs such as **fluoxetine**, **paroxetine**, or **sertraline** may be suitable alternatives, as they seem unlikely to inhibit tacrine metabolism (they do not inhibit CYP1A2 to a clinically relevant extent).

Anticholinesterases; Centrally acting + Tobacco

Smoking tobacco reduces the plasma levels of tacrine and increases the clearance of rivastigmine.

Clinical evidence, mechanism, importance and management

A comparative study in 7 tobacco smokers and 4 non-smokers found that the AUC of a single 40-mg dose of **tacrine** in the smokers was about 10% of that in the non-smokers. The elimination half-life in the smokers was also reduced, to about two-thirds of that in non-smokers. The increase in **tacrine** metabolism in smokers is thought to occur because some of the components of tobacco smoke increase the activity of the cytochrome P450 isoenzyme CYP1A2 in the liver, by which **tacrine** is metabolised.[1] In practical terms it would appear that smokers are likely to need larger doses of **tacrine** than non-smokers, although this needs confirmation in multiple-dose studies. Theoretically, other centrally acting anticholinesterases (**donepezil**, **galantamine**, **rivastigmine**) would not be expected to interact in this way, as they are not metabolised by CYP1A2. However, the US manufacturer[2] notes that population pharmacokinetic analysis (75 smokers and 549 non-smokers) showed that nicotine use increases **rivastigmine** clearance by 23%, and so other mechanisms may have a part to play.

One observational study has suggested that patients with Alzheimer's disease who are smokers may be more likely to have an improved response to the digit symbol substitution test (a psychomotor test) when taking centrally-acting anticholinesterases than non-smokers; however, this was not associated with improved functional ability.[3] Furthermore, smoking may also increase the risk of dementia and cognitive decline.[4]

Anticholinesterases; Centrally acting + Tricyclic antidepressants

The tricyclics may affect the outcome of using a centrally-acting anticholinesterase.

Clinical evidence, mechanism, importance and management

A population pharmacokinetic analysis of a database of 852 patients with Alzheimer's disease found that the clearance of galantamine was decreased by about 25 to 33% by the concurrent use of inhibitors of the cytochrome P450 isoenzyme CYP2D6, which was said to include 17 patients receiving amitriptyline.[1] However, note that amitriptyline is more usually considered a substrate, rather than an inhibitor of this isoenzyme. Further, the effects of a reduction in clearance of galantamine of this magnitude do not appear to have been studied.

Also, note that amitriptyline and other tricyclic antidepressants have antimuscarinic adverse effects, which might affect the actions of the centrally-acting anticholinesterases, see 'Anticholinesterases; Centrally acting + Other drugs that affect acetylcholine', p.401.

1. Razadyne ER (Galantamine hydrobromide). Ortho-McNeil-Janssen Pharmaceuticals, Inc. US Prescribing information, April 2008.

Donepezil + Ginkgo (*Ginkgo biloba*)

Ginkgo does not appear to affect the pharmacokinetics or effects of donepezil.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 14 elderly patients with Alzheimer's disease were given donepezil 5 mg daily for at least 20 weeks, after which ginkgo extract 90 mg daily was also given for a further 30 days. Concurrent use did not affect the pharmacokinetics or cholinesterase activity of donepezil, and cognitive function appeared to be unchanged.[1] Therefore, over the course of 30 days, concurrent use appears neither beneficial nor detrimental.

1. Yasui-Furukori N, Furukori H, Kaneda A, Kaneko S, Tateishi T. The effects of *Ginkgo biloba* extracts on the pharmacokinetics and pharmacodynamics of donepezil. *J Clin Pharmacol* (2004) 44, 538–42.

Tacrine + Ibuprofen

An isolated report describes a woman taking tacrine who became delirious when she also started to take ibuprofen.

Clinical evidence, mechanism, importance and management

A 71-year-old diabetic woman with probable Alzheimer's disease developed delirium while taking tacrine 40 mg four times daily. The symptoms included delusions, hallucinations, and fluctuating awareness. She was also bradycardic, diaphoretic and dizzy.[1] She was eventually stabilised with tacrine 20 mg four times daily, and continued this for 8 months without problems, but became delirious again 2 weeks after starting to take ibuprofen 600 mg daily. The delirium resolved when both drugs were withdrawn. The reasons for this reaction are unknown. This is the first and only report of this apparent interaction and its general importance is probably small, especially as the patient had previously experienced delirium with tacrine alone.

1. Hooten WM, Pearlson G. Delirium caused by tacrine and ibuprofen interaction. *Am J Psychiatry* (1996) 153, 842.

Tacrine + Quinolones

Enoxacin possibly increases the effects of tacrine.

Clinical evidence, mechanism, importance and management

In vitro studies with human and *rat* liver microsomes found that **enoxacin**, a specific inhibitor of the cytochrome P450 isoenzyme CYP1A2, significantly inhibited all known routes by which tacrine is metabolised.[1] A reasonable conclusion to be drawn from this is that the effects of tacrine (both beneficial and adverse) would be increased by **enoxacin**, but this interaction does not appear to have been studied in patients or healthy subjects. The same study also suggested that **enoxacin** possibly inhibits the production of the hepatotoxic metabolites of tacrine.[1]

Other quinolones vary in the extent to which they inhibit CYP1A2 (see 'Theophylline + Quinolones', p.1452), so that any interaction with other quinolones would be expected to reflect this variation.

Anticoagulants

The blood clotting process

When blood is lost or clotting is initiated in some other way, a complex cascade of biochemical reactions is set in motion, which ends in the formation of a network or clot of insoluble protein threads enmeshing the blood cells. These threads are produced by the polymerisation of the molecules of fibrinogen (a soluble protein present in the plasma) into threads of insoluble fibrin. The penultimate step in the chain of reactions requires the presence of an enzyme, thrombin, which is produced from its precursor prothrombin, already present in the plasma. This is initiated by factor III (tissue thromboplastin), and subsequently involves various factors including activated factor VII, IX, X, XI and XII, and is inhibited by antithrombin III. Platelets are also involved in the coagulation process. Fibrinolysis is the mechanism of dissolution of fibrin clots, which can be promoted with thrombolytics. For further information on platelet aggregation and clot dissolution, see 'Antiplatelet drugs and thrombolytics', (p.813).

Mode of action of the anticoagulants

Anticoagulants may be divided into direct anticoagulants, which have an immediate effect, and the indirect anticoagulants, which inhibit the formation of coagulation factors, so have a delayed effect as they do not inactivate coagulation factors already formed. See 'Table 12.1', (below), for a list.

(a) Direct anticoagulants

The direct anticoagulants include **heparin**, which principally enhances the effect of antithrombin III, thereby inhibiting the effect of thrombin (factor IIa) and activated factor X (factor Xa). **Low-molecular-weight heparins** are salts of fragments of heparin and act similarly, except that they have a greater effect on factor Xa than factor IIa. They have a longer duration of action than heparin and usually require less monitoring. The **heparinoids** (such as **danaparoid**) are similar. A more recent introduction is the synthetic polysaccharide **fondaparinux**, which is an inhibitor of factor Xa.

The other group of direct anticoagulants are the **thrombin inhibitors**, which bind to the active thrombin site. These include recombinant forms or synthetic analogues of **hirudin** such as bivalirudin and lepirudin. They also include **argatroban**, which is given intravenously, and the oral thrombin inhibitors, **dabigatran etexilate**, the prodrug of dabigatran, and **rivaroxaban**. Melagatran and its oral prodrug **ximelagatran** act similarly, but have been withdrawn because of liver toxicity.

(b) Indirect anticoagulants

The indirect anticoagulants inhibit the vitamin K-dependent synthesis of factors VII, IX, X and II (prothrombin) in the liver, and may also be referred to as **vitamin K antagonists**. The most commonly used are the **coumarins**, principally warfarin, but also acenocoumarol and phenprocoumon. Their target site of action is vitamin K epoxide reductase complex subunit 1 (VKORC1), and increasing evidence suggests that genetic polymorphisms in VKORC1 affect dose-requirements. The **indanediones** such as phenindione are now less frequently used. For many decades, the indirect anticoagulants have had the advantage over direct anticoagulants as they are orally active. They are often therefore referred to as **oral anticoagulants**, but this term has become misleading with the development of direct-acting oral anticoagulants, such as dabigatran and rivaroxaban, which have different monitoring requirements and interactions.

Table 12.1 Anticoagulants

Route of administration	*Class*	*Drugs*
Parenteral anticoagulants	**Activated Factor X inhibitor**	Fondaparinux sodium
	Heparins	
	Heparin	Heparin calcium, Heparin sodium
	Low-molecular weight heparins	Bemiparin, Certoparin, Dalteparin, Enoxaparin, Nadroparin, Parnoparin, Reviparin, Tinzaparin
	Heparinoids	Danaparoid, Dermatan sulphate, Pentosan polysulfate, Suleparoid, Sulodexide
	Thrombin inhibitors, direct	
	Hirudin analogues and recombinant hirudins	Bivalirudin, Desirudin, Lepirudin
	Synthetic thrombin inhibitors	Argotroban
Oral anticoagulants	**Activated Factor X inhibitor**	Rivaroxaban
	Thrombin inhibitors, direct	Dabigatran etexilate
	Vitamin K antagonists	
	Coumarins	Acenocoumarol, Dicoumarol, Ethyl biscoumacetate, Phenprocoumon, Warfarin
	Indanediones	Fluindione, Phenindione

Coagulation tests

During anticoagulant therapy the aim is to give protection against intravascular clotting, without too great a risk of bleeding. To achieve this, doses of heparin and oral anticoagulants should be individually titrated until the desired response is attained. With the coumarin and indanedione oral anticoagulants, this procedure normally takes several days because they do not act directly on the blood clotting factors already in circulation, but on the rate of synthesis of new factors by the liver. The successful titration is determined by one of a number of different but closely related laboratory tests, see 'Table 12.2', (below), and under the subsections, below. Note that routine monitoring of the anticoagulant effect is not required for low-molecular-weight heparins or heparinoids, except in patients at increased risk of bleeding such as those with renal impairment; or those who are overweight. Also, note that these tests cannot be used to monitor the anticoagulant effect of fondaparinux or the direct thrombin inhibitors, but these drugs do not require routine anticoagulant monitoring.

(a) Prothrombin time

The prothrombin time test (PT, Pro-Time, tissue factor induced coagulation time) is the most common coagulation test employed in clinical situations. It measures the time taken for a fibrin clot to form in a citrated plasma sample containing calcium ions and tissue thromboplastin. The PT is usually reported as the International Normalised Ratio (INR).

1. International normalised ratio (INR). The INR was adopted by the WHO in 1982 to standardise (using the International Sensitivity Index) oral anticoagulant therapy to take into account the sensitivities of the different thromboplastins used in laboratories across the world. The formula for calculating the INR is as follows:
INR = (patient's prothrombin time in seconds/mean normal prothrombin time in seconds)^{ISI}
The PT values obtained from the patient's sample are compared to a control, and this gives the INR. The higher the INR, the higher the PT value so if the patient's ratio is 2, this means the PT (and therefore clotting) is twice as long as the normal plasma. The British Corrected Ratio is essentially the same, but was calculated to a standard British thromboplastin.

2. Quick Value. The Quick Value is expressed as a percentage; the lower the value, the longer the blood takes to coagulate. Therefore as the Quick Value increases, the corresponding INR value gets smaller and vice versa.

(b) Activated partial thromboplastin time

The activated partial thromboplastin time (aPTT) is the second most common method for monitoring anticoagulant therapy, measuring all the clotting factors in the intrinsic pathway as opposed to the PT test, which measures the extrinsic pathway.

(c) Other methods of assessing clotting

Other tests used, which in some instances offer more sensitivity to specific aspects of therapy, include the prothrombin-proconvertin ratio (PP), the thrombotest, the thrombin clotting time test (TCT) the activated clotting time (ACT or activated coagulation time), the platelet count and the bleeding time test. The use of the most appropriate test will depend on the situation and the desired result.

Anticoagulant interactions

Stable oral anticoagulant therapy is difficult to achieve even during close monitoring. For example, in one controlled study in patients with atrial fibrillation, only 61% of INR values were within the target range of 2 to 3, despite monitoring the INR monthly and adjusting the warfarin dose appropriately.[1] A large number of factors can influence levels of coagulation, including diet, disease (fever, diarrhoea, heart failure, thyroid dysfunction), and the use of other drugs. It must therefore be remembered that it is particularly difficult to ascribe a change in INR specifically to a drug interaction in a single case report, and single case reports or a few isolated reports for widely used drugs do not prove that an interaction occurs. Nevertheless, either the addition or the withdrawal of drugs may upset the balance in a patient already well stabilised on an anticoagulant. Some drugs are well known to increase the activity of the anticoagulants and can cause bleeding if the dose of the anticoagulant is not reduced appropriately. Others reduce the activity and return the prothrombin time to normal. Both situations are serious and may be fatal, although excessive hypoprothrombinaemia manifests itself more obviously and immediately as bleeding and is usually regarded as the more serious. The interaction mechanism may be pharmacodynamic or pharmacokinetic: pharmacokinetic mechanisms are particularly well established and important for coumarin anticoagulants.

(a) Metabolism of the coumarins

The coumarins, warfarin, phenprocoumon and acenocoumarol, are racemic mixtures of *S*- and *R*-enantiomers. The *S*-enantiomers of these coumarins have several times more anticoagulant activity than the *R*-enantiomers. Reports suggest for example, that *S*-warfarin is three to five times more potent a vitamin K antagonist than *R*-warfarin. The *S*-enantiomer of warfarin is metabolised primarily by the cytochrome P450 isoenzyme CYP2C9. The metabolism of *R*-warfarin is more complex, but this enantiomer is primarily metabolised by CYP1A2, CYP3A4, CYP2C19 and CYP2C8. *S*-warfarin is eliminated in the bile and *R*-warfarin is excreted in the urine as inactive metabolites. There is much more known about the metabolism of warfarin compared with other anticoagulants, but it is established that *S*-phenprocoumon and *S*-acenocoumarol are also substrates for CYP2C9 and that they differ from warfarin in their hepatic metabolism, and stereospecific potency.[2]

It makes sense to assume therefore, that an inhibitor of CYP2C9 (e.g. fluconazole, see 'Coumarins + Azoles; Fluconazole', p.437) is likely to increase the concentration of the coumarin and enhance the anticoagulant effect. Drugs that induce CYP2C9 (e.g. rifampicin, see 'Coumarins + Antibacterials; Rifamycins', p.424) reduce plasma levels of the coumarins by increasing their clearance, and reduce the anticoagulant effect.

Genetic differences in the genes for these cytochrome P450 isoenzymes may have an important influence on drug metabolism of the coumarins. For example, different versions of the gene encoding CYP2C9 exist and the enzymatic activity of the most clinically important CYP2C9 variants, CYP2C9*2 and CYP2C9*3, is significantly reduced. Studies have suggested an association between patients possessing one or more of these variants and a low-dose requirement of warfarin. Similar observations have been made with the CYP2C9*3 variant and acenocoumarol.

While the metabolism of the coumarins, especially warfarin, are well

Table 12.2 Coagulation tests

Test	*Normal range*	*Therapeutic/diagnostic range*
Activated partial thromboplastin time	20 to 39 seconds after reagents added	1.5 to 2.5 x control
Bleeding time	1 to 9 minutes depending on method used	Critical value greater than 15 minutes
International normalised ratio	0.9 to 1.2	2 to 4 depending on indication for anticoagulation
Plasma thrombin time test	10 to 15 seconds	Greater than 15 seconds
Prothrombin-proconvertin ratio	70 to 130%	10 to 30%
Prothrombin time	10 to 15 seconds	1 to 2 x control
Quick value	70 to 130%	10 to 20%
Thrombin clotting time	70 to 120 seconds	150 to 600 seconds depending on indication for anticoagulation
Thrombotest	100%	10 to 20%

known, the numerous interaction pathways and the variability in patient responses makes the clinical consequences of affecting their metabolism less accurate to predict than with other drugs.

(b) Other mechanisms for anticoagulant interactions

Some drugs, such as colestyramine (see 'Coumarins and related drugs + Bile-acid binding resins', p.443) may prevent the absorption of the coumarins and reduce their bioavailability. See also 'Drug absorption interactions', (p.3). An increased risk of bleeding can occur if anticoagulants are given with other drugs that also impair coagulation by other mechanisms such as those drugs with an antiplatelet effect (see 'Coumarins and related drugs + Clopidogrel', p.448. Coumarins and indanediones act as vitamin K antagonists, and so dietary intake of vitamin K can also reduce or abolish their effects. Protein-binding displacement is another possible drug interaction mechanism but this usually plays a minor role compared with other mechanisms.[3] Consider also'Protein-binding displacement', (p.3).

Bleeding and its treatment

When prothrombin times become excessive, bleeding can occur. In order of decreasing frequency the bleeding shows itself as ecchymoses, blood in the urine, uterine bleeding, black faeces, bruising, nose-bleeding, haematoma, gum bleeding, coughing and vomiting blood.

Vitamin K is an antagonist of the coumarin and indanedione oral anticoagulants. The British Society for Haematology has given advice on the appropriate course of action if bleeding occurs in patients taking warfarin, and this is readily available in summarised form in the British National Formulary.

If the effects of heparin are excessive it is usually sufficient just to stop the heparin, but protamine sulfate is a specific antidote if a rapid effect is required. Protamine sulfate only partially reverses the effect of low-molecular-weight heparins.

There is currently no known specific antidote for fondaparinux, or for the direct thrombin inhibitors.

Coumarins + ACE inhibitors

There is a single, isolated and unexplained case of melaena attributed to an interaction between acenocoumarol and fosinopril. No other ACE inhibitor studied has so far been shown to interact to a clinically relevant extent with the coumarins.

Clinical evidence

(a) Benazepril

In healthy subjects benazepril 20 mg daily for 7 days did not affect the steady-state plasma levels of either **warfarin** or **acenocoumarol**. The anticoagulant activity of **acenocoumarol** was not altered. The effects of **warfarin** were slightly reduced, as demonstrated by a mean reduction in PT of about 4%, but this is not enough to be clinically important.[1]

(b) Cilazapril

In 26 patients taking long-term **acenocoumarol** or **phenprocoumon**, cilazapril 2.5 mg daily for 3 weeks had no effect on the thrombotest times or coagulation factors II, VII and X.[2]

(c) Enalapril

Enalapril 20 mg for 5 days did not affect the anticoagulant effects of **warfarin** 2.5 to 7.5 mg daily, according to a brief summary of unpublished data cited in a review.[3]

(d) Fosinopril

A 74-year-old patient stabilised on **acenocoumarol**, **enalapril**, piretanide, and digoxin had the piretanide and **enalapril** switched to furosemide and fosinopril. Eleven days later, he presented with dark faeces (melaena) and had a low haemoglobin level. Fosinopril and acenocoumarol were stopped, and then **enalapril** and acenocoumarol were restarted. On gastrointestinal endoscopy, no explanation for the melaena was found, and his haemoglobin level had returned to normal 15 days later. This case was attributed to possible potentiation of the effect of acenocoumarol by fosinopril.[4]

(e) Moexipril

In 10 healthy subjects, the pharmacokinetics and pharmacodynamics of a single 50-mg dose of **warfarin** were not altered when it was given with the first dose of moexipril 15 mg daily for 6 days.[5]

(f) Ramipril

In 8 healthy subjects, ramipril 5 mg daily for 7 days had no effect on the steady-state pharmacokinetics or anticoagulant effects of **phenprocoumon**.[6] Similarly, ramipril 5 mg daily for 3 weeks did not alter the anticoagulant effects of **acenocoumarol** or **phenprocoumon** in patients stabilised on these anticoagulants, when compared with placebo.[7]

(g) Temocapril

In 24 healthy subjects, temocapril 20 mg daily for 2 weeks had no effect on the steady-state pharmacokinetics or pharmacodynamics of **warfarin**.[8] The absence of an interaction between **warfarin** and temocapril was also shown in another study.[9]

(h) Trandolapril

In a study in 19 healthy subjects,[10] **trandolapril** 2 mg daily for 13 days did not affect the pharmacodynamics of a single 25-mg dose of **warfarin** given on day 8.

Mechanism, importance and management

No important pharmacokinetic or pharmacodynamic interaction has been demonstrated for any ACE inhibitor and coumarin anticoagulant. Contrasting with all this evidence, there is a single, unexplained and isolated case of melaena attributed to an interaction between acenocoumarol and fosinopril. There seems to be no other evidence that fosinopril normally interacts with the oral anticoagulants and so this case report is unlikely to be of general significance. No special precautions would therefore seem necessary if any of these coumarin anticoagulants and ACE inhibitors are used concurrently.

Coumarins and related drugs + Alcohol

The effects of the coumarins are unlikely to be changed in those with normal liver function who drink small or moderate amounts of alcoholic beverages such as wine or spirits. A non-significant trend has been reported of an increased risk of serious bleeding in patients taking warfarin with a history of binge drinking.

Clinical evidence

(a) Patients and subjects free from liver disease

In a study in 8 healthy subjects anticoagulated with **warfarin**, the daily consumption of one pint (about 560 mL) of Californian white table wine for a 3-week period at meal times had no significant effects on either the serum **warfarin** levels or the anticoagulant response.[1]

Other studies in both patients[2,3] and healthy subjects[4,5] taking either **warfarin**[2,3,5] or **phenprocoumon**[4] have very clearly confirmed the absence of an interaction with wine,[3,5] gin,[4] or alcohol 40%.[2] In one of these studies the subjects were given almost 600 mL of a table wine (alcohol 12%) or 300 mL of a fortified wine (alcohol 20%) without adverse effects on coagulation.[5] Moreover, in men randomised to receive low-dose **warfarin** in a post-coronary artery bypass graft study, there was no significant difference in the incidence of an INR above 2 between 323 non-drinkers, 181 light drinkers (one to 6 drinks weekly), 75 moderate drinkers (7 to 13 drinks weekly) and 46 heavy drinkers (14 drinks or more weekly).[6]

In contrast to the above studies, a 58-year-old man stabilised on **warfarin** experienced a sharp rise in his INR to 8 when he started to drink half a can of light beer (5.35 g of alcohol) every other day. In the previous 5 months he had an INR in the range of 1.9 to 2.5 with a stable **warfarin** dose, and no other explanation for the change in INR was found. He stopped taking the alcohol, and was eventually restabilised on the original dose of **warfarin**.[7] In a prospective, longitudinal study of patients taking **warfarin**, there was a slight statistically significant increased risk of self-reported bleeding events in patients who had increased their alcohol consumption in the previous week (35 bleeds in 245 weeks, none of which were major; odds ratio 1.24).[8]

In a case-control study of risk factors for excessive anticoagulation, self-reported alcohol use (ranging from one drink every other day to 2 drinks daily) was actually associated with an 80% *lower* risk of an INR greater than 6 with **warfarin**.[9]

(b) Chronic alcoholics or those with liver disease

In one study, 15 alcoholics who had been drinking heavily (250 g of ethanol or more daily) for at least 3 months and 11 control subjects (minimal social drinkers or non-drinkers) were given a single 40-mg dose of **warfarin**. The half-life of **warfarin** was lower in the alcoholics (26.5 hours versus 41.1 hours), but a comparison of the prothrombin times with those of healthy subjects found no differences.[10]

One patient with liver cirrhosis had marked fluctuations in prothrombin times and **warfarin** levels associated with weekend binge drinking of vodka.[2] Another patient with abnormal liver function had a fall in plasma **warfarin** levels and effect when he stopped drinking 50 mL of whiskey daily. When rechallenged with alcohol, **warfarin** levels and effect rose, and he had a nosebleed.[11] In contrast, a large retrospective cohort study did not find a significantly increased risk of serious bleeding in 140 patients with a history of alcoholic binge drinking who were taking **warfarin**. The

relative risk was 1.3 (0.8 to 1.9) compared with patients who had no record of alcohol abuse.[12]

Mechanism

It seems probable that, as in *rats*,[13] continuous heavy drinking stimulates the hepatic enzymes concerned with the metabolism of warfarin, leading to more rapid elimination.[10,14] The fluctuations in prothrombin times in those with liver impairment[2,11] may possibly occur because sudden large amounts of alcohol exacerbate the general dysfunction of the liver and this might affect the way it metabolises warfarin. Alcohol may also change the ability of the liver to synthesise clotting factors.[15] Constituents of beer other than alcohol may affect warfarin metabolism.[7]

Importance and management

The absence of an interaction between warfarin or phenprocoumon and alcohol in those free from liver disease is well documented and well established. It appears to be quite safe for patients taking oral anticoagulants to drink small or moderate amounts of wine or spirits (e.g. drinking within the generally accepted healthy daily limits). Even much less conservative amounts (up to 8 oz/250 mL of spirits[4] or a pint of wine (about 560 mL) daily[1]) do not create problems with anticoagulant control, so that there appears to be a good margin of safety even for the less than abstemious. Only warfarin and phenprocoumon appear to have been investigated, but other coumarin anticoagulants would be expected to behave similarly. The single case of increased INR in a patient who started to drink beer is unexplained, and therefore, further study with beer is needed to throw light on this possible interaction.

On the other hand, those who drink heavily may possibly need above-average doses of the coumarin, while limited evidence suggests that those with liver damage who binge drink may experience marked fluctuations in their prothrombin times. It might be prudent to avoid anticoagulation in this type of patient unless they can abstain from drinking. Nevertheless, although one cohort study in patients taking warfarin found a slight trend towards serious bleeding events in patients with a history of binge drinking, this was not significant, and other risk factors for bleeding were more important (highly variable prothrombin time ratio, or prothrombin time ratio greater than 2).[12]

Some sources also say that the indanedione **phenindione** may interact with alcohol, but there seems no direct evidence available to support this prediction.

Coumarins + Aliskiren

Aliskiren did not alter the pharmacodynamics or pharmacokinetics of a single dose of acenocoumarol, nor does it appear to interact with warfarin. Warfarin does not increase the levels of aliskiren.

Clinical evidence, mechanism, importance and management

(a) Acenocoumarol

In a well-controlled study in 18 healthy subjects, aliskiren 300 mg daily for 10 days did not alter the anticoagulant effect of a single 10-mg dose of acenocoumarol given on day 8. No significant changes in the pharmacokinetics of either *R*- and *S*-acenocoumarol were reported.[1] This study suggests that no acenocoumarol dose adjustment or additional monitoring would be expected to be needed if aliskiren is used in patients taking acenocoumarol.

(b) Warfarin

In a placebo-controlled, crossover study in 15 healthy subjects, aliskiren 150 mg daily for 11 days did not alter the pharmacodynamics of a single dose of warfarin given on day 8. In addition, there was no change in the AUC or half-life of *R*- and *S*-warfarin.[2] However, the manufacturer says that there were technical difficulties with this study, which was considered deficient.[3] They therefore state in their product information that the effects of aliskiren on warfarin pharmacokinetics have not been evaluated.[4] Nevertheless, aliskiren did not interact with acenocoumarol, which has very similar metabolism to warfarin; therefore no interaction with warfarin would be anticipated.

The US manufacturers state that warfarin does not increase the levels of aliskiren.[5]

Coumarins + Allopurinol

A number of studies and case reports suggest that allopurinol does not alter the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, a few case reports suggest that allopurinol might have increased the effect of warfarin, and similar cases have been reported with phenprocoumon. Allopurinol increased the half-life of dicoumarol in some healthy subjects, but there do not appear to be any reports of a clinically significant interaction.

Clinical evidence

(a) Dicoumarol

In 6 healthy subjects, allopurinol 2.5 mg/kg twice daily for 14 days increased the mean half-life of a single 4-mg/kg dose of dicoumarol from 51 hours to 153 hours, with large inter-individual variation.[1] In another similar study, only one of 3 healthy subjects had an increase in their dicoumarol half-life (from 13 hours to 17 hours) when they were also given allopurinol.[2]

(b) Phenprocoumon

Two patients, who had been stabilised on phenprocoumon for a few weeks, developed prolonged bleeding times, with haematuria in one of them, within 4 to 5 weeks of starting to take allopurinol 300 mg daily.[3]

(c) Warfarin

In a study in 8 healthy subjects, the half-life of a single 25-mg dose of warfarin was not altered by pretreatment with allopurinol 100 mg twice daily for 10 days.[2] Similarly, in 6 subjects, the elimination of a single 50-mg dose of warfarin was not altered by allopurinol 100 mg three times daily for 2 to 4 weeks, although one subject had a 30% reduction in the elimination of warfarin after 4 weeks.[4] No change was seen in the prothrombin ratios of 2 patients taking warfarin who took allopurinol 100 mg three times daily for 3 weeks.[4] In contrast, one patient stabilised on warfarin had a 42% increase in his prothrombin ratio after taking allopurinol 100 mg daily for 2 days.[5]

In a retrospective study[6] of the adverse effects of allopurinol in 1835 patients, 3 patients were identified who had developed excessive anticoagulation while taking warfarin and allopurinol. One of them developed extensive intrapulmonary haemorrhage and had a prothrombin time of

71 seconds. An increase in prothrombin time to 42 seconds was reported in an 82-year-old woman who had started taking warfarin 11 days previously, when she was also started on both allopurinol 300 mg daily and 'indometacin', (p.486). The precise role of the allopurinol in this case is unclear.[7]

Mechanism

It has been suggested that, as in *rats*, allopurinol inhibits the metabolism of the anticoagulants by the liver, thereby prolonging their effects and half-lives.[1,2,5] There is a wide individual variability in the effects of allopurinol on drug metabolism,[4] so that only a few individuals are affected.

Importance and management

Documentation for an interaction between allopurinol and the coumarins is poor, and a pharmacokinetic interaction is not established. There appear to be few case reports of any important interaction. Nevertheless, consider increased monitoring of the anticoagulant effect in any patient taking a coumarin with allopurinol.

Coumarins + Alpha blockers

Tamsulosin does not appear to alter the pharmacokinetics or anticoagulant effect of acenocoumarol, and alfuzosin, doxazosin and terazosin do not appear to affect the response to warfarin.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

The UK manufacturer of alfuzosin reports that no pharmacodynamic or pharmacokinetic interaction was seen in healthy subjects given alfuzosin with **warfarin**.[1] The US manufacturer reports that in 6 healthy subjects, alfuzosin 5 mg twice daily for 6 days did not affect the pharmacological response to a single 25-mg dose of **warfarin**.[2] No warfarin dose adjustment would be expected to be needed on concurrent use.

(b) Doxazosin

The manufacturer of doxazosin reports that doxazosin has no effect on the protein binding of **warfarin** *in vitro*, and that no adverse effects have been reported with anticoagulants (unspecified).[3] No warfarin dose adjustment would be expected to be needed on concurrent use.

(c) Tamsulosin

In a double-blind, placebo-controlled, crossover study in 12 healthy subjects, tamsulosin 400 micrograms daily for 9 days had no effect on the pharmacokinetics or anticoagulant effects of a single 10-mg dose of **acenocoumarol** given on day five.[4] However, the UK manufacturer of tamsulosin states that **warfarin** might increase the elimination rate of tamsulosin.[5] The US manufacturer states that the findings of an *in vitro* metabolic interaction study between tamsulosin and **warfarin** were equivocal, and that they have not done a definitive drug interaction study; they therefore recommend caution with concurrent use.[6] Nevertheless, there do not appear to be any published cases of problems with the concurrent use of tamsulosin and **warfarin**, and the clinical study with **acenocoumarol**, which is metabolised in a similar way to **warfarin**, suggests that an interaction is unlikely.

(d) Terazosin

In a retrospective study of 26 men stabilised on **warfarin**, starting terazosin had no effect on their INRs. The patients had stable INRs for a least 2 consecutive measurements before receiving terazosin, and an INR taken within 14 days (9 patients) or 30 days (17 patients) of starting the terazosin.[7] Another study in 29 patients taking **warfarin** found that starting terazosin did not have a significant effect on anticoagulation.[8] Terazosin was used as a control comparator drug in these studies because of its lack of interaction with **warfarin**.[7,8] No warfarin dose adjustment would be expected to be needed on concurrent use.

Coumarins + 5-Alpha reductase inhibitors

Dutasteride and finasteride have no clinically significant effect on the pharmacokinetics or pharmacodynamics of warfarin.

Clinical evidence, mechanism, importance and management

In a study in 23 healthy subjects, dutasteride 500 micrograms daily taken with **warfarin** for 35 days had no effect on the pharmacokinetics of *S*- or *R*-warfarin, and the prothrombin time was unaffected by dutasteride.[1]

Similarly, the manufacturer of finasteride briefly notes that no clinically meaningful interaction was seen with **warfarin**.[2,3]

Therefore, no warfarin dose adjustment would be expected to be necessary on concurrent use of these 5-alpha reductase inhibitors.

Coumarins + 5-Aminosalicylates

A single case report describes reduced warfarin effects in a patient given mesalazine. Another single case report describes a marked reduction in the response to warfarin when mesalazine was switched to sulfasalazine.

Clinical evidence

A woman stabilised on **warfarin** 5 mg daily, with INRs between 2 and 3, started taking **mesalazine** 800 mg three times daily for the treatment of a caecal ulcer. Four weeks later she presented to hospital with left leg pain, which was diagnosed as an acute popliteal vein thrombosis, and at the same time it was found that her prothrombin time and INR had fallen to 11.3 seconds and 0.9, respectively. The patient was treated with intravenous heparin. Over the next 10 days INRs of up to 1.7 were achieved by increasing the doses of **warfarin** up to 10 mg daily, but a satisfactory INR of 2.1 was only reached when the **mesalazine** was stopped. The report says that serum **warfarin** levels were not detectable during the use of **mesalazine**.[1] A 37-year-old woman taking **warfarin** 30 mg weekly with stable INRs between 2 and 3 in the previous 2 years (and also taking beclometasone, salbutamol, aspirin, azathioprine,and ethinyloestradiol with norgestrel), had her treatment for arthritis and ulcerative colitis changed from **mesalazine** to **sulfasalazine** 1 g four times daily. The day after the change her INR was found to be subtherapeutic (1.5) and she needed numerous increases in the **warfarin** doses over the next 6 weeks, eventually needing **warfarin** 75 mg weekly before acceptable INRs were achieved. During this period she developed a new deep vein thrombosis. When the **sulfasalazine** was later stopped and the **mesalazine** restarted, her **warfarin** dose was only 45 mg weekly.[2]

Mechanism

Not understood. Sulfasalazine is broken down in the colon to a sulfonamide, sulfapyridine, and 5-aminosalicylic acid (mesalazine). Some sulfon-

amides (see 'Coumarins and related drugs + Antibacterials; Sulfonamides and/or Trimethoprim', p.425) are known inhibitors of warfarin metabolism, and increase the effects of warfarin. In contrast, in the case with sulfasalazine, a marked decrease was noted.

Importance and management

Not established. The case of a reduction in effect of warfarin on starting mesalazine appears to be the first and only report of an interaction, which suggests that it is unlikely to be of general importance. Similarly, the case when mesalazine was switched to sulfasalazine is an unexplained and isolated case, and its validity has been debated.[3,4] There are no other reports in the literature and this possible interaction also seems unlikely to be of general importance. Consider these cases in the event of an unexpected response to treatment.

Coumarins and related drugs + Amiodarone

The anticoagulant effects of warfarin, phenprocoumon and acenocoumarol are increased by amiodarone and bleeding may occur. The interaction may be maximal in 2 to 7 weeks, and may persist long after the amiodarone has been withdrawn. Amiodarone-induced thyrotoxicosis may also alter the INR in patients taking warfarin.

Clinical evidence

A. Inhibition of coumarin metabolism

(a) Acenocoumarol

A number of retrospective studies[1-4] have found that patients stabilised on acenocoumarol require a dose reduction when they are given amiodarone, the combined range in these studies being 4 to 69%. In a prospective study, 10 patients stabilised on acenocoumarol were given amiodarone 600 mg daily for a week, then 400 mg daily. Eight of the 10 patients had a decrease in prothrombin time after a mean of 4 days of amiodarone. Six patients required a decrease in their acenocoumarol dose of 60% while taking amiodarone 600 mg daily, but by the third week of taking amiodarone 400 mg daily the effects had diminished, and only a 33% reduction in dose was necessary.[5] A couple of case reports of the interaction have also been published.[6,7]

(b) Phenprocoumon

Amiodarone appears to increase the effects of **phenprocoumon**, with one case series in 7 patients reporting that a 9 to 59% phenprocoumon dose reduction was required within 1 to 3 weeks of starting amiodarone.[8] Conversely, an early study in 12 patients stabilised on **phenprocoumon** and given amiodarone 400 mg to 1 g daily did not find any interaction.[9]

(c) Warfarin

In the one of the first reports of an interaction between amiodarone and warfarin, 5 out of 9 patients who were stabilised on warfarin developed signs of bleeding (4 had microscopic haematuria and one had diffuse ecchymoses) within 3 to 4 weeks of starting to take amiodarone (dose not stated). All 9 had increases in their prothrombin times averaging 21 seconds. It was necessary to decrease the warfarin dose by an average of one-third (range 16 to 45%) to return their prothrombin times to the therapeutic range. The effects of amiodarone persisted for 6 to 16 weeks in 4 of the patients from whom it was withdrawn.[10]

Since then numerous other case reports have described a prolongation in prothrombin times and/or bleeding in patients taking warfarin and also given amiodarone (maintenance doses of 100 to 800 mg daily, sometimes with initial higher loading doses).[11-20] One patient died of haemorrhage.[15] Warfarin dose reductions varied between about 25 to 60%,[13,15,17,20] with only a few patients not needing a reduction.[13] In one retrospective study, the required dose of warfarin was related to the amiodarone maintenance dose, leading to the recommendation that the warfarin dose should be reduced by 40% for a daily maintenance dose of amiodarone of 400 mg, by 35% for 300 mg, by 30% for 200 mg and by 25% for 100 mg.[20] Other studies have also found that amiodarone use was associated with a lower required warfarin dose.[21,22] One 80-week study reported that a clinically significant interaction defined as an INR above 5 was most likely in the first 12 weeks of concurrent use, and was minimal thereafter.[23] Conversely, one large cohort study found no significant increased risk of haemorrhage with the concurrent use of warfarin and amiodarone,[24] but it is possible that the patients were on stable therapy, or that the interaction was anticipated and managed accordingly.

A few pharmacokinetic studies have shown that amiodarone decreased the clearance of warfarin by 44 to 55% in patients,[16,25] and by 20 to 37% in healthy subjects given a single dose of warfarin after taking amiodarone for 3 to 4 days.[26,27] In the two studies in healthy subjects, amiodarone caused a similar decrease in the clearance of both *R*- and *S*-warfarin.[26,27] However, a recent study in patients concluded that amiodarone had a much greater effect on *S*-warfarin than on *R*-warfarin.[28]

B. Thyrotoxicosis (Hyperthyroidism)

The INR of a patient stabilised on **warfarin** and amiodarone was noted to increase from about 2 to 5.5 after he developed amiodarone-induced thyrotoxicosis.[29] Another three well-described cases of this potential interaction have been reported.[30]

Mechanism

Amiodarone inhibits the metabolism of warfarin, probably because it, and/or its metabolite desethylamiodarone,[31] inhibit the cytochrome P450 isoenzymes CYP2C9, CYP3A4 and CYP1A2 (see 'metabolism of the coumarins', (p.405)).

Thyrotoxicosis, which can be caused by amiodarone, potentiates the effect of warfarin, see 'Coumarins and related drugs + Thyroid and Antithyroid compounds', p.513. As a result less warfarin would be required to prolong the prothrombin time.[29,30]

Importance and management

The potentiating effect of amiodarone on coumarin anticoagulants is a well documented, established and clinically important interaction. It appears to occur in most patients.[10,13,17] It would seem prudent to adjust the doses of the coumarin anticoagulants based on INR measurements. Some recommend that the dose of warfarin should initially be reduced by 25%[17] or 50%[13] when amiodarone is added to established anticoagulant treatment, with increased INR monitoring until a new steady-state is achieved. The potentiation of coumarins starts within a few days and is usually maximal by 2 to 7 weeks.[17,20,28] The final reduction in warfarin dose required may depend on the amiodarone maintenance dose: average warfarin dose reductions of 25% have been required for amiodarone 100 mg daily, 30 to 35% for amiodarone 200 mg daily, 35% for amiodarone 300 mg daily, 40 to 50% for amiodarone 400 mg daily, and 65% for amiodarone 600 mg daily.[16,20] These suggested reductions are broad generalisations and individual patients may need more or less.[4,32] If established amiodarone therapy is withdrawn in a patient taking warfarin, it is likely that the dose of warfarin will need increasing gradually over the first few months after amiodarone is stopped. This is because amiodarone has such a long half-life. If warfarin is required in a patient on established amiodarone therapy, a lower initial dose of warfarin should be used.

Similar advice applies to acenocoumarol and phenprocoumon, and probably also other coumarins. Some recommend an initial reduction in acenocoumarol dose of 50% when amiodarone is added,[1] whereas others recommend that the INR should be closely monitored, and the dose of acenocoumarol only reduced in response to an increase in INR.[32]

In patients stabilised on a coumarin and amiodarone, the possibility of amiodarone-induced thyroid dysfunction should be considered if an abrupt increase in INR occurs,[29,30] see 'Coumarins and related drugs + Thyroid and Antithyroid compounds', p.513.

Some sources say that the metabolism of the indanedione **phenindione** is inhibited by amiodarone, but this appears to be an extrapolation from the known interaction with warfarin. There seems no clinical evidence available to support this prediction.

Coumarins and related drugs + Anabolic steroids or Androgens

Increased anticoagulant effects and bleeding have been seen in patients taking a coumarin or the indanedione, phenindione, and an anabolic steroid or testosterone.

Clinical evidence

(a) Anabolic steroids

Six patients stabilised on **warfarin** or **phenindione** were given **oxymetholone** 15 mg daily. One patient developed extensive subcutaneous bleeding and another had haematuria. After 15 to 30 days all 6 patients had thrombotests of less than 5%, which returned to the therapeutic range within a few days of **oxymetholone** being withdrawn.[1] Other similar cases have been reported with **oxymetholone** and **warfarin**,[2-4] or **acenocoumarol**.[5] In 3 of the reports[1,3,4] the interaction was severe enough to discontinue the **oxymetholone**. In one patient[2] the **warfarin** dose was reduced by 59%, and in another[5] the **acenocoumarol** dose was reduced by 66 to 75%. Similarly increased anticoagulant effects and bleeding have been described in studies and case reports involving:

- **dicoumarol** with **norethandrolone**,[6]
- **dicoumarol** with **stanozolol**,[7]
- **phenindione** with **methandienone**,[8]
- **phenindione** with **ethylestrenol**,[9]
- **warfarin** with **methandienone**[2,8,10,11] (62% to 73% decrease in dose required in 3 cases[2] and 38% in 7 others[8]),
- **warfarin** with **stanozolol**[12-15] (40% and 64% decrease in dose required in 2 patients and about a 70% increase required after stopping stanozolol[12]).

In a pharmacokinetic study in 15 healthy subjects, the concurrent use of **warfarin** and **oxandrolone** 5 or 10 mg twice daily increased the *S*-warfarin AUC by 2.65-fold and doubled its half-life, and had similar effects on *R*-warfarin.[16] Microscopic haematuria occurred in 9 subjects and gingival bleeding in one. An 80 to 85% decrease in the dose of **warfarin** was necessary to maintain a target INR of 1.5.

(b) Androgens

A 58-year-old man receiving **methyltestosterone** replacement therapy 37.5 mg daily required a maintenance dose of **phenprocoumon** of just 0.94 mg daily compared with control subjects who required 2.62 mg daily.[17] One report notes that 3 patients receiving **warfarin** and *Sustanon* (containing four combined esters of **testosterone**) had no changes in their anticoagulant requirements,[4] whereas another report describes a woman who had a 78% and a 65% increase in prothrombin times on two occasions when using a 2% **testosterone propionate** vaginal ointment twice daily. She needed a 25% reduction in her **warfarin** dose.[18]

Mechanism

Not understood. One study found that norethandrolone did not alter the metabolism of dicoumarol, and did not alter the plasma levels of vitamin-K dependent clotting factors.[6] However, a more recent study of oxandrolone and warfarin suggests a pharmacokinetic basis for this interaction.[16]

Importance and management

The interactions between warfarin and the anabolic steroids are well documented, well established and clinically important. The effect develops rapidly, possibly within 2 to 3 days. Most, if not all, patients are affected.[1,6] If concurrent use cannot be avoided, the dose of the anticoagulant should be appropriately reduced. In a few cases, where patients have been able to be stabilised on the combination, up to 75% reductions in anticoagulant dose have been required, and the study with oxandrolone[16] suggests that an 85% reduction in the dose of warfarin might be necessary. After withdrawal of the interacting drug the anticoagulant dose will need to be increased.

It seems probable that all the coumarin and indanedione anticoagulants will interact with any 17-alkyl substituted anabolic steroid; effects have been seen on acenocoumarol, dicoumarol and phenindione. The situation with testosterone and other non 17-alkylated steroids is not clear as there are only case reports, which are conflicting. Until more is known it would seem prudent to increase the frequency of INR monitoring if these drugs are given with coumarins or indanediones.

Coumarins + Angiotensin II receptor antagonists

None of the angiotensin II receptor antagonists appear to interact with warfarin to a clinically relevant extent.

Clinical evidence

(a) Candesartan

In healthy subjects stabilised on individualised doses of **warfarin**, candesartan cilexetil 16 mg daily for 10 days reduced the trough serum levels of **warfarin** by 7%, but this had no effect on prothrombin times.[1]

(b) Eprosartan

No clinically relevant changes in anticoagulation occurred in 18 healthy subjects stabilised on **warfarin** with INRs between 1.3 and 1.6 when they were given eprosartan 300 mg twice daily for 7 days.[2]

(c) Irbesartan

Warfarin 2.5 to 10 mg daily was given to 16 healthy subjects for 2 weeks, with irbesartan 300 mg or a placebo daily for a further week. There was no evidence that irbesartan affected the pharmacokinetics or pharmacodynamics of **warfarin**.[3]

(d) Losartan

In a placebo-controlled, randomised, crossover study, 10 healthy subjects were given losartan 100 mg daily for 13 days with a single 30-mg dose of **warfarin** on day 7. The pharmacokinetics of **warfarin** (both *R*- and *S*-enantiomers) and its anticoagulant effects were not altered. Losartan, given alone for one week, also had no effect on prothrombin times.[4]

(e) Olmesartan

In a study in 24 healthy subjects given **warfarin** titrated to a Quick value of between 1.4 and 1.8 for 2 weeks, the addition of olmesartan 40 mg daily for a further 7 days had no effect on the pharmacokinetics of either *R*- or *S*-warfarin. There was also no change in Quick value or partial prothrombin time.[5]

(f) Telmisartan

Telmisartan 120 mg daily for 10 days was given to 12 healthy subjects stabilised on **warfarin**, with INRs of between 1.2 and 1.8. A small 11% decrease in the mean trough plasma **warfarin** concentration occurred, but the anticoagulation effect remained unchanged.[6]

(g) Valsartan

In a study in 12 healthy subjects, valsartan 160 mg daily was given for 7 days with **warfarin** 10 mg daily for the first 3 days. **Warfarin** had no effect on the pharmacokinetics of valsartan. Valsartan caused a small increase in prothrombin time of about 12%, which was not considered clinically important. **Warfarin** pharmacokinetics were not assessed.[7,8]

Mechanism

In vitro, various angiotensin II antagonists have some cytochrome P450 isoenzyme CYP2C9 inhibitory activity,[9] and it is therefore possible that they might reduce warfarin metabolism.

Importance and management

Despite the reported *in vitro* inhibitory effects on CYP2C9 reported for some angiotensin II antagonists, the available pharmacokinetic and pharmacodynamic studies show that the angiotensin II receptor antagonists (candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan) do not interact with warfarin to a clinically relevant extent. The lack of any published evidence to the contrary suggests that no warfarin dose adjustments should be needed if these drugs are given together.

Coumarins + Antacids

There is some evidence that the absorption of dicoumarol may be increased by magnesium hydroxide. Aluminium hydroxide does not interact with either warfarin or dicoumarol, and magnesium hydroxide does not interact with warfarin.

Clinical evidence

(a) Dicoumarol

In a study in 6 healthy subjects, **magnesium hydroxide** (*Milk of Magnesia*) 15 mL, taken with and 3 hours after a single dose of dicoumarol, was found to raise the peak plasma levels and AUC of dicoumarol by 75% and 50%, respectively. Conversely, **aluminium hydroxide** (*Amphogel*) 30 mL did not alter dicoumarol levels.[1]

(b) Warfarin

In a study in 6 healthy subjects, **aluminium/magnesium hydroxide** (*Maalox*) 30 mL, given with and for four 2-hourly doses after warfarin, had no effect on the plasma warfarin levels or on the anticoagulant response.[2] Similarly, neither **aluminium hydroxide** (*Amphogel*) 30 mL nor **magnesium hydroxide** (*Milk of Magnesia*) 15 mL, taken with and 3 hours after a single 75-mg dose of warfarin, had any effect on warfarin peak levels or AUC.[1]

Mechanism

It is suggested that dicoumarol forms a more readily absorbed chelate with magnesium so that its effects are increased.[1,3] An *in vitro* study suggested that the absorption of warfarin may be decreased by **magnesium trisilicate**,[4] where as another *in vitro* study found no effect.[5]

Importance and management

No special precautions need be taken if aluminium or magnesium hydroxide antacids are given to patients taking warfarin, or if aluminium hydroxide is given to those taking dicoumarol. Despite the evidence of increased absorption of dicoumarol with magnesium hydroxide, there seems to be no direct clinical evidence of any important adverse interaction for this combination, or indeed between any coumarin and an antacid.

Coumarins + Antibacterials

Altered (usually enhanced) response to anticoagulation with a coumarin has been reported with virtually every class of antibacterial. While some such as sulfamethoxazole, clearly have a pharmacokinetic interaction, for others there is no clear explanation for why an interaction might be expected. Theoretical mechanisms include reduced intestinal bacterial production of vitamin K_2 substances, or reduced enterohepatic recycling. Possible confounding mechanisms include a reduction in dietary vitamin K_1

intake because of illness, or the effect of fever or infection on coagulation or drug metabolism.

Clinical evidence and mechanism

Various studies have implicated antibacterials in general as being a risk factor for over-anticoagulation. For example, in a large prospective cohort study, INR levels of greater than 7 were recorded in 31 patients. When compared with 100 patients with stable INRs, these 31 patients were more likely to have been treated with an antibacterial (not specified) in the previous 4 weeks (odds ratio 6.2), and more likely to have an intercurrent illness (odds ratio 4.48).[1] Various mechanisms may be responsible for these findings, and these are discussed below.

(a) Confounding effects relating to the infection

1. Dietary factors. Patients taking coumarins and related drugs are advised to maintain a constant dietary intake of vitamin K_1 as sustained changes in intake of vitamin K_1-rich foods, such as green leafy vegetables, causes clinically relevant changes in anticoagulation. See 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464. It is therefore possible that patients who stop eating for more than a day or so could develop over-anticoagulation. The same could happen with a reduced appetite leading to a sustained reduction in intake of vitamin K_1-rich foods.

2. Fever. Fever might possibly be a confounding factor in reports of interactions between antibacterials and warfarin, because it might increase the catabolism of vitamin K-dependent coagulation factors by producing a hypermetabolic state. However, in one cohort study, there was no difference in the frequency of fever between patients who developed over-anticoagulation (INR greater than 6) while taking antibacterials and those who did not develop over-anticoagulation while taking antibacterials.[2]

3. Reduced metabolism. There is some evidence from *animal* studies that infection can down regulate cytochrome P450 isoenzymes, which might result in reduced drug metabolism.[3] Whether the metabolism of warfarin is different during an acute infection does not appear to have been studied.

(b) Effects relating to the antibacterial

1. Direct anticoagulant effects. Cephalosporins and related beta lactams with an *N*-methylthiotetrazole or similar side-chain can occasionally cause enough hypoprothrombinaemia for bleeding to occur when they are used alone, and this effect might therefore be additive with coumarins, although there is not that much evidence to support this, see 'Coumarins and related drugs + Antibacterials; Cephalosporins and related drugs', p.415.

2. Intestinal production of vitamin K_2 substances by bacteria. The activity of intestinal microflora produces menaquinones (vitamin K_2 substances). Suppression of the microflora might therefore result in reduced vitamin K_2, and hence reduced synthesis of vitamin-K dependent clotting factors. There is some evidence from studies in healthy subjects receiving vitamin-K_1 restricted diets and taking warfarin that giving menaquinones (an extract of bacterially synthesised material) decreases the response to warfarin.[4] In addition, natto, a fermented soya bean product which is a rich source of bacterially-derived menaquinones, markedly inhibits the effect of warfarin (see 'Coumarins + Food; Soya bean products', p.463). It is therefore possible that antibacterials that decimate gut microflora might increase the effect of warfarin by reducing vitamin K_2 levels. However, this effect might be important only if vitamin-K_1 intake from dietary sources is also reduced.

3. Protein-binding displacement. Many drugs can displace warfarin from protein-binding sites leading to an increase in unbound (active) concentrations of warfarin. However, any effect is transient, as the unbound warfarin is quickly metabolised. The exception to this is if the metabolism of warfarin is markedly inhibited at the same time. On rare example of a drug that is known to interact by both these mechanisms is phenylbutazone, see 'Coumarins and related drugs + NSAIDs; Phenylbutazone and related drugs', p.488. Altered protein binding has not clearly been shown to be an important mechanism in any interaction between warfarin and an antibacterial, but it is often suggested as one.

4. Reduced or increased metabolism. Sulfamethoxazole clearly inhibits the metabolism of warfarin by the cytochrome P450 isoenzyme CYP2C9, so enhancing its effect. Some macrolides such as erythromycin inhibit CYP3A4, and therefore have a minor inhibitory effect on *R*-warfarin, which would, on its own, be unlikely to be of any clinical relevance. Conversely, rifampicin (rifampin), see 'Coumarins + Antibacterials; Rifamycins', p.424, is a well established inducer of drug metabolism, and clearly reduces the effect of warfarin. Nafcillin (see 'Coumarins + Antibacterials; Penicillins', p.421) also appears to markedly reduce the effects of warfarin. Most other antibacterial classes have no clinically relevant effect on warfarin pharmacokinetics.

Importance and management

All these factors in their own right might affect the intensity of anticoagulation. Therefore, a few case reports of an enhanced response to warfarin on starting a specific antibacterial does not necessarily imply that the antibacterial has a direct interaction with warfarin. Conversely, demonstration of a lack of a specific interaction between an antibacterial and warfarin in a controlled study does not mean that a patient prescribed that drug for an infection will not have a change in coagulation status. Therefore, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected. Monitor within 3 days of starting the antibacterial. The expectation of an interaction should not exclude the use of an antibacterial if it is considered clinically appropriate.

Coumarins and related drugs + Antibacterials; Aminoglycosides

Limited data suggest that no clinically significant interaction occurs between dicoumarol or warfarin and oral neomycin or paromomycin in most patients. However, individual patients have shown some alteration in anticoagulant effect (usually increases) when given oral neomycin and parenteral streptomycin, and a marked increased risk of hospitalisation for bleeding has been reported in patients taking acenocoumarol and phenprocoumon and given neomycin.

Clinical evidence

(a) Neomycin

Six out of 10 patients taking **warfarin** who were given oral neomycin (2 g daily[1] or 4 g daily[2]) over a 3-week period had a gradual increase in their prothrombin times averaging 5.6 seconds.[1,2] Similarly, in patients taking an unnamed anticoagulant, 2 of 5 given oral neomycin with bacitracin had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% to less than 6%. This suggests an *increase* in anticoagulant effect.

Five of 7 patients taking unnamed anticoagulants had no change in their mean daily dose of anticoagulant when given oral **neomycin** 1 to 2 g daily for 18 weeks. Of the remaining two, one required an increase of about 100%, and one required a small 27% decrease.[3]

In a retrospective cohort study,[4] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given neomycin was very high (relative risk 43). However, as the incidence of concurrent use was low (only 25 patients), the confidence interval was very broad (range 6 to 308).

(b) Paromomycin

The concurrent use of oral **paromomycin** 2 g daily with **dicoumarol** or **warfarin** did not alter anticoagulant requirements in 2 subjects.[5]

(c) Streptomycin

One of 3 patients given parenteral **streptomycin** 500 mg twice daily, and 2 patients given parenteral **streptomycin** 500 mg twice daily with 1 million units of penicillin daily had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% down to 6 to 9%. This suggests an *increase* in anticoagulant effect.[6]

Mechanism

Not understood. One idea is that these antibacterials increase the effects of these coumarins by diminishing the bacterial population in the gut, there-

by reducing their production of vitamin K_2 substances, see 'Coumarins + Antibacterials', p.413. Another suggestion is that these antibacterials decrease the vitamin K_1 absorption as part of a general antibacterial-induced malabsorption syndrome.[7]

Importance and management

A sparsely documented interaction. The data implies that, rarely, an increased risk of bleeding may occur if aminoglycosides are given with coumarins but common experience seems to confirm that normally no interaction of any significance occurs. The data relating to acenocoumarol and phenprocoumon and neomycin need confirming.

One manufacturer of **gentamicin** suggests that concurrent use with oral anticoagulants may decrease thrombin levels,[8] which would be expected to increase the risk of bleeding, but there appears to be little evidence to suggest that this usually occurs. However, occasionally vitamin K deficiency and/or spontaneous bleeding is seen after the prolonged use of broad-spectrum antibacterials in association with a totally inadequate diet, starvation or some other condition in which the intake of vitamin K is very limited.[9,10] Under these circumstances the effects of the vitamin-K antagonist anticoagulants (both coumarins and **indanediones**) would be expected to be significantly increased and appropriate precautions should be taken.

Coumarins + Antibacterials; Aminosalicylic acid and/or Isoniazid

A report attributes bleeding in a patient taking warfarin to the concurrent use of isoniazid. Another report describes a markedly increased anticoagulant response in a patient taking warfarin when the dose was doubled and aminosalicylic acid and isoniazid were started.

Clinical evidence

A man who had recently started to take **warfarin** 10 mg daily and isoniazid 300 mg daily began to bleed (haematuria, bleeding gums) within 10 days of accidentally doubling his dose of isoniazid. His prothrombin time had increased from about 26 seconds to 53 seconds.[1] Another patient taking digoxin, potassium chloride, docusate, diazepam and **warfarin** 2.5 mg daily, was also given aminosalicylic acid 12 g, isoniazid 300 mg and pyridoxine 100 mg daily, and at the same time the warfarin dose was doubled to 5 mg daily. His prothrombin time increased from 18 seconds to 130 seconds over 20 days but no signs of bleeding were seen.[2]

Mechanism

Not understood. It seems possible that isoniazid may inhibit the metabolism of the coumarin anticoagulants, because *in vitro* study in human liver microsomes has shown that it inhibits *S*-warfarin 7-hydroxylation by the cytochrome P450 isoenzyme CYP2C9,[3] but this needs confirmation *in vivo*. Isoniazid increased the anticoagulant effects of dicoumarol in *dogs*[4] but not of warfarin in *rabbits*.[5] Two patients taking isoniazid, aminosalicylic acid and streptomycin (but not taking anticoagulants) developed haemorrhage, which was attributed to the effects of isoniazid alone.[6]

Importance and management

These two isolated cases of possible interactions are far from conclusive, and the interactions of warfarin with isoniazid and aminosalicylic acid are not established. Nevertheless, given that the *in vitro* data suggest that isoniazid might inhibit warfarin metabolism, some caution might be appropriate. If this is the case, similar caution may also need to be extended to other coumarins that are metabolised in the same way as warfarin, such as **acenocoumarol**. Further study is needed.

Coumarins and related drugs + Antibacterials; Cephalosporins and related drugs

Cephalosporins and related beta lactams with an *N*-methylthiotetrazole or similar side-chain can occasionally cause bleeding when they are used alone. These effects could therefore be additive with those of the coumarins. Some studies and cases of raised INRs and bleeding have been reported with both warfarin and acenocoumarol.

Of the cephalosporins not having an *N*-methylthiotetrazole or related side-chain, a few cases of over-anticoagulation have been reported for cefixime and cefaclor with coumarins and phenindione, and an increased risk of haemorrhage has been reported in patients taking coumarins with cefuroxime and cefradine.

Clinical evidence

(a) Cephalosporins with N-methylthiotetrazole or similar side-chains

Note that cephalosporins with N-methylthiotetrazole or similar side-chains can cause bleeding alone. For example, serious bleeding following the use of **cefamandole** (in the absence of an anticoagulant) has been described in 3 out of 37 patients in one report,[1] and a further report highlights a further 16 cases.[2] Other similar cephalosporins and related beta lactams that have been reported to cause hypoprothrombinaemia when used alone include **cefoperazone**,[3-7] **cefotetan**,[8] **ceftriaxone**,[9] **cefalotin**,[10] **cefazolin**,[11-13] and **latamoxef**.[14,15] The incidence is very variable: in some instances only isolated cases have been reported whereas a 15% bleeding rate was found in one study[15] with **latamoxef** alone, 22% in another[14], but only 8% with **cefoxitin** alone.[14] These cephalosporins might therefore worsen the risk of bleeding by simple addition if given with coumarin or **indanedione** anticoagulants. In addition, some of them may also inhibit platelet function.[16]

1. Cefamandole or cefazolin. Two patients who had received prophylactic cefamandole before cardiac valve replacement developed unusually high prothrombin times, with bleeding in one case, within 48 hours of an initial dose of **warfarin** 10 mg. Because of this, the records of a total of 60 other patients who had undergone heart valve replacement surgery were reviewed. They had been given prophylactic antibacterials before the chest incision was made, and every 6 hours thereafter for about 72 hours. The 44 patients given cefamandole 2 g showed a much greater anticoagulant response than the 16 patients given vancomycin 500 mg. Fourteen of the cefamandole group had a prothrombin time greater than 32 seconds after the initial **warfarin** dose, compared with only one of the vancomycin group.[17] In a later randomised study by the same workers, the prothrombin times as a percentage of activity after 3 days of concurrent use with **warfarin** were cefamandole 29%, cefazolin 38%, and vancomycin 51%. This suggests that cefamandole had a much greater effect on anticoagulant response than vancomycin.[18]

2. Cefonicid. In a study in 9 patients stabilised on **warfarin**, there was no change in prothrombin times when they were given intravenous cefonicid 2 g daily for 7 days.[19] In contrast, a later study identified 9 patients taking **acenocoumarol** who had increased INRs within 3 to 8 days of being given cefonicid. They needed a reduction in the anticoagulant dose of about

one-third to one-half.[20] Another patient stabilised on **acenocoumarol**, with a prothrombin index of 28% bled 2 days after starting cefonicid 1 g daily and had a prothrombin index of less than 5%.[21]

3. Cefotiam. Severe haemorrhage has been reported in 3 patients taking **acenocoumarol** with cefotiam. One developed an abdominal haematoma and an INR of 10.4 within 2 days. Another had gastrointestinal bleeding and melaena after one day of concurrent use. The third died from intracranial haemorrhage on the day she started cefotiam.[22]

(b) Cephalosporins without N-methylthiotetrazole or similar side-chains

1. Cefaclor. Over the period 1979 to 1997, there had been 3 cases of raised INRs with or without clinical bleeding in patients taking **acenocoumarol**, **warfarin** or an unknown anticoagulant and cefaclor reported to the CSM in the UK.[23] No cases seem to have been published.

2. Cefixime. Cefixime has also been implicated in a handful of cases of bleeding and/or increased INRs in patients taking **warfarin** or the indanedione **phenindione**, but the evidence is inconclusive.[24] No cases seem to have been published.

3. Cefradine. In a retrospective cohort study, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and also taking cefradine was very high (relative risk 43). This equated to 1 major bleed per 100 cefradine dispensings during coumarin use.[25]

4. Cefuroxime. In a retrospective case-control study,[26] there was a moderate increased risk of hospitalisation for haemorrhage in acutely ill elderly patients who had received cefuroxime prior to admission (odds ratio 1.62). A retrospective review of the effect of antibacterials on INR in children taking **warfarin** mentions that a 2-and-a-half-year-old child had an INR of 6.7 five days after starting oral cefuroxime.[27]

(c) Unnamed cephalosporins

In a prospective study of the effect of antibacterials on anticoagulation, none of the 36 patients taking **warfarin** and prescribed an oral cephalosporin (not named) experienced a change in their INR.[28] Conversely, a mean INR rise of 1.2 was reported in 12 children taking **warfarin** and receiving cephalosporins.[27] In a large analysis of claims data, use of cephalosporins (unnamed) with **warfarin** was associated with a very slight increase in risk of haemorrhage of 1.16, which was statistically significant.[29]

Mechanism

Cephalosporins with an *N*-methylthiotetrazole side-chain can, like the oral anticoagulants, act as vitamin K antagonists to reduce the production of some blood clotting factors. They can therefore cause bleeding on their own, which would be expected to be additive when used with an anticoagulant. Some of these cephalosporins may also inhibit platelet function.[16]

Ceftriaxone seems to act similarly although it has an *N*-methylthio*triazine* ring instead, as does cefazolin, which has an *N*-methylthiadiazolethiol side-chain. **Aztreonam** can also increase the prothrombin time.[30-33]

Importance and management

Most cephalosporins and related beta lactams do not normally cause bleeding so would not be expected to have an additive interaction with the oral anticoagulants. In contrast, cephalosporins with the *N*-methylthiotetrazole or similar side-chains appear to increase the risk of bleeding, and might therefore interact. Both **cefamandole** and to a lesser extent **cefazolin** have been shown to increase the response to warfarin, and cases of over-anticoagulation have been reported for **cefonicid** and **cefotiam**. All other cephalosporins and related beta-lactams with the *N*-methylthiotetrazole or similar side-chains might be expected to interact similarly, but have not so far been reported to specifically interact with anticoagulants. These include **cefalotin**, **cefmenoxime**, **cefmetazole**, **cefminox**, **cefoperazone**, **ceforanide**, **cefotetan**, **cefpiramide**, **ceftriaxone**, and **latamoxef**. **Aztreonam** has also been predicted to interact similarly, although, again there are no reports. Patients most at risk seem to be those whose intake of vitamin K is restricted (poor diet, malabsorption syndromes, etc.) and those with renal impairment. The use of an anticoagulant represents just another factor that may precipitate bleeding.

A possible solution to the problem is to use a non-interacting cephalosporin. Alternatively the outcome should be closely monitored, particularly in the early stages of treatment, adjusting the anticoagulant dosage if necessary. Excessive hypoprothrombinaemia can be controlled with vitamin K. Although they do not an *N*-methylthiotetrazole side-chain, the manufacturers of **cefixime** and **cefaclor** have a few cases of over-anticoagulation on record, and an increased risk of haemorrhage has been reported for cefradine and cefuroxime.

Even with non-interacting cephalosporins, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status (see 'Coumarins + Antibacterials', p.413). Monitor within 3 days of starting the antibacterial.

Coumarins + Antibacterials; Chloramphenicol

There is some limited evidence to suggest that the anticoagulant effects of acenocoumarol and dicoumarol can be increased by oral chloramphenicol. An isolated report attributes a marked rise in the INR of a patient taking warfarin to the use of chloramphenicol eye drops.

Clinical evidence

A study in 4 patients found that the half-life of **dicoumarol** was increased on average from 8 hours to 25 hours when they were given oral chloramphenicol 2 g daily for 5 to 8 days.[1]

Three out of 9 patients taking an unnamed anticoagulant had a fall in their prothrombin-proconvertin values from a range of 10 to 30% down to less than 6% (suggesting an increased anticoagulant effect) when given oral chloramphenicol 1 to 2 g daily for 4 to 6 days. One patient had a smaller reduction.[2] In early clinical experience with **acenocoumarol**, one of 3 patients taking chloramphenicol had greater sensitivity to the anticoagulant.[3]

An isolated report describes an 83-year-old woman stabilised on **warfarin** who had a rise in her INR to about 8.9 from her normal range of 1.9 to 2.8 within 2 weeks of starting to use eye drops containing chloramphenicol 5 mg/mL, dexamethasone sodium phosphate 1 mg/mL and tetrahydrozoline hydrochloride 0.25 mg/mL. She used one drop in each eye four times daily.[4] Hypoprothrombinaemia and bleeding have also been described in patients given intramuscular,[5] intravenous,[5] or oral[6] chloramphenicol in the absence of an anticoagulant.

Mechanism

Uncertain. One suggestion is that the chloramphenicol inhibits the liver enzymes concerned with the metabolism of the anticoagulants so that their effects are prolonged and increased.[4] An *in vitro* study with human liver microsomes found that chloramphenicol did not inhibit the hydroxylation of *S*-warfarin, but it did inhibit *R*-warfarin metabolism, probably by the cytochrome P450 isoenzyme CYP3A4.[7] Another suggestion is that the antibacterial diminishes the gut bacteria thereby decreasing a source of vitamin K, but it is doubtful if these bacteria are normally an important source of the vitamin except in exceptional cases where dietary levels are very inadequate.[8] A third suggestion is that chloramphenicol blocks the production of prothrombin by the liver.[5] See also 'Coumarins + Antibacterials', p.413.

Importance and management

The documentation for the interaction between anticoagulants and oral chloramphenicol is very sparse and poor (the best being the pharmacokinetic report about dicoumarol) so that this interaction is by no means adequately established. There would therefore appear to be little reason for avoiding concurrent use, but it would seem prudent to monitor prothrombin times if oral chloramphenicol is started in patients taking a coumarin, being alert for the need to reduce the anticoagulant dose.

The report about an apparent interaction between warfarin and topical chloramphenicol is surprising because the amount of chloramphenicol absorbed from eye drops is relatively small and because, despite the very widespread use of warfarin and chloramphenicol for very many years, this report appears to be the only one. This suggests that any such interaction is very unlikely indeed.

Coumarins + Antibacterials; Clindamycin

Two isolated cases of a marked increase in INR and/or bleeding have been attributed to an interaction with clindamycin. However, a report found no cases of a serious increase in INR in patients taking acenocoumarol or phenprocoumon with clindamycin.

Clinical evidence, mechanism, importance and management

A 47-year-old woman with multiple medical problems stabilised on **warfarin** (and also taking azathioprine, captopril, furosemide, insulin, captopril, prednisone, levothyroxine, valproic acid and zolpidem) had all her teeth removed under general anaesthetic. Sixteen days later she needed a dental abscess drained and was given oral clindamycin 300 mg four times daily with ibuprofen 600 mg for any discomfort. On day 17 she needed a suture to stop some bleeding and her INR was found to be 3.5. By day 20 she had developed more severe oral bleeding, which needed emergency room treatment. Her INR was found to have risen to 13 and her haematocrit decreased to 18%. She was treated successfully with a blood transfusion and vitamin K.[1]

A retrospective review of the effect of antibacterials on INR in children taking **warfarin** mentions that an INR of 8.5 was noted in a 4-year-old child, 6 days after clindamycin was started.[2]

These appear to be isolated cases, from which no general conclusions should be drawn because the whole picture is so uncertain. Note that in a cohort study, none of 37 patients stabilised on **acenocoumarol** or **phenprocoumon** developed over-anticoagulation (an INR greater than 6) when they were given clindamycin.[3] However, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected. Monitor within 3 days of starting the antibacterial (see also 'Coumarins + Antibacterials', p.413).

Coumarins + Antibacterials; Linezolid

Linezolid had only minor effects on the pharmacokinetics and anticoagulant activity of single-dose warfarin in one study.

Clinical evidence, mechanism, importance and management

Linezolid 600 mg twice daily was given to 13 healthy subjects for 5 days followed by a single 25-mg dose of **warfarin**. The pharmacokinetics of **warfarin** with linezolid were within 20% of those seen with **warfarin** alone, and the INR was minimally affected (about a 10% increase in maximal INR).[1] These effects were not considered to be clinically relevant.

However, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected. Monitor within 3 days of starting the antibacterial. See also 'Coumarins + Antibacterials', p.413.

Coumarins + Antibacterials; Macrolides

Most controlled studies suggest that macrolides do not cause clinically relevant changes in the pharmacokinetics or anticoagulant effects of warfarin. There is less information about other anticoagulants, but two retrospective studies of acenocoumarol and phenprocoumon have variously shown an increased risk (azithromycin, clarithromycin), a non-significant increased risk (erythromycin) or no increased risk of bleeding (clarithromycin, erythromycin, roxithromycin). Furthermore, a number of case reports describe marked increases in INRs and/or bleeding in patients taking coumarins and macrolides.

Clinical evidence

(a) Azithromycin

There are no studies of the effect of azithromycin on the pharmacokinetics of coumarins. One pharmacodynamic study and two retrospective studies suggest that no interaction occurs with warfarin. However, two retrospective studies and at least 7 published case reports suggest an interaction might occur with coumarins. These are discussed below.

1. Acenocoumarol or Phenprocoumon. In a retrospective cohort study, the relative risk of hospitalisation for bleeding in patients taking acenocoumarol or phenprocoumon and given azithromycin was 4.1. This only just reached statistical significance (confidence interval range, 1 to 16.2), and represented one major bleed per 1250 azithromycin dispensings.[1]

2. Warfarin. The manufacturer notes that, in healthy subjects, a 5-day course of azithromycin (500 mg on day one then 250 mg daily for 4 days) did not affect the prothrombin time response to a single 15-mg dose of warfarin.[2,3]

A retrospective study of 26 patients stabilised on warfarin found no evidence that the use of azithromycin had any effect on their INRs. The patients had stable INRs for a least 2 consecutive measurements before receiving azithromycin, and an INR taken within 14 days (9 patients) or 30 days (17 patients) of starting the azithromycin.[4] The same finding was reported in another similar smaller study in 17 patients.[5] A major disadvantage of these 2 retrospective studies is the small numbers of patients who had an INR measurement within 7 days of starting azithromycin.

In contrast, in another retrospective study of 32 patients stabilised on warfarin, there was a mean increase in INR of 0.51 after starting azithromycin (5 patients had an INR of greater than 4, and one patient had an INR greater than 5). The patients had stable INRs for a least 2 consecutive measurements before receiving azithromycin, and an INR taken within 3 to 15 days of starting the azithromycin.[6] Moreover, there are now a number of published case reports suggesting that azithromycin might potentiate the activity of warfarin.[7-14] In one of these cases, a 57-year-old woman stabilised on warfarin with an INR ranging from 1.75 to 3.03 in the previous 3 months took a 5-day course of azithromycin (500 mg on day one, then 250 mg daily for 4 days) for a possible upper respiratory tract infection. Two days after completing the azithromycin, a routine INR was found to be 8.32. She had no signs or symptoms of bleeding. During the infection she had a fever on the second day, and she reduced her 'smoking', (p.514), from one pack of cigarettes daily to one pack over 3 days.[11] In other cases, a rise in INR of 40% to sixfold occurred within 1 to 7 days of starting azithromycin.[7-10,12,13] Three patients had bleeding complications,[8,9,12] and 4 required vitamin K administration.[8-10,12] Most of these patients had possible confounding factors such as recent increases in warfarin dose,[9,10] other concurrent antibacterials,[10,13] fever and decreased appetite,[7,12] or complex disease states and heart failure.[8-10,12]

The manufacturers[15] say that as of December 1998, they had received 47 reports (40 in the US, 7 elsewhere in the world, including 2 in the UK) of possible interactions between azithromycin and warfarin. A 2004 report from the Australian Adverse Drug Reactions Advisory Committee said they had received 3 reports of interactions between warfarin and azithromycin,[16] which presumably includes the 2 published cases.[10]

(b) Clarithromycin

There are no studies of the effect of clarithromycin on the pharmacokinetics of coumarins. However, there are at least 13 cases of increased INRs in published reports, and one cohort study suggesting that the use of clarithromycin is associated with an increased risk of bleeding in patients taking coumarins. Conversely, in another cohort study the increased risk was small and not significant. These are discussed below.

1. Acenocoumarol or Phenprocoumon. The INR of a 75-year-old woman stabilised on acenocoumarol rose from 2.1 to 9 within a week of starting to take clarithromycin 250 mg twice daily.[17] Five patients stabilised on acenocoumarol had a mean increase in their INRs from about 2.5 to 5.5 when they took clarithromycin.[18] The largest increase was from 1.95 to 7.01.

A 70-year-old woman stabilised on phenprocoumon developed a marked increase in prothrombin time from a range of 140 to 180 seconds up to 304 seconds, but no bleeding, within 4 days of starting to take clarithromycin 500 mg daily. The phenprocoumon was stopped and phytomenadione given. When the antibacterial was withdrawn she was restabilised on the original dose of phenprocoumon.[19]

In one cohort study in patients taking acenocoumarol or phenprocoumon, clarithromycin significantly increased the risk of over-anticoagulation (INR greater than 6: relative risk of 11.7 range 3.6 to 37.8). The risk was highest during the first 3 days of concurrent use.[20] However, in another retrospective cohort study[1] by the same research group, the relative risk of hospitalisation for haemorrhage in patients taking acenocoumarol or phenprocoumon and clarithromycin was just 1.8, and was not statistically significant (range 0.4 to 7).

2. Warfarin. In 1992 the CSM in the UK notified prescribers in the UK of a case of a woman taking warfarin for mitral valve disease who suffered a fatal cerebrovascular bleed 3 days after starting to take clarithromycin.[21] Her INR was above 10. A further patient stabilised on warfarin had a suprachoroidal haemorrhage 7 days after starting clarithromycin 250 mg twice daily, with permanent vision loss. Her INR was 8.2. She had a normal INR (2.3) three days before starting clarithromycin, and also 3 days after starting clarithromycin (2.9).[22]

Other patients taking warfarin have been found to have INRs ranging from 5.6 to 90.3 within 4 to 12 days of starting, or 5 to 14 days of finishing, a course of clarithromycin.[23-26] None of these patients had bleeding complications. In a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia state that they had received 6 reports of interactions between clarithromycin and warfarin (median INR of 7.6), two of which were symptomatic.[16]

(c) Dirithromycin

In a study in 15 healthy subjects the pharmacokinetics and pharmacodynamics of a single 0.5-mg/kg dose of warfarin were not altered when it was given on day 10 of a 14-day course of dirithromycin 500 mg daily.[27]

(d) Erythromycin

Erythromycin caused a minor inhibition of warfarin metabolism in three pharmacokinetic studies. There are also quite a few case reports that describe this interaction. These are discussed below.

1. Acenocoumarol or Phenprocoumon. Haematuria occurred in a patient stabilised on acenocoumarol on the last day of a 14-day course of erythromycin.[28] Another patient stabilised on acenocoumarol with an INR in the range of 3 to 4.5 was found to have an INR of 15 a week after starting to take erythromycin ethylsuccinate 1.5 g daily but no bleeding was seen.[29]

Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients taking erythromycin (78 patients received this antibacterial).[20] Note that this study did show an increase for *clarithromycin*, see above. In yet another retrospective cohort study[1] by the same research group, the relative risk of hospitalisation for haemorrhage in patients taking acenocoumarol or phenprocoumon and erythromycin was 4.2, but this was not statistically significant (confidence interval range 0.6 to 30).

2. Warfarin. A study in 12 healthy subjects found that the clearance of a single 1-mg/kg dose of warfarin was reduced by an average of 14% (range 0 to about 30%) when taken on day 5 of an 8-day course of erythromycin 250 mg every 6 hours. This change was greatest in those subjects with relatively slow warfarin clearance rates.[30] In another similar study, warfarin 0.5 mg/kg, given on day 10 of a 14-day course of erythromycin 250 mg four times daily increased the AUC of *S*-warfarin by 11% and of *R*-warfarin by 12%. The INR increased by 10%.[27] Similar effects were seen in another study in 8 patients stabilised on warfarin and who did not have infections. In these patients, erythromycin 333 mg three times daily for 7 days caused a mean 10% increase in the prothrombin time ratio, which was maximal by day 2 to 5. There was also a mean 9% increase in the total plasma warfarin level, which was similar for the *S*- and *R*-enantiomers, and was maximal by day 7. No patient had a prothrombin time ratio above the therapeutic range and none required a reduction in warfarin dose.[31]

In contrast to the modest effects in the above studies, various case reports have demonstrated a marked increase in INR. For example, an elderly woman taking warfarin developed haematuria and bruising within a week of starting to take erythromycin stearate 500 mg four times daily for a chest infection. Her prothrombin time had risen to 64 seconds (prothrombin time ratio about 5.5). Within the previous month she had started taking digoxin and quinidine, and had her warfarin dose increased because of a decrease in prothrombin time.[32] At least 10 other cases of bleeding and/or an increase in prothrombin time or INR have been described in patients taking warfarin with erythromycin (as the base, ethylsuccinate, stearate, or lactobionate).[14,33-40] In addition, in a brief report in 2004, the Adverse Drug Reactions Advisory Committee of Australia stated that they had received 19 reports of interactions between erythromycin and warfarin (median INR of 9.7), only 4 of which were symptomatic.[16]

There is also a case report of sulfonamide-induced bullous haemorrhagic eruption in a patient taking warfarin, 'co-trimoxazole', (p.425), and erythromycin, in which the authors considered an interaction between warfarin and erythromycin may have contributed to the haemorrhagic component.[41]

(e) Midecamycin diacetate

The pharmacokinetics of a single 8-mg oral dose of acenocoumarol were not significantly changed when it was taken on day 4 of a 9-day course of midecamycin diacetate 800 mg twice daily.[42]

(f) Roxithromycin

Roxithromycin did not alter the pharmacokinetics or effect of warfarin in one study. However, there are at least 2 published cases of interactions with coumarins, and one report reviewing 16 cases. These are discussed below.

1. Acenocoumarol. A 79-year-old man stabilised on acenocoumarol developed an abdominal wall haematoma 2 days after starting to take roxithromycin 150 mg twice daily for a lung infection.[43] Six days later, on admission to hospital, his INR was found to be 5.9. Conversely, in one cohort study in patients taking acenocoumarol or phenprocoumon, no cases of over-anticoagulation (INR greater than 6) occurred in patients treated with roxithromycin (only 14 patients received this antibacterial).[20] Note that this study did show an increase for *clarithromycin*, see above.

2. Phenprocoumon. A 75-year-old man taking phenprocoumon developed a marked increase in prothrombin time but no bleeding when he was given roxithromycin 300 mg daily for 5 days. The phenprocoumon was stopped and phytomenadione given. When the antibacterial was withdrawn he was restabilised on the original dose of phenprocoumon.[19] For mention of a cohort study in patients stabilised on phenprocoumon or acenocoumarol showing no increased risk of over-anticoagulation with roxithromycin, see *Acenocoumarol*, above.

3. Warfarin. In a study in which warfarin was given at a daily dose sufficient to maintain the thrombotest percentages at 10 to 20%, there was no difference in warfarin dose or AUC between 10 subjects given roxithromycin 150 mg twice daily for 2 weeks and 11 subjects given placebo. The dose of warfarin and the AUC of warfarin increased by about 10% in both the roxithromycin group and the placebo group, which was taken as indicating that steady state had not been achieved. Serum roxithromycin levels were unchanged by warfarin.[44] In contrast, during the 1992 to 1995 period The Centre for Adverse Reactions Monitoring of New Zealand (ADRAC) received 7 reports of a possible interaction with roxithromycin resulting in increased warfarin effects, and, during the same period, the Adverse Drug Reactions Advisory Committee of Australia received 9 similar reports. Review of the 16 cases found that 7 patients had clinical symptoms of over-anticoagulation, and the other 9 were asymptomatic and detected by routine testing.[45] In a 2004 update from ADRAC, it was noted that they now had on record 56 cases of an interaction between roxithromycin and warfarin, with 27 cases being symptomatic. The median INR was 8.8, and the median time to onset was 6 days. One fatality occurred in a 79-year-old woman who started taking warfarin and roxithromycin at the same time. By day 8, she had an INR of 11.6, and subsequently died from widespread bleeding.[16]

(g) Telithromycin

In a placebo-controlled, crossover study in healthy subjects, telithromycin 800 mg daily for 7 days did not alter the pharmacodynamics of a single-dose of warfarin 25 mg given on day 4. There was a small 20% increase in the AUC of *R*-warfarin, and a 5% increase in the AUC of *S*-warfarin,[46] effects which the manufacturer does not consider to be clinically relevant.[47,48]

Conversely, a 73-year-old man taking warfarin for a metallic valve replacement started taking telithromycin 800 mg daily for 5 days for a cough. On the last day of treatment he developed haemoptysis and was found to have an INR of 11. His INR 10 days before telithromycin was started was 3.1. The telithromycin was stopped and he was subsequently restabilised on warfarin.[49] Moreover, Health Canada reported that from May 2003 to September 2004 they had received 7 reports of suspected coagulation disorder interactions with telithromycin, 6 with warfarin and one with an unspecified oral anticoagulant. The INR was increased in 6 of the reports and decreased in the seventh.[50] A case of a rectal sheath haematoma with an INR rise to 6 occurred 6 days after starting telithromycin 800 mg daily in a patient stabilised on acenocoumarol.[51]

(h) Unspecified macrolides

In a prospective study of the effect of antibacterials on anticoagulation, the INR increased by an estimated 0.319 when 35 patients taking warfarin also took an oral macrolide (not named).[52] In a retrospective review of the effect of antibacterials on INR in children taking warfarin, the mean INR increase in 18 children who had received a macrolide was just 0.9, and a large part of this was due to two children who had marked INR rises with erythromycin and azithromycin.[14]

Mechanism

Erythromycin, clarithromycin and telithromycin are known inhibitors of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the 'metabolism of warfarin', (p.405), specifically the less active *R*-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. However, it is possible that even these small changes might be important in a very few patients, particularly those with a low prothrombin complex activity.[30] Other macrolides (azithromycin, dirithromycin, roxithromycin) have much less effect on CYP3A4 than erythromycin or clarithromycin, and consequently would be expected to have even less effect on the pharmacokinetics of warfarin or acenocoumarol, which is borne out in the few studies available. Nevertheless, cases of interactions have been reported for nearly all these macrolides. Moreover, one cohort study found that clarithromycin increased the risk of an interaction and erythromycin did not. It is possible that there is some other, as yet unidentified, mechanism involved. Alternatively, it is equally possible that the relatively few cases just represent idiosyncratic effects attributable to other factors, such as those secondary to being acutely ill, and not to any interaction (see also 'Coumarins + Antibacterials', p.413).

Importance and management

The minor pharmacokinetic interaction with erythromycin and warfarin is established, but would not generally be expected to be clinically relevant. This is borne out by the relatively few published reports of an interaction (11 published case reports worldwide and 19 cases reported to the Adverse Drug Reactions Advisory Committee of Australia). Other macrolides would be even less likely to inhibit the metabolism of warfarin or acenocoumarol than erythromycin, and this is borne out by studies with dirithromycin, midecamycin and roxithromycin. Nevertheless, cases of important interactions have been reported for most of the other macrolides (azithromycin, clarithromycin, roxithromycin, and telithromycin). Moreover, one cohort study found an increased risk of over-anticoagulation with clarithromycin but not with erythromycin. Taken together, the available evidence suggests that, occasionally and unpredictably the effects of warfarin, acenocoumarol or phenprocoumon may be markedly increased by the macrolides. It would therefore be prudent to increase monitoring in all patients when they are first given any macrolide antibacterial. There is some evidence that this may be particularly important in those who clear warfarin and other anticoagulants slowly and who therefore only need low doses. The elderly in particular would seem to fall into this higher risk category. With azithromycin, bear in mind that, because of its long half-life, the interaction may possibly not become apparent until a couple of days after a short course of azithromycin has been stopped.

If a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected, see also 'Coumarins + Antibacterials', p.413. Monitor within 3 days of starting the antibacterial.

Coumarins + Antibacterials; Metronidazole and related drugs

Limited evidence suggests that metronidazole may cause a marked increase in INR, without bleeding, and increase the risk of haemorrhage in patients also taking warfarin. A few case reports support these findings. One early study found that metronidazole increased the half-life of a single dose of warfarin by one-third and increased its effects. Nimorazole and tinidazole may interact similarly.

Clinical evidence

(a) Metronidazole

In 8 healthy subjects, metronidazole 250 mg three times daily for one week increased the half-life of a single 1.5-mg/kg dose of **warfarin** by about one-third (from 35 to 46 hours), and increased the prothrombin time from a mean of 100 seconds to 142 seconds. When the warfarin enantiomers were given separately, the anticoagulant effects of *S*-warfarin were virtually doubled and the half-life increased by 60%, but the response to *R*-warfarin was only affected in one subject.[1] In a retrospective cohort study, 32 patients taking **warfarin** had an INR reading before and during concurrent metronidazole use. In these patients, the mean INR increased from 2.2 to a maximum of 4.3 by day 8. Fourteen of the 32 patients had an INR above 4, but no bleeding events were recorded.[2] In a large analysis of claims data, the use of metronidazole with **warfarin** was associated with an increased risk of haemorrhage (odds ratio of 1.6).[3]

Bleeding has been seen in 2 patients taking **warfarin** and metronidazole.[4,5] One of them had severe pain in one leg, ecchymoses, and haemorrhage of both legs, and an increase in her prothrombin time from 17 to 19 seconds, up to 147 seconds within 17 days of starting metronidazole.[4] A further report describes 3 elderly patients taking **warfarin**, who developed raised INRs after being given intravenous metronidazole.[6] In the first patient, the INR on admission was 4.6, and so warfarin was stopped. The next day metronidazole was given for about 24 hours, and on day 4 the INR had reached 10.3. In the second patient the INR on admission was 4.9 and so the warfarin was stopped. Later that day metronidazole was started, and the INR was reduced to 1.7 with fresh frozen plasma. Nevertheless by day 5 the INR had reached 6 (metronidazole had been stopped on day 2). In the third patient the INR on admission was 4 and so the warfarin was stopped. Later that day metronidazole was given, and the INR was reduced to 2.1 with fresh frozen plasma. Nevertheless by day 5 (while still receiving metronidazole) the INR had reached 10. In another case, an elderly woman taking **warfarin** developed a profuse nosebleed after a fall with an INR of 8 nine days after starting metronidazole and levofloxacin (which may also interact, see 'Coumarins + Antibacterials; Quinolones', p.422). She was found to have an intracerebral haemorrhage.[7] A cohort study describes one patient taking **warfarin** who had severe bleeding and was found to have an INR of 4.5 two days after starting metronidazole.[8]

(b) Nimorazole

A 66-year-old man who had been taking **phenprocoumon** for 15 years with an INR around 2.5 was diagnosed with carcinoma of the glottis.[9] He received radiotherapy 6 times a week with nimorazole 2.5 g given 1.5 hours before the radiotherapy as a radiosensitiser. At the 16th dose, he had haemoptysis, on the 17th dose continuous haematuria, and then on the 22nd dose his INR was found to be 7.5. Fluconazole (which is also known to interact, see 'Coumarins + Azoles; Fluconazole', p.437), had been started 4 days previously. When the patient had recovered and restarted **phenprocoumon**, he was rechallenged with nimorazole before his last 5 days of radiotherapy, with an INR increase from 3.7 to 5.3.

Mechanism

In the early study, it was suggested that metronidazole probably inhibits the activity of the enzymes responsible for the metabolism (ring oxidation) of the more potent isomer *S*-warfarin, but not *R*-warfarin.[1] Reduction of protein binding coupled with reduced metabolism was suggested by other authors.[6] Nimorazole may act similarly. Note also that infection may affect coagulation status, see 'Coumarins + Antibacterials', p.413.

Importance and management

The interaction between metronidazole and warfarin appears to be established and clinically important, although the documentation is limited. Monitor the INR when both drugs are used and adjust the warfarin dose accordingly. Nothing seems to be documented about other anticoagulants but it would be prudent to expect other coumarins to behave similarly. The single case with nimorazole suggests that caution may also be warranted with this drug, and therefore probably all 5-nitroimidazoles, including **tinidazole**. Note that, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected, see also 'Coumarins + Antibacterials', p.413. Monitor within 3 days of starting the antibacterial.

Coumarins + Antibacterials; Penicillins

Isolated cases of increased prothrombin times and/or bleeding in patients taking coumarins have been seen in patients given amoxicillin (with or without clavulanic acid), intravenous benzylpenicillin, or pheneticillin. There is also some evidence that phenoxymethylpenicillin (penicillin V) does not increase the risk of bleeding in patients taking coumarins.
In contrast, several cases of markedly *reduced* warfarin effects have been seen with nafcillin. Similarly, dicloxacillin may cause a modest reduction in warfarin effects, and an isolated case of thrombosis has been reported.

Clinical evidence

(a) Amoxicillin ± Clavulanic acid

An 81-year-old woman taking **acenocoumarol** 3 mg daily (INR 2.5 to 4) developed bruising and an increased INR of 7.1 within a week of starting amoxicillin 500 mg every 8 hours.[1] In another case, a man stabilised on **warfarin** (INR 2 to 3) had an INR of 5.7 and developed a rectus sheath haematoma 3 days after completing a 7-day-course of co-amoxiclav (amoxicillin with clavulanic acid).[2] In one case, an 85-year-old woman taking **warfarin** was found collapsed at home one week after completing a course of co-amoxiclav. She had an INR of greater than 10 and widespread haemorrhage, and died shortly afterwards.[3] Two cases of raised INRs have been reported in patients who took prophylactic single 3-g doses of amoxicillin before dental treatment.[3] Other possible cases of an interaction between **warfarin** and amoxicillin[4,5] and amoxicillin with clavulanic acid[5,6] have been reported.

In one case control study, use of co-amoxiclav was found to be associated with an increased risk of an INR of greater than 6 (odds ratio 4.1; range 0.9 to 19.2) in patients stabilised on either **acenocoumarol** or **phenprocoumon**. Amoxicillin alone was associated with a smaller increased risk (odds ratio 1.7; range 0.6 to 4.7).[7] Conversely, in a population-based cohort study in similar patients conducted by the same research group, the risk of over-anticoagulation (INR greater than or equal to 6) was greater for amoxicillin alone than amoxicillin plus an enzyme inhibitor. The relative risk for amoxicillin alone was 10.5 (range 5.1 to 21.7) and for amoxicillin plus an enzyme inhibitor was 5.1 (range 1.9 to 13.9).[8] The increased risk was observed in the early stages of concurrent use but was greater after 4 or more days of treatment.[8] In two further cohort studies by this same research group, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given co-amoxiclav was 7 and 4.4, respectively,[9,10] and was 3.1 for amoxicillin alone.[10] Nevertheless, they estimated that the individual risk of major bleeding was low at 1 per 1000 co-amoxiclav dispensings.[10] In another retrospective study of paediatric patients taking **warfarin**, the mean INR increased by 0.8 in 20 children given amoxicillin and in 25 children given co-amoxiclav.[5]

In contrast to these reports of increased anticoagulation, a very brief report states that in an audit of an anticoagulant clinic, 5 patients who had taken amoxicillin had an unspecified decrease in prothrombin time.[11]

(b) Benzylpenicillin

One patient stabilised on **warfarin** (prothrombin time 20 seconds) was found to have an increased prothrombin time of 32 seconds 8 days after starting intravenous benzylpenicillin [14.4 g] daily for subacute bacterial endocarditis. The benzylpenicillin was continued, and the warfarin dose reduced for 18 days. However, the prothrombin time dropped below the therapeutic range, and the warfarin dose was increased back to the original dose, still with continuation of the benzylpenicillin for a further 3 weeks.[12]

In a retrospective cohort study,[10] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given benzathine benzylpenicillin was 5.8, but it was not statistically significant (range 0.8 to 41.5).

(c) Dicloxacillin

In a controlled study in 7 patients stabilised on **warfarin** and without infections, dicloxacillin 500 mg four times daily for 7 days reduced the mean prothrombin time by 1.9 seconds. One patient had a 5.6 second reduction.[13] This study was conducted because the authors had noted a case of a patient receiving **warfarin** who had a decrease in prothrombin time when dicloxacillin was started.[13] Another patient stabilised on **warfarin** had a 17% fall in prothrombin times within 4 to 5 days of starting dicloxacillin 500 mg four times daily, with a documented 20 to 25% reduction in both *S*- and *R*-warfarin levels.[14] In a retrospective review, 7 other patients similarly treated were also identified as having a 17% reduction in prothrombin times.[14] In yet another case, a patient who had previously required **warfarin** 10 mg daily subsequently needed an increased dosage of 15 mg daily while taking dicloxacillin 4 g daily long-term.[15] However, another case report suggested a greater effect of dicloxacillin: a patient taking dicloxacillin 500 mg every 6 hours required an increase in **warfarin** dose from a range of 35 to 40 mg weekly up to 50 to 60 mg weekly, with INRs still being subtherapeutic (about 1.5).[16] Moreover, when a woman taking **warfarin** was given dicloxacillin 500 mg four times daily she developed a heart valve thrombosis, suggesting inadequate anticoagulation. Her INR was 1.4, and an increased **warfarin** dose was required for 3 weeks after she stopped dicloxacillin.[17]

(d) Flucloxacillin

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, no cases of over-anticoagulation (INR greater than 6) occurred in patients taking flucloxacillin (25 patients received this antibacterial).[8] Note that this study did find an increase for *amoxicillin*, see above. In another cohort study[10] by the same research group, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given flucloxacillin was slightly increased at 2.2 but this was not statistically significant (range 0.7 to 6.9).

(e) Nafcillin

The prothrombin time of a 29-year-old patient stabilised on **warfarin** fell from a range of 20 to 25 seconds down to 16 seconds five days after intravenous nafcillin 2 g every 4 hours was started for endocarditis.[18] Over the next 2 weeks the prothrombin time ranged between 14 and 17 seconds despite an eventual doubling of the **warfarin** dose, and heparin was substituted. In this patient the half-life of a single 30-mg dose of **warfarin** was 11 hours when nafcillin was taken, 17 hours four days after stopping nafcillin, and 44 hours eight months after the nafcillin was discontinued. A case report describes a 39-year-old man taking warfarin 32 mg weekly, who required an eventual 2.75-fold dose increase to 88 mg weekly when his antibacterial for septic arthritis was changed from intravenous cefazolin to intravenous nafcillin 2 g every 4 hours. When the nafcillin was discontinued, he was eventually stabilised on **warfarin** 42 to 48 mg weekly.[19] At least 10 other cases of this **warfarin** resistance have been reported with high-dose nafcillin.[15,20-24]

(f) Pheneticillin

In one cohort study[8] in patients taking **acenocoumarol** or **phenprocoumon**, one case of over-anticoagulation (INR greater than 6) occurred in a group of 219 patients taking pheneticillin, giving a calculated relative risk of 0.9. In a further cohort study by the same research group,[10] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given pheneticillin was 4.6.

(g) Phenoxymethylpenicillin (Penicillin V)

When 10 patients taking an unnamed anticoagulant were given intravenous phenoxymethylpenicillin calcium [187.5 mg] four times daily for 4 days, none had a change in their prothrombin-proconvertin value.[25] For mention that, in another study no patients taking penicillins including phenoxymethylpenicillin had an increase in INR see under *Unspecified penicillins*, below. However, in a retrospective cohort study,[10] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given phenoxymethylpenicillin was 4.7, but it was not statistically significant (range 0.7 to 33.2).

(h) Unspecified penicillins

In one analysis of patients taking **warfarin** with antibacterials, there was no association between use of penicillins (**phenoxymethylpenicillin** (**penicillin V**) and broad-spectrum penicillins) and an increase in INR. The estimated change in INR was 0.117 in 109 patients given the combination.[26]

Mechanism

Not understood. The interaction between nafcillin and warfarin is possibly due to increases in the metabolism of warfarin by the liver. Dicloxacillin also possibly reduces serum warfarin levels.[14] Other penicillins (ampicillin,[27] benzylpenicillin,[27,28] carbenicillin,[29-34] methicillin,[27] ticarcillin[35]) have caused increased bleeding times when given alone, principally due to platelet inhibition,[27-29] which might be additive with the effects of the anticoagulants. Broad-spectrum antibacterials may decrease the gut flora and thereby possibly decrease production of vitamin K. Other factors relating to the disease may be important, see 'Coumarins + Antibacterials' p.413.

Importance and management

The reduced effect of warfarin with **dicloxacillin** and **nafcillin** appears to be established. If these penicillins are used, increase monitoring of the INR and anticipate the need to increase the warfarin dose. Some patients taking nafcillin have been warfarin resistant, and needed heparin treatment.

Documented reports of interactions between the coumarins and other penicillins are relatively rare, bearing in mind how frequently these drugs are used, so that the broad picture is that no clinically relevant interaction normally occurs with most other penicillins. This lack of interaction was supported by one clinical study.[26] However, in one case-control study, co-amoxiclav increased the risk of bleeding, and the authors recommended avoiding this combination,[7] although a later cohort study by the same authors just recommended increased monitoring with amoxicillin or co-amoxiclav.[8] In yet another study, they estimated that the individual risk of major bleeding was low at 1 per 1000 co-amoxiclav dispensings.[10]

Although there appear to be no reports of an interaction, if the mechanism of the interaction is correct, the **indanediones** are also likely to be affected. However, these interactions may be due to a number of different factors, and these are discussed in detail in the monograph 'Coumarins + Antibacterials', p.413. Therefore concurrent use should be monitored, so that the very occasional and unpredictable cases (increases or decreases in the anticoagulant effects) can be identified and handled accordingly.

Coumarins + Antibacterials; Quinolones

Quinolones have, at most, a small, clinically insignificant effect on the pharmacokinetics and pharmacodynamics of warfarin. However, isolated cases of increased effects and even bleeding have been reported in patients taking a coumarin with a quinolone and retrospective studies suggest that there may be an increased risk of over-anticoagulation in patients taking acenocoumarol or phenprocoumon with norfloxacin and ciprofloxacin, and warfarin with gatifloxacin or levofloxacin.

Clinical evidence

(a) Ciprofloxacin

In a randomised, placebo-controlled study in 32 patients stabilised on **warfarin** and without infections, ciprofloxacin 750 mg twice daily for 12 days had no clinically relevant effect on measures of anticoagulation. There was a mean increase in prothrombin time ratio of just 3% (range 0 to 6%), with a 10 to 13% decrease in the levels of clotting factors II and VII. In this study, ciprofloxacin had no effect on *S*-warfarin levels, but did slightly increase *R*-warfarin levels by 14.7%.[1] Similarly, ciprofloxacin had no clinically relevant effects on **warfarin** anticoagulation in a range of other studies, including two studies in a total of 16 patients without infections given ciprofloxacin 500 mg twice daily for 7 or 10 days,[2,3] a single-dose study with a controlled-release formulation of ciprofloxacin.[4]

In contrast, there are reports where ciprofloxacin has apparently been responsible for moderate to markedly increased prothrombin times and/or bleeding in patients taking **warfarin**. There have been around almost 100 cases reported, in individual case reports,[5-11] and to the FDA in the US,[12] Health Canada[13] and the Australia Adverse Drug Reactions Advisory Committee.[14] In addition this interaction has resulted in at least two fatalities.[13,15] Data, mainly from the reports to the FDA in the US, suggests that the median prothrombin time increase was 38 seconds, the INR 10, and the median time to detection after starting ciprofloxacin was 5.5 days. Hospitalisation was reported in 15 cases, bleeding in 25 cases and death in one case.[12]

In a population-based cohort study,[16] there were no cases of over-anticoagulation (INR greater than 6) in patients taking **acenocoumarol** or **phenprocoumon** with ciprofloxacin (just 19 patients received ciprofloxacin). However, in another cohort study by the same research group,[17] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given ciprofloxacin was significant (3.2, range 1.3 to 7.7).

(b) Clinafloxacin

Clinafloxacin 200 mg twice daily for 14 days had no effect on the steady-state levels of *S*-warfarin in healthy subjects, but the levels of the less active enantiomer *R*-warfarin were increased by 32% and the mean INR was increased by 13%.[18]

(c) Enoxacin

When a single 25-mg dose of **warfarin** was given to 6 healthy subjects on day 8 of a 14-day course of enoxacin 400 mg twice daily, the pharmacokinetics of *S*-warfarin were not altered, but the clearance of *R*-warfarin was decreased by 32% and its elimination half-life was prolonged from 36.8 hours to 52.2 hours. The overall anticoagulant response to the **warfarin** was unaltered.[19] Another report about one patient taking **warfarin**

also suggested that the use of enoxacin does not alter the prothrombin time ratio.[20]

(d) Fleroxacin

The pharmacokinetics of *R*- and *S*-warfarin, the prothrombin time and factor VII clotting time were unaffected when 12 healthy subjects were given a single 25-mg dose of **warfarin** on day 4 of a 9-day course of fleroxacin 400 mg daily.[21]

(e) Gatifloxacin

Gatifloxacin 400 mg daily for 11 days had no effect on the pharmacokinetics of a single 25-mg dose of **warfarin**, nor was the prothrombin time altered.[22] In contrast, in a review of 94 patients taking **warfarin** and given antibacterials for community-acquired pneumonia, 22 of the 40 patients (55%) taking gatifloxacin had INRs greater than 3 during or within 48 hours after stopping gatifloxacin, compared with 20 of 54 patients (37%) taking ceftriaxone and/or azithromycin. In the gatifloxacin group, 38% needed a **warfarin** dose adjustment, compared with 18% of patients taking other antibacterials. There was no difference in infection severity between the two groups.[23] In another retrospective analysis, 8 of 38 patients taking warfarin had an INR of greater than 4 after taking gatifloxacin, and 4 were subsequently treated with vitamin K. This was higher than the incidence with levofloxacin.[24] For the period February 2001 to January 2004, Health Canada had received 13 reports of suspected coagulation disorders associated with gatifloxacin and **warfarin**, all of which were considered serious, and 2 of which were fatal.[13] There is also a case of an INR which was too high to be determined in a patient taking numerous drugs including warfarin, and who had been taking gatifloxacin 400 mg daily.[25]

(f) Gemifloxacin

A double-blind, randomised, placebo-controlled study found that healthy subjects taking fixed doses of **warfarin** and with INRs in the range of 1.3 to 1.8 had no INR changes when they were given gemifloxacin 320 mg daily for 7 days.[26]

(g) Levofloxacin

In a study[27] in 15 healthy subjects given a single 30-mg dose of **warfarin** on day 4, levofloxacin 500 mg twice daily for 9 days had no effect on the pharmacokinetics or pharmacodynamics of *R*- and *S*-warfarin. In an uncontrolled prospective study, 18 patients stabilised on **warfarin** were given a course of levofloxacin for various infections. There was no difference in the mean INR obtained before levofloxacin and the first INR taken a median of 5 days after levofloxacin was started (2.61 versus 2.74). However, 4 patients had an increase in INR (to a range of 3.89 to 4.2) and 3 had a decrease in INR (to a range of 1.39 to 1.84) outside of the therapeutic range (2 to 3), and required **warfarin** dose adjustments. Only 7 patients had INRs that were therapeutic (range 2 to 3) throughout the study (before, during, and after levofloxacin) and did not require an adjustment in **warfarin** dose.[28] Similar findings were reported in two other retrospective analyses of patients taking **warfarin** with levofloxacin,[29,30] whereas just one of 54 patients taking **warfarin** had an INR above 4 after taking levofloxacin in another retrospective analysis.[24] In a retrospective case-control study,[31] there was no significant increased risk of hospitalisation for haemorrhage in acutely ill elderly patients taking **warfarin** who had received levofloxacin before admission (odds ratio 1.21).

Cases of an interaction have also been reported. Two elderly patients taking **warfarin** were found to have increased INRs (of 5.7 and 7.9) on routine testing shortly after stopping levofloxacin 500 mg daily.[32] Nine other cases of modest to markedly increased INRs have been reported in patients stabilised on **warfarin** who were given courses of levofloxacin 500 mg daily for 5 to 10 days (or unstated);[33-35] bleeding complications (epistaxis, haemopericardium) occurred in some of these cases,[34,35] and one patient died.[35] Moreover, for the period November 1997 to January 2004, Health Canada had received 16 reports of suspected coagulation disorders associated with levofloxacin and **warfarin**, 14 of which were considered serious, and one of which was fatal.[13]

One study assessed the impact of pre-emptively reducing the **warfarin** dose by 10 to 20% in patients starting levofloxacin. In 10 patients who had a **warfarin** dose reduction, there was no change in mean INR before and after levofloxacin. However, 4 patients developed a *sub-therapeutic* INR, including two with borderline low INR values beforehand. In 13 patients who had no pre-emptive **warfarin** dose reduction, the INR increased from a mean of about 2.5 to about 4. Note that most of the patients had little change in their INR, but one patient had a marked increase in INR requiring oral vitamin K.[36]

(h) Moxifloxacin

The pharmacokinetics of *R*- and *S*-warfarin were not altered when a single 25-mg dose of **warfarin** was given on day 5 of an 8-day course of moxifloxacin 400 mg daily in healthy subjects. The prothrombin time increased by 3% (0 to 6%), which is not clinically relevant.[37]

In contrast, there are at least 3 reports of raised INRs in patients taking **warfarin** and given moxifloxacin.[38-40] In one of these, 5 patients taking **warfarin** had INRs raised to 5.7 to 12.8 within 4 to 12 days of starting moxifloxacin, with one case of haemorrhage.[40] For the period October 2000 to January 2004, Health Canada had received 12 reports of suspected coagulation disorders associated with moxifloxacin and **warfarin**, 11 of which were considered serious.[13] Similarly, in February 2006, the Australia Adverse Drug Reactions Advisory Committee stated they had received one report of a suspected interaction between **warfarin** and moxifloxacin. In this patient the INR rose from around 2 to greater than 10, four days after starting moxifloxacin.[14]

(i) Nalidixic acid

A patient stabilised on **warfarin** (prothrombin ratio 2), developed a purpuric rash and bruising within 6 days of starting nalidixic acid 500 mg four times daily. Her prothrombin ratio had risen to 3.46.[41] Another patient, previously well controlled on **warfarin**, developed a prothrombin time of 60 seconds 10 days after starting nalidixic acid 1 g three times daily.[42] The INR of an 84-year-old woman taking **warfarin** rose from 1.9 to 9.6 when nalidixic acid was added.[43] Similarly, a patient taking **acenocoumarol** developed hypoprothrombinaemia after receiving nalidixic acid 1 g daily.[44]

(j) Norfloxacin

In a study[45] in 10 healthy subjects, norfloxacin 400 mg twice daily for 9 days was found not to alter either the pharmacokinetics or anticoagulant effects of a single 30-mg dose of **warfarin** given on day 4.

In contrast, a 91-year-old woman taking **warfarin** and digoxin developed a brain haemorrhage within 11 days of starting to take norfloxacin (precise dose not stated). Her prothrombin times had risen from 21.6 to 36.5 seconds. At this time, the manufacturers of norfloxacin were said to have 6 other reports of an interaction between **warfarin** and norfloxacin on file.[46] In a population-based cohort study, patients taking **acenocoumarol** or **phenprocoumon** were found to have an increased risk of over-anticoagulation (INR greater than or equal to 6) during norfloxacin treatment (relative risk 9.8). The risk was greatest during the first 3 days of treatment.[16] In another cohort study by this same research group,[47] the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given norfloxacin was 5.9. However, in yet another similar cohort study by the same research group,[17] the relative risk of hospitalisation for bleeding in these patients was just 2.2 and this did not reach statistical significance (range 0.7 to 6.7).

Furthermore, for the period December 1986 to January 2004, Health Canada had received 6 reports of suspected coagulation disorders associated with norfloxacin and **warfarin**, 4 of which were considered serious.[13] Similarly, in February 2006, the Australia Adverse Drug Reactions Advisory Committee stated they had received 11 reports of a suspected interaction between **warfarin** and norfloxacin.[14]

(k) Ofloxacin

Ofloxacin 200 mg daily for 7 days did not significantly affect the prothrombin times of 7 healthy subjects stabilised on **phenprocoumon**.[48] In a population-based cohort study,[16] there were no cases of over-anticoagulation (INR greater than 6) in patients taking **acenocoumarol** or **phenprocoumon** with ofloxacin (33 received ofloxacin). Nevertheless, in another similar cohort study by the same research group,[17] the relative risk of hospitalisation for bleeding in these patients was just 2.8 and this did not reach statistical significance (range 0.7 to 11.3). Furthermore, for the period December 1990 to January 2004, Health Canada had not received any reports of suspected coagulation disorders associated with ofloxacin and **warfarin**.[13]

In contrast, a woman who had recently started to take **warfarin** 5 mg daily, had a marked increase in her INR (from 2.5 to 4.4) within 2 days of starting to take ofloxacin 200 mg three times daily.[49] Two days later her INR had risen to 5.8. Another patient stabilised on **warfarin** developed gross haematuria and a prothrombin time of 78 seconds 5 days after starting to take ofloxacin 400 mg twice daily.[50]

(l) Pefloxacin

A patient had a marked increase in the effects of **acenocoumarol** (Quick time reduced from 26% to less than 5%) within 5 days of starting to take pefloxacin 800 mg daily and rifampicin 1.2 g daily.[51] Rifampicin is an

enzyme inducer, which normally causes a reduction in the effects of acenocoumarol (see 'Coumarins + Antibacterials; Rifamycins', below), so the findings in this case are surprising.

Mechanism

Uncertain. It is not clear what other factors might have been responsible in those cases where the effects of the anticoagulants were increased. Factors relating to acute infection rather than the antibacterial used to treat it may be responsible for increased INRs, see also 'Coumarins + Antibacterials', p.413. However, one study that controlled for severity of infection indicated this was not the case and that an interaction between the quinolone and anticoagulant probably occurs.[23] *In vitro* experiments[52,53] have shown that nalidixic acid can displace warfarin from its binding sites on human plasma albumin, but this mechanism on its own is almost certainly not the full explanation. In a single-dose study enoxacin was shown to inhibit the metabolism of the less potent *R*-warfarin isomer, without affecting the anticoagulant response.[19] This effect may become important if accumulation of the *R*-warfarin isomer (which is cleared slowly) occurred during prolonged dosing.[3] Other quinolones may have a similar effects. It has also been suggested that fluoroquinolones may suppress vitamin K-producing gut bacteria with resultant potentiation of anticoagulant effects,[49] see also 'Coumarins + Antibacterials', p.413.

Importance and management

The minor pharmacokinetic interaction between ciprofloxacin and warfarin in patients taking warfarin would appear to be established, but unlikely to be clinically relevant. Similarly, no other quinolone has been shown to have a clinically significant interaction with warfarin in a controlled prospective study. Despite this, there are numerous published case reports of marked over-anticoagulation with many of the quinolones, and other known unpublished cases reported to regulatory authorities. In addition, for levofloxacin there is some information from uncontrolled studies supporting an interaction in some patients. Nevertheless, given the widespread use of warfarin and quinolones, these interactions would appear to be rare.

The overall picture is that no adverse interaction normally occurs between the quinolones and coumarins, but rarely and unpredictably increased anticoagulant effects and even bleeding can occur with some of them. There is no need to avoid using any of the quinolones with the coumarins, and, in one study, pre-emptive warfarin dose reduction resulted in sub-therapeutic INRs in some patients given levofloxacin, and was considered unnecessary.[36] Monitoring the INR within 3 to 5 days of starting the quinolone was considered reasonable. Note that, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected, see also 'Coumarins + Antibacterials', p.413.

Coumarins + Antibacterials; Rifamycins

The anticoagulant effects of warfarin are markedly reduced by rifampicin (rifampin), with two to fivefold increases in dose needed to maintain efficacy in a number of case reports. Acenocoumarol and phenprocoumon are similarly affected.

Clinical evidence

(a) Acenocoumarol

The dose of acenocoumarol needed to be markedly increased in 18 patients who were given rifampicin 450 mg twice daily for 7 days to maintain the Quick value within the therapeutic range. The effect was apparent 5 to 8 days after starting the rifampicin, and had not reached a maximum at 14 days, at which point a mean 76% increase in the acenocoumarol dose

was needed.[1] In another study, the Quick time of a single dose of acenocoumarol, measured 35 hours after the dose, was reduced by 44% when rifampicin 10 mg/kg daily was given for 2 weeks.[2] In one 73-year-old, a sixfold increase in the dose of acenocoumarol was insufficient to maintain a therapeutic INR after starting rifampicin for endocarditis.[3]

(b) Phenprocoumon

In a study in healthy subjects, rifampicin 600 mg daily for 14 days increased the clearance of a single dose of phenprocoumon 2.2-fold.[4] Similarly, two patients stabilised on phenprocoumon required the dose to be doubled while taking rifampicin 600 mg daily (and isoniazid with or without ethambutol). In one case, the patient developed severe gross haematuria 3 months after rifampicin had been discontinued because the phenprocoumon dose had not been reduced.[5]

(c) Warfarin

In one controlled study in 8 healthy subjects, rifampicin 600 mg daily for 21 days reduced the steady-state plasma warfarin levels by 85% (range 64% to 100%). In addition, rifampicin abolished the anticoagulant effect of warfarin (the prothrombin time averaged 27% of normal during warfarin alone, and 85% of normal when rifampicin was taken).[6] Similar findings were seen in two other single-dose warfarin studies.[7,8] One of these measured the isomers of warfarin separately and found that rifampicin increased the clearance of *R*-warfarin threefold and *S*-warfarin twofold.[8] This interaction has also been described in a number of case reports.[9-14] In these reports the dose of warfarin was doubled[9,11] or even tripled[11] to accommodate this interaction, and reduced by an equivalent amount over two[10] to three weeks[12] following withdrawal of the rifampicin. In one well-described case, a threefold increase in warfarin dose from 5 to 15 mg daily over 4 months failed to achieve a therapeutic INR during the long-term use of rifampicin, and eventually a fivefold increase in dose (25 mg daily) attained an INR of 1.7 and 1.9. A gradual 70% dose reduction over 4 to 5 weeks was required when the rifampicin was discontinued.[14] In yet another case, a five to sixfold increase in warfarin dose was not sufficient to maintain the INR in the therapeutic range, and enoxaparin was used instead of warfarin.[15]

A retrospective study[16] similarly found that the concurrent use of enzyme inducers (including rifampicin) significantly influenced the total weekly warfarin dose; further analysis found that an average additional amount of warfarin required in patients taking these drugs was 17.2 mg weekly.

Mechanism

Rifampicin is a potent non-specific liver enzyme inducer, which increases the metabolism and clearance of the anticoagulants from the body, thereby reducing their effects.[8] Other mechanisms may also be involved.[12] See also 'Coumarins + Antibacterials', p.413.

Importance and management

The interaction between rifampicin and the coumarins is very well documented, clinically important, and occurs in most patients. A marked reduction in the anticoagulant effects may be expected within one week of starting the rifampicin, and persisting for about 2 to 5 weeks after the rifampicin has been withdrawn. With warfarin there is evidence that the dose may need to be markedly increased (two to fivefold) over a number of weeks to accommodate this interaction, and reduced slowly by an equivalent amount following withdrawal of the rifampicin. Warfarin dose titrations should be carried out with close monitoring. Bridging therapy with heparin or a LMWH might be appropriate until the warfarin dose is restabilised.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including oral anticoagulants.[17,18]

Coumarins and related drugs + Antibacterials; Sulfonamides and/or Trimethoprim

Co-trimoxazole (sulfamethoxazole with trimethoprim) modestly inhibits the metabolism of *S*-warfarin, and a number of case reports show that the anticoagulant effects of the coumarins can be markedly increased. Case reports suggest that sulfafurazole, sulfadoxine, and sulfamethizole may have similar effects. Two cohort studies have suggested that trimethoprim alone may be associated with an increased risk of over-anticoagulation. Anecdotal evidence suggests that phenindione might not interact with co-trimoxazole, but sulfaphenazole has been reported to increase the effects of phenindione.

Clinical evidence

(a) Co-trimoxazole (Sulfamethoxazole with Trimethoprim)

1. Coumarins. Six out of 20 patients taking **warfarin** had an increase in their prothrombin ratios (to about 4 to 6) within 2 to 6 days of starting to take co-trimoxazole 960 mg twice daily.[1] One patient had a gastrointestinal haemorrhage and needed to be given vitamin K. The **warfarin** was temporarily withdrawn from 5 patients and the dose was reduced in one patient to control excessive hypoprothrombinaemia.[1]

Similarly, an increase in the effects of **warfarin**, with or without bleeding complications, in patients given co-trimoxazole has been described in a number of other case reports.[2-17] In a retrospective study of 16 patients stabilised on **warfarin**, there was a mean increase in INR of 1.75 after starting co-trimoxazole (7 patients had an INR of greater than 4, and 5 patients had an INR greater than 5). The patients had stable INRs for a least two consecutive measurements before receiving co-trimoxazole, and an INR was taken within 3 to 15 days of starting the co-trimoxazole.[18] In one study in healthy subjects, co-trimoxazole 480 mg four times daily for 8 days increased the prothrombin time after a single dose of **warfarin** by 50%, but no change in the half-life of **warfarin** was seen.[19] However, a later similar study by the same research group, in which **warfarin** was given as its separate isomers, co-trimoxazole increased the AUC of *S*-warfarin by 22% and caused a 5% decrease in AUC of *R*-warfarin.[20]

In a population based cohort study[21] in patients taking **acenocoumarol** or **phenprocoumon**, co-trimoxazole was associated with an increased risk of over-anticoagulation (INR greater than or equal to 6); the adjusted relative risk of over-anticoagulation was noted to be 20.1 (range 10.7 to 37.9). The risk was increased in the first 3 days of use (relative risk 16.6), but was greatest after 4 days of concurrent use (relative risk 23.2). In two other cohort studies by this same research group, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given co-trimoxazole was lower at 6.2 and 5.1, respectively.[22,23]

In a study looking at management of the interaction, the risk of both moderate and severe over-anticoagulation with co-trimoxazole was markedly lower in patients who had their dose of anticoagulant reduced before receiving the antibacterials (preventive dose reduction) compared with those who did not (mean dose reduction 15% for **acenocoumarol** and 18% for **phenprocoumon**). Nevertheless, all patients who had taken co-trimoxazole spent significantly more time with subtherapeutic INRs in the 6 weeks after the antibacterial, although this tended to be less in patients

who had a preventive dose reduction, and less if the preventive dose reduction was less than 20%.[24] In another study of preventive **warfarin** dose reduction (10 to 20%) in patients also taking co-trimoxazole,[25] none of 8 patients had a subtherapeutic INR and none had an INR of greater than 6, although 2 patients had a INR between 4 and 6. However, in the control group with no preventive dose reduction, 4 out of 9 patients had an INR greater than 6, with values ranging from 7.1 to 17.4.

2. Indanediones. In one anecdotal report, the author noted that in several years experience of the use of **phenindione** in an anticoagulant clinic serving 1 000 patients, he had not come across a clinically important case of anticoagulant potentiation with co-trimoxazole.[26] Nothing else seems to have been published on the combination, but note that another sulphonamide, sulfaphenazole, potentiated the effect of **phenindione**, see *Sulfaphenazole*, below.

(b) Sulfadoxine

A 19-year-old with a valve replacement and taking **warfarin** presented with melaena and coughing up blood about a week after self-medicating with *Fansidar* (sulfadoxine with pyrimethamine). He had not had his anticoagulant control monitored.[27]

(c) Sulfafurazole (Sulfisoxazole)

A man taking digitalis, diuretics, antacids and **warfarin** was later given sulfafurazole 500 mg every 6 hours. After 9 days, his prothrombin time had risen from 20 seconds to 28 seconds, and after 14 days he bled (haematuria, haemoptysis, gum bleeding). His prothrombin time had risen to 60 seconds.[28]

Another patient who had recently started taking **warfarin** developed haematuria and had a prolonged prothrombin time 7 days after also starting sulfafurazole.[29]

(d) Sulfamethizole

The half-life of **warfarin** was increased by over 40% (from 65 to 93 hours) in 2 patients taking sulfamethizole 1 g four times daily for a week.[30]

(e) Sulfaphenazole

Sixteen patients given single oral doses of **phenindione** and sulfaphenazole 500 mg had prothrombin time increases after 24 hours of 16.8 seconds, compared with 10.3 seconds in 12 other patients who took **phenindione** alone.[31]

(f) Trimethoprim

Trimethoprim with sulfamethoxazole (co-trimoxazole) is known to interact with coumarins, see *Co-trimoxazole*, above. However, there appear to be no controlled studies of the effect of trimethoprim alone on these drugs, and no case reports of any interaction. In one cohort study,12 patients taking **warfarin** had a small INR increase of about 0.36 when given trimethoprim, but this was not statistically significant.[32] In another cohort study in patients taking **acenocoumarol** or **phenprocoumon**, the use of trimethoprim was associated with an increased risk of over-anticoagulation (INR greater than or equal to 6). The adjusted relative risk of over-anticoagulation was noted to be 5.6 (range 1.3 to 23.1), and the greatest risk was in the first 3 days of concurrent use. The risk from trimethoprim alone in this study was less than that for co-trimoxazole.[21] However, a further cohort study by this same research group, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given trimethoprim was just 1.3, and it was not statistically significant (0.3 to 5.4).[23]

Mechanism

Not fully understood. Sulfamethoxazole is a known inhibitor of the cytochrome P450 isoenzyme CYP2C9, by which *S*-warfarin in predominantly metabolised. The finding that co-trimoxazole (sulfamethoxazole with trimethoprim) caused a modest 22% increase in *S*-warfarin levels supports this mechanism.[20,33] Acenocoumarol and phenprocoumon are also metabolised by CYP2C9 and might be expected to be similarly affected. Plasma protein binding displacement has been suggested as a mechanism,[34,35] but on its own it does not provide an adequate explanation because the interaction is sustained.[21,33] Sulfonamides can drastically reduce the intestinal bacterial synthesis of vitamin K, but this is not normally an essential source of the vitamin unless dietary sources are exceptionally low,[33,36] see also 'Coumarins + Antibacterials', p.413.

Importance and management

The interaction between co-trimoxazole and the coumarins is well documented and well established. The incidence appears to be high. If bleeding is to be avoided the INR should be well monitored and the warfarin, acenocoumarol, or phenprocoumon dose should be reduced. Some consider that a pre-emptive warfarin dose reduction of about 10 to 20% reduces the risk of over-anticoagulation without increasing the risk of subtherapeutic INRs.[25] However, others suggest that co-trimoxazole should be avoided in patients taking coumarins, because they found that management of the interaction (either preventive or reactive dose reduction) resulted in an increased period of under-anticoagulation after the antibacterial. They suggest that an alternative antibacterial to co-trimoxazole is always available.[24]

Anecdotal evidence suggests that co-trimoxazole may not interact with phenindione, but note that sulfaphenazole did, so some caution is still appropriate.

The other interactions are poorly documented. However, it would seem prudent to follow the precautions suggested for co-trimoxazole if any sulfonamide is given with a coumarin or indanedione.

The relative silence in the literature for trimethoprim alone would suggest that, in practice, any interaction, if it occurs, is of only minor importance, and the anticoagulant dose probably needs little or no adjustment. However, note that two cohort studies have shown some increased risk when trimethoprim was given with warfarin, acenocoumarol or phenprocoumon so an interaction cannot entirely be dismissed.

Coumarins + Antibacterials; Teicoplanin or Vancomycin

An isolated case report describes a marked reduction in the effects of warfarin, which was attributed to the use of teicoplanin, although this could equally be explained by rifampicin treatment. Vancomycin possibly causes a small increase in the effects of warfarin, and may increase the risk of over-anticoagulation with acenocoumarol or phenprocoumon.

Clinical evidence, mechanism, importance and management

(a) Teicoplanin

A 60-year-old woman taking digoxin, furosemide and **warfarin** (INR 3.5 to 5) developed a fever after mitral valve replacement surgery and was given rifampicin 450 mg twice daily and teicoplanin 400 mg twice daily. Within 3 days her INR began to fall and by day 6 the anticoagulant effect was completely lost. Despite progressive **warfarin** increases to 10, 15, and then 20 mg daily, her INR stayed between 1.2 and 1.6, even when rifampicin was stopped, and remained low for a further 20 days, at which point the teicoplanin was also stopped.[1] Some of this resistance to **warfarin** was undoubtedly due to the rifampicin (a known and potent inducer of **warfarin** metabolism) but as the INRs remained depressed for a further 20 days after rifampicin was withdrawn the authors suggested that the teicoplanin had its own part to play. However, rifampicin has been shown is several cases to decrease the effects of warfarin for three or more weeks after its withdrawal (see 'Coumarins + Antibacterials; Rifamycins' p.424), so an interaction with teicoplanin would seem doubtful.

(b) Vancomycin

In a retrospective review of 60 patients undergoing heart valve replacement surgery and receiving prophylactic antibacterials, 44 patients given cefamandole had a much greater anticoagulant response to their first dose of **warfarin** than 16 patients given **vancomycin**.[2] In a later prospective study by the same workers, in patients taking warfarin with an antibacterial, after 3 days the prothrombin times as a percentage of activity were as follows: cefamandole 29%, cefazolin 38%, and **vancomycin** 51%, suggesting that 'cefamandole', (p.415), had a much greater effect on the anticoagulant response than **vancomycin**.[3]

In a cohort study, the use of **vancomycin** was associated with an increased risk of over-anticoagulation (an INR greater than 6) in patients stabilised on **acenocoumarol** or **phenprocoumon**. The relative risk was 13.6; however, the confidence interval was very large (1.7 to 107), so it is not possible to draw any firm conclusions from this.[4]

If a patient is unwell enough to require antibacterial therapy, it may be prudent to increase the monitoring of coagulation status even if no specific drug interaction is expected, see also 'Coumarins + Antibacterials', p.413.

Coumarins and related drugs + Antibacterials; Tetracyclines

Isolated cases suggest that doxycycline and tetracycline can increase the effects of coumarins. Similarly, some small studies (none controlled) suggest that chlortetracycline (alone or with oxytetracycline), doxycycline, or the tetracyclines as a class may increase the risks of over-anticoagulation, but there appear to be no studies of the effect of tetracyclines on the pharmacokinetics of coumarins. However, the related antibacterial, tigecycline, increased the AUC of warfarin, and has been found to increase the prothrombin time when given alone.

Clinical evidence

There are no controlled studies of the effect of any tetracycline on the pharmacokinetics or pharmacodynamics of warfarin or other coumarins, although there are data for tigecycline, a new glycylcycline antibacterial structurally related to the tetracyclines.

(a) Chlortetracycline

Six out of 9 patients taking an unnamed anticoagulant had a fall in their prothrombin-proconvertin concentration from a range of 10 to 30% to less than 6% when given chlortetracycline 250 mg four times a day for 4 days. Although the anticoagulant effects were increased, there was no evidence of bleeding.[1] In one early study of **dicoumarol** and **ethyl biscoumacetate**, the authors briefly comment that 4 cases of the concurrent use of chlortetracycline and oxytetracycline increased the prothrombin response.[2]

(b) Doxycycline

A woman stabilised on **warfarin** developed menorrhagia after taking doxycycline 100 mg twice daily for 10 days, and her prothrombin time ratio had increased from about 2 to 4.4.[3] Two other patients stabilised on **acenocoumarol** or **warfarin** developed markedly increased prothrombin ratios (3.82 and 4.09, respectively) with bruising, haematomas and bleeding when they took doxycycline.[4] Another patient with multiple medical problems, taking **warfarin** developed peritoneal bleeding and an INR of 7.2 (previously 2.6) 6 days after starting doxycycline 100 mg twice daily.[5] Yet another patient taking **warfarin** had an INR increase from 2.3 to 6.5 with prominent bruising when given doxycycline.[6]

In a population-based cohort study in patients taking **acenocoumarol** or **phenprocoumon**, doxycycline was found to increase the risk of over-anticoagulation (INR greater than or equal to 6) with an adjusted relative risk of 4.3 (range 1.8 to 10.4). The risks were greatest after 4 or more days of concurrent use.[7] In two other cohort studies by this same research group, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given doxycycline was 4.2 and 2.4, respectively.[8,9] Nevertheless, they estimated that the individual risk of major bleeding was low at one per 2000 doxycycline dispensings.[9]

(c) Oxytetracycline

In one early study of **dicoumarol** and **ethyl biscoumacetate**, the authors briefly comment that 4 cases of the concurrent use of chlortetracycline and **oxytetracycline** increased the prothrombin response.[2]

(d) Tetracycline

In one analysis of haemorrhagic events in patients taking **dicoumarol** and antibacterials, one patient out of 20 who received tetracycline had a bleeding event.[10] A patient stabilised on **warfarin** had a marked increase in INR (from about 2 to 7.7) 6 weeks after starting to take tetracycline 250 mg four times daily. Warfarin was withheld for a few days, and then restarted at a 40% lower dose. The INR decreased over the following months, broadly in parallel with decreases in the tetracycline dose.[11] A patient taking **warfarin** bled (right temporal lobe haematoma) and had an extended prothrombin time a week after starting to take tetracycline and nystatin.[12] Another patient taking **warfarin** also bled (epistaxis, haematemesis, melaena) 3 weeks after starting to take tetracycline and nystatin.[12]

In a retrospective cohort study, the relative risk of hospitalisation for bleeding in patients taking **acenocoumarol** or **phenprocoumon** and given tetracycline was 8.7. However, the incidence of concurrent use was low so the confidence interval was very broad (range 1.2 to 62).[9]

(e) Tigecycline

The manufacturer notes that, in healthy subjects, intravenous tigecycline 100 mg then 50 mg every 12 hours decreased the clearance of *R*-warfarin by 40% and *S*-warfarin by 23% after a single 25-mg dose of **warfarin**. The AUCs of *R*- and *S*-warfarin were increased by 68% and 29%, respectively. However, the INR was not affected.[13,14]

(f) Unnamed tetracyclines

In a prospective study of the effect of antibacterials on anticoagulation, there was an estimated 0.53 increase in the INR in 9 patients taking warfarin and a tetracycline (unnamed). The effect with tetracyclines was greater than the effect of other antibacterials studied (penicillins, cephalosporins, macrolides).[15]

Mechanism

Not understood. Tetracyclines, in the absence of anticoagulants, can reduce prothrombin activity,[16] and both hypoprothrombinaemia and bleeding have been described.[17,18] It seems possible that very occasionally the anticoagulant and the tetracycline have additive hypoprothrombinaemic effects. In clinical studies, tigecycline alone has commonly caused a prolonged prothrombin time (incidence 1 to 10%) or uncommonly caused an increased INR (incidence 0.1 to 1%).[13] It is also possible that antibacterials can diminish the intestinal flora of the gut thereby depleting the body of vitamin K_2, although this might be clinically important only where normal dietary intake of vitamin K_1 is extremely low, see 'Coumarins + Antibacterials', p.413. There appear to be no data on the effect of tetracyclines on the pharmacokinetics of coumarins. Although tigecycline decreased the clearance of warfarin, the mechanism for this is unclear, and is not thought to be as a result of decreased cytochrome P450 metabolism.[13,14]

Importance and management

A relatively sparsely documented interaction, bearing in mind that the tetracyclines have been in very widespread use for many years. It can therefore reasonably be concluded that normally any changes are of little clinical relevance. As a few patients have unpredictably had increased anticoagulant effects and even bleeding, bear the possibility of an interaction in mind when a tetracycline is first added to established anticoagulant treatment with a coumarin. Moreover, if a patient is unwell enough to require an antibacterial, it may be prudent to increase monitoring of coagulation status even if no specific drug interaction is expected, see also 'Coumarins + Antibacterials', p.413. Monitor within 3 days of starting the antibacterial.

Because tigecycline decreased the clearance of warfarin, and because tigecycline alone may cause an increase in INR, it is recommended that the INR be closely monitored if patients taking warfarin are given tigecycline.[13,14]

There appears to be no information about the **indanediones**, but if the mechanism suggested is correct they may also interact like the coumarins.

Coumarins + Anticholinesterases; Centrally acting

Donepezil, galantamine, rivastigmine and tacrine do not appear to alter the pharmacokinetics or effects of warfarin.

Clinical evidence, mechanism, importance and management

(a) Donepezil

In an open-label, crossover study, 12 healthy men were given donepezil 10 mg daily for 19 days with a single 25-mg dose of **warfarin** on day 14. The pharmacokinetics of *R*- and *S*-warfarin and the prothrombin times were unchanged by the presence of the donepezil, and vital signs, ECG and laboratory tests were unaltered.[1] Therefore, no special precautions are needed on concurrent use.

(b) Galantamine

The manufacturers say that galantamine 24 mg daily had no effect on the pharmacokinetics of *R*- and *S*-warfarin after a single 25-mg dose of **warfarin**. In addition, galantamine did not alter the prothrombin time.[2,3] Therefore, no special precautions are needed on concurrent use.

(c) Rivastigmine

The manufacturers of rivastigmine[4,5] say that no pharmacokinetic interaction has been noted between rivastigmine and **warfarin** in healthy subjects. In addition, rivastigmine did not affect the increase in prothrombin time seen with **warfarin**. Therefore, no special precautions are needed on concurrent use.

(d) Tacrine

In a study in 10 patients stabilised on **warfarin,** the addition of tacrine 20 mg four times daily for 5 days had no significant effect on prothrombin times.[6] Therefore, no special precautions are needed on concurrent use.

Coumarins + Antidiabetics; Alpha-glucosidase inhibitors

Miglitol and voglibose do not appear to alter the pharmacokinetics or effects of warfarin. There are isolated cases of reduced or increased INRs in patients given warfarin and acarbose.

Clinical evidence, mechanism, importance and management

(a) Acarbose

A 66-year-old man taking fosinopril, hydrochlorothiazide, diphenhydramine, insulin, glipizide and **warfarin** started taking acarbose to improve the control of his diabetes. Four days before starting acarbose his INR was 3.09, but after 2 weeks (25 mg acarbose daily for week one and then 50 mg daily for week 2) his INR had *risen* to 4.85. The **warfarin** was temporarily stopped, then it was reintroduced at a lower dose, and finally the acarbose was withdrawn, resulting in an INR of 2.84. No bleeding was seen.[1] In contrast, in 1997, the manufacturer had on record 2 other cases of patients taking **warfarin** whose INRs were *reduced* when acarbose was added. One of them stopped taking the acarbose, whereupon her INR

returned to its previous value. The other patient needed an increased **warfarin** dose.[2]

These appear to be the only cases on record, and therefore the general picture is that usually no interaction occurs, but in isolated cases some changes in **warfarin** requirements occur. Bear this potential interaction in mind if anticoagulant control alters in a patient taking acarbose.

(b) Miglitol

In a double-blind, randomised, placebo-controlled study, 24 healthy subjects were given miglitol 100 mg three times daily for 7 days, with a single 25-mg oral dose of **warfarin** on day 4. Neither the pharmacokinetics nor the pharmacodynamics of *R*- or *S*-warfarin were affected by the miglitol.[3] No special precautions would therefore appear to be needed if these two drugs are used concurrently.

(c) Voglibose

Twelve healthy male subjects were given individually adjusted doses of **warfarin** to give Quick values of 30 to 40%, and then from day 11 to 15 they were also given voglibose 5 mg three times daily. It was found that the voglibose had no effect on the pharmacokinetics of **warfarin** nor on its anticoagulant effects.[4] No special precautions would therefore appear to be needed if these two drugs are used concurrently.

Coumarins + Antidiabetics; Biguanides

One patient had a marked increase in the effects of phenprocoumon when she stopped taking metformin for a short period, and there is some evidence that metformin increases the metabolism of phenprocoumon.
One patient taking warfarin developed haematuria with a therapeutic prothrombin time three months after starting phenformin. Another patient developed metformin-induced lactic acidosis after warfarin-induced bleeding caused renal obstruction.

Clinical evidence

(a) Phenprocoumon

The Quick value of a 58-year-old woman stabilised on **metformin** 1.7 g twice daily and phenprocoumon 3 to 4.5 mg daily fell from a range of 20 to 30% down to 0% when she stopped taking the **metformin** while on holiday. Despite the increased anticoagulant effect no signs of bleeding were observed, and she was eventually restabilised on the original doses of both drugs.[1] This case prompted a further observational study in 13 patients with type 2 diabetes. It was found that the 7 patients taking **metformin** 1.1 to 3 g daily were less well anticoagulated than those taking only 400 mg to 1 g of **metformin**, even though the mean phenprocoumon dose was slightly higher in those taking the higher **metformin** dose (2.57 mg daily versus 2.27 mg daily).[1] In another study, the half-life of phenprocoumon was reduced by about one-third (from 123 to 85 hours) by **metformin** 1.7 g daily.[1]

(b) Warfarin

An elderly woman taking warfarin 5 mg daily and **metformin** 1 g twice daily developed fatigue, epistaxis, haematuria and gingival bleeding, with an INR of 16.9, which was treated with vitamin K. The following morning, she was given **metformin**, then she was found to have a retroperitoneal haematoma and bilateral perinephric blood with obstruction of both renal collecting systems. Over the next 8 hours, she developed progressive metabolic acidosis and suffered a cardiopulmonary arrest. Her **metformin** level was 7.3 micrograms/mL (therapeutic range 1 to 2 micrograms/mL). It was suggested that **metformin** accumulation occurred because of renal impairment caused by the site of renal bleeding secondary to the excessive effects of warfarin. This then resulted in metabolic acidosis.[2]

Haematuria occurred in a patient taking warfarin 3 months after **phenformin** was started. Her prothrombin values were normal.[3] **Phenformin** may have increased fibrinolysis to the point where it was additive with the effects of the warfarin.

Mechanism

Metformin possibly reduces the effects of phenprocoumon by altering blood flow to the liver and interfering with enterohepatic circulation.

Importance and management

The information about a biguanide interaction with warfarin appears to be limited to these isolated reports, none of which definitively suggest that the biguanide altered anticoagulant effects. In general no interaction would be expected between metformin or phenformin and warfarin.

There is some evidence that a small increase in the dose of phenprocoumon may be necessary if metformin is given, but it seems likely that this can be managed with routine anticoagulant monitoring.

3. Hamblin TJ. Interaction between warfarin and phenformin. *Lancet* (1971) ii, 1323.

Coumarins + Antidiabetics; Exenatide

Exenatide does not affect the response to warfarin.

Clinical evidence, mechanism, importance and management

In a controlled study in 15 healthy subjects, subcutaneous exenatide 5 micrograms twice daily for 2 days then 10 micrograms twice daily for 9 days had no effect on the pharmacokinetics of a single dose of **warfarin** 25 mg given on day 4. There was a slight 12% decrease in the maximum INR (1.72 versus 1.95).[1] Given the lack of a pharmacokinetic interaction, and slight decrease in anticoagulant effect, no **warfarin** dose adjustments are likely to be needed when exenatide is started.

1. Soon D, Kothare PA, Linnebjerg H, Park S, Yuen E, Mace KF, Wise SD. Effect of exenatide on the pharmacokinetics and pharmacodynamics of warfarin in healthy Asian men. *J Clin Pharmacol* (2006) 46, 1179–87.

Coumarins + Antidiabetics; Nateglinide or Repaglinide

Nateglinide and repaglinide do not appear to interact with warfarin, and nateglinide does not interact with acenocoumarol.

Clinical evidence, mechanism, importance and management

(a) Nateglinide

In a randomised, double-blind study, 11 healthy subjects were given nateglinide 120 mg three times daily for 5 days, with a single 10-mg dose of **acenocoumarol** on day 3. Nateglinide had no effect on the tolerability, pharmacokinetics or anticoagulant activity of **acenocoumarol**.[1]

In another study,12 healthy subjects were given nateglinide 120 mg three times daily for 4 days with a single 30-mg dose of **warfarin** on day 2. No pharmacokinetic or pharmacodynamic interaction was noted.[2] No dose adjustments would therefore be expected to be necessary if nateglinide is taken with either acenocoumarol or warfarin.

(b) Repaglinide

In a double-blind, placebo-controlled study in 28 healthy subjects who were stabilised on **warfarin**, repaglinide did not alter the anticoagulant effects of **warfarin** or the steady-state warfarin pharmacokinetics.[3] Therefore, no **warfarin** dose adjustment would be expected to be necessary on concurrent use.

3. Rosenberg M, Strange P, Cohen A. Assessment of pharmacokinetic (PK) and pharmacodynamic (PD) interaction between warfarin and repaglinide. *Diabetes* (1999) 48 (Suppl 1), A356.

Coumarins + Antidiabetics; Pioglitazone or Rosiglitazone

Pioglitazone does not appear to alter the pharmacokinetics or anticoagulant effect of warfarin or phenprocoumon, and rosiglitazone does not affect the pharmacokinetics of warfarin. However, there is one isolated report of two patients who required markedly increased warfarin doses after starting to take pioglitazone or rosiglitazone.

Clinical evidence

(a) Pioglitazone

In a study, pioglitazone 45 mg daily for 7 days did not alter the steady-state pharmacokinetics of **warfarin** and there was no significant change in prothrombin time.[1,2] Similar results were noted with **phenprocoumon**.[2] The US manufacturer also briefly mentions that pioglitazone had no effect on prothrombin time when it was given to patients stabilised on **warfarin**.[1]

However, there is an isolated report of an 84-year old woman (who had been on a stable maintenance dose of **warfarin** for the previous year) who, 12 weeks after starting to take pioglitazone 15 mg daily, had a subtherapeutic INR of 1.2. The patient denied any recent changes in diet or medication, including non-prescription and herbal medicines. An INR of 2.3 was eventually reached after her **warfarin** dose was increased by 88% from 8.5 mg to 16 mg weekly. A therapeutic INR was subsequently maintained at a similar dose over the following 18 months.[3]

(b) Rosiglitazone

The manufacturer briefly notes that rosiglitazone has been found to have no clinically relevant effect on the steady-state pharmacokinetics of **warfarin**.[4]

However, there is an isolated report of a 76-year-old man (who had been taking a stable dose of **warfarin** for the previous 18 months) who, 4 weeks after starting to take rosiglitazone 4 mg daily, had a subtherapeutic INR of 1.1. The patient denied any recent changes in diet or medication, including non-prescription and herbal medicines. An INR of 1.9 was eventually reached after increasing the **warfarin** dose by 75% from 24 mg weekly to 42 mg weekly. A therapeutic INR was subsequently maintained at a similar dose over the following 12 months.[3]

Mechanism

In vitro, troglitazone (the first thiazolidinedione, which has now been withdrawn) significantly inhibited the metabolism (7-hydroxylation) of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9; however, pioglitazone and rosiglitazone only slightly inhibited this activity.[5] Any inhibitory activity would be expected to increase warfarin effects, whereas the two cases suggest reduced effects. The authors suggest that the weak CYP3A4-inducing effect of pioglitazone might explain the interaction.[3] However, as CYP3A4 is only a minor enzyme in 'warfarin metabolism', (p.405), and controlled pharmacokinetic studies have not shown an effect on warfarin pharmacokinetics, this explanation is unlikely.

Importance and management

Controlled studies have found no interaction between pioglitazone and warfarin or phenprocoumon, or between rosiglitazone and warfarin. This suggests that coumarin dose adjustments are unlikely to be needed when these antidiabetics are also given. Nevertheless, one report describes two patients who required increases in warfarin doses 4 to 12 weeks after starting pioglitazone or rosiglitazone. The general relevance of these two cases is uncertain, and such effects are likely to be picked up by routine INR monitoring.

Coumarins + Antidiabetics; Sitagliptin and Vildagliptin

Sitagliptin and vildagliptin do not appear to alter the pharmacokinetics or anticoagulant effect of warfarin.

Clinical evidence, mechanism, importance and management

In a controlled study in 15 healthy subjects, vildagliptin 100 mg daily for six days had no effect on the pharmacokinetics of *R*- and *S*-warfarin when a single dose of **warfarin** 25 mg was given on day 2. Similarly, the anticoagulant effect (prothrombin time and INR) of **warfarin** was not altered by vildagliptin.[1]

The manufacturers state that in a study, multiple dose sitagliptin did not meaningfully affect the pharmacokinetics of *S*- or *R*-warfarin after a single dose of **warfarin**,[2,3] and the anticoagulant effect (INR) was not altered.[2]

Given the lack of a pharmacokinetic or pharmacodynamic interaction, no **warfarin** dose adjustments are likely to be needed on starting these antidiabetics.

Coumarins and related drugs + Antidiabetics; Sulfonylureas

Dicoumarol inhibits the metabolism of tolbutamide and increases its effects; cases of hypoglycaemic coma have been reported. Chlorpropamide may be similarly affected. Although isolated cases of interactions (raised prothrombin times, bleeding or hypoglycaemia) have been seen in patients taking other sulfonylureas and other coumarins, in general, no important interaction appears to occur. There also appears to be no interaction between phenindione and tolbutamide.

Clinical evidence

A. Coumarins

(a) Chlorpropamide

1. Acenocoumarol. A woman with normal renal function had an increase in the half-life of chlorpropamide to 88 hours (normally about 36 hours) when she took acenocoumarol.[1]

2. Dicoumarol. A 67-year-old non-diabetic man taking chlorpropamide for Parkinson's disease developed severe hypoglycaemia about 3 months after starting dicoumarol. He had high chlorpropamide levels with a half-life of 80 to 90 hours. Dicoumarol was withdrawn, and 3 weeks later his chlorpropamide half-life was 30 hours.[2] This observation prompted further study in 3 other patients and 2 non-diabetics. Dicoumarol doubled the serum chlorpropamide levels within 3 to 4 days and also more than doubled the half-life.[2]

(b) Glibenclamide (Glyburide)

1. Phenprocoumon. A small study in 4 subjects reported that the pharmacokinetics of glibenclamide were unchanged by phenprocoumon.[3] Similarly, the plasma levels and half-life of single doses of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibenclamide (9 patients).[4]

2. Warfarin. There do not appear to be any controlled studies on the effect of glibenclamide on the pharmacokinetics of warfarin, although *in vitro* data suggest that an effect is possible because glibenclamide inhibited *S*-warfarin hydroxylation (a 7 to 37% *in vivo* inhibition was predicted).[5] Moreover, an isolated report describes increased warfarin effects (INR increased from 2.3 to 6.6 with haematomas) in a patient given glibenclamide.[6]

(c) Glibornuride

Phenprocoumon, given to 3 subjects for 4 days, slightly increased the half-life of a single 25-mg dose of glibornuride by 29%.[7] The plasma lev-

els and half-life of a single dose of **phenprocoumon** did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking glibornuride (12 patients).[4]

(d) Glimepiride

In healthy subjects, glimepiride 4 mg daily caused only minor, clinically unimportant changes in the prothrombin times (about 10% decrease in mean maximum prothrombin time) in response to single 25-mg doses of **warfarin**. In addition, glimepiride had no effect on the pharmacokinetics of *R*- and *S*-warfarin.[8]

(e) Tolbutamide

1. Dicoumarol. Dicoumarol has been found to increase the serum levels of tolbutamide, prolong its half-life (more than threefold), and reduce blood-glucose levels in both diabetics[9,10] and healthy subjects.[9-12] This may become excessive in a few patients and hypoglycaemic coma has been described in 3 diabetics,[9,13,14] and one non-diabetic.[15]

Two patients taking dicoumarol had marked increases in prothrombin times (a rise from 33 to 60 seconds) within 2 days of starting to take tolbutamide, but no bleeding occurred. However, no increases were seen in 3 other patients taking dicoumarol when they started tolbutamide.[16] Conversely, the half-life of dicoumarol was approximately halved in 2 out of 4 healthy subjects given tolbutamide, but the hypoprothrombinaemic effects were unchanged.[12] However, in a retrospective study there was no difference in the initial or average dose of dicoumarol between 15 patients taking tolbutamide and 24 control subjects taking insulin.[17]

2. Phenprocoumon. In 3 subjects, phenprocoumon, given for one week, did not alter the half-life of a single intravenous dose of tolbutamide 1 g.[10] Similarly, there was no difference in monthly tolbutamide levels, taken over a year, between 7 patients taking tolbutamide alone and 2 patients also taking phenprocoumon.[18]

The plasma levels and half-life of single doses of phenprocoumon did not differ between patients with type 2 diabetes managed by diet alone (12 patients) and those taking tolbutamide (10 patients).[4]

3. Warfarin. Giving warfarin for one week did not alter the half-life of a single intravenous dose of tolbutamide 1 g in 2 subjects.[10] Similarly, giving warfarin for a week did not alter serum tolbutamide levels in 2 patients with diabetes.[10] In a retrospective study, there was no difference in the initial or average dose of warfarin between 42 patients taking tolbutamide and 54 control subjects taking insulin.[17]

(f) Unspecified sulfonylureas

In a retrospective study, the initial rate of warfarin anticoagulation was faster (threefold faster rise in INR) in 6 patients also taking sulfonylurea antidiabetics than in 160 control patients and 16 patients with diabetes not taking sulfonylureas.[19] The findings of this study require confirmation in a controlled, prospective study.

B. Indanediones

In early studies, phenindione given for 6 days did not affect the half-life of a single dose of **tolbutamide** in a few subjects.[9,10] Similarly, the average plasma levels of **tolbutamide** in 3 patients taking phenindione were not different from 4 patients not taking phenindione.[9]

Mechanism

Dicoumarol appears to increase the effects of tolbutamide by inhibiting its metabolism by the liver.[9,11] This may also be true for chlorpropamide.[2] The increase in the anticoagulant effects of dicoumarol by tolbutamide may, in part, be due to a plasma protein binding interaction. In the case of phenprocoumon there seem to be several different mutually opposing processes going on, which cancel each other out.[12] There is no clear explanation for most of the isolated cases.

Importance and management

Information is patchy and very incomplete. The effect of dicoumarol on tolbutamide has been the most thoroughly investigated, and the interaction is clinically important. Increased blood-glucose lowering effects may be expected if dicoumarol is given to patients taking tolbutamide, and there is a risk of hypoglycaemic coma. Whether tolbutamide alters the anticoagulant response to dicoumarol is unclear. Avoid concurrent use unless the outcome can be well monitored and dose adjustments made. The same precautions should be taken with dicoumarol and chlorpropamide, but information is limited to one study.

Information on other interactions is limited to isolated cases, and these are therefore of doubtful general significance.

Coumarins + Antihistamines

Findings from a retrospective review suggest that the anticoagulant effects of acenocoumarol may be reduced by loratadine, ebastine, or cetirizine. Conversely, an isolated report describes bleeding and a markedly raised INR in an elderly man taking acenocoumarol and cetirizine.

Clinical evidence, mechanism, importance and management

A retrospective review of patients taking **acenocoumarol** with **loratadine**, **ebastine**, or **cetirizine** found that INRs were decreased during concurrent use, but no thromboembolic event was noted. The authors consider that temporary increases in the anticoagulant dose might be required in patients taking both drugs.[1]

In contrast, there is a case report of an 88-year-old man taking **acenocoumarol** for a deep vein thrombosis who developed acute and severe epistaxis after a fall. He had started to take **cetirizine** 10 mg daily for allergic rhinitis 3 days before the fall.[2] His INR was found to have risen from 1.5 to 14. The **cetirizine** concentration was found to be particularly high, possibly because of some degree of renal impairment, and it was thought that these high levels may have displaced **acenocoumarol** from its plasma protein binding sites. However, this mechanism on its own is now largely discredited as an explanation for interactions between anticoagulants and highly protein-bound drugs.

Information is limited, and given the widespread use of these drugs, any consistent clinically significant interaction might have been expected to have come to light by now. No specific precautions seem necessary if these drugs are given in combination, but bear the interaction in mind in the case of an unexpected response to treatment.

Coumarins + Antineoplastics; Miscellaneous cytotoxics

A number of case reports describe an increase in the effects of warfarin, accompanied by bleeding in some cases, caused by antineoplastic regimens including carboplatin, chlormethine, cyclophosphamide, doxorubicin, etoposide, ifosfamide with mesna, methotrexate, paclitaxel, procarbazine, vincristine or vindesine, and gemcitabine alone. Conversely, a decrease in the effects of warfarin has been seen in individual cases with cyclophosphamide alone and mitotane alone, and no change in warfarin effect has been seen in one patient while receiving busulfan, cyclophosphamide, cytarabine, and melphalan each given alone.

Clinical evidence

(a) Busulfan

A man well stabilised on **warfarin** had no change in his anticoagulant response while taking busulfan for 6 weeks.[1]

(b) Carboplatin

The INR of a man taking **warfarin** increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.[2]

(c) Cyclophosphamide

A woman taking **warfarin** had a marked rise in her prothrombin time when her treatment with cyclophosphamide was withdrawn, suggesting that cyclophosphamide reduced the anticoagulant response.[3] Another patient had an increase in anticoagulant effect of **warfarin** while taking a combination regimen containing cyclophosphamide, see *ProMace-Mopp*, below. In contrast, a man well stabilised on **warfarin** had no change in anticoagulant response while taking cyclophosphamide for 6 weeks.[1]

(d) Cytarabine

A man well stabilised on **warfarin** had no change in anticoagulant response while taking cytarabine for 6 weeks.[1]

(e) Etoposide

The INR of a man taking **warfarin** increased from a baseline range of 1.15 to 2.11 up to 12.6 within 16 days of a first course of chemotherapy with carboplatin and etoposide.[2] Another elderly man taking **warfarin** had a marked increase in prothrombin times (prolongation of 8 to 15 seconds) on two occasions when he took etoposide 500 mg and **vindesine** 5 mg.[4] Another patient had an increase in anticoagulant effect of **warfarin** while taking a combination regimen containing cyclophosphamide, see *ProMace-Mopp*, below.

(f) Gemcitabine

A 63-year-old man needed a reduction in his weekly **warfarin** dose from 59.23 mg to 50.75 mg in order to keep his INR at about 2.5 during 2 cycles of gemcitabine. When the gemcitabine was stopped his **warfarin** dose had to be increased again.[5] The manufacturers have information on 4 cases of suspected interactions between gemcitabine and **warfarin**, and one with **phenprocoumon** (reported by December 2000). Based on 724 reports of the concurrent use of gemcitabine and **anticoagulants**, this represents an incidence of the suspected interaction of 0.8%, which is low if there were a specific interaction.[6]

(g) Hydroxycarbamide

A man well stabilised on **warfarin** had no change in anticoagulant response while taking hydroxycarbamide for 6 weeks.[1]

(h) Ifosfamide

Three patients taking **warfarin** had a marked and very rapid increase in their INRs when given ifosfamide; with **mesna** and **cisplatin** with **etoposide**; or **doxorubicin**; or **doxorubicin** with **vincristine**.[7]

(i) Melphalan

A man well stabilised on **warfarin** had no change in anticoagulant response while taking melphalan for 6 weeks.[1]

(j) Mitotane

A patient who started to take mitotane 4 g [daily] for adrenal carcinoma was also given warfarin (5 mg and 2.5 mg on alternate days) 2 days later for a deep vein thrombosis. This patient required several increases in her warfarin dose to 12.5 mg daily over 4-month period to maintain a therapeutic prothrombin time of about 22 seconds. A few weeks later she was found to have an increase in her prothrombin time to 27.1 seconds, so her warfarin dose was decreased to 10 mg daily. However, 3 months later she was admitted to hospital with haematemesis and gingival bleeding, and her prothrombin time was found to be 74.6 seconds. She was found to have a haemorrhage of a tumour in the right posterior fossa, and she died that day.[8]

(k) Paclitaxel

A woman who had been stable on **warfarin** for 2 months had an INR increase from 3 to 5.2 on the day after receiving paclitaxel and **carboplatin**. A rise in INR occurred on each subsequent cycle of chemotherapy.[9]

(l) ProMace-Mopp

The prothrombin times of an elderly man given **warfarin** increased by 50 to 100% in the middle of three cycles of treatment with ProMace-Mopp (**cyclophosphamide**, **doxorubicin**, **etoposide**, **chlormethine**, **vincristine**, **procarbazine**, **methotrexate** and prednisone), and he developed a subconjunctival haemorrhage during the first cycle.[10]

Mechanism

Not well understood. Coagulation control can be altered by many factors in severely ill patients with cancer including altered diet due to lack of appetite, and nausea and vomiting caused by antineoplastics. Antineoplastics that cause gastrointestinal toxicity might also alter the absorption of warfarin. The authors of the case report of an interaction with paclitaxel suggest that the likely mechanism of action is displacement of warfarin from protein binding sites by paclitaxel. However, altered protein binding has not clearly been shown to be an important mechanism in warfarin interactions, as any effect is usually transient.

Importance and management

These are isolated cases, and no specific drug interaction is established for any of the cytotoxic antineoplastics covered here. Nevertheless, other factors due to the disease or patient might alter the response to anticoagulants. Therefore, the anticoagulant doses may need adjustment. Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.

Note that some cytotoxic antineoplastics do have specific interactions with coumarins, see 'Coumarins + Azathioprine or Mercaptopurine', p.436, and 'Coumarins + Fluorouracil and related prodrugs', p.460.

Coumarins + Aprepitant

Aprepitant modestly reduces warfarin levels and slightly decreases the INR in healthy subjects. It is expected to interact similarly with acenocoumarol. Fosaprepitant, a prodrug of aprepitant, would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

In a double-blind study, healthy subjects were stabilised on **warfarin** and then given either aprepitant (125 mg on day one, then 80 mg daily on days 2 and 3) or placebo. On day 3, there was no change in **warfarin** lev-

els. However, by day 8 (5 days after stopping aprepitant) there was a 34% decrease in trough *S*-warfarin levels, and a 14% decrease in INR in the aprepitant group.[1]

Aprepitant is a moderate inducer of the cytochrome P450 isoenzyme CYP2C9, by which *S*-warfarin is metabolised. The manufacturer recommends that, in patients taking **warfarin**, the INR should be monitored closely for 2 weeks, particularly at 7 to 10 days,[2] after each 3-day course of aprepitant,[2,3] and this seems a prudent precaution. The UK manufacturer[3] similarly recommends caution with **acenocoumarol**, which is also metabolised by CYP2C9. **Fosaprepitant**, a prodrug of aprepitant, is expected to interact similarly, and the manufacturers recommend similar advice to manage the interaction.[4,5]

Coumarins + Aromatase inhibitors

The anticoagulant effects of warfarin and acenocoumarol can be markedly reduced by aminoglutethimide. An isolated case of thromboembolism has been loosely attributed to an interaction between letrozole and warfarin. However, anastrozole and letrozole do not affect the pharmacokinetics of warfarin, and exemestane would not be expected to interact.

Clinical evidence

(a) Aminoglutethimide

In a study in 9 patients being treated for breast cancer, aminoglutethimide 125 mg twice daily increased the clearance of a single-dose of *R*- or *S*-warfarin by 41% with marked variability between individuals (range 15 to 103%). Aminoglutethimide 250 mg four times daily increased the clearance of **warfarin** by 91%. The effects of the interaction had developed fully by 14 days. Both enantiomers of **warfarin** were equally affected.[1]

One 79-year-old woman taking aminoglutethimide 250 mg four times daily was resistant to **warfarin** requiring a dose of 17.5 to 20 mg daily. Two weeks after the aminoglutethimide was stopped, the required dose of **warfarin** gradually declined, eventually reaching a level of 3.75 and 5 mg on alternate days (about a fourfold reduction).[2] Another patient stabilised on **warfarin** gradually needed about a threefold increase in the **warfarin** dose after starting aminoglutethimide 250 mg four times a day.[2] The increased requirement persisted for 2 weeks after the aminoglutethimide was stopped, and then declined. A study briefly mentions a patient who needed greatly increased doses of **warfarin** after starting aminoglutethimide.[3] Three patients taking **acenocoumarol** needed a doubled dose to maintain adequate anticoagulation when they took aminoglutethimide 250 mg four times daily for 3 to 4 weeks.[4]

(b) Anastrozole

In a well-controlled study in 16 healthy men,[5] anastrozole (7 mg loading dose followed by 1 mg daily for a further 10 days) had no effect on the pharmacokinetics or pharmacodynamics of a single dose of **warfarin** given on day 3.

(c) Letrozole

The manufacturers report that letrozole had no clinically relevant effect on the pharmacokinetics of **warfarin**.[6,7]

A 72-year-old woman with breast cancer developed deep vein thrombosis while taking tamoxifen. **Warfarin** was started and the tamoxifen was switched to letrozole. Five months later she developed a pulmonary thromboembolism, and her INR was noted to be subtherapeutic. The authors suggested that the low INR may be due to an interaction between **warfarin** and letrozole; however, they also note that many other factors may have contributed to this patient developing a pulmonary embolism, such as a possible adverse effect of letrozole, obesity and related immobility, and therefore the exact cause is unknown.[8]

Mechanism

Uncertain. The most likely explanation is that aminoglutethimide, like glutethimide, stimulates the activity of the liver enzymes concerned with the metabolism of the coumarin anticoagulants, thereby reducing their levels and efficacy. Alternatively, it has been suggested that aminoglutethimide may affect blood steroid levels, which in turn might affect coagulation.[2] Letrozole is not reported to be an inducer of the cytochrome P450 isoenzymes CYP2C9 or CYP3A4, which are involved in the metabolism of coumarin anticoagulants.

Importance and management

The interaction of warfarin and acenocoumarol with aminoglutethimide is established and clinically important. Monitor the effects of adding aminoglutethimide to patients already taking these drugs and increase the anticoagulant dose as necessary. Up to four times the dose may be needed. The extent of the effects would appear to be related to the dose of aminoglutethimide used. Monitor the INR and reduce the anticoagulant dose accordingly if aminoglutethimide is withdrawn. Information about other coumarins is lacking but it would be prudent to apply the same precautions with any of them.

Conversely, controlled studies have shown no interaction between anastrozole or letrozole and warfarin, and the isolated case report does not firmly implicate an interaction with warfarin. Overall, this suggests that coumarin dose adjustments are unlikely to be needed when these aromatase inhibitors are used. There appears to be no published information of an interaction with **exemestane**. The US manufacturers state that it does not inhibit CYP2C9 or CYP3A4, therefore it is unlikely to have any significant pharmacokinetic interaction with warfarin.[9]

Note that tamoxifen also interacts with warfarin and possibly other coumarin anticoagulants in some patients, see 'Coumarins + Tamoxifen or Toremifene', p.511, for further information.

Consider also that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[10]

Coumarins + Ascorbic acid (Vitamin C)

Although two isolated cases have been reported in which the effects of warfarin were reduced by ascorbic acid, four subsequent prospective studies have not found any interaction.

Clinical evidence

In a woman recently stabilised on **warfarin** 7.5 mg daily, who began to simultaneously take ascorbic acid (dose not stated) with her warfarin, the prothrombin time fell steadily from 23 seconds, to 19, 17, and then 14 seconds, with no response to an increase in the dose of **warfarin** to 10 mg, 15 mg, and finally 20 mg daily. The prothrombin time returned to 28 seconds within 2 days of stopping the ascorbic acid.[1] Another woman recently stabilised on warfarin 5 mg daily had a recurrence of acute thrombophlebitis with a prothrombin time of 12 seconds. She was unusually resistant to the actions of **warfarin** and required 25 mg daily before a significant increase in prothrombin times was achieved. On questioning, she had been taking massive amounts of ascorbic acid (about 16 g daily) for several weeks. She was eventually stabilised on warfarin 10 mg daily.[2]

In contrast, in prospective studies, no changes in the effects of **warfarin** were seen:

- in 5 patients given ascorbic acid 1 g daily for a fortnight,[3]
- in 11 patients (some taking **dicoumarol**) given ascorbic acid 4 g daily for 2 weeks,[4]
- in 14 patients given ascorbic acid 3 g then 5 g daily for one week or 5 patients given 10 g daily for one week:[5] a mean fall of 18% in total plasma **warfarin** concentrations was seen at all doses,
- in a 10-week study, where the proportion of patients requiring a change in **warfarin** dose did not differ between 84 patients given ascorbic acid (dose unstated) and 96 control patients (31 patients versus 18 patients required a dose reduction, and 7 versus 13 required a dose increase, respectively).[6]

Mechanism

Not understood. One *animal* study has demonstrated this interaction[7] and others have not,[8,9] but none of them has provided any definite clues about why it ever occurs. One suggestion is that high doses of ascorbic acid can cause diarrhoea, which might prevent adequate absorption of the anticoagulant.

Importance and management

Four clinical studies in patients stabilised on warfarin have not found that ascorbic acid alters the anticoagulant effect of warfarin, even using very large doses of ascorbic acid (up to 10 g daily), even though there are two isolated reports of reduced warfarin efficacy. All these data are from the 1970s, and nothing further seems to have been published. Coumarin dose adjustments are therefore unlikely to be needed when ascorbic acid is also used.

Coumarins and related drugs + Aspirin or other Salicylates

Antiplatelet doses of aspirin (75 to 325 mg daily) increase the risk of bleeding when given with warfarin by about 1.5 to 2.5-fold, although, in most studies the absolute risks have been small. The overall benefits of concurrent use outweigh the risks in certain patient groups; however, for some warfarin indications, there is not enough data to assess this. In addition to increased bleeding, high doses of aspirin (4 g daily or more) can increase prothrombin times.

Clinical evidence

A. Analgesic-dose aspirin

In a pharmacological study in patients stabilised on **acenocoumarol**, aspirin 2.4 g daily for one week increased faecal blood loss from an average of 1.1 mL to 4.7 mL. While taking aspirin, 11 of 17 patients required a 29% reduction in their **acenocoumarol** dose from a mean of 3.1 mg to 2.2 mg. One patient required a slight increase of 0.5 mg, and the remaining 5 required a dose reduction of less than 0.5 mg.[1]

In another study in healthy subjects, aspirin 1.95 g daily for 11 days had no effect on the prothrombin time response to a single dose of **warfarin** given on day 4. When 11 healthy subjects were stabilised on **dicoumarol** or **warfarin** and given aspirin 1.95 g daily, 7 had no significant change in prothrombin time activity, and 4 had a slight reduction (of 5 to 10% points). Two subjects had signs of bleeding, but neither had a reduction in prothrombin time activity. A further 4 subjects stabilised on **warfarin** received a higher dose of aspirin (3.9 g daily), and all 4 had a reduction in prothrombin time activity of 6 to 12% points and signs of bleeding occurred. The bleeding time was significantly prolonged by the combination of aspirin 1.95 g daily and **warfarin** than by **warfarin** alone (10.3 minutes versus 4 minutes).[2] In a study in 12 healthy subjects stabilised on **warfarin**, aspirin 2.6 g daily for one week reduced the mean prothrombin concentrations by about 2.75%.[3] In two further studies in healthy subjects, aspirin 6 g daily moderately prolonged prothrombin times,[4,5] and in one study this effect tended to be reversed by vitamin K.[4]

In contrast, in another study in 10 patients, adding aspirin 3 g daily to **warfarin** for 2 weeks had no effect on prothrombin times (20.9 seconds versus 21.2 seconds).[6]

B. Antiplatelet-dose aspirin

In a study in healthy subjects, low-dose aspirin 75 mg daily doubled the normal blood loss from the gastric mucosa. However, concurrent **warfarin** (dose individualised to achieve an INR of 1.4 to 1.6) did not increase the gastric mucosal bleeding any further.[7]

In a large population-based, retrospective case control-study using records from the UK General Practice Research Database from 2000 to 2005, the use of **warfarin** with aspirin was associated with a marked increased risk of gastrointestinal bleeding when compared with either drug alone (rate ratio of 6.48 for concurrent use compared with 1.94 for **warfarin** and 1.39 for aspirin).[8] This study did not specify the indication for concurrent use. In a similar retrospective cohort study from the Netherlands, the use of **acenocoumarol** or **phenprocoumon** with antithrombotic salicylates (not specified) was associated with an increased risk of major bleeding (relative risk 3).[9]

(a) Atrial fibrillation

In a large study in patients with atrial fibrillation, the cumulative incidence of bleeding events after 3 years was no different in those receiving fixed low-dose **warfarin** 1.25 mg daily with aspirin 300 mg daily (24.4%) than with fixed low-dose **warfarin** alone (24.7%) or aspirin 300 mg daily alone (30%).[10] This study also contained an adjusted-dose **warfarin**-only group, which proved more effective than the other group, so the study was terminated early. Other studies have found similar results.[11]

In another study, the combination of adjusted dose **fluindione** (INR 2 to 2.6) with aspirin 100 mg daily was associated with a much higher incidence of haemorrhagic complications than **fluindione** alone (13.1% versus 1.2%). The overall balance of benefit to risk could not be assessed because of the low incidence of the primary endpoint (ischaemic events).[12]

(b) Myocardial infarction

1. Primary prevention. In a large primary prevention study in men at high risk of ischaemic heart disease, the incidence of haematuria was twofold higher in those receiving both low-dose aspirin 75 mg daily and low-intensity **warfarin** (INR 1.5) than in those receiving low-dose aspirin alone, or low-intensity **warfarin** alone. Similarly, the incidence of minor episodes of bleeding (nose bleeds, bruising, rectal bleeding, pink/red urine) was 1.27-fold higher in those receiving the combination than in those receiving low-dose aspirin alone, or low-intensity **warfarin** alone (49% versus 38% and 39%, respectively), although the difference was not statistically significant. There was no difference in incidence of major and intermediate episodes of bleeding.[13]

2. Secondary prevention. In a meta-analysis of randomised, controlled studies[14] in patients following myocardial infarction or acute coronary syndrome, intensive **warfarin** (INR greater than 2) with aspirin 80 to 325 mg daily was associated with 2.5-fold increased risk of major bleeding, when compared with aspirin alone, although the actual incidence was low (1.5% versus 0.6%). This analysis excluded studies of coronary stenting. In another similar meta-analysis, the concurrent use of aspirin and **warfarin** (INR 2 to 3) was associated with a 2.3 odds ratio of a major bleed, when compared with aspirin alone.[15] The number needed to treat to cause one major bleed was 100. This compared with a number needed to treat to avoid one major adverse event (death, myocardial infarction or stroke) of 33.

Similarly, in an observational cohort study of elderly survivors of acute myocardial infarction, the rate of bleeding was higher in patients receiving **warfarin** with aspirin (0.08 per patient year), than in patients receiving aspirin alone (0.03 per patient-year).[16] Using lower intensity **warfarin** with the low-dose aspirin was still associated with more major bleeding than aspirin alone (1.77 in one study, although this is less than higher intensity **warfarin**; 2.3 as mentioned above). Nevertheless, low-intensity **warfarin** with low-dose aspirin does not appear to be any more effective than aspirin alone.[15,17]

(c) Peripheral arterial disease

In a meta-analysis of studies of patients with peripheral arterial disease, the concurrent use of **oral anticoagulants** with aspirin increased the risk of major bleeding about twofold when compared with aspirin alone, and appeared to be associated with increased mortality.[18]

In one open-label, randomised, clinical study, patients with peripheral arterial disease were assigned to take an antiplatelet alone (1081 patients taking aspirin, clopidogrel or ticlopidine) or to take an antiplatelet with **warfarin** or **acenocoumarol** (1080 patients, target INR of 2 to 3). The risk of life-threatening bleeding was 3.4-fold higher with the concurrent use of an anticoagulant and an antiplatelet than with the antiplatelet alone (4% versus 1.2%), and moderate and minor bleeding were also increased (relative risk of 2.8 and 3.6, respectively).[19]

(d) Prosthetic heart valves

In one randomised study in patients with artificial heart valves, the risk of bleeding episodes requiring blood transfusion or hospitalisation was much higher among those taking aspirin 500 mg daily and **warfarin** (14%), when compared with those taking **warfarin** and dipyridamole 400 mg daily (4%), and compared with a non-randomised control group taking **warfarin** alone (5%). Bleeding was mainly gastrointestinal or cerebral. All of those with intracerebral bleeding died.[20]

A further study found that aspirin 1 g daily, given with **unnamed anticoagulants**, was associated with a threefold higher incidence of bleeding episodes than those taking anticoagulants alone (13.9 per 100 patients per year versus 4.7 per 100 patients per year).[21,22] However, in another study there was no difference in haemorrhagic risk between patients receiving aspirin 500 mg daily and **acenocoumarol** or **acenocoumarol** alone.[23]

More recent studies have used lower doses of aspirin. In one study in patients stabilised on **warfarin** with a target INR of 3.0 to 4.5, the addition of aspirin 100 mg daily increased the risk of any bleeding 1.55-fold, when compared with placebo (35% versus 22% per year), mainly due to an increase in minor haematuria, nosebleeds and bruising. However, the risk was more than offset by the overall reduction in mortality.[24]

The preliminary report of a meta-analysis of these four studies, concluded that the concurrent use of **oral anticoagulants** and aspirin (100 mg to 1 g daily) significantly reduced mortality and embolic complications in patients with prosthetic heart valves, with an estimated increased odds ratio of major bleeds of 1.7 and of total bleeds of 1.98. Nevertheless the overall picture was that the benefits possibly outweighed the problems.[25] In a subsequent meta-analysis,[26] which excluded one non-randomised study,[20] but included two other randomised controlled studies, the risk of major bleeding for the combination of **warfarin** and aspirin was 1.53. For the two studies using low-dose aspirin (100 mg daily), there did not appear to be an excess risk of major bleeding.[26] Another analysis of these studies provided essentially the same risk of increased major bleeding with the combination.[27]

Mechanism

Aspirin has a direct irritant effect on the stomach lining and can cause gastrointestinal bleeding, even in doses as low as 75 mg daily.[28] It also decreases platelet aggregation and prolongs bleeding times. At low doses of aspirin, this increases the risk of haemorrhage with warfarin without elevating the INR. In addition, large doses of aspirin (4 g daily or more) alone are known to have a direct hypoprothrombinaemic effect, which is reversible by vitamin K.[4,5] This effect of aspirin can be additive with the effects of the anticoagulant.

Importance and management

The interaction of aspirin at high doses and warfarin is not well documented, but is clinically important. It is usual to avoid normal analgesic and anti-inflammatory doses of aspirin while taking any coumarin anticoagulant, although only dicoumarol, acenocoumarol and warfarin appear to have been investigated. Patients should be told that many non-prescription analgesic, antipyretic, cold and influenza preparations may contain substantial amounts of aspirin. Warn them that it may be listed as acetylsalicylic acid. Paracetamol is a safer analgesic substitute (but not entirely without problems, see 'Coumarins and related drugs + Paracetamol (Acetaminophen)', p.492).

The effect of low-dose aspirin, used for its antiplatelet effects, with warfarin has been far more extensively studied. Overall, the evidence shows that the combination is still associated with an increased risk of bleeding over either drug alone, and, from controlled studies, this is in the region of 1.5- to 2.5-fold, although two population studies have suggested that the risk might be greater in the primary care setting.[8,9] Nevertheless, the absolute risk is small. A twofold increased risk of haematuria and a slight increased risk of minor bleeding of 1.27 was still seen in the study using the lowest dose of warfarin (INR 1.5) with just 75 mg of aspirin a day.[13] In certain patient groups the benefits of concurrent use have been clearly shown to outweigh this increased risk of bleeding, such as patients with prosthetic heart valves at high risk of thromboembolism. In these patients, those who are at risk of gastrointestinal bleeding should additionally receive gastroprotection such as proton pump inhibitors. In addition, in the long-term, aspirin doses should be limited to no more than 81 mg daily.[29] However, in many of the common indications for warfarin, such as atrial fibrillation, there is insufficient evidence to answer the question of whether the combination should be used.[27]

For a review of the risk of bleeding when using warfarin with dual antiplatelet therapy such as low-dose aspirin and clopidogrel, see 'Coumarins and related drugs + Clopidogrel', p.448.

Coumarins + Azathioprine or Mercaptopurine

A number of cases of a marked decrease in the effects of warfarin have been seen with azathioprine and mercaptopurine. A decrease in the effects of acenocoumarol has also been seen with mercaptopurine, and a decrease in the effects of phenprocoumon has been seen with azathioprine.

Clinical evidence

(a) Azathioprine

In a survey of 103 patients with antiphospholipid syndrome taking **warfarin**, the use of azathioprine appeared to increase **warfarin** requirements. Twelve of 26 patients (46%) requiring more than 10 mg of **warfarin** daily were taking azathioprine when compared with 15 of 77 patients (19%) requiring less than 10 mg **warfarin** daily.[1] There are a number of case reports of an interaction between coumarins and azathioprine. In one case, a woman who was resistant to **warfarin**, needing 14 to 17 mg daily while taking azathioprine, began to bleed (epistaxis, haematemesis) when the azathioprine was stopped. She was restabilised on **warfarin** 5 mg daily.[2] Reduced **warfarin** effects were seen in 2 other patients taking azathioprine,[3,4] one of whom had a marked fall in serum **warfarin** levels during azathioprine treatment.[4] Two women with systemic lupus erythematosus taking **phenprocoumon**[5] and a third taking **warfarin**[6] had marked falls in their INRs during treatment with azathioprine. Another woman needed an almost fourfold increase in the dose of **warfarin** when she was given azathioprine.[7] In a retrospective analysis of patients with antiphospholipid syndrome admitted to hospital with serious bleeding, 3 patients taking azathioprine had a serious bleed, and in two of these cases the bleed occurred when their azathioprine dose was reduced.[8] In another case, a patient required about double the **warfarin** dose when her azathioprine dose was increased from 150 mg daily to 200 mg daily. Four weeks after the azathioprine was stopped abruptly because of suspected liver toxicity, her INR had increased from 1.8 to 14, and she had bruising and mild epistaxis.[9] A further case has been reported where a patient required a warfarin dose increase from 37.5 mg weekly to 112 mg weekly when azathioprine 150 mg daily was started in order to maintain an INR of 2.5.[10] In two other cases, significant warfarin dose increases were needed in patients given azathioprine.[11]

(b) Mercaptopurine

A man well stabilised on **warfarin** had a marked reduction in his anticoagulant response on two occasions while taking mercaptopurine 100 mg to 150 mg daily: the anticoagulant response returned when mercaptopurine was stopped. He had previously had no changes in anticoagulant response when receiving 6-week courses of single drugs including **busulfan**, **cyclophosphamide**, **cytarabine**, **hydroxycarbamide**, **mitobronitol**, **demecolcine** and **melphalan**.[12] A woman needed a marked increase in her dosage of **acenocoumarol**, from 21 mg weekly to 70 mg weekly, when she was given mercaptopurine 100 mg daily.[13] Another patient had a drop in INR from 3 to 1.1 two weeks after starting mercaptopurine and methotrexate. His **warfarin** requirements varied up to about threefold over three cycles of this chemotherapy, increasing during the mercaptopurine cycle and decreasing when in between cycles of treatment.[14]

Mechanism

Not well understood. From early studies in *rats*, it was concluded that mercaptopurine possibly increases the synthesis or activation of prothrombin, and that it does not alter the half-life, volume of distribution or clearance of warfarin.[15] The authors of one case report noted lower plasma warfarin levels during the use of azathioprine in one patient.[4] Azathioprine is metabolised to mercaptopurine, and would therefore be expected to interact similarly.

Importance and management

Although the evidence is limited, it seems that mercaptopurine and azathioprine may markedly decrease the anticoagulant response to coumarins, and that the anticoagulant doses may need to be significantly increased to achieve adequate anticoagulation. It would therefore be prudent to closely monitor concurrent use.

Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.

Coumarins + Azoles; Econazole

A case report describes a raised INR and bleeding in a patient taking warfarin, when he used econazole cream.

Clinical evidence, mechanism, importance and management

A 79-year-old man, taking long-term warfarin, was given econazole cream for a fungal groin infection. Within one week of starting to apply the cream, he noticed bruising, including a large area on his hip, resulting from a trivial injury, and prolonged bleeding from a small cut.[1] His INR was found to have increased from 2.2 to 12. He was also taking glucosamine with chondroitin, which seems unlikely to have been responsible as this was not a new medication.

Econazole is structurally similar to miconazole, an inhibitor of the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, which have major and minor roles, respectively, in warfarin metabolism. It seems likely that sufficient econazole was absorbed through the infected skin in the groin (which is thin, and in this particular case, macerated due to the fungal infection) to inhibit warfarin metabolism, leading to raised levels, and the increase in INR seen.

Econazole normally has very low systemic availability after topical application, and therefore the manufacturer notes that clinically relevant interactions are rare;[2,3] however, they do advise monitoring patients taking warfarin or acenocoumarol. In general, an interaction seems unlikely (this case appears to be the only one reported), but it would seem prudent to consider monitoring any patient receiving a coumarin if they need to use large amounts of econazole, especially on broken or damaged skin.

Coumarins + Azoles; Fluconazole

Fluconazole causes a dose-related reduction in the metabolism of warfarin, and increases its anticoagulant effect. Cases of minor to major bleeding have been reported. There is one similar case report with acenocoumarol and fluconazole.

Clinical evidence

(a) Acenocoumarol

A patient stabilised on acenocoumarol suffered an intracranial haemorrhage (prothrombin time 170 seconds) 5 days after starting to take fluconazole 200 mg daily for the management of relapsed prosthetic valve candidal endocarditis.[1]

(b) Warfarin

1. Multiple-dose fluconazole. In a well-designed study in healthy subjects, fluconazole was given at three dose levels (100 mg, 200 mg and 400 mg daily) for 14 days with a single dose of warfarin given both before fluconazole and on day 7 at each fluconazole dose level. In this study, fluconazole markedly potentiated the anticoagulant effect of warfarin in a dose-related manner. The duration of anticoagulant effect was 4 to 7 days for the single dose of warfarin alone, 5 to 9 days with fluconazole 100 mg daily, 6 to 11 days with fluconazole 200 mg daily, and 8 to 15 days with fluconazole 400 mg daily. Fluconazole increased the levels of both *R*- and *S*-warfarin. With fluconazole 100 mg, 200 mg and 400 mg, the AUC of *R*-warfarin was increased by 28%, 63%, and 70%, respectively, and that of *S*-warfarin by 35%, 86%, and 100%, respectively.[2] Two other studies in healthy subjects have found broadly similar results.[3-5]

The clinical importance of this interaction was shown in an earlier study, which found that when fluconazole 100 mg daily was given to 7 patients stabilised on warfarin, the prothrombin time increased from 15.8 seconds on day one, to 18.9 seconds on day 5, and 21.9 seconds on day 8. The fluconazole was stopped early in 3 of the patients due to high prothrombin times, but none exceeded an increase of more than 9.7 seconds, and no bleeding occurred.[6]

At least 6 reports have described increased prothrombin times or INRs in patients stabilised on warfarin who took fluconazole in doses of 50 to 400 mg daily.[7-13] Several patients had haemorrhagic effects (gastrointestinal bleeding, melaena, ocular haemorrhage, spinal epidural haematoma).[7,9,11-13]

2. Single-dose fluconazole. Six women taking stable doses of warfarin with an INR between 2 and 3 were given a single 150-mg dose of fluconazole, and their prothrombin time measured on days 2, 5 and 8. The prothrombin time increased by 11% on day 2, 34% on day 5, and 2% on day 8, although none of these differences was statistically significant. However, three of the women had an increase in the INR to above 4 or had bleeding.[14]

Mechanism

In vitro studies using human liver microsomes clearly demonstrate that fluconazole inhibits the metabolism (7-hydroxylation) of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9 and the metabolism of *R*-warfarin by CYP3A4, and possibly other isoenzymes involved in the metabolism of warfarin.[15] *In vivo*, this results in the accumulation of warfarin and in an increase in its effects, possibly leading to bleeding.[5]

Importance and management

An established and clinically important interaction. If fluconazole is given to patients taking warfarin or acenocoumarol the prothrombin times should be very well monitored and the anticoagulant dose reduced as necessary. On the basis of pharmacokinetic studies it has been predicted that the warfarin dose may need to be reduced by about 20% when using fluconazole 50 mg daily, ranging to a reduction of about 70% when using fluconazole 600 mg daily. These larger reductions should be gradual over 5 days or so.[16] However, remember that individual variations between patients can be considerable. Most of the available data relate to multiple-dose fluconazole, with just one small study with a single-dose of fluconazole 150 mg. Although the effect in this study was not as great as that for multiple-dose fluconazole, it suggests that careful monitoring of prothrombin times is still required.[14]

Of the other azole antifungals, ketoconazole (see 'Coumarins + Azoles; Ketoconazole', p.438) and itraconazole (see 'Coumarins + Azoles; Itraconazole', below), appear less likely to interact.

Coumarins + Azoles; Itraconazole

An isolated report describes a very marked increase in the anticoagulant effects of warfarin, accompanied by bruising and bleeding, in a patient given itraconazole. One case suggests that itraconazole may increase the risk of over-anticoagulation with acenocoumarol or phenprocoumon.

Clinical evidence

A woman stabilised on **warfarin** 5 mg daily and also taking ipratropium bromide, salbutamol, budesonide, quinine sulfate and omeprazole, was given itraconazole 200 mg twice daily for oral candidiasis caused by the inhaled steroid. Within 4 days she developed generalised bleeding and recurrent nosebleeds. Her INR had risen to more than 8. The **warfarin** and itraconazole were stopped, but the next day she had to be admitted to hospital for intractable bleeding and increased bruising, for which she was treated with fresh frozen plasma. Two days later, when the bleeding had stopped and her INR had returned to 2.4, she was restarted on **warfarin** and later restabilised on her original dose.[1]

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, itraconazole significantly increased the risk of over-anticoagulation (INR greater than 6: relative risk of 13.9, range 1.7 to 115). However, the authors say this figure should be interpreted cautiously since it was based on just one case.[2]

Mechanism

Itraconazole is a known potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme is involved only in the metabolism of the less potent *R*-warfarin, and therefore inhibition would not be expected to have a marked effect on 'warfarin metabolism', (p.405). However, there appear to be no pharmacological studies to confirm this. Omeprazole (see 'Coumarins + Proton pump inhibitors', p.499) may also have had some minor part to play in the case described.[1]

Importance and management

A minor to modest pharmacokinetic interaction would be predicted between itraconazole and the coumarins, but as yet there appear to be no studies to confirm this. The case report and cohort study suggest that this

interaction might be clinically important in some individuals. Therefore, it would be prudent to increase monitoring of anticoagulant control when any patient on a coumarin is given itraconazole. Further study is needed.

Coumarins + Azoles; Ketoconazole

Limited evidence suggests that the anticoagulant effect of warfarin is unchanged by ketoconazole. However, there are three isolated cases of an increase in the anticoagulant effects of warfarin with ketoconazole. Topical ketoconazole does not appear to interact with acenocoumarol or phenprocoumon.

Clinical evidence

(a) Systemic ketoconazole

Two healthy subjects had no changes in their anticoagulant response to **warfarin** when they were given ketoconazole 200 mg daily over a 3 week period.[1,2] However, an elderly woman, stabilised on **warfarin** for 3 years, complained of spontaneous bruising 3 weeks after starting a course of ketoconazole 200 mg twice daily. Her British Comparative Ratio was found to have risen from 1.9 to 5.4. Her liver function was normal. She was restabilised on her previous **warfarin** dose 3 weeks after the ketoconazole was withdrawn.[3] In 1984, the CSM in the UK had one report of an 84-year-old man taking **warfarin** whose British Comparative Ratio rose to 4.8 when he was given ketoconazole, and fell to 1.4 when it was withdrawn.[3] In 1986, the manufacturers of ketoconazole had one other report of an elderly man taking **warfarin** whose prothrombin time rose from a range of 34 to 39 seconds to over 60 seconds when he was given ketoconazole 400 mg daily.[4]

(b) Topical ketoconazole

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, topical ketoconazole did not significantly increase the relative risk of over-anticoagulation (INR greater than 6; relative risk 1.1, range 0.3 to 4.3). However, this figure should be interpreted cautiously as it was based on just two patients.[5]

Mechanism

In a study in *rats*,[6] ketoconazole potentiated the anticoagulant effect of acenocoumarol, but at much higher doses than miconazole (which is known to interact, see 'Coumarins and related drugs + Azoles; Miconazole', p.438. It is now known that ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, but this isoenzyme has only a minor role in the 'metabolism of warfarin' (p.405), specifically the less active *R*-isomer.

Importance and management

Information about this interaction seems to be limited to the reports cited. Its general importance and incidence is therefore uncertain, but it is probably quite small. However, it would seem prudent to bear the possibility of an interaction in mind should any unexplained increase in the coumarin anticoagulant effects occur in a patient given both drugs.

Coumarins and related drugs + Azoles; Miconazole

The anticoagulant effects of acenocoumarol, phenprocoumon, and warfarin can be markedly increased if miconazole is given orally as an oral (buccal) gel, and bleeding can occur. Oral miconazole has also been reported to interact with ethyl biscoumacetate, fluindione, phenindione and tioclomarol in a few reports. The interaction has also rarely been seen in some women using intravaginal miconazole, and in those using a miconazole cream on the skin.

Clinical evidence

(a) Oral gel

In one early report, a patient with a prosthetic heart valve and stabilised on **warfarin** developed blood blisters and bruised easily 12 days after starting miconazole gel 250 g four times a day for a presumed fungal mouth infection. Her prothrombin time ratio had risen from less than 3 to about 16. She was subsequently restabilised in the absence of miconazole on her former dose of **warfarin**.[1]

Numerous other cases of this interaction with **warfarin** have been reported, and, where stated, often involved the use of 5 mL (125 mg) of the gel four times daily for oral candidiasis.[2-14] However, cases have occurred with lower doses; one case of an increase in INR to 11.4 with frank haematuria and spontaneous bruising was reported in a woman who had used 30 g of non-prescription miconazole (*Daktarin*) over 8 days (estimated daily dose of 75 mg),[7] and three other cases have occurred with non-prescription miconazole.[13-15] In another case, the interaction occurred with use of the miconazole gel locally around the corners of the lips for angular cheilitis.[11]

In 1996, the New Zealand Centre for Adverse Reactions Monitoring reported 5 patients taking **warfarin** whose INRs rose from normal values to between 7.5 and 18 within 7 to 15 days of starting to use miconazole oral gel.[5] In 2002, the Australian Adverse Drug Reactions Advisory Committee (ADRAC) stated that they had received 18 reports of this interaction. In the 17 cases for which it was documented, the INR was above 7.5. Eight of the cases had bleeding complications, 9 required vitamin K, and 5 required fresh frozen plasma.[16]

A few similar cases have also been reported for **acenocoumarol**[17-19] with miconazole oral gel. In addition, in one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of oral miconazole (form and doses not stated) markedly increased the risk of over-anticoagulation (INR greater than 6: adjusted relative risk 36.6; range 12.4 to 108). When analysed separately, the adjusted relative risk was higher for **acenocoumarol** than **phenprocoumon** (35.1 versus 16.5).[20]

A case has also been reported with the indanedione, **fluindione**.[21]

(b) Skin creams

An 80-year-old man stabilised on **warfarin** with an INR of 2.2 to 3.1 was found to have an INR of 21.4 at a routine check 2 weeks after starting to use miconazole cream for a fungal infection in his groin. He showed no evidence of bruising or bleeding.[22] In 2001, Health Canada reported that they had on record a case of an 80-year-old man taking **warfarin** and using topical miconazole who had a cerebral vascular accident, although this case was complicated by multiple medical conditions and medications.[23] In 2002, the Australian Adverse Drug Reactions Advisory Committee stated that they had received one report of an interaction involving topical miconazole cream.[16]

In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, the use of topical miconazole was associated with a small increased risk of over-anticoagulation (INR greater than 6: adjusted relative risk 1.4) but this was not statistically significant. Note that this was markedly less than the increased risk seen with oral miconazole (relative risk 36.6).[20]

(c) Tablets

In a study in 6 healthy subjects, miconazole 125 mg daily for 18 days (in the form of *tablets*) caused a very marked fivefold increase in the prothrombin time response to a single dose of **warfarin** given on day 3. In addition, there was a threefold increase in the AUC of warfarin, with *S*-warfarin most affected (fourfold), and *R*-warfarin increased 1.7 fold.[24] In one early case report with warfarin, one patient with a prosthetic heart valve and stabilised on **warfarin** was found to have a

prothrombin time ratio of 23.4 within 10 days of starting miconazole tablets 250 mg four times a day for a suspected fungal diarrhoea. He developed two haematomas soon after both drugs were withdrawn, and was subsequently restabilised, in the absence of miconazole, on his former dose of **warfarin**.[1]

The Centres de Pharmacovigilance Hospitalière in Bordeaux have on record 5 cases where miconazole (oral doses of 500 mg daily, where stated; form not mentioned) was responsible for a marked increase in prothrombin times and/or bleeding (haematomas, haematuria, gastrointestinal bleeding) in patients taking the coumarins **acenocoumarol** (2 cases), **ethyl biscoumacetate** (1 case) and **tioclomarol** (1 case) and the indanedione **phenindione** (1 case).[25] Other cases and reports of this interaction involving **acenocoumarol** have been described elsewhere.[26-28]

(d) Vaginal dose forms

In 1999, the Netherlands Pharmacovigilance Foundation LAREB reported 2 elderly women patients taking **acenocoumarol** whose INRs rose sharply and rapidly when they were given miconazole pessaries 400 mg daily for 3 days.[29] Another report describes the development of bruising and an INR of almost 10 in a 55-year-old woman taking **warfarin** on the third day of using 200-mg miconazole pessaries. For a subsequent course of intravaginal miconazole 100 mg daily for 7 days, the dose of warfarin was decreased by 28%, and her INR was 3.27.[30] Yet another report describes haemorrhage of the kidney in a 52-year old woman taking **warfarin** after she used vaginal miconazole for 12 days.[23] In one cohort study in patients taking **acenocoumarol** or **phenprocoumon**, use of vaginal miconazole was associated with a small increased risk of over-anticoagulation (INR greater than 6: adjusted relative risk 4.3) but this was not statistically significant. Note that this was markedly less than the increased risk seen with oral miconazole (relative risk 36.6).[20]

Mechanism

There is evidence that miconazole is a very potent inhibitor of the metabolism of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9, and that it also inhibits the metabolism of *R*-warfarin to a lesser extent.[24] Even low oral doses of miconazole (125 mg daily) markedly inhibit warfarin metabolism, so it is not surprising that prescription doses of miconazole oral gel (480 to 960 mg daily) interact, as this is swallowed after retaining in the mouth. Very unusually, the low absorption of miconazole from the vagina and even exceptionally through the skin, can result in increased anticoagulant effects. Acenocoumarol would be expected to be similarly affected.

Importance and management

The interaction of **miconazole oral gel** and **miconazole tablets** with the coumarins is a very well established and potentially serious interaction. Most of the reports are about warfarin or acenocoumarol, but many other coumarins and indanediones, have been implicated. In some cases the bleeding has taken 7 to 15 days to develop,[1,3,25] whereas others have bled within only 3 days.[27,30] Raised INRs have been seen even sooner. Given the marked nature of the interaction, usual prescription doses of miconazole oral gel (5 to 10 mL (120 to 240 mg) four times daily) should generally be avoided in patients taking any oral anticoagulant. Should concurrent use be necessary, prothrombin times should be closely monitored and suitable dose reductions made. The interaction has also been seen with non-prescription miconazole (one 30 g tube given over 8 days, or about 75 mg daily), which is not surprising in the context of the pharmacokinetic study, and suggests that patients taking coumarins and indanediones should also avoid using non-prescription miconazole. Nevertheless, the UK patient information leaflet for non-prescription *Daktarin* oral gel just advises patients taking oral anticoagulants to talk to their doctor or pharmacist, and does not advise avoiding the product.[31] Nystatin and amphotericin are possible alternative antifungals to miconazole for mouth infections.

An interaction with **intravaginal miconazole** would not normally be expected because its systemic absorption is usually very low (less than 2%) in healthy women of child-bearing age.[32] However, the reports cited above show that significant absorption could apparently occur in a few patients with particular conditions (possibly in postmenopausal women with inflamed vaginal tissue), which allows an interaction to occur. Appropriate monitoring is therefore needed even with this route of administration in potentially at-risk women.

Topical (cutaneous) miconazole would also not be expected to interact, but the few reports cited shows that some caution might be warranted.

Coumarins + Azoles; Voriconazole

In one pharmacodynamic study, voriconazole approximately doubled the prothrombin time in response to warfarin.

Clinical evidence, mechanism, importance and management

In a study, when 16 healthy subjects were given voriconazole 300 mg twice daily for 12 days, with a single 30-mg dose of **warfarin** on day 7, the maximal increase in prothrombin time was about doubled.[1] The increase in prothrombin time was still present 6 days after the **warfarin** dose, at which point the prothrombin time had returned to values seen with **warfarin** alone. Two subjects were withdrawn from the study because of an increased prothrombin time.[1]

Voriconazole is a known inhibitor of the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, by which the coumarins are metabolised. If voriconazole is added to treatment with any coumarin the prothrombin times

should be very well monitored and the anticoagulant dose reduced as necessary.

Coumarins + Barbiturates

The effects of the coumarins are substantially reduced by the barbiturates. Primidone is metabolised to phenobarbital and is expected to interact similarly.

Clinical evidence

(a) Phenobarbital

A study in 16 patients stabilised on **warfarin** found that when they were also given phenobarbital 2 mg/kg their average daily **warfarin** requirements rose over a 4-week period by 25% (from 5.7 to 7.1 mg daily).[1] In another study in patients stabilised on **warfarin**, phenobarbital 100 mg at night for 4 weeks reduced the mean prothrombin time by 13%.[2] In a prospective cohort study in children, the use of phenobarbital or carbamazepine was associated with a higher dose of **warfarin** to maintain the target INR (0.24 mg/kg versus 0.15 mg/kg).[3]

Other studies have found that phenobarbital causes a 29% or 46% reduction in the half-life of **warfarin**,[4,5] and that the reduction was similar for both *R*- and *S*-warfarin.[6] A retrospective analysis in patients taking **warfarin** revealed that the use of phenobarbital was associated with more erratic anticoagulation control, and that discontinuation of phenobarbital in a patient taking **warfarin** resulted in severe hypoprothrombinaemia and haematuria 2 weeks later.[7]

A reduced anticoagulant response has also been described in studies with phenobarbital and **dicoumarol**,[8-10] and 2 cases have been reported with phenobarbital and **ethyl biscoumacetate**.[11] One retrospective study[12] found that the concurrent use of enzyme inducers (including phenobarbital and **primidone**) significantly influenced the total weekly **warfarin** dose; further analysis found that an average additional amount of **warfarin** required in patients taking these drugs was 17.2 mg weekly.

In contrast, there is one isolated report of a woman stabilised on **warfarin** who developed haematuria 3 days after starting to take phenobarbital 60 mg four times daily.[13]

(b) Other barbiturates

An investigation in 12 patients taking either **warfarin** or **phenprocoumon** found that **secbutabarbital sodium**, 15 mg four times daily for the first week and 30 mg four times daily for the next 2 weeks, increased their anticoagulant requirements by 35 to 60%, reaching a maximum after 4 to 5 weeks.[14]

This interaction has also been described in pharmacological studies between:

- **acenocoumarol** and **pentobarbital**,[15] or **heptabarb**;[16]
- **dicoumarol** and **aprobarbitone**,[17] **heptabarb**,[16,18] or **vinbarbital**;[17]
- **ethyl biscoumacetate** and **heptabarb**;[16]
- **warfarin** and **amobarbital**,[19-21] **heptabarb**,[22] **secobarbital**,[2,19-21,23-25] or **secbutobarbital**.[14]

Cases have been described in patients taking **ethyl biscoumacetate** who were taking **amobarbital**, **heptabarb**, or **secobarbital**.[11] Cases have also been described of apparent resistance to coumarins in patients taking barbiturates,[17,26] and of bleeding in patients who were stabilised on a coumarin and a barbiturate when they stopped taking the barbiturate.[17,26,27]

Mechanism

Pharmacokinetic studies in man and *animals*[4,5,20-22,24] clearly show that the barbiturates are potent liver enzyme inducers, which increase the metabolism and clearance of the coumarins. The effect is similar on both *R*- and *S*-warfarin.[6,25] Barbiturates may also reduce the absorption of dicoumarol from the gut.[18]

Importance and management

The interactions between the coumarins and barbiturates are clinically important and very well documented. The reduced anticoagulant effects expose the patient to the risk of thrombus formation if the dose is not increased appropriately. A very large number of coumarin and barbiturate pairs have been found to interact and the others may be expected to behave similarly. The reduction in the anticoagulant effects begins within one week, sometimes within 2 to 4 days, reaching a maximum after about 3 weeks, and it may still be evident up to 6 weeks after stopping the barbiturate.[14] Patients' responses can vary considerably. Stable anticoagulant control can be re-established[28] in the presence of the barbiturate by increasing the anticoagulant dose by about 30 to 60%.[1,7,10,14] Care must be taken not to withdraw the barbiturate without also reducing the anticoagulant dose, otherwise over-anticoagulation will occur. Alternative non-interacting drugs, such as the benzodiazepines (see 'Coumarins + Benzodiazepines and related drugs', p.441), are now considered more appropriate sedatives than the barbiturates.

Primidone is metabolised to phenobarbital and is therefore expected to have a similar effect to phenobarbital. This is suggested by the findings of the retrospective study, and therefore, it would be prudent to be alert for reduced anticoagulant effects if primidone is given concurrently with a coumarin.

Coumarins + Benfluorex

Benfluorex does not alter the anticoagulant effects of phenprocoumon.

Clinical evidence, mechanism, importance and management

No significant changes occurred in the prothrombin times of 22 patients stabilised on **phenprocoumon** when they were given benfluorex 150 mg

three times daily for 9 weeks, when compared with equivalent periods before and after taking benfluorex.[1]

1. De Witte P, Brems HM. Co-administration of benfluorex with oral anticoagulant therapy. *Curr Med Res Opin* (1980) 6, 478–80.

Coumarins and related drugs + Benzbromarone or Benziodarone

The anticoagulant effects of warfarin are increased by benzbromarone and bleeding has been seen. Similarly, the anticoagulant effects of acenocoumarol, ethyl biscoumacetate, diphenadione and warfarin are increased by benziodarone. Clorindione, dicoumarol and phenindione were not affected by benziodarone in one study. Phenprocoumon was not affected by benziodarone in one study, but was in another.

Clinical evidence

(a) Benzbromarone

The observation that 2 patients bled (haematuria, gastrointestinal bleeding) when given **warfarin** and benzbromarone, prompted a more detailed study in 7 other patients who were stabilised on both drugs. The thrombotest values of these 7 averaged 24.7% while taking both **warfarin** and benzbromarone (average dosage 57.1 mg daily), but when the benzbromarone was stopped for a week they rose to 47.3%. On restarting the benzbromarone the thrombotest values decreased to 30.3% (indicating an enhanced anticoagulant effect). The Factor II activity paralleled the thrombotest values. The total plasma **warfarin** levels were reduced during the period that benzbromarone was stopped.[1] Another later study found that the **warfarin** requirements of 13 patients given benzbromarone 50 mg daily were 36% lower than in 18 other patients given **warfarin** alone (3.9 versus 2.5 mg daily). The oral clearance of *S*-warfarin was 54% lower in the benzbromarone recipients, but the clearance of *R*-warfarin did not differ between the groups.[2] These two studies confirm observations in other patients with prosthetic valve replacements who had haemorrhagic tendencies when given both drugs.[1]

Early information about benzbromarone noted that no increase in the anticoagulant effects of the coumarins **acenocoumarol** and **ethyl biscoumacetate** or the indanedione **phenindione** had been seen in a few patients also given benzbromarone.[3]

(b) Benziodarone

Benziodarone 200 mg three times daily for 2 days then 100 mg three times daily thereafter was given to 90 patients taking various anticoagulants. To maintain constant prothrombin-proconvertin percentages the coumarin anticoagulant doses were reduced as follows: **ethyl biscoumacetate** 17% (9 patients), **acenocoumarol** 25% (7) and **warfarin** 46% (15). No changes in dose were needed in patients taking **dicoumarol** (9) or **phenprocoumon** (8). For the indanedione anticoagulants, a dose reduction of 42% was required in 8 patients taking **diphenadione**, but no changes were needed in those taking **clorindione** (5 patients) or **phenindione** (10 patients).[4] A parallel study in healthy subjects also found that benziodarone 300 mg or 600 mg daily increased the effects of a single dose of **warfarin**.[4]

In another study, benziodarone 300 to 600 mg daily increased the anticoagulant effects of **phenprocoumon** in just 9 out of 29 patients.[5] Plasma levels of **ethyl biscoumacetate** after a single intravenous dose were increased by pre-treatment with benziodarone 600 mg daily for 6 days.[5]

Mechanism

Benzbromarone selectively inhibits the metabolism of *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9 so that its effects are increased. The metabolism of the *R*-warfarin remains unchanged.[2] Acenocoumarol and phenprocoumon are also known to be metabolised by CYP2C9, and would therefore be expected to interact similarly. Benziodarone is another benzofuran derivative with a similar structure to benzbromarone, and therefore probably interacts by a similar mechanism.

Importance and management

The interaction between warfarin and benzbromarone or benziodarone is established and clinically important. If benzbromarone is given to a patient taking warfarin, monitor prothrombin times and be alert for the need to reduce the dosage by about one-third to prevent over-anticoagulation. Information about other coumarins is limited, but what is known about the mechanism of action suggests that acenocoumarol and phenprocoumon would also be predicted to interact, and this has been shown for benziodarone and acenocoumarol or phenprocoumon, in a few patients. The limited evidence suggesting an interaction with some indanediones also suggests that some caution is appropriate with these drugs as well.

Coumarins + Benzethonium chloride

A rise in INR occurred in a couple who took a grapefruit seed extract product containing considerable amounts of the preservative benzethonium chloride for three days, and one of them developed a minor haematoma.

Clinical evidence

A couple, both well stabilised on warfarin, took some drops of a grapefruit seed extract product (*Estratto di Semillas di Pompelmo*, Lakshmi, Italy) for 3 days. No more was taken, but after a further 3 days the woman developed a minor subcutaneous haematoma, and her INR was found to be 7.9. The man was found to have an INR of 5.1, with no evidence of bleeding.[1]

Mechanism

The product used was stated to contain grapefruit seed extract, glycerol and water. However, chemical analysis of this product revealed that it also contained considerable amounts (77 mg/mL) of the preservative, benzethonium chloride, and did not contain any significant amount of natural substances from grapefruit seeds. The constituents of two other commercial grapefruit seed products were similar on analysis (*Citroseed* and *Citricidal*).

Further, *in vitro* analysis found that benzethonium chloride, and the three products, were potent inhibitors of the cytochrome P450 isoenzyme CYP2C9, suggesting that they could inhibit the metabolism of warfarin.

Importance and management

Data presented in this report, and other papers (one of which is cited as an example[2]), suggests that the primary constituent of many grapefruit seed extract products appears to be the preservative benzethonium chloride. The evidence from the two cases, backed by *in vitro* data, suggests that this has the potential to interact with warfarin. On this basis, it would probably be prudent for patients taking warfarin to avoid grapefruit seed extract products, or for concurrent use to be monitored closely. Some caution might also be appropriate with other pharmaceutical preparations containing benzethonium chloride.

Coumarins + Benzodiazepines and related drugs

A large number of combinations of coumarins and benzodiazepines have been studied, without finding any evidence of an adverse interaction. An interaction between any coumarin and a benzodiazepine is therefore unlikely, but there are three unex-

plained and unconfirmed cases of increased or decreased anticoagulant responses, which were attributed to an interaction.

Clinical evidence

A. Benzodiazepines

(a) Chlordiazepoxide

In a placebo-controlled study in 7 patients stabilised on **warfarin**, chlordiazepoxide 10 mg three times daily for 2 weeks had no effect on anticoagulant control.[1] Other studies in healthy subjects[2,3] and patients[4] have similarly found that chlordiazepoxide does not alter the anticoagulant effect or the half-life of **warfarin**. Similarly, chlordiazepoxide 10 mg three times daily for 10 days had no effect on the half-life of a single intravenous dose of **ethyl biscoumacetate** in healthy subjects.[5] However, one patient stabilised on warfarin had a small 18% fall in mean plasma **warfarin** levels with a corresponding change in the anticoagulant response when given chlordiazepoxide 15 mg daily.[6]

(b) Diazepam

In 4 patients stabilised on **warfarin**, diazepam 5 mg three times daily for 30 days had no effect on anticoagulant control (thrombotest). In one of the patients, the half-life of **warfarin** was measured, and this was not changed by diazepam.[4] Similarly, diazepam 5 mg daily did not alter the anticoagulant response or the half-life of a single dose of **warfarin** in healthy subjects.[3]

However, there are two discordant reports. A patient stabilised on **dicoumarol** developed multiple ecchymoses and a prothrombin time of 53 seconds within 2 weeks of starting to take **diazepam** 5 mg four times daily.[7] The New Zealand Committee on Adverse Drug Reactions has received one report of an increased anticoagulant effect in a patient taking **warfarin** with **diazepam**.[8] It is by no means certain that these responses were due to an interaction.

(c) Flurazepam

In healthy subjects, flurazepam 30 mg at bedtime for 28 days had no effect on the half-life of a single dose of **warfarin** given on days 14 and 28, but there was a slight statistically significant reduction in prothrombin time. In a further placebo-controlled study in 12 patients stabilised on **warfarin**, flurazepam 30 mg at night for 28 days had no effect on prothrombin time or plasma warfarin concentrations.[9]

(d) Midazolam

In a pharmacokinetic study in 12 healthy subjects, **warfarin** and midazolam were given together as probe substrates for the cytochrome P450 isoenzymes CYP2C9 and CYP3A4, respectively. The *S*-warfarin AUC and midazolam plasma clearance were not altered by concurrent use.[10]

(e) Nitrazepam

In two reports by the same researchers, nitrazepam 10 mg at night for 30 days had no effect on steady-state **warfarin** levels or anticoagulant control in a few patients stabilised on **warfarin**.[4,6] In a placebo-controlled study in 22 patients stabilised on **phenprocoumon**, nitrazepam 5 mg at night for 2 weeks had no effect on thrombotest times.[11]

(f) Oxazepam

Oxazepam 10 mg in the morning and 10 to 20 mg in the evening for 3 weeks had no effect on anticoagulant response in 21 patients stabilised on **phenprocoumon**.[12]

B. Non-benzodiazepine hypnotics

(a) Eszopiclone

In a study in healthy subjects, eszopiclone 3 mg daily for 5 days had no effect on the AUC of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin** and there was no change in the INR.[13]

(b) Zaleplon

In a study in healthy subjects, zaleplon 20 mg daily for 12 days had no effect on the AUC of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin**. There was a minor 17% increase in the maximum serum levels of *S*-warfarin. However, zaleplon did not alter the prothrombin time response to **warfarin**.[14,15]

(c) Zolpidem

The prothrombin times of 8 healthy subjects given **warfarin** were unaffected by zolpidem 20 mg daily for 4 days.[16]

Mechanism

The three discordant reports describing an interaction are not understood. Enzyme induction is a possible explanation in one case with chlordiazepoxide,[6] because increases in the urinary excretion of 6-beta-hydroxycortisol (a marker of enzyme induction) have been described during chlordiazepoxide use.[4,6]

Importance and management

The weight of evidence and common experience shows that the benzodiazepines do not interact with the coumarins. Not all of the coumarins and benzodiazepines have been examined, but none of the possible pairs would be expected to interact. Similarly, based on pharmacodynamic studies, no interaction would be anticipated with the newer non-benzodiazepine hypnotics eszopiclone, zaleplon or zolpidem. As eszopiclone is metabolised to **zopiclone**, an interaction between zopiclone and warfarin would also not be expected, although there is no published data to confirm this.

Coumarins and related drugs + Beta blockers

The effects of the coumarins are not normally altered by any beta blocker. However, propranolol has caused small increases in warfarin levels in a couple of studies, and an isolated case described an increased INR in a patient taking warfarin and propranolol.

Clinical evidence

(a) Acenocoumarol

In a study in 4 patients stabilised on acenocoumarol there was no difference in anticoagulation tests when **atenolol** 100 mg daily, **metoprolol** 100 mg twice daily, or placebo, was given for 3 weeks.[1]

(b) Phenindione

In one early clinical study, haemorrhagic tendencies without any changes in Quick value or any other impairment of coagulation were described in three patients stabilised on phenindione within 6 weeks of starting **propranolol**.[2]

(c) Phenprocoumon

In healthy subjects, a single dose of **atenolol** 100 mg or **metoprolol** 100 mg did not affect the AUC of a single dose of phenprocoumon, although phenprocoumon levels were slightly higher at 4 and 6 hours after the **metoprolol** dose. Nevertheless, neither beta blocker altered the prothrombin time response.[3]

In healthy subjects, **carvedilol** 25 mg daily for 7 days had no effect on

the pharmacokinetics of a single 15-mg dose of phenprocoumon given on day 5 phenprocoumon.[4]

In 12 patients stabilised on phenprocoumon, there was no difference in Quick time between those randomised to receive **pindolol** 5 mg three times daily for 6 weeks and those who received placebo.[5]

(d) Warfarin

In 6 patients stabilised on warfarin, **acebutolol** 300 mg three times daily for 3 days had no effect on prothrombin time response.[6] Similarly, in one patient taking warfarin, neither **atenolol** 100 mg daily nor **metoprolol** 100 mg twice daily for 3 weeks had any effect on prothrombin time.[1] Similarly, in studies in healthy subjects the following beta blockers had no clinically relevant effects on the pharmacokinetics and/or anticoagulant response to warfarin; **atenolol** 100 mg daily,[7] **betaxolol** 20 mg daily,[8] **bisoprolol** 10 mg daily,[9] **esmolol**,[10] **metoprolol** 100 mg twice daily[7] or **nebivolol** 10 mg daily.[11]

In contrast, the minimum steady-state plasma **warfarin** levels of 6 healthy subjects rose by 15% when they took **propranolol** 80 mg twice daily in one study.[12] Similarly, in another study in 6 healthy subjects given **propranolol** 80 mg twice daily for 7 days with a single dose of warfarin on day 4, the AUC of warfarin was increased by about 16% and the in maximum serum level was increased by 23%, but there was no change in the prothrombin time.[7] A patient stabilised on **warfarin** had a rise in his British Corrected Ratio from a low of 1.3 up to 2.5 while taking **propranolol** 80 mg twice daily.[13]

Mechanism

None known.

Importance and management

Overall, the findings of these pharmacological studies in patients and healthy subjects confirm the general clinical experience that the effects of the coumarins are not normally altered by the beta blockers. No special precautions are needed on concurrent use. The only uncertainty is with propranolol, which has caused a small rise in warfarin levels in two studies, and for which there is one case report describing an increased INR with warfarin. Even so, a clinically significant interaction would seem to be extremely rare.

Coumarins + Bicalutamide, Flutamide or Nilutamide

A few cases have been reported of flutamide possibly increasing the anticoagulant effects of warfarin. Based on limited *in vitro* evidence, it has been predicted that bicalutamide and nilutamide might interact with coumarins.

Clinical evidence and mechanism

(a) Bicalutamide

The manufacturers say that *in vitro* studies show that bicalutamide can displace **warfarin** from its protein binding sites.[1,2] It used to be thought that the displacement of **warfarin** from its protein binding sites by other drugs normally resulted in clinically important interactions, but that is now known to rarely be true (see 'Protein-binding interactions', (p.3)). In 1995, the manufacturers said that they did not know of any reports of an interaction between **warfarin** and bicalutamide, apart from an isolated case of a raised INR in one patient taking **warfarin** with bicalutamide 150 mg, but no causal link with bicalutamide was established.[3] In a clinical study of bicalutamide and finasteride, it was briefly stated that one patient developed a prolonged prothrombin time while also taking **warfarin**.[4] To date, there appear to be no other published cases of an interaction.

(b) Flutamide

In 1990, the manufacturer had 5 cases on record of patients with prostatic cancer receiving **warfarin** whose prothrombin times had increased when they were given flutamide. For example, one patient needed reductions in his **warfarin** dose from 35 mg weekly to 22.5 mg weekly over a 2-month period. Another had a prothrombin time rise from 15 seconds to 37 seconds within 4 days of starting flutamide 750 mg daily.[5] There appears to be no published information about this interaction.

(c) Nilutamide

The manufacturer notes that, *in vitro*, nilutamide has been shown to inhibit cytochrome P450 isoenzymes (specific isoenzymes not stated). Because of this, they suggest that nilutamide might increase the toxicity of drugs with a low therapeutic margin such as the vitamin K antagonists (i.e. **coumarins** and **indanediones**). There appears to be no published information about this interaction.

Importance and management

No interaction is established, and had there been any interaction, it might have been expected to come to light by now. The lack of any published case reports suggests that there is little reason to believe that these non-steroidal anti-androgens specifically interact with warfarin. Despite this, the manufacturers of bicalutamide, flutamide and nilutamide recommend that the prothrombin time be carefully monitored when these drugs are given with coumarins, adjusting the dose when necessary.[2,6,7]

Consider also that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[8]

Coumarins and related drugs + Bile-acid binding resins

The anticoagulant effects of phenprocoumon and warfarin can be reduced by colestyramine. Conversely, an isolated report describes unexpected sensitivity to warfarin in a patient taking colestyramine, which was attributed to a possible reduction in vitamin K absorption with colestyramine. Colestipol does not alter the absorption or effect of phenprocoumon or warfarin, and colesevelam does not alter the pharmacokinetics of warfarin.

Clinical evidence

(a) Colesevelam

In a single-dose study in 24 healthy subjects, colesevelam 4.5 g had no effect on the pharmacokinetics of **warfarin** 10 mg.[1]

(b) Colestipol

In a placebo-controlled, single-dose study in 4 healthy subjects, **phenprocoumon** plasma levels and the prothrombin response were unaffected by colestipol 8 g given at the same time as **phenprocoumon** 12 mg.[2] Similarly, in a study in healthy subjects quoted in a review,[3] the concurrent use of colestipol 10 g did not cause any changes in the absorption of a single 10-mg dose of **warfarin**.

The long-term use of colestipol might have the potential to decrease fat soluble vitamins such as vitamin K, which result in a prolonged prothrombin time,[4] and thereby increase the effect of warfarin. However, the manufacturers report that in a study, the use of colestipol resulted in a prolonged prothrombin time in only one patient.[4]

(c) Colestyramine

1. Phenprocoumon. It was noted that establishing effective anticoagulation was difficult in patients taking phenprocoumon with colestyramine, in spite of doubling the dose of phenprocoumon. This prompted a study in healthy subjects in which it was found that concurrent single doses of phenprocoumon and colestyramine markedly reduced the plasma levels and effect of phenprocoumon.[5] In another study using *intravenous* phenprocoumon, colestyramine reduced the effect of the anticoagulant by this route, presumably by reducing enterohepatic recycling.[6] This fact has been used clinically to enhance the elimination of phenprocoumon after phenprocoumon overdose. In one case, the half-life of phenprocoumon was measured as 6.8 days without colestyramine, and 3.5 days with colestyramine 4 g three times daily.[7]

A patient stabilised on phenprocoumon developed a fatal valve thrombosis after starting colestyramine, despite separation of doses in accordance with the manufacturer's instructions.[8]

2. Warfarin. In a study, 10 subjects were given warfarin alone or with colestyramine, for one-week periods. When warfarin was taken 30 minutes after colestyramine, peak warfarin levels were reduced by 52% and the prolongation in prothrombin times was reduced by 27%, compared with warfarin alone. However, when warfarin was taken 6 hours after colestyramine, peak warfarin levels were reduced by only 16%, and the prolongation in prothrombin times was the same as with warfarin alone.[9]

Comparable results were found in another similar study; simultaneous administration of warfarin and colestyramine reduced the prothrombin time response by 21%, and separation by 3 hours still caused an 11% reduction in the prothrombin time response.[10] Another study using *intravenous* warfarin has shown that colestyramine also reduces the effect of warfarin by this route, presumably by reducing enterohepatic recycling.[11] Note that colestyramine has been used to speed up the elimination of warfarin in cases of over-anticoagulation.[12,13]

Another report describes a patient taking colestyramine 4 g three times daily who was successfully stabilised on warfarin with alternating doses of 5 mg and 7.5 mg daily. The warfarin was given at 8 am, then the colestyramine at 12 noon with lunch, with dinner, and with an evening snack.[14]

In contrast, an isolated report describes a 77-year-old patient taking multiple medications including colestyramine who was found to have a very high prothrombin time of 78.9 seconds and microscopic haematuria 6 weeks after starting warfarin 5 mg daily. Four days after starting the warfarin her prothrombin time was 17.1 seconds, and it had not been checked again.[15] However, as it is not certain that this patient was properly stabilised on warfarin this may simply have been an effect of the warfarin alone.

Mechanism

Colestyramine binds to coumarins in the gut, thereby preventing their absorption.[5,10,16,17] Data with *intravenous* warfarin and phenprocoumon show that they undergo enterohepatic recycling, and that colestyramine can reduce this as well.[6,11] The long-term use of colestyramine also reduces the absorption of fat-soluble vitamins such as vitamin K so that it can have some direct hypoprothrombinaemic effects of its own.[18,19] This may to some extent offset the full effects of its interaction with anticoagulants. Colestipol on the other hand appears not to bind to any great extent at the pH values in the gut,[2] although, in the same way as colestyramine, it might reduce absorption of vitamin K and prolong the prothrombin time.[4] The paradoxical increase in the effects of warfarin in the isolated case cited above was attributed to the effect of colestyramine on vitamin K.[15]

Importance and management

The interaction of colestyramine with phenprocoumon and warfarin is established, and can be clinically important. If concurrent use is thought necessary, prothrombin times should be monitored and the dose of the anticoagulant increased appropriately. Giving the colestyramine 4 to 6 hours after the anticoagulant has been shown to minimise the effects of this interaction,[9,14] and it is a standard recommendation that other drugs should be given one hour before or 4 to 6 hours after colestyramine. However, despite adequate separation of doses, one patient taking phenprocoumon developed fatal valve thrombosis when given colestyramine, leading the authors to suggest that colestyramine should not be used in patients taking oral anticoagulants.[8] Information about other anticoagulants is lacking but as colestyramine interacts with dicoumarol and ethyl biscoumacetate in *animals*[17] it would be prudent to expect all coumarins to interact similarly. Bear in mind that long-term colestyramine can reduce vitamin K absorption and can cause hypoprothrombinaemia. This might result in an increased effect of warfarin, as has been suggested in one unconfirmed case report, but there seems to be no other evidence to suggest that this is clinically relevant.

No special precautions appear to be necessary if warfarin or phenprocoumon and colestipol or colesevelam are given concurrently. But, as with colestyramine, bear in mind that the long-term use of colestipol might reduce vitamin K absorption and cause hypoprothrombinaemia. This might result in an increased effect of warfarin.

There appear to be no reports of an interaction with the **indanediones**, however, should long-term use of a bile-acid binding resin result in reduced vitamin K absorption and subsequent hypoprothrombinaemia, this would be expected to be additive with the anticoagulant effects of these drugs.

Coumarins + Boldo or Fenugreek

A report describes a woman taking warfarin whose INR rose modestly when she began to take boldo and fenugreek.

Clinical evidence

A woman taking **warfarin** for atrial fibrillation whose INR was normally within the range 2 to 3 had a modest rise in her INR to 3.4, apparently due to the use of 10 drops of boldo after meals and one capsule of fenugreek before meals. A week after stopping these two herbal medicines her INR had fallen to 2.6. When she restarted them, her INR rose to 3.1 after a week, and to 3.4 after 2 weeks. Her INR was later restabilised in her normal range while continuing to take these two herbs by reducing the **war-**

farin dose by 15%.[1] The patient had no undesirable reactions (e.g. bruising or bleeding).

Mechanism

The mechanism of this apparent interaction remains unknown, and it is not known whether both herbs or just one was responsible for what happened. Both boldo and fenugreek have been reported to contain natural coumarins, but it is unclear whether they have any anticoagulant activity. Consider also, 'Coumarins + Herbal medicines; Miscellaneous', p.472.

Importance and management

Evidence is limited to one isolated case. Because of the many other factors influencing anticoagulant control, it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects.

1. Lambert JP, Cormier A. Potential interaction between warfarin and boldo-fenugreek. *Pharmacotherapy* (2001) 21, 509–12.

Coumarins + Broxuridine

A case report describes an increase in the effects of warfarin in a patient taking broxuridine.

Clinical evidence, mechanism, importance and management

A man taking **warfarin** and with grade III anaplastic astrocytoma was given intravenous broxuridine as a radiosensitiser. His prothrombin times were unaffected by the first course of broxuridine 1.4 g daily for 4 days, but became more prolonged with successive courses, and after the fourth course his prothrombin time reached about 45 seconds. This was managed with 10 mg of vitamin K. Warfarin was stopped after a significant increase in his prothrombin time also took place with a fifth cycle of broxuridine 990 mg daily.[1] The clinical relevance of this single case is uncertain.

Coumarins + Bucolome

Bucolome increases the anticoagulant effects of warfarin by inhibiting its metabolism.

Clinical evidence

A study in Japanese patients stabilised on **warfarin** found that the addition of bucolome 300 mg daily increased the INR of 21 patients by 50% despite a 58% reduction in the **warfarin** dose, when compared with another group of 34 patients taking **warfarin** and not receiving bucolome.[1] In another 7-day study, 25 Japanese patients with heart disease taking **warfarin** and bucolome 300 mg daily were compared with another control group of 30 patients taking **warfarin** alone. It was found that bucolome had no effect on the serum levels of *R*-warfarin but both the serum levels of *S*-warfarin and the prothrombin times rose. These changes were complete within 7 days.[2] In one analysis, the daily dose of **warfarin** was found to be about 40% lower in 78 patients taking bucolome, when compared with 99 patients not taking bucolome, although the thrombotest values were lower in those also taking bucolome (suggesting greater anticoagulation). Bucolome appeared to reduce the between patient variation in intrinsic hepatic clearance of warfarin.[3]

A patient who had been taking **warfarin** with bucolome for 18 days developed gross haematuria. He was found to have an intraluminal ureteral haematoma and an excessively prolonged prothrombin time, and was treated with intravenous vitamin K.[4]

Mechanism

In vitro studies show that the bucolome can inhibit the metabolism of the more potent enantiomer *S*-warfarin by the cytochrome P450 isoenzyme CYP2C9, thereby reducing its clearance and increasing its effects.[1]

Importance and management

Information appears to be limited to the reports cited here but the interaction would seem to be established and clinically important. Monitor the INR closely. A reduced warfarin dose (the study[2] cited above suggests a 30 to 60% reduction) is likely to be needed if both drugs are used concurrently to avoid excessive anticoagulation and possible bleeding. Note that bucolome is sometimes used with warfarin to enhance its therapeutic effect.[3] Based on the mechanism of action, **acenocoumarol** and **phenprocoumon** would be anticipated to be similarly affected.

Coumarins + Buflomedil

Buflomedil does not alter the anticoagulant effect of acenocoumarol.

Clinical evidence, mechanism, importance and management

In a randomised study in patients with severe or recurrent venous thrombosis, there was no difference in dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with buflomedil 600 mg daily and 100 patients taking **acenocoumarol** alone. No patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria).[1] This suggests that no **acenocoumarol** dose adjustments are likely to be needed when it is used with buflomedil.

1. Moriau M, Lavenne-Pardonge E, Crasborn L, von Frenckell R, Col-Debeys C. The treatment of severe or recurrent deep venous thrombosis. Beneficial effect of the co-administration of antiplatelet agents with or without rheological effects, and anticoagulants. *Thromb Res* (1995) 78, 469–82.

Coumarins and related drugs + Calcium-channel blockers

Amlodipine and felodipine do not affect the anticoagulant effects of warfarin. Diltiazem, and possibly verapamil, may cause a minor decrease in warfarin metabolism, but the anticoagulant effect of warfarin is unlikely to be affected. Verapamil does not appear to alter the anticoagulant effects of phenindione.

Clinical evidence

(a) Dihydropyridine calcium-channel blockers

The manufacturers say that **amlodipine** did not significantly alter the effect of **warfarin** on prothrombin times in healthy subjects.[1,2]

In healthy subjects given **warfarin** until steady state, **felodipine** 10 mg daily for 14 days did not alter the dose of **warfarin** required to maintain a stable INR, or affect the pharmacokinetics of *S*- or *R*-warfarin.[3] Because **felodipine** does not interact with **warfarin** it has been used as a control drug in retrospective cohort studies assessing **warfarin** drug interactions.[4,5]

(b) Diltiazem

In a study, 11 healthy men were given racemic **warfarin**, and 8 were given *R*-warfarin, both as a single 1.5-mg/kg intravenous dose. Another 10 subjects were given *S*-warfarin as a single 0.75-mg/kg intravenous dose. After taking diltiazem 120 mg three times daily (for 4 days before and 9 days after the dose of **warfarin**) the clearance of *R*-warfarin was decreased by about 20% but the more potent *S*-warfarin remained unaffected. The total anticoagulant response remained unchanged.[6] Similarly, in another study in 20 healthy subjects, diltiazem 30 mg three times daily for one week caused no clinically relevant changes in the anticoagulant effects of a single dose of **warfarin**. There was a small 13% decrease in **warfarin** clear-

ance and an 8% increase in its AUC in the presence of diltiazem, but these changes were not statistically significant.[7]

However, one report describes a patient stabilised on **warfarin** with an INR in the range of 2.5 to 3 who was found to have an INR of 4.2 two weeks after starting diltiazem 180 mg daily.[8]

(c) Verapamil

In a small study in 20 patients to investigate the effectiveness of verapamil 80 mg three times daily for 2 weeks for angina, 10 of these patients were also taking **phenindione** during the study. Although not specifically studied, the authors of this study reported that there was no significant change in the sensitivity of these 10 patients to **phenindione** during the use of verapamil.[9]

Mechanism

Diltiazem is a known inhibitor of the cytochrome P450 isoenzyme CYP3A4. However, this isoenzyme has only a minor role in the 'metabolism of warfarin', (p.405), specifically in the metabolism of the less active *R*-isomer of warfarin. Consequently, only minor increases in the levels of warfarin have been seen in pharmacokinetic studies, which would generally not be expected to be clinically relevant. Verapamil is also an inhibitor of CYP3A4, but the dihydropyridine calcium-channel blockers are not.

Importance and management

No special precautions would seem to be necessary during the concurrent use of warfarin and dihydropyridine calcium-channel blockers. Although the minor pharmacokinetic interaction between diltiazem and warfarin would appear to be established, in the studies cited this did not change anticoagulant control, and is therefore unlikely to be of clinical importance. Verapamil would be expected to cause a similar, minor pharmacokinetic interaction to diltiazem, which would be unlikely to result in clinically significant effects, although the only available data to confirm this appears to be the small study reported above. The absence of adverse reports about these very widely used drugs suggests that concurrent use is normally uneventful.

Coumarins + Carbamazepine or Oxcarbazepine

The anticoagulant effects of warfarin can be markedly reduced by carbamazepine. Two case reports suggest phenprocoumon is similarly affected, and one case has been described with acenocoumarol. Oxcarbazepine appears not to interact significantly with warfarin.

Clinical evidence

(a) Carbamazepine

1. Acenocoumarol. A man taking stable doses of acenocoumarol and carbamazepine 200 mg daily started coughing up blood about 4 weeks after the carbamazepine was stopped, and he was found to be over-anticoagulated. The acenocoumarol was stopped for 48 hours and he was given vitamin K.[1]

2. Phenprocoumon. A man in his mid-twenties developed multiple thrombotic episodes due to hereditary resistance to activated protein C. Because of cerebral embolic strokes he developed epileptic seizures and was given carbamazepine 400 mg daily, followed 6 days later by phenprocoumon. It was found that relatively large doses of phenprocoumon (8 mg daily) had to be given without achieving adequate anticoagulation (Quick value 50 to 60%; target 10 to 20%) until the carbamazepine was withdrawn, whereupon the phenprocoumon dose could be reduced to 1.5 mg daily with a Quick value of 30 to 40%.[2] Similarly, another patient stabilised on phenprocoumon was found to have a markedly reduced anticoagulant effect (a dramatic increase in his Quick value) 21 days after he started taking carbamazepine 400 mg daily. The values returned to normal when the carbamazepine was stopped.[3]

3. Warfarin. In one study, 2 patients taking warfarin with carbamazepine (200 mg daily for the first week, 400 mg daily for the second and 600 mg for the third) had a fall of about 50% in their serum warfarin levels, and sharp rises in their prothrombin-proconvertin percentages.[4] The half-life of a single intravenous dose of warfarin in three other patients fell by about 11%, 53%, and 60%, respectively, when they were similarly treated.[4] In another analysis, warfarin dose requirements were 2.3-fold higher in 5 patients stabilised on warfarin and carbamazepine than in 54 patients taking warfarin without any interacting drugs (median 9 mg daily versus 3.86 mg daily). The 5 patients taking carbamazepine had higher clearances of both *R*- and *S*-warfarin, and had about 11-fold higher plasma levels of the 10-hydroxymetabolite of warfarin.[5] In a prospective cohort study in children, the use of phenobarbital or carbamazepine was associated with a higher dose of warfarin to maintain the target INR (0.24 mg/kg versus 0.15 mg/kg).[6] A retrospective study[7] similarly found that the concurrent use of enzyme inducers (including carbamazepine) significantly influenced the total weekly warfarin dose; further analysis found that an average additional amount of warfarin required in patients taking these drugs was 17.2 mg weekly.

An interaction between warfarin and carbamazepine has been described in 5 case reports.[8-12] One of them describes a patient stabilised on warfarin and carbamazepine who developed widespread dermal ecchymoses and a prothrombin time of 70 seconds, one week after stopping carbamazepine. She was restabilised on approximately half the dose of warfarin in the absence of carbamazepine.[11]

(b) Oxcarbazepine

In a study in 7 healthy subjects given **warfarin** until steady-state, oxcarbazepine 450 mg twice daily for one week slightly increased the mean Quick values from 36.6% to only 38.1%, which was not statistically significant.[13]

Mechanism

Carbamazepine is a known enzyme inducer, and increases the metabolism of warfarin. Acenocoumarol and phenprocoumon would be similarly affected. Oxcarbazepine has less enzyme-inducing activity than carbamazepine, and, in the study described,[13] this was not sufficient to significantly alter the effects of warfarin.

Importance and management

The interaction between warfarin and carbamazepine is moderately well documented, established and clinically important, although the incidence is uncertain. Monitor the anticoagulant response if carbamazepine is added to established treatment with warfarin and anticipate the need to double the dose. Similarly, anticipate the need to decrease the warfarin dose if carbamazepine is stopped. Oxcarbazepine appears to be a relatively non-interacting alternative.

Information about an interaction between phenprocoumon or acenocoumarol and carbamazepine seems to be limited to the three reports cited. Nevertheless it would be prudent to monitor concurrent use in any patient, being alert for the need to increase the coumarin dose.

Coumarins + Carbon tetrachloride

A single case report describes an increase in the anticoagulant effects of dicoumarol in a patient who accidentally drank some cleaning liquid containing carbon tetrachloride.

Clinical evidence, mechanism, importance and management

A patient, well stabilised on **dicoumarol**, accidentally drank a small amount of cleaning liquid later estimated to contain just 0.1 mL of carbon tetrachloride. The next day his prothrombin time had risen to 41 seconds. This value was about the same after another day even though the **dicoumarol** had been withdrawn, and marked hypoprothrombinaemia persisted for another 5 days.[1]

The probable reason for this reaction is that carbon tetrachloride is very toxic to the liver, the changed anticoagulant response being a manifestation of this. Carbon tetrachloride, once used as an anthelmintic in man, is no longer used in human medicine, but is still employed as an industrial solvent and degreasing agent. On theoretical grounds it would seem possible for anticoagulated patients exposed to substantial amounts of the vapour to experience this interaction, but this has not been reported.

1. Luton EF. Carbon tetrachloride exposure during anticoagulant therapy. Dangerous enhancement of hypoprothrombinemic effect. *JAMA* (1965) 194, 1386–7.

Coumarins + Chamomile

A single case report describes a woman stabilised on warfarin who developed a marked increase in her INR with bleeding complications five days after she started using two chamomile products.

Clinical evidence

A 70-year-old woman stabilised on **warfarin** with an INR of 3.6 started drinking 4 to 5 cups of chamomile tea (an infusion of *Matricaria chamomilla*) daily for chest congestion, and using a chamomile-based skin lotion 4 to 5 times daily for foot oedema. About 5 days later she developed ecchymoses and was found to have an INR of 7.9, a retroperitoneal haematoma and other internal haemorrhages.[1]

Mechanism

German chamomile contains the natural coumarin compounds, umbelliferone and heniarin, However, these compounds do not possess the minimum structural requirements (a C-4 hydroxyl substituent and a C-3 non-polar carbon substituent) required for anticoagulant activity. German chamomile essential oil extracts do not appear to significantly affect the cytochrome P450 isoenzyme CYP2C9, the main isoenzyme involved in the metabolism of warfarin, but the effects of chamomile tea do not appear to have been studied.

Importance and management

This appears to be the first report of an interaction between warfarin and German chamomile. There seem to be no reports of German chamomile alone causing anticoagulation, and the natural coumarin constituents of German chamomile do not appear to possess anticoagulant activity, which might suggest that the risk of an additive effect is small. Furthermore, a pharmacokinetic basis for this interaction has not been established. Because of the many other factors influencing anticoagulant control, it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects.

Coumarins + Chinese angelica (*Angelica sinensis*)

Two case reports describe a very marked increase in the anticoagulant effects of warfarin when Chinese angelica was given.

Clinical evidence

A 46-year-old African-American woman with atrial fibrillation taking **warfarin** had a greater than twofold increase in her prothrombin time and INR after taking Chinese angelica for 4 weeks. The prothrombin time and INR were back to normal 4 weeks after stopping Chinese angelica.[1] In another case, a woman who had been taking **warfarin** for 10 years developed widespread bruising and an INR of 10, a month after starting to take Chinese angelica.[2]

Mechanism

The reasons for this interaction are not fully understood but Chinese angelica is known to contain natural coumarin derivatives, which may possibly have anticoagulant properties: these could be additive with those of warfarin. The data suggest that alteration of warfarin levels is not involved, but other studies suggest that the herb may inhibit the cytochrome P450 isoenzyme CYP2C9, which is the main route of warfarin metabolism.

Importance and management

Clinical evidence for an interaction between Chinese angelica and warfarin appears to be limited to the case reports cited, and an interaction is not fully established. Nevertheless, it would seem prudent to warn patients taking warfarin, and possibly other coumarin anticoagulants, of the potential risks of also taking Chinese angelica. For safety, the use of Chinese angelica should be avoided unless the effects on anticoagulation can be monitored. More study is needed.

Coumarins and related drugs + Chitosan

An isolated report describes an increase in the INR of an elderly man taking warfarin when he also took chitosan.

Clinical evidence

A case report describes an 83-year-old man, with type 2 diabetes who was receiving **warfarin** (2.5 mg daily for one year, with an INR of between 2 and 3) for atrial fibrillation. At a routine blood test his INR was found to be about 3.7, and, although the dose of **warfarin** was halved, 3 days later his INR was more than 9. On discussion, it was established that he had recently started taking chitosan 1.2 g twice daily. He was advised to stop this supplement and was subsequently restabilised on **warfarin**. About one month later, the patient restarted the chitosan, which again resulted in a raised INR.[1]

Mechanism

Chitosan sulfate has been reported to have anticoagulant activity, but this has not been found with chitosan. The authors therefore suggest that chitosan impaired the absorption of fat soluble vitamins, including vitamin K. Warfarin is a vitamin-K antagonist and a reduction in vitamin K would be expected to enhance its effects.

Importance and management

Evidence is limited to this case, and the mechanism is largely speculative; however an interaction seems probable. The evidence is too slim to forbid patients taking warfarin from also taking chitosan, but it would seem prudent to discuss the possible outcome and advise an increase in the frequency of anticoagulant monitoring; measuring the INR after a few days of concurrent use seems reasonable. There appears to be no evidence regarding other anticoagulants, but if the mechanism is correct, all vitamin K an-

tagonists (coumarins and **indanediones**) would be expected to be similarly affected.

1. Huang S-S, Sung S-H, Chiang C-E. Chitosan potentiation of warfarin effect. *Ann Pharmacother* (2007) 41, 1912–14.

Coumarins + Chlorpromazine

Chlorpromazine probably does not interact significantly with the coumarins.

Clinical evidence, mechanism, importance and management

Although in one early report, chlorpromazine 40 to 100 mg daily was said to have 'slightly sensitised' 2 out of 8 patients to the effects of **acenocoumarol**[1] and in another was reported to increase its anticoagulant effects in *animals*,[2] there appears to be nothing else published to suggest that an interaction occurs. *In vitro* study in human liver microsomes[3] found that chlorpromazine did not inhibit CYP2C9, the cytochrome P450 isoenzyme predominantly involved in the 'metabolism of **warfarin**', (p.405), and other coumarins. No coumarin dose adjustments would therefore be expected to be needed on concurrent use.

Coumarins and related drugs + Cilostazol

Cilostazol does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, as with other antiplatelet drugs, concurrent use might increase the bleeding risk.

Clinical evidence, mechanism, importance and management

In a well-controlled study in 15 healthy subjects, cilostazol 100 mg twice daily for 13 days did not alter the pharmacokinetics of a single 25-mg dose of warfarin given on day 7. Also, prothrombin times, aPTT and Ivy bleeding time were unaffected.[1]

This suggests that no specific interaction is likely during concurrent use. Nevertheless, because cilostazol is an antiplatelet drug, the manufacturer advises caution with the concurrent use of anticoagulants, with more frequent monitoring to reduce the possibility of bleeding.[2] Consider also, 'Coumarins and related drugs + Aspirin or other Salicylates', p.434.

2. Pletal (Cilostazol). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, November 2008.

Coumarins + Cinacalcet

Cinacalcet does not appear to affect the pharmacokinetics or anticoagulant effects of warfarin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 21 healthy subjects were given cinacalcet 30 mg twice daily for 15 doses, with a single 25-mg dose of warfarin on day 5. Cinacalcet did not affect the pharmacokinetics of warfarin or its effects on prothrombin time.[1] This study suggests that the dose of warfarin is unlikely to need adjusting in patients given cinacalcet.

1. Padhi D, Sullivan JT. Cinacalcet does not affect the pharmacokinetics or pharmacodynamics of warfarin. *Drugs R D* (2007) 8, 79–87.

Coumarins and related drugs + Clopidogrel

Clopidogrel does not appear to have a clinically relevant effect on the pharmacokinetics or pharmacodynamics of warfarin. Nevertheless, the concurrent use of clopidogrel, either with warfarin or when given with warfarin and aspirin, increases the bleeding risk.

Clinical evidence

(a) Pharmacokinetics

In a well-controlled study involving 43 patients who had been taking **warfarin** for at least 2 months, the addition of clopidogrel 75 mg daily for 8 days had no effect on plasma **warfarin** levels or INRs. No bleeding occurred with clopidogrel and no serious adverse events were reported.[1]

(b) Triple therapy

Dual antiplatelet therapy (usually low-dose aspirin with clopidogrel) is increasingly used in acute coronary syndromes in situations where the benefits have been shown to outweigh the small increased risk of bleeding with the combination (see 'Antiplatelet drugs + Aspirin', p.814). Some of these patients also require anticoagulants for additional indications, for example, for atrial fibrillation or mechanical valves. However, there are limited clinical study data on the benefits and risks of anticoagulants given with dual antiplatelet therapy (triple therapy).

In a 2008 review of 12 studies (mostly retrospective cohort studies),[2] the increased risk of bleeding events for triple therapy versus dual therapy was three- to sixfold in 8 of the studies, with 4 of the studies reporting no increased risk of major bleeding events. In one of these studies, patients who had been taking **warfarin** long-term and who underwent stent implantation and were subsequently discharged taking aspirin, clopidogrel and **warfarin**, had a higher risk of bleeding compared with those taking dual therapy: the incidence of major bleeding was 6.6% and the incidence of minor bleeding was 14.9% in those taking triple therapy compared with 0% and 3.8% for major and minor bleeding, respectively, in patients taking dual therapy with no **warfarin**.[3] Another of the meta-analysis studies reported an incidence of 9.2% of bleeding in patients who had undergone stent placement and received **warfarin**, aspirin and clopidogrel.[4] In an observational cohort study of elderly survivors of acute myocardial infarction, the rate of bleeding was higher in patients receiving **warfarin** with aspirin (0.08 per patient year), or the triple drug combination of **warfarin** and aspirin with either clopidogrel or ticlopidine (0.09 per patient year), than in patients receiving aspirin alone (0.03 per patient year).[5]

Mechanism

As with other antiplatelet drugs (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), concurrent use of clopidogrel and oral anticoagulants might increase the risk or intensity of bleeding.

Importance and management

The concurrent use of warfarin and clopidogrel (with or without aspirin) increases the risk of bleeding. These combinations should therefore be used only when there is a clear indication for using both an anticoagulant and antiplatelet, and the expected benefits are likely to outweigh the increased risks of bleeding. The American College of Cardiology and American Heart Association 2007 joint guidelines for acute coronary syndromes recommend that if warfarin is added to dual antiplatelet therapy, the lowest effective INR (e.g. 2 to 2.5) should be targeted and concurrent use undertaken for the shortest reasonable duration.[6] In addition, a 2008 guideline states that a proton pump inhibitor should be used for gastroprotection,[7] although note that the use of clopidogrel with a proton pump inhibitor is controversial (see 'Clopidogrel + Proton pump inhibitors and other CYP2C19 inhibitors', p.821). The joint American and European 2006 guidelines for atrial fibrillation specifically recommend that, in patients undergoing percutaneous coronary intervention, aspirin may be given temporarily but that the maintenance regimen should then consist of clopidogrel and warfarin (INR 2 to 3) without aspirin. Although there are no adequate studies, the consensus of the authors was that the addition of aspirin to oral anticoagulation rather than clopidogrel contributes more risks than benefits,[8] although this has been questioned.[9]

Note that, in the UK, the manufacturers of clopidogrel actually state that the concurrent use of warfarin is not recommended,[10] whereas the US manufacturers just recommend caution.[11]

The manufacturers of clopidogrel note that *in vitro* it has been reported to inhibit the cytochrome P450 isoenzyme CYP2C9.[10,11] They therefore predict that the metabolism of drugs that are substrates of this isoenzyme, such as warfarin[11], may be affected. However, no relevant increase in warfarin levels was found in the study[1] reported above, and the UK manufac-

turer notes that no clinically relevant interaction was reported in patients taking phenytoin or tolbutamide during the CAPRIE study. Also, no significant interaction occurs between clopidogrel and fluvastatin (see 'Clopidogrel + Statins', p.823), another substrate of CYP2C9. Therefore a pharmacokinetic interaction between clopidogrel and warfarin seems unlikely.

Coumarins + Cloral hydrate and related drugs

The anticoagulant effects of warfarin are increased in the first few days of cloral hydrate use, but this is normally of little or no clinical importance. Cloral betaine and triclofos may be expected to behave similarly.

Clinical evidence

In a retrospective study in patients just starting **warfarin**, the same loading doses of **warfarin** were given to 32 patients taking **cloral hydrate** daily and 67 patient who did not receive cloral hydrate. The **warfarin** requirements of the **cloral** group during the first 4 days fell by about one-third, but rose again to control requirements by the fifth day.[1]

In a study in 8 subjects, the concurrent use of **warfarin** (loading dose 25 mg then 5 mg daily for 5 days) and **cloral hydrate** 1 g each night resulted in potentiation of the effect of **warfarin**, when compared with placebo (increase in prothrombin time of about 3 to 4 seconds). However, in a longer term study, the addition of **cloral hydrate** 500 mg at night for 4 weeks to subjects stabilised on **warfarin** did not alter the average prothrombin time before, during, and after the use of **cloral** (18.9 seconds, 19.3 seconds, and 19.2 seconds, respectively).[2,3] Similar results have been described in other studies in patients taking **warfarin** and **cloral hydrate**[4-8] or **triclofos**.[9] **Cloral betaine** appears to behave similarly.[10] An isolated and by no means fully explained case of fatal hypoprothrombinaemia occurred in a patient taking **dicoumarol** who was given **cloral hydrate** for 10 days, later replaced by secobarbital.[11] Another patient taking **dicoumarol** had a reduction in prothrombin times when given **cloral hydrate**.[11]

Mechanism

Cloral hydrate is mainly metabolised to trichloroacetic acid, which then successfully competes with warfarin for its binding sites on plasma proteins.[6] As a result, free and active molecules of warfarin are displaced into the plasma water and the effects of the warfarin are increased. However, this effect is only short-lived because the warfarin molecules become exposed to metabolism by the liver, so the warfarin level is reduced.

Importance and management

The interaction between warfarin and cloral hydrate is well documented and well understood, but normally of little or no clinical importance. There is very good evidence that concurrent use need not be avoided.[1-8] However, it may be prudent to keep an eye on the anticoagulant response during the first 4 to 5 days, just to make sure it does not become excessive. It is not certain whether other anticoagulants behave in the same way because the evidence is sparse, indirect and inconclusive,[11,12] but what is known suggests that the coumarins probably do. Triclofos and cloral betaine appear to behave like cloral hydrate. Dichloralphenazone on the other hand interacts quite differently (see 'Coumarins + Dichloralphenazone', p.453).

Coumarins + Coenzyme Q_{10} (Ubidecarenone)

Ubidecarenone did not alter the INR or required warfarin dose in a controlled study in patients stabilised on warfarin. However, two reports describe reduced anticoagulant effects of warfarin in four patients taking ubidecarenone. A transient increase in INR has been reported in one patient taking ubidecarenone and warfarin. A 4-month prospective, longitudinal study describes an increased risk of self-reported bleeding events in patients taking coenzyme Q_{10} with warfarin.

Clinical evidence

In a randomised, crossover study in 21 patients stabilised on **warfarin**, coenzyme Q_{10} 100 mg daily (*Bio-Quinone*) for 4 weeks did not alter the INR or the required dose of **warfarin**, when compared with placebo.[1] Similarly, 2 patients taking coenzyme Q_{10} to treat alopecia caused by **warfarin** treatment did not have any notable changes in INR, except that one had a transient INR *increase* when coenzyme Q_{10} was started.[2]

In a 4-month prospective, longitudinal study of 78 patients taking **warfarin** and a herbal product or dietary supplement, there was a statistically significant *increased* risk of self-reported bleeding events in 14 patients taking **warfarin** and coenzyme Q_{10} (57 bleeding events, none major, in a total of 181 weeks of concurrent use for an odds ratio of 3.7).[3] There were 4 elevated INRs (specific values not given) for 55 weeks of concurrent use, but this was not a statistically significant increase in risk. Note that the coenzyme Q_{10} products used were not mentioned and some patients were taking more than one potentially interacting supplement. The authors acknowledge that their finding might be due to chance and not a true interaction.

In contrast, another report describes 3 patients taking **warfarin** who had a reduction in their INR while taking coenzyme Q_{10}. In two of these patients, INR reductions from about 2.5 to 1.4 occurred when they took coenzyme Q_{10} 30 mg daily for 2 weeks. The INRs rapidly returned to normal when the coenzyme Q_{10} was stopped.[4] In two other cases, patients appeared to have a reduced response to **warfarin** while taking coenzyme Q_{10}, and responded normally when it was stopped.[5,6]

Mechanism

Not known. Coenzyme Q_{10} may have some vitamin K-like activity, which would explain the decrease in INR. In a study in *rats*, coenzyme Q_{10} reduced the anticoagulant effect of warfarin and increased the clearance of both enantiomers of warfarin.[7] Explanations for the increase in bleeding or INRs are unknown.

Importance and management

The well-controlled study suggests that coenzyme Q_{10} does not interact with warfarin, and that no warfarin dose adjustment would be expected to be necessary in patients who take this substance. However, the contrasting findings of a *decrease* in warfarin effect in the case reports, and an *increase* in bleeding events in the epidemiological study, introduce a note of caution. Moreover, the authors of the controlled study do recommend close monitoring of the INR if a patient decides to use coenzyme Q_{10}, because the underlying health problem resulting in them choosing to take this substance may alter their response to warfarin.[1] Until more is known it would seem prudent to increase the frequency of INR monitoring in patients taking warfarin if coenzyme Q_{10} is started.

Coumarins and related drugs + Colchicine

Five cases of a possible marked increase in the effect of fluindione caused by colchicine have been reported.

Clinical evidence, mechanism, importance and management

The national pharmacovigilance system in France has reported 5 cases where colchicine appeared to increase the anticoagulant effect of the indanedione **fluindione**. All 5 patients were stabilised on **fluindione** and were given short-term colchicine 1 to 6 mg daily for an acute attack of gout. All 5 patients had markedly raised INRs (6.5 to in excess of 18), but only one had clinical bleeding (haemorrhoidal bleeding).[1] The authors[1] consider that colchicine may have been a factor in a case of raised INR with **warfarin**,[2] which was attributed solely to fluvoxamine (consider also 'Coumarins and related drugs + SSRIs', p.504).

The mechanism of this interaction is unknown, although the authors rule out protein binding or P-glycoprotein alterations. They suggest that it may occur because colchicine decreases the expression of various cytochrome P450 isoenzymes, so decreasing the metabolism of **fluindione**.[1]

This appears to be the only evidence of an interaction of coumarins or indanediones with colchicine, and is insufficient to justify increased monitoring in all patients.

Coumarins + COMT inhibitors

Entacapone slightly increases *R*-warfarin levels and causes a slight increase in INR. Tolcapone is not expected to alter the pharmacokinetics of *S*-warfarin.

Clinical evidence

In a double-blind, crossover study in 12 healthy subjects given individualised **warfarin** doses to achieve an INR of between 1.4 and 1.8, **entacapone** 200 mg four times daily slightly increased the INR by 13%. The AUC of *R*-warfarin was increased by 18%, with no change in the AUC of the more potent *S*-warfarin.[1]

Mechanism

Not known. Based on *in vitro* data, both entacapone and tolcapone were thought to potentially interfere with the metabolism of drugs by the cytochrome P450 isoenzyme CYP2C9, such as *S*-warfarin.[2-4] However, the above study found that entacapone does not alter *S*-warfarin pharmacokinetics, and tolcapone is also not expected to interact by this mechanism because it does not interact with tolbutamide, another CYP2C9 substrate. Consider also 'Sulfonylureas; Tolbutamide + Tolcapone', p.589.

Importance and management

The minor pharmacokinetic interaction between entacapone and warfarin would appear to be established, but its clinical relevance is uncertain. Changes of this magnitude would not generally be expected to be clinically relevant, and there do not appear to be any published case reports of problems. Nevertheless, it is possible that some patients might show a greater effect, and the manufacturer in the UK recommends that the INR be monitored when entacapone is started in patients taking warfarin.[2]

Similarly, although the manufacturers do not predict a pharmacokinetic interaction between **tolcapone** and warfarin, they still recommend monitoring because of the limited clinical information on the combination.[3,4]

Coumarins and related drugs + Corticosteroids or Corticotropin

The general picture is that high doses of corticosteroids and corticotrophin significantly increase the INR in patients taking coumarins or fluindione: this has resulted in bleeding in some patients. However, one study found that prednisone opposes the effect of dicoumarol, and case reports describe a reduction in the effects of ethyl biscoumacetate in patients given corticotrophin or cortisone.

Clinical evidence

(a) Corticotropin

Ten out of 14 patients receiving long-term treatment with either **dicoumarol** or **phenindione** had a small but definite increase in their anticoagulant responses when they were given intramuscular or intravenous corticotropin for 4 to 9 days.[1] A patient stable on **ethyl biscoumacetate** developed frank melaena and microscopic haematuria within 3 days of starting treatment with intravenous corticotropin 10 mg twice daily.[2]

In contrast, a decrease in the anticoagulant effects of **ethyl biscoumacetate** was described in one patient given corticotropin and one patient given **cortisone**.[3]

(b) Dexamethasone

The INR and plasma anticoagulant levels were studied in 9 patients stabilised on anticoagulants (8 taking **fluindione** and one taking **warfarin**) during a total of 10 cycles of dexamethasone (40 mg/day for 4 days every 28 days) alone (4 patients) or with melphalan (5 patients). The INR increased in all patients from a mean of 2.75 at baseline to 5.22 within 3 to 6 days of starting dexamethasone. No major bleeding occurred, although 2 cases of minor bleeding were reported. Oral anticoagulants were temporarily withheld during 8 out of 10 cycles, and oral vitamin K 1 mg was taken by 2 patients during 2 cycles. An increase in the plasma levels of fluindione of about 37% was noted (4 patients monitored), and the only patient taking warfarin had an increase in warfarin plasma levels (of about 28%), although neither of these results was statistically significant.[4]

(c) Methylprednisolone

A sharp increase in the INR of a patient with antiphospholipid syndrome occurred after methylprednisolone was added to treatment with an unnamed oral anticoagulant.[5,6] This prompted a controlled study in 10 patients stabilised on anticoagulants (8 taking **fluindione** and 2 taking **acenocoumarol**) and 5 patients not taking an anticoagulant. It was found that

pulse high-dose intravenous methylprednisolone (500 mg or 1 g) increased the mean INR of those patients taking an anticoagulant from a baseline of 2.75 to 8.04, but had no effect on the prothrombin time in those taking methylprednisolone alone.[5,6] Two patients stabilised on **warfarin** are also reported to have had significant prolongations in their prothrombin times when given high-dose methylprednisolone (960 mg or 1 g, followed by **dexamethasone** 60 mg three times daily for 3 days in one case) for the treatment of multiple sclerosis.[7]

Moreover, in a retrospective study, short-term oral corticosteroid use (methylprednisolone or prednisone) was associated with an increase in INR in patients taking **warfarin**, see under *Prednisone*, below.

(d) Prednisone

An early study in 24 patients anticoagulated for several days with **dicoumarol** found that 2 hours after receiving prednisone 10 mg their silicone coagulation time had decreased from 28 minutes to 24 minutes, and 2 hours later was down to 22 minutes, suggesting that prednisone opposes the effect of dicoumarol.[8]

In contrast, in a retrospective analysis of 24 patients stabilised on **warfarin**, short-term oral corticosteroid use (prednisone in 12 patients and **methylprednisolone** in 12 patients for between 5 and 30 days, doses not specified) increased the INR on 29 of 32 occasions, decreased it on 2 occasions, and did not change it on one occasion. The mean INR increased from 2.33 to 3.57 (measured at a mean of 6.7 days after starting the corticosteroid). Warfarin dose adjustments (reduction and/or withheld dose) were required on 16 occasions. On 5 occasions the INR was elevated to greater than 5 (three times with prednisone and twice with **methylprednisolone**).[9] Similarly, in a study of in children with acute leukaemia receiving high-dose prednisone 60 mg/m^2 daily with low-dose **warfarin** for the prevention of central line-associated thrombosis, the warfarin requirement while they were taking the steroid was about half that required during periods without it (0.057 mg/kg versus 0.12 mg/kg daily).[10] Moreover, there is case report of a man taking **warfarin** and prednisone whose INR fluctuations appeared to correlate with when he stopped (subtherapeutic) or re-started (supratherapeutic) prednisone.[11]

(e) Unspecified corticosteroids

An analysis of a cohort of children receiving **warfarin** found that there was no difference in the dose of **warfarin** required to achieve and maintain the target INR between **warfarin** courses if corticosteroids were given (38 courses) and courses where corticosteroids were not given (314 courses). However, courses with corticosteroids were associated with a higher percentage of INR measurements greater than the target (21% versus 14%).[12]

Mechanism

Not understood. Corticotropin, cortisone and prednisone can increase the coagulability of the blood in the absence of anticoagulants, and might therefore antagonise their effects.[13,14] Conversely, it has been suggested that methylprednisolone and prednisone might inhibit the metabolism of anticoagulants increasing their effects.[6] However, note that, if anything, corticosteroids, particularly dexamethasone, are usually considered to be inducers of cytochrome P450 isoenzymes.

Importance and management

The interaction of low to moderate doses of corticosteroids with coumarins is by no means established. There are a few reports from the 1950s and 60s, with very little appearing to have been published until more recently. Nevertheless, in two of the more recent retrospective analyses, the use of corticosteroids appeared to be associated with a higher incidence of INRs over the target range or lower warfarin requirements. The most constructive thing that can be said is that if corticotropin (corticotrophin, ACTH) or any low-dose corticosteroid is given to patients taking anticoagulants, be aware that a modest change in coagulation requirements might occur.

Although the evidence is limited, marked INR increases have been reported with high-dose dexamethasone, prednisone or methylprednisolone, and INRs should be closely monitored (daily has been recommended[6]) if these or other high-dose corticosteroids are added to established treatment with any coumarin or indanedione oral anticoagulant. Also note that corticosteroids are associated with a weak increase in peptic ulceration and gastrointestinal bleeding, and the risk of this could theoretically be increased if over-anticoagulation occurs.

Coumarins + Cranberry juice

A number of case reports suggest that cranberry juice can increase the INR of patients taking warfarin, and one patient has died as a result of this interaction. Other patients have developed unstable INRs, or, in one isolated case, a *reduced* INR. However, in four controlled studies, cranberry juice did not alter the anticoagulant effect of warfarin, or had only very minor effects on the INR. Neither cranberry juice nor the extract altered warfarin pharmacokinetics.

Clinical evidence

(a) Case reports

In September 2003, the MHRA/CSM in the UK noted that they had received 5 reports suggesting an interaction between **warfarin** and cranberry juice since 1999 (3 cases of INR increases, one case of unstable INR and one case of a decrease in INR).[1] By October 2004, the MHRA/CSM reported that they had now received 12 reports of a suspected interaction, including 5 additional cases of bleeding episodes and two additional cases of unstable INRs in patients drinking cranberry juice while taking warfarin.[2] The most serious case involved a man taking **warfarin** whose INR markedly increased (INR greater than 50) 6 weeks after starting to drink cranberry juice. He died from gastrointestinal and pericardial haemorrhages.[1,3] Further details of this case included that he had recently been taking cefalexin (not known to interact) for a chest infection, and had been eating virtually nothing for at least 2 weeks,[3] a fact that would have contributed to the increase in anticoagulation.

In a further published case report, a patient stabilised on **warfarin** was found to have INRs of 10 to 12 during the surgical procedure, although he had no previous record of an INR greater than 4. Vitamin K was given, and heparin was substituted for warfarin. When warfarin was restarted postoperatively, the INR quickly rose to 8 and then to 11 with haematuria, and postoperative bleeding. The patient was drinking almost 2 litres of cranberry juice daily, because of recurrent urinary tract infections, and was advised to stop drinking this. Three days later the INR had stabilised at 3 with no further intervention.[4] Another case of fluctuating INR (between 1 and 10) in a patient taking **warfarin** has been attributed to cranberry juice.[5]

In the US, a case of major bleeding and a high INR has been reported in a man taking **warfarin**, which occurred shortly after cranberry juice 710 mL daily was started.[6] Another case, describes an increase in the INR

of a patient receiving **warfarin**, from below 3 to 6.45, without bleeding, after the patient drank about 2 litres of cranberry/apple juice over the last week. Of note, the patient was subsequently re-stabilised on a lower dose of warfarin and may have taken an extra dose of warfarin in the week before the raised INR was measured.[7]

(b) Controlled studies

In one controlled crossover study, 7 male patients with atrial fibrillation who were taking stable doses of **warfarin** drank 250 mL of cranberry juice or placebo [daily] for a week without any significant change in their INR from baseline values.[8] The same finding was reported in another very similar study in patients taking **warfarin**.[9] However, note that the daily volume of cranberry juice in these studies was lower than the daily volume in the couple of case reports where cranberry juice intake is known. Nevertheless, in another controlled study in 10 healthy subjects, a higher volume of cranberry juice (200 mL three times daily) for 10 days did not alter the effect of a single 10-mg dose of **warfarin** (given on day 5) on the maximum thromboplastin time or AUC of the thromboplastin time.[10] In addition, cranberry juice had no effect on warfarin pharmacokinetics, except that there was a slight non-significant 7% *decrease* in the AUC of *S*-warfarin.

In yet another study in 12 healthy subjects, cranberry juice concentrate 2 capsules three times daily for 21 days (equivalent to 57 g of fruit daily) had no effect on the maximum INR after a single 25-mg dose of **warfarin** given on day 15 (2.8 versus 2.6). However, the AUC of the INR was slightly increased by 28%, which was statistically significant, but the clinical relevance of this measure is uncertain. The cranberry concentrate had no effect on platelet aggregation, and had no effect on the pharmacokinetics of either *R*- or *S*-warfarin.[11]

Mechanism

Not known. It was originally suggested that one or more of the constituents of cranberry juice might inhibit the metabolism of warfarin by the cytochrome P450 isoenzyme CYP2C9, thereby reducing its clearance from the body and increasing its effects.[1] However, four studies have shown that cranberry juice or cranberry extracts do not alter the pharmacokinetics of warfarin, and cranberry juice had no effect on flurbiprofen pharmacokinetics, a drug used as a surrogate index of CYP2C9 activity.[12] An interaction might therefore be via a pharmacodynamic mechanism. For example, the salicylate constituent of commercial cranberry juice might cause hypoprothrombinaemia.[13]

Importance and management

An interaction is not established. Controlled studies have not found a pharmacokinetic interaction, and only one of four studies found any evidence for an increase in warfarin effect. Moreover, the clinical relevance of the finding of this study of a 0.2 increase in INR and 28% increase in AUC of the INR is likely to be slight at most, and does not fit with the sometimes marked increase in INR seen in some case reports. This might be explained if the interaction is dose dependent (in one of the cases where cranberry intake was mentioned a quantity of 2 litres daily was being consumed), or if it is product dependent (i.e. due to a constituent present in the cranberry juice that is not standardised for and varies widely). However, it could also be that there is no specific interaction, and that the case reports just represent idiosyncratic reactions in which other unknown factors (e.g. altered diet) were more important.

In 2004, on the basis of the then available case reports and lack of controlled studies, the CSM/MHRA in the UK advised that patients taking warfarin should avoid drinking cranberry juice unless the health benefits are considered to outweigh any risks. They recommended increased INR monitoring for any patient taking warfarin and who has a regular intake of cranberry juice.[2] They also advised similar precautions with other cranberry products (such as capsules or concentrates).[2] These might still be prudent precautions, although the controlled studies now available do provide some reassurance that, in otherwise healthy individuals, moderate doses of cranberry juice are unlikely to have an important impact on anticoagulation control.

Coumarins + *Curbicin*

The INR of one patient taking warfarin modestly increased after he took *Curbicin* (saw palmetto, cucurbita, and vitamin E). This product has also been associated with an increased INR in a patient not taking anticoagulants. Excessive bleeding during surgery has been reported in another patient who had been taking saw palmetto.

Clinical evidence

A 61-year-old man taking **warfarin** and simvastatin, with a stable INR of around 2.4, had an increase in his INR to 3.4 within 6 days of starting to take 5 tablets of *Curbicin* daily. Within a week of stopping the *Curbicin*, his INR had fallen to its previous value. Another elderly man who was not taking any anticoagulants and was taking 3 tablets of *Curbicin* daily was found to have an INR of 2.1 (normal 0.9 to 1.2). His INR decreased (1.3 to 1.4) when he was given vitamin K, but did not normalise until a week after the *Curbicin* was stopped. *Curbicin* is a herbal remedy used for micturition problems, and contains extracts from the fruit of *Serenoa repens* (**saw palmetto**) and the seed of *Cucurbita pepo*.[1]

In addition, saw palmetto has been attributed to excessive bleeding in a 53-year-old man undergoing a surgical procedure to remove a brain tumour. An estimated 2 litres of blood was lost during surgery and bleeding time did not return to normal for 5 days. The patient denied taking NSAIDs pre-operatively but admitted to taking saw palmetto for benign prostatic hypertrophy.[2]

Mechanism

The authors of the first report suggest that what happened was possibly due to the presence of vitamin E in the *Curbicin* preparation (each tablet contains 10 mg), but vitamin E does not normally affect INRs. Experimental evidence suggests that saw palmetto may inhibit the cytochrome P450 isoenzyme CYP2C9, which is an important route of warfarin metabolism.

Importance and management

Evidence appears to be limited to case reports and an experimental study of unknown clinical relevance. Because of the many other factors influencing anticoagulant control, it is not possible to reliably ascribe a change in INR specifically to a drug interaction in a single case report without other supporting evidence. It may be better to advise patients to discuss the use of any herbal products they wish to try, and to increase monitoring if this is thought advisable. Cases of uneventful use should be reported, as they are as useful as possible cases of adverse effects.

Coumarins + Danazol or Gestrinone

Increased anticoagulant effects and bleeding have been seen in a few patients taking warfarin with danazol. A case describes similar effects in a patient taking warfarin and gestrinone.

Clinical evidence

(a) Danazol

A 40-year-old woman stabilised on **warfarin** 6 mg daily with a prothrombin ratio of 2.3 presented after vomiting blood. She was found to have a prothrombin ratio of 14, and required fresh frozen plasma and 2 litres of blood. Three weeks previously she had been prescribed danazol 200 mg twice daily.[1] Four other similar cases of this interaction with danazol have been reported.[2-4] In two of the cases the patients were subsequently stabilised on **warfarin** and danazol, but with 50 to 70% lower **warfarin** doses.[3,4]

(b) Gestrinone

A bulletin includes a brief mention of an increased INR with vaginal bleeding and multiple bruising in a woman taking **warfarin** and gestrinone.[5]

Mechanism

The reason for this interaction is unknown, but both danazol and gestrinone have androgenic properties, and anabolic steroids (see 'Coumarins and related drugs + Anabolic steroids or Androgens', p.412), are known to increase the effects of warfarin.

Importance and management

Although data are limited, the interaction with danazol would appear to be established, and close monitoring of the INR is advisable if danazol is added to established treatment with a coumarin. Some suggest that the initial dose of the anticoagulant should be halved when danazol is started.[2] However, others note that this may not be appropriate in patients at high thrombogenic risk, such as those with mechanical valves. In these patients, they recommend a cautious reduction in dose with weekly monitoring of the INR until it becomes stable (several weeks).[4] Gestrinone might be expected to interact similarly, and some caution is therefore appropriate.

Coumarins and related drugs + Danshen (*Salvia miltiorrhiza*)

Three case reports indicate that danshen may increase the effects of warfarin, resulting in bleeding.

Clinical evidence

A woman taking **warfarin**, furosemide and digoxin, who began to take danshen on alternate days, was hospitalised a month later with anaemia and bleeding (prothrombin time greater than 60 seconds, INR greater than 5.62). The anaemia was attributed to occult gastrointestinal bleeding and the over-anticoagulation to an interaction with the danshen. She was later restabilised on warfarin in the absence of the danshen with an INR of 2.5, and within 4 months her haemoglobin levels were normal.[1]

A man taking **warfarin**, digoxin, captopril and furosemide with an INR of about 3, developed chest pain and breathlessness about 2 weeks after starting to take danshen. He was found to have a massive pleural effusion, and an INR of more than 8.4. He was later discharged on his usual dose of warfarin with an INR stable at 3, in the absence of the danshen.[2]

Over-anticoagulation was investigated in Chinese patients admitted to a medical unit during a 9-month period in 1994/1995. An interaction with **warfarin** was reported in a patient using a medicated oil product that contained methyl salicylate 15%, and an analgesic balm that contained danshen, methyl salicylate 50% and diclofenac.[3]

Mechanism

Danshen has antiplatelet actions, which may be additive with the anticoagulant effect of warfarin. The mechanism for the increase in warfarin levels is unknown, because the studies suggest that the usual extracts of danshen do not inhibit the cytochrome P450 isoenzyme CYP2C9, the main route of warfarin metabolism.

Importance and management

Evidence appears to be limited to three case studies, which alone would be insufficient to establish an interaction. Further, one of these cases included the use of methyl salicylate, which has been shown to interact with warfarin. The pharmacokinetic effects of the usual extracts of danshen seem to suggest that an interaction resulting in raised warfarin levels is unlikely in most patients. However, because danshen may have antiplatelet effects, an interaction between warfarin and danshen, resulting in increased bleeding, is possible. Clinically the use of an antiplatelet drug with an anticoagulant should generally be avoided in the absence of a specific indication. It may therefore be prudent to advise against concurrent use. However, if concurrent use is felt desirable it would seem sensible to warn patients to be alert for any signs of bruising or bleeding, and report these immediately, should they occur.

Coumarins + Darifenacin or Solifenacin

Solifenacin does not appear to alter the pharmacokinetics or anticoagulant response to warfarin. Darifenacin does not alter the prothrombin time in response to warfarin.

Clinical evidence, mechanism, importance and management

(a) Darifenacin

The manufacturer notes that steady state darifenacin 30 mg daily did not alter the prothrombin time after a single 30-mg dose of **warfarin**.[1] Therefore, no **warfarin** dose adjustment or additional monitoring would be expected to be needed on concurrent use.

(b) Solifenacin

In a placebo-controlled, crossover study in healthy subjects, solifenacin 10 mg daily for 10 days had no effect on the pharmacokinetics of *S*- or *R*-warfarin after a single 25-mg dose of **warfarin** was given on day 10. In addition, solifenacin did not alter the prothrombin time.[2] This study suggests that no pharmacokinetic or pharmacodynamic interaction occurs, and that no **warfarin** dose adjustment would be expected to be needed on concurrent use.

Coumarins + Dichloralphenazone

The anticoagulant effects of warfarin are reduced by dichloralphenazone.

Clinical evidence

Five patients stabilised taking **warfarin** long-term and given dichloralphenazone 1.3 g each night for 30 days had a reduction of about 50% (range 20 to 69%) in plasma **warfarin** levels and a fall in the anticoagulant response during the last 14 days of concurrent use. Another patient given dichloralphenazone 1.3 g nightly for one month had a 70% fall in plasma **warfarin** levels and a thrombotest percentage rise from 9% to 55% (indicating a reduced anticoagulant effect). These values returned to normal when the hypnotic was withdrawn.[1,2]

Mechanism

The phenazone component of dichloralphenazone is a potent liver enzyme inducer (see 'Coumarins + NSAIDs; Phenazone (Antipyrine)', p.488), which increases the metabolism and clearance of the warfarin, thereby reducing its effects.[1,2] The effects of the cloral hydrate component (see

'Coumarins + Cloral hydrate and related drugs', p.449) appear to be minimal.

Importance and management

Information is limited, but the interaction between warfarin and dichloralphenazone appears to be established and clinically important, probably affecting most patients. The dose of warfarin will need to be increased to accommodate this interaction. If the effect of warfarin has been reduced by using dichloralphenazone, it may take up to a month for it to restabilise. There does not appear to be any information about other anticoagulants, but other coumarins would be expected to be similarly affected. The benzodiazepines (see 'Coumarins + Benzodiazepines and related drugs', p.441) are generally preferred hypnotics, and do not interact.

Coumarins and related drugs + Dipyridamole

The concurrent use of dipyridamole and a coumarin does not alter the prothrombin time, but it might cause an increased risk of serious bleeding. There is some evidence that the risk of bleeding may be lower, without a reduction in efficacy, if the INR is maintained within a lower range.

Clinical evidence

(a) Prosthetic heart valves

In a short-term study in 6 patients stabilised on **warfarin**, the addition of dipyridamole 75 mg three times daily did not alter prothrombin time ratios measured 8 times over 17 days.[1]

A meta-analysis of 6 randomised, controlled studies of the combined use of an oral anticoagulant [presumably a coumarin or indanedione] and dipyridamole compared with an oral anticoagulant alone, found no increased risk of *any* bleeding events when dipyridamole was given (odds ratio 1.001).[2] In contrast, in a later meta-analysis of the same studies, the risk of *major* bleeding with the addition of dipyridamole was increased (odds ratio 2.22). In addition to the difference in classification of bleeding events, the authors of the second analysis stated that they had used published data from two studies, which showed a slightly higher bleeding risk, whereas the earlier meta-analysis had used unpublished data from these studies, showing a lower bleeding risk.[3]

In one randomised study, the risk of excessive bleeding was 4% in patients taking **warfarin** and dipyridamole 400 mg daily, compared with 14% in patients taking **warfarin** and aspirin 500 mg daily. When compared with a non-randomised control group taking **warfarin** alone, the risk of excessive bleeding was not increased by dipyridamole (4% with both drugs versus 5% with **warfarin** alone).[4]

In another randomised study, the risk of bleeding was lower (1% versus 3.7%) in patients receiving dipyridamole 225 mg daily with **phenindione** at a target INR of 2 to 2.5 than in patients receiving **phenindione** alone with a target INR of 2.5 to 3.5, and the combination was more effective.[5] Similarly, the risk of bleeding was lower with a lower target INR of 2 to 3 than with a target INR of 3 to 4.5 (3.9% versus 20.8%) in patients taking **acenocoumarol**, aspirin 330 mg twice daily and dipyridamole 75 mg twice daily.[6]

(b) Other conditions

In a randomised study in patients with severe or recurrent venous thrombosis, there was no difference in dose of **acenocoumarol** necessary to reach an INR of 2.5 to 3.5 between 100 patients taking **acenocoumarol** with dipyridamole 400 mg daily and 100 patients taking **acenocoumarol** alone. None of the patients had severe bleeding, and 3 to 4% of patients in both groups had moderate bleeding (haematomas, haematuria).[7]

Thirty patients with glomerulonephritis stabilised on either **warfarin** (28 patients) or **phenindione** (2 patients) with a prothrombin activity of between 20 to 30% of control had no significant changes in prothrombin times when they were given dipyridamole in doses increased from 100 mg daily up to a maximum of 400 mg daily over about a month. Twelve to 19 days after starting dipyridamole, 3 patients with normal renal function developed mild bleeding (epistaxis, bruising, haematuria), which resolved when either drug was withdrawn or the dose reduced.[8]

In a retrospective, cohort study in patients taking oral anticoagulants with or without antiplatelet drugs, including dipyridamole, the concurrent use of an antiplatelet drug was found to significantly increase the risk of bleeding compared with an oral anticoagulant alone: 4.2% of patients receiving an anticoagulant and an antiplatelet drug had a bleeding event compared with 2% of the patients taking an oral anticoagulant alone. No additional beneficial reduction in the risk of thromboembolism was found.[9]

Mechanism

Dipyridamole reduces platelet adhesiveness or aggregation, which prolongs bleeding time. This may increase the risk or severity of bleeding if over-anticoagulation occurs.

Importance and management

There is clearly some uncertainty regarding the increased risk of bleeding with the combination of warfarin and dipyridamole, with one analysis finding no increased risk,[2] and a second finding about a doubling of risk of serious bleeding.[3] The authors of the second analysis consider that their results represent a more conservative estimate of bleeding risk.[3] There is some evidence that maintaining anticoagulant control at the lower end of the therapeutic range minimises possible bleeding complications and it would therefore seem prudent to consider this wherever possible.

Coumarins + Disopyramide

In two small uncontrolled studies, the anticoagulant effects of warfarin were slightly reduced by disopyramide. In contrast, there is an isolated report of a patient who needed his warfarin dose to be doubled after *stopping* disopyramide.

Clinical evidence

In a preliminary report of a study in 10 patients with recent atrial fibrillation taking **warfarin** and with a British Corrected Ratio of 2 to 3, disopyramide (dose not stated) increased the clearance of **warfarin** by 21%.[1] Similarly, another study found that 2 out of 3 patients needed a slight **warfarin** dose increase of about 10% after cardioversion and after starting disopyramide 200 mg three times daily for atrial fibrillation.[2]

In contrast, another report describes a patient who, following a myocardial infarction, was given **warfarin** 3 mg daily and disopyramide 100 mg every 6 hours with digoxin, furosemide and potassium supplements. When the disopyramide was withdrawn his **warfarin** requirements doubled over a 9-day period.[3,4]

Mechanism

Unknown. One idea is that when the disopyramide controls fibrillation, changes occur in cardiac output and in the flow of blood through the liver, which might have an effect on the synthesis of the blood clotting factors.[2,5] But the discordant response in the isolated case remains unexplained.

Importance and management

The interaction between disopyramide and warfarin is very poorly documented and not established. Limited data suggest only a minor interaction occurs (a slight reduction in anticoagulant effect), but an isolated case suggests a greater and opposite effect. Bear the possibility of an interaction in mind in the case of an unexpected response to warfarin in a patient starting or stopping disopyramide.

Coumarins + Disulfiram

The anticoagulant effects of warfarin were increased by disulfiram in two studies, and two cases showing this effect have also been reported.

Clinical evidence

In one study in 7 healthy subjects, **warfarin** (adjusted to maintain a prothrombin activity of 40%) was given alone for 21 days, then given with disulfiram 500 mg daily for 21 days. The plasma **warfarin** levels of 5 of the 7 subjects rose by an average of 20% and their prothrombin activity fell from about 34% to 24% of normal (suggesting an increased anticoagulant effect); one of the subjects had little change, and the other had the opposite effect.[1] Other experiments with single doses of **warfarin** confirm these results.[1] However, a further study found that, although disulfiram potentiated the effect of *S*-warfarin, it did not change the plasma levels of either *R*- or *S*-warfarin.[2]

An alcoholic patient stabilised on **warfarin** had an increase in his prothrombin time associated with gross haematuria when disulfiram 250 mg daily was given. Two subsequent attempts to introduce disulfiram 250 mg on alternate days also had a similar effect. He was eventually stabilised on a 43% lower daily dose of warfarin and disulfiram 250 mg daily.[3] Another case of increased prothrombin time and the need for a reduced warfarin dose has been reported.[4]

Mechanism

Not fully understood. The suggestion[1] that disulfiram inhibits the liver enzymes concerned with the metabolism of warfarin has not been confirmed by later studies.[2] It has instead been suggested[2] that disulfiram may chelate with the metal ions necessary for the production of active thrombin from prothrombin, thereby augmenting the actions of warfarin.

Importance and management

An interaction appears to be established, although direct information about patients is very limited. What is known suggests that most individuals will demonstrate this interaction. If concurrent use is thought appropriate, the effects of warfarin should be monitored and suitable dose adjustments made when adding or withdrawing disulfiram. Care should be taken when starting warfarin in patients already taking disulfiram, and consideration should be given to using a smaller loading dose.

Coumarins and related drugs + Ditazole

Ditazole does not alter the anticoagulant effects of acenocoumarol. Nevertheless, as with other antiplatelet drugs, concurrent use might increase bleeding risk.

Clinical evidence, mechanism, importance and management

Fifty patients with artificial heart valves taking **acenocoumarol** had no changes in their prothrombin times while taking ditazole 800 mg daily.[1] Nevertheless, as with other antiplatelet drugs, such as aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), concurrent use with oral anticoagulants might increase the risk or intensity of bleeding. Some caution is therefore appropriate on concurrent use.

Coumarins + Diuretics

The loop diuretics, bumetanide, furosemide and torasemide, the potassium-sparing diuretic spironolactone, and the thiazides, chlortalidone and chlorothiazide, have all been found either not to interact or to cause only a small reduction in the effects of the coumarin anticoagulants. The exception is tienilic acid, which has a pharmacokinetic interaction with warfarin and increases its effects, and possibly etacrynic acid, which on rare occasions has caused a marked increase in the effects of warfarin.

Clinical evidence

A. Loop diuretics

(a) Bumetanide

In 10 healthy subjects, bumetanide 1 mg daily for 14 days did not alter the anticoagulant effect of a single-dose of **warfarin** given on day 8, and did not alter serum **warfarin** levels.[1] This confirms findings of a previous study in 5 healthy subjects given single-dose **warfarin** after bumetanide 2 mg daily for 5 days.[2]

(b) Etacrynic acid

A case report describes a marked increase in the anticoagulant effects of **warfarin** in a woman with hypoalbuminaemia on two occasions when she was given etacrynic acid 150 mg to 300 mg daily.[3] In a preliminary report of a cohort study, it was stated that a therapeutically significant interaction between **warfarin** and etacrynic acid was documented, but no details are given.[4]

(c) Furosemide

In 6 healthy subjects, plasma levels, half-lives and prothrombin times were not altered when a single 50-mg dose of **warfarin** was given after furosemide 80 mg daily for 5 days.[2] However, a 28% decrease in the INR of one patient taking **warfarin** was seen when furosemide was taken on a regular basis. This was attributed to volume depletion caused by the diuretic, although interpretation of this case is complicated by the patient's admission of previous non-compliance and abuse of alcohol and cocaine.[5] In a pharmacokinetic study in 17 healthy subjects, furosemide 40 mg twice daily had no effect on the pharmacokinetics of a single 0.22-mg/kg dose of **phenprocoumon**.[6] In another study in 22 patients with congestive heart failure stabilised on **phenprocoumon**, furosemide 40 mg daily for 8 days did not alter the anticoagulant effects or required dose of **phenprocoumon**.[7]

(d) Tienilic acid (Ticrynafen)

In 6 healthy subjects, tienilic acid 250 mg daily for about 14 days caused a mean 265% increase in the anticoagulant effect of a single dose of **warfarin** given on day 4. Analysis showed the interaction was stereoselective, with the AUC of *S*-warfarin increased by 192%, with the AUC for *R*-warfarin increased by only 8%.[8] Two patients taking **ethyl biscoumacetate** began to bleed spontaneously (haematuria, ecchymoses of the legs and gastrointestinal bleeding) when they started to take tienilic acid 250 mg daily. The thrombotest percentage of one of them was found to have fallen by 10%.[9] Increased anticoagulant effects and/or bleeding, which began within a few days, have been described in a number of other case reports in patients given tienilic acid while taking **ethyl biscoumacetate**,[10,11] **acenocoumarol**[12] or **warfarin**.[10,13]

(e) Torasemide

In a study in 24 patients with congestive heart failure stabilised on **phenprocoumon**, torasemide 20 mg daily for 8 days did not alter the anticoagulant effects or required dose of **phenprocoumon**.[7]

B. Potassium-sparing diuretics

In a study in 9 healthy subjects, **spironolactone** 50 mg four times daily for about 16 days reduced the prothrombin time response to a single dose of warfarin given on day 8 by 24%, when compared with **warfarin** alone. Plasma **warfarin** levels remained unchanged.[14]

C. Thiazides

(a) Chlortalidone

Six healthy subjects given a single 1.5-mg/kg dose of **warfarin** had reduced hypoprothrombinaemia (prothrombin activity reduced from 77 to 58 units) when they were also given chlortalidone 100 mg daily for 7 days with the **warfarin** given on the first day, although the plasma **warfarin** levels remained unaltered.[15] Similarly, reduced anticoagulant effects have been described when chlortalidone was given with **phenprocoumon**, but no significant effects were seen when chlortalidone was given with **acenocoumarol**.[16]

(b) Chlorothiazide

A study in 8 healthy subjects given single 40 to 60-mg doses of **warfarin** before and after chlorothiazide 1 g daily for 21 days found that the mean half-life of the anticoagulant was increased from 39 hours to 44 hours, but the prothrombin time was only decreased by 0.3 seconds.[17]

Mechanism

It has been suggested that the diuresis induced by chlortalidone, furosemide and spironolactone reduces plasma water, which leads to a concentration of the blood clotting factors.[5,14,15] Etacrynic acid can displace warfarin from its plasma protein binding sites,[18] and it was originally thought that other diuretics also interacted by drug displacement.[9,19,20] Only 3% of total plasma warfarin is in the free active form, thus a small displacement could result in marked enhancement of activity,[3] but it is almost certain that this, on its own, does not explain the interaction described.[4] Tienilic acid (ticrynafen), a loop diuretic which is structurally related to etacrynic acid, reduces the metabolism of *S*-warfarin (but not *R*-warfarin) thereby prolonging its stay in the body and increasing its effects.[8] It is possible that etacrynic acid interacts via a similar mechanism.

Importance and management

The documentation relating to diuretics in general (other than tienilic acid) is limited and seems to be confined to the reports cited here, most of which are single-dose pharmacological studies. The evidence suggests that these diuretics either do not interact at all with the coumarins, or interact only to an extent which is of little clinical relevance. This seems to be supported by the lack of case reports of problems with these combinations, and is in general agreement with common experience. No special precautions normally seem to be necessary, except possibly with etacrynic acid where it might be prudent to monitor the outcome particularly in those with hypoalbuminaemia or renal impairment.

The interaction between the coumarins and tienilic acid is established and of clinical importance, but the incidence is uncertain. Concurrent use should be avoided. If that is not possible, prothrombin times should be closely monitored and the anticoagulant dose reduced as necessary. Note that tienilic acid has been withdrawn in many countries because of its hepatotoxicity.

Coumarins + Dofetilide

Dofetilide did not alter the anticoagulant effect of warfarin in one study.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 14 healthy subjects, dofetilide 750 micrograms twice daily for 8 days had no effect on the prothrombin time in response to a single 40-mg dose of **warfarin** given on day 5.[1] No dose adjustment of **warfarin** would be anticipated to be needed on concurrent use.

Coumarins + Endothelin receptor antagonists

Bosentan appears to cause a modest reduction in warfarin levels, which may result in an increase in warfarin requirements in some patients. Sitaxentan inhibits the metabolism of warfarin and a lower dose of warfarin is likely to be needed. Ambrisentan did not have any clinically relevant effect on warfarin pharmacokinetics or pharmacodynamics in one study.

Clinical evidence

(a) Ambrisentan

In a study in 22 healthy subjects, ambrisentan 10 mg daily for 8 days had no clinically relevant effect on the pharmacokinetics or pharmacodynamics of a single 25-mg dose of **warfarin** given on day 8. There was a minor 5% increase in AUC of *R*-warfarin, and a minor 8% and 10% decrease in maximum levels of *R*- and *S*-warfarin, respectively. The maximum prothrombin time was decreased by about 14%.[1] The manufacturer notes that, in healthy subjects, ambrisentan did not alter the weekly **warfarin** dose, prothrombin time or INR. The pharmacokinetics of ambrisentan are also not affected by warfarin.[2]

(b) Bosentan

In a well-controlled study, 12 healthy subjects were given bosentan 500 mg twice daily or placebo for 10 days, with a single 26-mg dose of **warfarin** on day 6. Bosentan reduced the AUC of *R*-warfarin by 38% and reduced the AUC of *S*-warfarin by 29%. A significant decrease in the anticoagulant effects of **warfarin** was also noted, with a 23% reduction in prothrombin time occurring with bosentan.[3]

Two case reports highlight the clinical significance of this interaction. A 35-year-old woman taking **warfarin** with a stable INR of 2 to 3 over three months started taking bosentan 62.5 mg twice daily. After 10 days her INR was 1.7, and remained at this level over the next 4 weeks, despite an increase in her weekly **warfarin** dose from 27.5 mg to 40 mg. The bosentan dose was then increased to the maintenance dose of 125 mg twice daily, and two further weekly increases in **warfarin** dose were made. The INR was then high (3.2 to 4.1) for 3 weeks, before she was finally stabilised on **warfarin** 45 mg each week.[4] In a second case, the INR decreased to 1.5 on starting bosentan, necessitating an increase in **warfarin** dose from 30 mg weekly to 40 mg weekly. However, when the bosentan dose was later decreased from 250 mg daily to 125 mg daily, the INR increased to 4.6, and the warfarin dose was reduced to 35 mg weekly.[5]

The manufacturer of bosentan notes that, in clinical experience, the use

of bosentan with **warfarin** did not result in clinically relevant changes in the INR or **warfarin** dose. There was no difference in the frequency of **warfarin** dose changes (due to INR changes or adverse effects) between bosentan or placebo recipients.[6] However, in the STRIDE-2 study where 52 patients with pulmonary arterial hypertension took bosentan at usual prescribed doses, daily warfarin dose requirements were 5.1 mg daily, compared with 3.7 mg in 51 patients given placebo. The average number of patients with an INR greater than 3.5 during this study was 20% lower than in the placebo group.[7]

(c) Sitaxentan

Sitaxentan increases the exposure to *S*-warfarin 2.4-fold: patients receiving warfarin tend to require lower doses of warfarin to achieve therapeutic INR values in the presence of sitaxentan.[8] In the STRIDE-2 study in patients with pulmonary arterial hypertension, the average warfarin dose after 18 weeks of the concurrent use of sitaxentan 50 mg or 100 mg daily was 2.8 mg daily and 2.1 mg daily, respectively, compared with 3.7 mg in a placebo group. However, the number of patients taking sitaxentan with an INR of more than 3.5 was similar to the placebo group. Note that in this study an initial warfarin dose reduction of 80% was used in patients randomised to sitaxentan or placebo.[7]

Mechanism

Bosentan induces both the cytochrome P450 isoenzymes CYP3A4 and CYP2C9, which are involved in the metabolism of *R*-warfarin and *S*-warfarin, respectively.[3] In contrast. sitaxentan has been reported to *inhibit* these isoenzymes.[8] Therefore, the use of bosentan increases the metabolism of warfarin, leading to reduced anticoagulant effects, whereas sitaxentan decreases the metabolism of warfarin, resulting in increased anticoagulant effects. Ambrisentan appears to have little effect on warfarin metabolism.

Importance and management

Both the studies and the case reports suggest that a clinically significant reduction in the effects of warfarin may occur in some patients taking **bosentan**, although exactly how frequently this may occur is unclear. The UK manufacturer of bosentan states that the INR should be closely monitored in any patient taking warfarin when bosentan is started or stopped, or if the dose is altered,[6] and given the higher dose requirements reported in the STRIDE-2 study, this seems a prudent precaution. Other coumarins should be similarly monitored.

Sitaxentan increases warfarin levels, and a dose reduction of warfarin appears likely to be needed patients taking both drugs. The manufacturer of sitaxentan also predicts that acenocoumarol, phenprocoumon, and fluindione (and therefore presumably other indanediones) will interact similarly. They advise that if patients taking sitaxentan are started on one of these anticoagulants, they should be started on the lowest possible dose of anticoagulant and small dose increases (0.5 mg daily has been suggested[9]) should be made in order to reach the target INR. The Australian manufacturer recommends initiating warfarin at a dose of 0.5 mg daily in patients taking sitaxentan, and then adjusting according to the INR.[9] If sitaxentan is started in a patient already taking an anticoagulant, the dose of the anticoagulant should be reduced; the Australian manufacturer recommends a warfarin dose reduction of 80%.[9] The INR should be closely monitored in all patients taking both drugs.[8,9]

Available evidence suggests that no clinically significant interaction occurs between warfarin and **ambrisentan**, therefore no special precautions are necessary with concurrent use.

Coumarins + Etanercept

Etanercept did not alter the pharmacodynamics or pharmacokinetics of a single dose of warfarin in one study.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, subcutaneous etanercept 25 mg twice weekly for 7 doses did not alter the pharmacodynamics (INR) of a single dose of **warfarin** given with the last dose of etanercept. In addition, there was no change in the AUC of *R*- and *S*-warfarin.[1]

This study suggests that no **warfarin** dose adjustments would be expected to be needed if etanercept is used in patients taking **warfarin**.

Coumarins + Ethchlorvynol

The anticoagulant effects of dicoumarol and warfarin are reduced by ethchlorvynol.

Clinical evidence

Six patients who had recently started taking **dicoumarol** had a rise in their Quick index from 38% to 55% (indicating a reduction in anticoagulant effect) while taking ethchlorvynol 1 g daily over an 18-day period. Another patient stabilised on **dicoumarol** became over-anticoagulated and developed haematuria on two occasions when ethchlorvynol was withdrawn for periods of 6 days and 4 days.[1] A marked reduction in the anticoagulant effects of **warfarin** occurred in another patient given ethchlorvynol.[2]

Mechanism

Uncertain. The idea that ethchlorvynol increases the metabolism of the anticoagulants by the liver has not been confirmed by studies in *dogs* and *rats*.[3]

Importance and management

Information is very sparse and limited to dicoumarol and warfarin, but the interaction seems to be established. Be alert for other coumarins to behave similarly. Anticipate the need to alter the anticoagulant dose if ethchlorvynol is started or stopped. The benzodiazepines may be a useful non-interacting alternative to ethchlorvynol, see 'Coumarins + Benzodiazepines and related drugs', p.441.

Coumarins and related drugs + Ezetimibe

No clinically significant interaction occurred between ezetimibe and warfarin in one study. However, there have been post-marketing reports of raised INRs in patients taking warfarin or fluindione after they were also given ezetimibe.

Clinical evidence, mechanism, importance and management

In a two-way, crossover study, 12 healthy subjects were given ezetimibe 10 mg or placebo daily for 11 days, with a single 25-mg dose of **warfarin** on day 7. The pharmacokinetics and pharmacodynamics (prothrombin time) of **warfarin** were not significantly altered by ezetimibe. In addition, the pharmacokinetics of ezetimibe were similar to those previously seen with the drug alone.[1]

However, the UK manufacturers of ezetimibe state that there have been post-marketing reports of raised INRs in patients taking **warfarin** or **fluindione** after they were also given ezetimibe. They therefore advise that the INR should be monitored if ezetimibe is given with any coumarin or **fluindione**[2] (this is probably a prudent precaution for any **indanedione**), and the US manufacturer states the same for **warfarin**.[3] Neverthe-

less, there do not appear to be any published case reports, or other evidence, which suggests that any interaction is not established, and probably rare.

Coumarins + Felbamate

An isolated case report describes a marked increase in the effect of warfarin, which was attributed to starting felbamate, although stopping carbamazepine and phenobarbital could have been the cause.

Clinical evidence, mechanism, importance and management

A 62-year-old man with a seizure disorder who was receiving **warfarin** had his antiepileptic treatment with carbamazepine, phenobarbital and sodium valproate discontinued and replaced by felbamate 2.4 g daily and later 3.2 g daily. Within 14 days his INR had risen from his usual range of 2.5 to 3.5 up to 7.8. After stopping and later restarting **warfarin** his INR rose within about 14 days to 18.2. He was eventually restabilised on about half his former **warfarin** dose. The authors of the report suggest that the withdrawal of the carbamazepine and phenobarbital was an unlikely reason for this reaction because no increases in **warfarin** dose had been needed when they were started.[1] Suspicion therefore fell on the felbamate, but it is clearly difficult to be sure that the withdrawal of the enzyme-inducing antiepileptics did not have some part to play. A letter commenting on this report[2] favours the idea that what occurred was in fact due to the withdrawal of the carbamazepine (see 'Coumarins + Carbamazepine or Oxcarbazepine', p.446), and phenobarbital (see 'Coumarins + Barbiturates', p.440).

The general importance of this interaction (if such it is) is uncertain, and this appears to be the only case. Bear it in mind in the event of an unexpected response to **warfarin**.

Coumarins and related drugs + Fibrates

Bezafibrate, clofibrate, ciprofibrate and fenofibrate increase the effects of the coumarins, and clofibrate also interacts with phenindione. These interactions have been fatal in a few cases. Gemfibrozil did not interact with warfarin in a controlled study, although two cases of an interaction have been reported.

Clinical evidence

(a) Bezafibrate

In a study in patients with hyperlipidaemia, stabilised on **phenprocoumon**, it was necessary to reduce the anticoagulant dose by about 20% when bezafibrate 450 mg daily was given to 10 patients for 4 weeks, and by 33% when bezafibrate 600 mg daily was given to 5 patients.[1] In another study in 22 patients taking bezafibrate 400 mg daily, the dose of **acenocoumarol** had to be reduced by 20% to maintain a constant INR.[2]

A patient (with hypoalbuminaemia due to nephrotic syndrome and chronic renal failure) stabilised on **acenocoumarol** developed severe haematemesis with an INR of 25.9, two weeks after starting to take bezafibrate 800 mg daily.[3] A woman stabilised on **warfarin** and bezafibrate 400 mg daily had an increase in her INR to 5.29 after being given an incorrect double dose of bezafibrate for a few days, and a man had a reduced response to **warfarin** (INR 1.5) when he stopped taking bezafibrate for one week.[4]

(b) Ciprofibrate

In a well-controlled study, 12 young healthy men were given a single 25-mg dose of **warfarin** on day 21 of a 26-day course of ciprofibrate 100 mg daily. The ciprofibrate increased the anticoagulant response to **warfarin** by 50% and caused a 28% decrease in the apparent intrinsic clearance of *S*-warfarin, which is the more active enantiomer.[5]

(c) Clofibrate

1. Coumarins. In a study including 11 patients stabilised on **warfarin**, clofibrate with androsterone (*Atromid*), given for 5 to 7 months, reduced the weekly **warfarin** dose requirement in all patients by a mean of 32%, with variability between patients.[6,7] This interaction has been confirmed in a number of other similar studies in patients stabilised on **warfarin** and given clofibrate,[8,9] or clofibrate with androsterone,[10] with only 2 of 10 patients affected in one study[8] but all 13 patients affected in another study.[10] One fatal case of haemorrhage has been reported in a man stabilised on **warfarin** who was given clofibrate 500 mg four times daily for one week.[11]

The interaction has been studied in 4 healthy subjects given the enantiomers of **warfarin** separately. In this study, clofibrate increased the effect of *S*-warfarin without altering its clearance, whereas there was no alteration of the effect of *R*-warfarin and an increase in its clearance.[12] In another study in 10 healthy subjects, clofibrate 500 mg four times daily for 18 days increased the anticoagulant effect of a single dose of **dicoumarol** given on day 14 without altering the half-life or plasma **dicoumarol** levels.[13]

2. Indanediones. Ten out of 15 patients stabilised on **phenindione** needed a 33% reduction in **phenindione** dose and 5 of them bled (haematuria or haematoma) when they were given clofibrate, or clofibrate with androsterone (*Atromid*).[7] In another series, of 13 patients stabilised on **phenindione** and given clofibrate with androsterone (*Atromid*) there were 5 cases of haemorrhagic episodes, two of which were not associated with a prolonged prothrombin time, and one of which was fatal.[14,15] In yet another study, clofibrate with androsterone appeared to be less effective in reducing serum cholesterol in patients taking **phenindione** than in 12 other patients taking clofibrate alone.[16]

(d) Fenofibrate

In an early clinical study of fenofibrate, 2 patients stabilised on **acenocoumarol** needed a 30% reduction in their dose to maintain the same prothrombin time when they were given long-term fenofibrate 200 mg in the morning and 100 mg in the evening.[17] In other similar studies, reductions in the dose of unnamed **coumarins** of 12% (range 0 to 21%)[18] or about one-third[19] were needed when fenofibrate was given. One patient developed haematuria.[20]

A number of case reports of this interaction have subsequently been published, as follows:

- A patient taking **warfarin** had a rise in his INR to 8.5 (from a previous range of 2 to 2.5) within one week of starting to take fenofibrate 200 mg daily. His INR later restabilised when the **warfarin** dose was reduced by 27%.
- A patient taking **warfarin** had a marked INR rise from a range of 2.8 to 3.5 up to 5.6 within 10 days of starting to take fenofibrate (dose not stated).[21]
- A patient taking **warfarin** bled, and was found to have an INR of 18 when his gemfibrozil was replaced by fenofibrate.[22]
- In 2 cases, 30 to 40% reductions in the **warfarin** dose were required when fenofibrate was given.[23]

(e) Gemfibrozil

In a well-controlled study, gemfibrozil 600 mg twice daily for 8 days did not alter the anticoagulant effect of a single dose of **warfarin** given on day 3. In addition, gemfibrozil unexpectedly slightly decreased the AUC of both *R*- and *S*-warfarin (by 6% and 11%, respectively).[24] In contrast, a brief report describes bleeding ('menstrual cycle prolonged and lots of blood clots') and much higher prothrombin times (values not given) 2 weeks after a woman stabilised on **warfarin** started to take gemfibrozil 1.2 g daily in divided doses. Halving the **warfarin** dose resolved the problem.[25] Another patient stabilised on **warfarin** developed severe hypoprothrombinaemia (INR 43) and bleeding (melaena, bruising) 4 weeks after starting to take gemfibrozil 1.2 g daily.[26]

Mechanism

Uncertain. Clofibrate can displace warfarin from its plasma protein binding sites,[5,27-29] but this does not adequately explain the interaction. Another suggestion is that the fibrates have an additive pharmacodynamic effect with these anticoagulants.[1,12] Altered metabolism may also account for the

interaction with ciprofibrate, because it decreased the clearance of *S*-warfarin.[5] However, this did not occur with clofibrate[12,13] or gemfibrozil.[24]

Importance and management

The interactions of clofibrate with dicoumarol, warfarin and phenindione are established, clinically important and potentially serious. Severe bleeding (fatal in some instances) has been seen. The incidence of the interaction is reported to be between 20% and 100%, but it would be prudent to assume that all patients will be affected. Coumarin dose reductions of one-third to one-half may be needed to avoid the risk of bleeding. Monitor the INR and adjust the dose accordingly. Information about other coumarins and indanediones is lacking but it would be prudent to assume that they will interact with clofibrate in a similar way.

Bezafibrate, ciprofibrate and fenofibrate have interacted similarly with coumarins. Therefore, the same precautions suggested for clofibrate should be followed if any of these fibrates are given with any oral anticoagulant.

Gemfibrozil did not interact with warfarin in a pharmacological study, but 2 cases of an increased effect of warfarin have been reported, so it might be prudent to apply the same precautions.

Coumarins + Fish oils

The concurrent use of fish oils does not appear to alter warfarin efficacy, nor the incidence of bleeding episodes. However, there are a couple of reports of an increased INR in patients taking warfarin and fish oils, and one of a life-threatening bleed without an increase in INR in a patient taking high-dose fish oils with aspirin and warfarin.

Clinical evidence

In one early study, 40 patients took 4 g of a fish oil preparation daily for 4 weeks, and 18 of these patients were taking **warfarin**. In the group as a whole (40 patients), the bleeding time was significantly prolonged from 240 seconds to 270 seconds. In the subset of patients taking **warfarin** who had stable anticoagulant control in the preceding 3 months (15 patients), the thrombotest was shortened from 114 seconds to 90 seconds, although no changes in **warfarin** dose were made. One patient taking **warfarin** had a minor nosebleed.[1] In a large randomised study of the effect of fish oils or placebo, taken with either aspirin or **warfarin** over 9 months, there was no difference in the frequency of bleeding episodes between 132 patients taking **warfarin** and fish oil 4 g daily and 154 patients taking **warfarin** alone (17 versus 14, respectively).[2] In yet another small controlled study in 6 patients, the use of fish oil 3 g or 6 g daily for 4 weeks did not alter the INR in patients receiving stable **warfarin** therapy.[3]

Two cases of a possible interaction with a rise in INR have been reported. In one, a woman had INRs in the range of 2 to 3 for five months while taking **warfarin** 1.5 mg and 1 mg on alternate days. During this time, she started taking 1 g of a fish oil preparation daily with no change in her INR. Her **warfarin** was then increased to 1.5 mg daily, with stable INRs for about 5 months. A routine INR was then found to be 4.3 (raised from 2.8 one month earlier). One week previously, she had started to take fish oil 2 g daily (double the previous dose). The dose of **warfarin** was reduced to 1.5 mg and 1 mg on alternate days, and she was asked to reduce the fish oil back to 1 g daily. Eight days later her INR was 1.6, and the **warfarin** was increased back to 1.5 mg daily.[4] In another case, a rise in INR from between 2 and 3 up to 6, without bleeding complications, occurred 2 weeks after a patient started taking fish oil 2 g daily and trazodone 50 mg daily.[5]

In yet another report, a subdural haematoma developed after a minor fall in an elderly patient stabilised on **warfarin** and low-dose aspirin who had been taking omega-3 fatty acids 6 g daily for a year. His INR was only very slightly elevated at the time (3.2 compared with 2.8 previously).[6] Note that use of low-dose aspirin with **warfarin** increases the risk of bleeding, see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434.

Mechanism

Fish oils contain omega-3 fatty acids particularly **eicosapentaenoic acid** and **docosahexaenoic acid**. These are considered to have some antiplatelet activity, and may prolong the bleeding time. In addition, they might reduce levels of some coagulation factors. They might therefore increase the risk of bleeding when used with warfarin, similarly to antiplatelet doses of aspirin (see 'Coumarins and related drugs + Aspirin or other Salicylates', p.434), but this would not be expected to alter the INR.

Importance and management

An interaction between warfarin and fish oils is not established. One large study found no increase in bleeding episodes in over 150 patients taking warfarin and fish oils, suggesting that most patients do not develop an interaction. Nevertheless, a much larger study would be needed to quantify any excess risk in the order of that seen with antiplatelet doses of aspirin. Based on the possible moderate increase in bleeding times with high-dose fish oils, the manufacturers of one product, *Omacor* (omega-3-acid ethyl esters), say that although there have been no reports of haemorrhage with concurrent use, patients receiving anticoagulants should be monitored, and the dose of anticoagulant adjusted as necessary.[7] However, monitoring the INR would not pick up a pharmacodynamic interaction.

Coumarins + Fluorouracil and related prodrugs

Fluorouracil markedly increases the anticoagulant effects of warfarin, and cases of serious bleeding have been reported. The fluorouracil prodrugs capecitabine and tegafur appear to interact similarly.

Clinical evidence

(a) Capecitabine

In an open study, 4 patients with breast or colorectal cancer received a single 20-mg dose of **warfarin** 8 days before starting oral capecitabine (3 cycles of capecitabine 1250 mg/m^2 twice daily for 14 days, then 7 days rest), then again on day 12 of the third cycle of capecitabine. Capecitabine increased the AUC of *S*-warfarin by 57%, and increased its elimination half-life by 51%, without any significant changes to *R*-warfarin. The maximum INR was increased by 90% and the AUC of the INR increased 2.8-fold. Three of the patients required vitamin K. Because of the clear, statistically significant findings in these 4 patients, the study was terminated early.[1]

Various cases of this interaction have been reported.[2-6] In one of these reports, 2 patients starting **warfarin** developed gastrointestinal bleeding with an INR of greater than 10, after 2 cycles of capecitabine.[2] In another case, a patient who had been taking long-term **warfarin** required a gradual 85% reduction in the warfarin dose to 0.78 mg daily over 3 cycles of capecitabine and **irinotecan**, and required an increase to 4 mg daily over the 3 weeks after stopping chemotherapy.[4] Another patient required a 50% reduction in the **warfarin** dose while taking capecitabine. In addition, in a retrospective analysis of 21 patients who received **warfarin** with capecitabine, 6 patients required a warfarin dose reduction, and there were 4 episodes of major bleeding.[7] Conversely, in another analysis, there was not that much difference in rates of bleeding events and elevated INRs between patients receiving warfarin with capecitabine and those receiving warfarin alone, although the authors concluded that this might just reflect appropriate management of the interaction.[8]

The manufacturers of **capecitabine** also report that this interaction has occurred with other coumarins including **phenprocoumon**,[9,10] and that some cases have been fatal.[10]

(b) Fluorouracil and fluorouracil-based regimens

In an early clinical study, 25 patients with colon cancer were given bolus fluorouracil 15 to 20 mg/kg weekly and **warfarin** daily, titrated to maintain the prothrombin time in the 20 to 30% range, and modified weekly as necessary. Three patients developed blood loss from the gut, which was controlled by giving a transfusion (type unnamed) and stopping the **warfarin**. This study did not report the required dose of warfarin, or how often it needed adjusting in these patients.[11]

Various case reports have described clinically important over-anticoagulation with the concurrent use of dose-adjusted **warfarin** (for treatment of deep vein thrombosis, or in patients with prosthetic heart valves) and fluorouracil, either alone,[12,13] with folinic acid (leucovorin),[14-17] or levamisole.[15,18,19] In one well-described case, an elderly man taking **warfarin** long-term was found to have an INR of almost 40 (usual INR 3) four weeks after he started taking fluorouracil (450 mg/m^2 daily for 5 days then once weekly) and **levamisole** (50 mg every 8 hours for 3 days every other week). He required a two-thirds reduction in his **warfarin** dose. Later, when the chemotherapy was withheld for 5 weeks his INR became subtherapeutic, and then increased again when the chemotherapy was restarted.[18] In another retrospective case series, 4 patients taking **warfarin** long-term (target INR 2 to 3) required an 18 to 74% reduction in their **warfarin** dose during the use of fluorouracil and **folinic acid** or **levamisole**. The maximum INR in 3 of these patients was 3.66 to 8.15, and the other patient had a maximum INR of 23.7 and a retroperitoneal bleed.[15]

Other cases of over-anticoagulation have been reported with **warfarin** and fluorouracil-based regimens including CMF (**cyclophosphamide**, **methotrexate** and fluorouracil),[15,20,21] CMF plus **vincristine** and prednisone,[22] fluorouracil, **cisplatin** and **etoposide**,[23] and fluorouracil, **cisplatin** and **mitomycin**.[13]

A case has also been reported with the use of fixed-dose **warfarin** (1 mg daily) for prophylaxis of venous catheter-associated thrombosis in a patient receiving fluorouracil with **vinblastine**.[24] Similarly, in a large retrospective analysis of fixed dose **warfarin**, 31 of 95 patients given regimens based on continuous infusions of **fluorouracil** had INR elevations above 1.5, and, of these, 18 had an INR of 3 to 4.9 and seven had an INR of more than 5. Epistaxis and haematuria occurred in 8 of the patients. The regimens used were fluorouracil plus **folinic acid**; folinic acid, fluorouracil and **oxaliplatin** (FOLFOX); and folinic acid, fluorouracil and **irinotecan** (FOLFIRI).[25] In a further analysis of the use of fixed dose **warfarin** with the FOLFOX regimen, 25 of 50 patients had an INR greater than 1.5 (range 1.55 to 9.4). Two of these developed haematuria, and one had a nosebleed.[26]

(c) Tegafur

Increased INRs and bleeding (haemoptysis) were seen in a patient taking **warfarin** when *Orzel* (uracil with tegafur in a 4:1 molar ratio) was given, and a 63% reduction in the warfarin dose was needed.[27] The manufacturers of *Uftoral* (tegafur with uracil) also say that marked elevations in prothrombin times and INRs have been reported in patients taking **warfarin** when *Uftoral* was added.[28]

Mechanism

Uncertain. However, in a pharmacokinetic study in *rats*, fluorouracil significantly reduced the total clearance of *S*-warfarin by inhibiting its metabolism.[29] In addition, in a small clinical study, fluorouracil inhibited the metabolism of losartan, used as a probe substrate for the cytochrome P450 isoenzyme CYP2C9 (see 'Angiotensin II receptor antagonists; Losartan + Fluorouracil', p.44).[30] This suggests that fluorouracil possibly inhibits warfarin metabolism via CYP2C9 resulting in increased anticoagulant effects. Fluorouracil prodrugs such as capecitabine and tegafur would be expected to interact by the same mechanism.

Importance and management

Fairly well-documented and established interactions of clinical importance. Prothrombin times should be more frequently monitored in patients taking warfarin and other **coumarins** and requiring fluorouracil, capecitabine, tegafur or other fluorouracil pro-drugs, anticipating the need to reduce the warfarin dose. Note that, from a disease perspective, when treating venous thromboembolic disease in patients with cancer, warfarin is generally inferior (higher risk of major bleeds and recurrent thrombosis) to low-molecular-weight heparins.[31]

Coumarins + Flupirtine

Flupirtine does not appear to interact with phenprocoumon.

Clinical evidence, mechanism, importance and management

Twelve healthy subjects had no significant changes in their plasma levels of **phenprocoumon** 1.5 mg daily when they were given flupirtine 100 mg three times daily for 14 days. The prothrombin times were also not significantly changed.[1] Therefore, **phenprocoumon** dose adjustments would not be expected to be needed if these drugs are given concurrently.

1. Harder S, Thürmann P, Hermann R, Weller S, Mayer M. Effects of flupirtine coadministration on phenprocoumon plasma concentrations and prothrombin time. *Int J Clin Pharmacol Ther* (1994) 32, 577–581.

Coumarins + Fondaparinux

Warfarin does not alter the pharmacokinetics of fondaparinux, and fondaparinux does not alter the effect of warfarin on prothrombin time.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 12 healthy subjects were given subcutaneous fondaparinux 4 mg daily for 5 days, with warfarin 15 mg given on day 4 and 10 mg on day 5. Warfarin had no effect on fondaparinux pharmacokinetics. In addition, the effect of warfarin on prothrombin time was not altered by fondaparinux.[1]

Fondaparinux is an anticoagulant that is an indirect inhibitor of activated factor Xa, and it is sometimes used as a 'bridge' to oral anticoagulation. The findings of this study show that the prothrombin time (INR) can still be used to monitor the effect of coumarin anticoagulants during the switch from fondaparinux to oral anticoagulants.

Coumarins + Food

The rate of absorption of dicoumarol can be increased by food. Three patients had modest increases in warfarin requirements after starting high-protein, low-carbohydrate diets.

Clinical evidence and mechanism

(a) Dicoumarol

A study in 10 healthy subjects found that the peak serum concentrations of a single 250-mg dose of dicoumarol, were increased on average by 85% by food. Two subjects had increases of 242% and 206%, respectively.[1] Food might cause prolonged retention of dicoumarol in the upper part of the gut, leading to increased tablet dissolution and increased absorption.

(b) Warfarin

One report describes two patients who had well-documented decreases in INR values with modest increases in warfarin requirements (22% and 30%) after switching to high-protein, low-carbohydrate diets (the *Atkins* diet and the *South Beach* diet). On stopping these diets, both patients were eventually restabilised on their original warfarin doses.[2] Another similar case of a 16% increase in warfarin requirement has been reported.[3]

The mechanism for these cases is unknown, but suggested reasons include an increase in albumin with increased protein intake (leading to increased warfarin binding), an induction of cytochrome P450 isoenzymes with increased protein intake (increasing warfarin clearance), or increased intake of dietary vitamin-K, or a combination of these mechanisms.[4]

Importance and management

None of these interactions are very well documented, and their clinical relevance is unclear. Nevertheless, any big changes in diet have the potential to alter the effects of warfarin on the INR, and it would therefore be prudent to increase monitoring in patients wishing to start a diet. Note that vitamin K in food commonly interacts with warfarin, and these interactions are discussed in 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464.

Other food substances are discussed in their own monographs. Consider also:

Coumarins and related drugs + Food; Enteral and parenteral nutrition

A number of early case reports described warfarin resistance in patients taking enteral feeds that contained high levels of added vitamin K_1. However, products with a lower vitamin K_1 content have also been reported to interact. Lipid emulsions containing soya oil might contain sufficient natural vitamin K_1 to alter warfarin requirements. Parenteral multivitamin preparations may also contain vitamin K_1.

Clinical evidence

A. Enteral feeds

Case reports from the early 1980s described patients stabilised on **warfarin** who had reversal of the anticoagulant effect when they started taking the liquid dietary supplements *Ensure*,[1,2] or *Osmolite*.[3] Other patients who were resistant to **warfarin** were found to be taking *Ensure*[4] or *Ensure Plus*.[5,6] At this time, these products contained high levels of vitamin K_1 (240 to 380 micrograms per 240 or 250 mL, an amount equivalent to approximately 1 mg of vitamin K_1 for every 1 000 calories). Two of the patients were successfully anticoagulated with **warfarin** when their enteral nutrition was switched to *Compleat B* (vitamin K_1 16.6 micrograms/250 mL)[6] or *Meritene* (trace of vitamin K_1).[4] In response to these reports, *Ensure*, *Ensure-Plus*, and *Osmolite* were reformulated to reduce the vitamin K_1 content to 50 micrograms in 240 mL (140 micrograms per 1000 calories).[4] However, further case reports for *Ensure Plus*[7] and *Osmolite*[8] suggested that this lower level of vitamin K may still be sufficient to cause an interaction. The vitamin K_1 content of these products was reduced further to 36 to 37 micrograms per 1000 calories,[9] but even then one further case of increased **warfarin** requirement was reported with *Ensure*.[10] In another case, a patient taking *Osmolite* and intermittent *Ensure Plus* (total mean vitamin K_1 dose

81 micrograms daily) only achieved satisfactory anticoagulation with **warfarin** when the *Osmolite* was stopped, which reduced the vitamin K_1 intake to 36 micrograms daily.[11] Another patient given *Osmolite* (vitamin K_1 68.4 micrograms daily), only achieved satisfactory anticoagulation with **warfarin** when the dose was given separately from the *Osmolite*.[12]

In another case, *Isocal* 3550 mL daily (equivalent to 460 micrograms of vitamin K_1) caused an increase in **warfarin** requirement from 8 mg daily to 13 mg daily.[13] A further patient had a decrease in anticoagulant response requiring an increase in **warfarin** dose when she started a weight-reducing diet consisting solely of *Nutrilite 330* (vitamin K content unknown).[14] Another patient required twice the dose of **acenocoumarol** during a period of enteral feeding (vitamin K_1 200 micrograms daily).[15]

Isocal and *Sustacal* have also been implicated in cases of **warfarin** resistance in a further report, which attributed the mechanism to binding of the **warfarin** to protein in the enteral feed.[16] This suggested mechanism appears to be supported by a study in 6 patients that found a small increase in INR of 0.74 when continuous enteral feeding was withheld for one hour before and after warfarin administration, although the mean daily dose of **warfarin** did not significantly differ. However, note that there was also a small difference in vitamin K intake of 25 micrograms daily less during the period of separation of administration.[17]

In a prospective cohort study in 319 children, the use of enteral nutrition (mostly vitamin K supplemented formula, and some vitamin K supplemented tube feeds) was associated with a higher dose of **warfarin** to achieve a target INR (0.28 versus 0.16 mg/kg) and similarly a higher dose of **warfarin** was needed to maintain the INR (0.26 versus 0.11 mg/kg).[18]

B. Parenteral nutrition

(a) Intravenous lipids

Warfarin resistance was seen in a patient who was given a constant intravenous infusion of **soya oil emulsion** (*Intralipid*). In this case intravenous **warfarin** up to 15 mg daily only slightly prolonged the prothrombin time.[19] In another patient, an emulsified infusion of **propofol** containing 10% **soya oil** antagonised the effect of **warfarin**; anticoagulation was not achieved until the **propofol** was discontinued despite an increase in the **warfarin** dose to 30 mg daily. The dose of propofol given was estimated to provide about 154 to 231 micrograms of vitamin K_1 daily. The same effect was later see when the patient was given parenteral nutrition supplemented with 20% *Liposyn II*, which also contains **soya oil**, and was estimated to provide 53 micrograms of vitamin K_1 daily.[20]

(b) Multivitamins

The FDA in the US now requires that multivitamin products for inclusion in total parenteral nutrition contain 150 micrograms of vitamin K_1. The aim of this is to provide a daily physiological amount of the vitamin, rather than the previous practice of giving a large single weekly dose. Previously, patients taking anticoagulants were not given this single large weekly dose, therefore it is anticipated that with the new multivitamin preparation, **warfarin** doses for anticoagulation may be higher than previously needed. What effect this level of vitamin K_1 will have on the fixed-dose **warfarin** used for prophylaxis of catheter-associated thrombosis is not known.[21] In the UK, *Vitlipid N* contains vitamin K_1 (phytomenadione) 15 micrograms/mL for adults and 20 micrograms/mL for children under 11 years.

Mechanism

The coumarin and **indanedione** anticoagulants are vitamin K antagonists, and consequently giving vitamin K_1 reduces their effects. The dose at which this might become clinically important is not firmly established, but in one controlled study 150 micrograms of vitamin K_1 daily produced a clinically relevant effect in 25% of subjects (see 'Vitamin K_1-containing dietary supplements', (p.520)). There is also some evidence that a physicochemical interaction (possibly binding to protein) may occur between warfarin and enteral foods in the gut.[12,16] See also 'Coumarins + Food', p.461, for mention that high-protein diets appear to increase warfarin requirements.

Lipid emulsions given as part of parenteral nutrition often contain soya oil, which has a moderate level of vitamin K (see 'Table 12.3', (below)). These preparations may also have direct coagulation effects.[20] Parenteral nutrition may also be supplemented with vitamin K.

Table 12.3 Foods with a moderate to high content of Vitamin K_1 (phytomenadione)

Foods	*Vitamin K_1 content (micrograms/100 g)*
Vegetables	
Asparagus	51 to 80
Beet greens	484
Broccoli	101 to 156
Brussels sprouts	122 to 289
Cabbage	50 to 98
Collards (non-heading cabbage)	440 to 623
Endive	231
Kale	817 to 882
Kelp seaweed	66
Lettuce (iceberg to green leaf)	24 to 174
Parsley (fresh or dried)	360 to 1640
Spinach	270 to 575
Spring onions	207
Turnip greens	367 to 519
Fats and oils	
Soya oil	25 to 145
Rapeseed oil	112 to 150
Olive oil	30 to 60
Margarines	40 to 110
Fruit and nuts	
Avocado	14 to 20
Cashew nuts	19 to 64
Kiwi fruit	25 to 40
Pine nuts	33 to 74
Prunes, dried	1.4 to 68

Importance and management

Established interactions of clinical importance. Be aware that enteral feeds might contain sufficient vitamin K to alter coagulation status, so starting or stopping these feeds might affect dose requirements of vitamin K

antagonists such as warfarin. It is also possible that there is a local interaction in the gut, as in one case separating the administration of the warfarin and an enteral feed by 3 hours or more was effective,[12] and in another study withholding the enteral feed for one hour before and after warfarin administration slightly reduced the effect of any interaction.[17] Patients should be advised not to add or substitute dietary supplements such as *Ensure* without increased monitoring of their coagulation status. A consistent dose administration time is recommended, such as during the usual break in the feeding regimen, to minimise any possible interaction.[22]

Fat emulsions used for parenteral use containing soya oil may themselves contain sufficient vitamin K_1 for daily needs. Parenteral multivitamin preparations may also contain important levels of vitamin K_1. It would be advisable to keep the vitamin K_1 intake constant in any patient requiring long-term supplemental or total parenteral nutrition and warfarin. If the amount of lipid and/or multivitamins is altered, anticipate a change in warfarin requirement.

Although there is only a single case, bear in mind that propofol may interact because it is formulated with soya oil, which contains vitamin K_1.

Coumarins + Food; Ice cream

Two isolated reports describe antagonism of the effects of warfarin by ice cream.

Clinical evidence, mechanism and importance and management

A woman taking **warfarin** 22.5 mg daily did not have the expected prolongation of her prothrombin time. It was then discovered that she took the **warfarin** in the evening and she always ate ice cream before going to bed. When the **warfarin** was taken in the mornings, the prothrombin time increased.[1] Another patient's **warfarin** requirements almost doubled when she started to eat very large quantities of ice cream (one litre each evening). She took the **warfarin** at 6 pm and ate the ice cream at about 10 pm.[2] The effect was not seen when she ate normal amounts of ice cream (3 or 4 normal size portions weekly).

The reason for these isolated cases is unknown. Vitamin K in food commonly interacts with warfarin (see 'Coumarins and related drugs + Food; Vitamin K_1-rich', p.464), but ice cream does not contain important amounts of this vitamin. Given the rarity of reports, it would appear very unlikely that eating ice cream as part of a normal diet will have any effect on INR. However, be aware that any big changes in diet have the potential to alter the INR in response to **warfarin**. Consider also 'Coumarins + Food', p.461.

Coumarins + Food; Mango fruit

A daily intake of one to six mangoes was considered the reason for a moderate increase in the anticoagulant effects of warfarin in one report. None of the patients in whom this interaction was seen showed any evidence of bleeding.

Clinical evidence, mechanism, importance and management

In 13 patients taking **warfarin**, eating mango fruit appeared to increase their INRs by an average of 38% (from 2.79 to 3.85), but no bleeding occurred. No other explanation for the increased INRs could be identified. The patients were reported to have eaten one to 6 mangoes daily for 2 days to one month before attending the anticoagulant clinic. When mango was identified as a possible cause for their increased INRs, the patients were told to stop eating mango, whereupon their mean INR fell within 2 weeks, by almost 18%. When two of the patients whose mean INRs had originally risen by 13% were later rechallenged with mango (rather less than before), their mean INR rose by 9%.[1]

The reason for this apparent interaction is not known, but the authors of the report speculate about the possible role of vitamin A (reported to be 8061 units in an average sized mango of 130 g, without seed). In practical terms this increase in INR would not seem to represent a serious problem, although note that one patient's INR rose to 5.1 (a 54% increase).

There appear to be no other reports in the literature of an interaction between mango and **warfarin**, nor of interactions between mango and any other oral anticoagulant. More study of this interaction is needed, but at the present time there is insufficient reason to suggest that patients taking **warfarin** should avoid mango fruit.

Coumarins + Food; Soya bean products

Natto, a Japanese food made from fermented soya bean, can markedly reduce the effects of warfarin and acenocoumarol, because of the high levels of vitamin K_2 substance produced in the fermentation process. In one study, soya bean protein also modestly reduced the effects of warfarin, and a similar case has been reported with soy milk. Two cases of 'warfarin resistance' have been seen in patients given intravenous soya oil emulsions.

Clinical evidence

(a) Fermented soya bean products (natto)

In a controlled study in 12 healthy subjects stabilised on **acenocoumarol**, a single meal containing 100 g of natto decreased the mean INR from 2.1 to 1.5 after 24 hours, and the INR had still not returned to the original level after 7 days (INR 1.75 one week later). The effect was considered clinically important in 6 of the 12 subjects.[1] Similarly, in an earlier retrospective study in 10 patients taking **warfarin**, eating natto caused the thrombotest values to rise from a range of 12 to 29% up to a range of 33 to 100%. The extent of the rise appeared to be related to the amount of natto eaten. The thrombotest values fell again when the natto was stopped. A healthy subject taking **warfarin**, with a thrombotest value of 40%, ate 100 g of natto. Five hours later the thrombotest value was unchanged, but 24 hours later it was 86%, and after 48 hours it was 90% (suggesting that the anticoagulant effect was decreased).[2]

(b) Soya milk

In a 70-year-old man stabilised on **warfarin** 3 mg daily, consumption of soya milk 480 mL daily (240 mL of both *Sun Soy* and *8th Continent* mixed together) decreased the INR from 2.5 to 1.6 after about 4 weeks.[3] One week after stopping the soya milk, his INR was 1.9, and 4 weeks after it was 2.5.

(c) Soya oil

Soya oil is an important source of dietary vitamin K, see 'Table 12.3', (p.462). For two cases of 'warfarin resistance' with intravenous soya oil emulsions, see 'Coumarins and related drugs + Food; Enteral and parenteral nutrition', p.461.

(d) Soya protein

In a study in 10 patients with hypercholesterolaemia who were stabilised on **warfarin**, substitution of all animal protein for textured **soya protein** for 4 weeks caused a marked reduction (Quick value approximately doubled) in the anticoagulant effects of warfarin by the second week.[4]

Mechanism

Soya beans are a moderate source of vitamin K_1 (19 micrograms per 100 g),[5] and soya oil and products derived from it are an important dietary source of vitamin K. However, the soy milk brand taken in the case report did not contain vitamin K,[3] and another reference source lists soya milk as containing just 7.5 micrograms vitamin K per 250 mL,[5] which would not be expected to cause an interaction. Why this product decreased the effect of warfarin is therefore open to speculation.

The vitamin K content of textured soya protein is unknown. Note that **soy sauce** made from soya and wheat is reported to contain no vitamin K, and soft **tofu** made from the curds by coagulating soya milk contains only low levels (2 micrograms per 100 g).[5]

In contrast, fermented soya bean products such as natto contain very high levels of a particular vitamin K_2 substance (MK-7)[6], because of the fermentation process with *Bacillus natto*. In addition, the bacteria might continue to act in the gut to increase the synthesis and subsequent absorption of vitamin K_2.[2] Although the role of vitamin K_2 in anticoagulation is less well established than vitamin K_1, it appears that this also opposes the actions of coumarins and indanediones, which are vitamin K antagonists.

Importance and management

The interaction between warfarin and fermented soya bean products is established, marked, and is likely to be clinically relevant in all patients. Patients taking coumarin and probably **indanedione** anticoagulants should probably be advised to avoid natto, unless they want to consume a regular, constant amount.

Although information is limited, it appears that soya protein might also modestly reduce the effect of warfarin. In particular, complete substitution of animal protein for soya protein appears to reduce the effect of warfarin. A single report suggests that soy milk may also interact. Case reports suggest that soya milk and soya oil may also interact, and therefore some caution would be prudent with these products. On the basis of known vitamin K-content, **whole soya beans** could potentially reduce the effect of warfarin, whereas **soy sauce** should not.[5] Note that patients taking coumarins and **indanediones** are advised to have their INR checked if they markedly change their diet. This would seem particularly important if they decide to change their intake of soya-related products.

Coumarins and related drugs + Food; Vitamin K_1-rich

Unintentional and unwanted antagonism of warfarin has occurred in patients who ate exceptionally large amounts of some green vegetables, which can contain significant amounts of vitamin K_1. Isolated cases have also been reported with avocado, green tea (very large quantities), liver, and seaweed sushi. Foods containing significant amounts of vitamin K_2 substances such as fermented soya beans might also interact.

Clinical evidence and mechanism

The coumarin and indanedione oral anticoagulants are vitamin K antagonists, which inhibit the enzyme vitamin K epoxide reductase so reducing the synthesis of vitamin K-dependent blood clotting factors by the liver. If the intake of dietary vitamin K_1 increases, the synthesis of the blood clotting factors begins to return to normal. As a result the prothrombin time also begins to fall to its normal value. Naturally occurring vitamin K_1 (phytomenadione) is found only in plants.

A. Individual foodstuffs

(a) Avocado

Two women taking **warfarin** had a reduction in their INRs (from 2.5 to 1.7 and from 2.7 to 1.6, respectively) when they started to eat avocado 100 g daily, or 200 g of avocado on two consecutive days. Their INRs climbed again when the avocado was stopped.[1] Avocado contains a small to moderate amount of vitamin K_1, see 'Table 12.3', (p.462), so might occasionally reduce the efficacy of **warfarin** if eaten in these quantities.

(b) Green tea

A patient taking **warfarin** had a reduction in his INR from a range of 3.2 to 3.79 down to 1.37, which was attributed to the ingestion of very large quantities of green tea (about 2 to 4 litres each day for a week). This interaction was attributed to the vitamin-K content of the tea.[2] However, although dried tea, including green tea, is very high in vitamin-K_1, the brewed liquid made from the tea contains negligible amounts of vitamin K_1 (which is a fat-soluble vitamin),[1,3] and is therefore not considered to contribute any vitamin K_1 to the diet.[3] The reason for this interaction is therefore unclear, unless the patient was eating some of the brewed tea leaves. A pharmacokinetic interaction also appears unlikely, because, although black tea inhibited the cytochrome P450 isoenzyme CYP2C9 *in vitro*, brewed tea had no effect on the CYP2C9 substrate flurbiprofen in healthy subjects.[4] CYP2C9 is important in the metabolism of the more potent *S*-warfarin. For discussion of a case where a patient had an increase in INR after stopping taking a herbal preparation of which green tea leaves were one of 25 ingredients, see 'Coumarins + Vitamin K_1-rich herbal medicines', p.521.

(c) Green vegetables

In a formal study in patients stabilised on **warfarin**, one day of a high intake of vitamin K_1-rich vegetables (**brussels sprouts** 400 g, **broccoli** 400 g, **lettuce** 750 g, or **spinach** 300 g, estimated to contain 1 mg of vitamin K_1 daily) decreased anticoagulant effects: the thrombotest values rose above the normal range of 10 to 25% in 2 of 5 patients in 2 to 3 days. Two days of a high intake of the same vegetable caused values above the therapeutic range in 3 of 7 patients, and 7 days intake did the same in 9 of 13 patients.[5] In another similar study, intake of **spinach** 250 g or **broccoli** 250 g daily for 7 days increased the mean thrombotest values to above the therapeutic limit of 15%, and the effect was similar to that of a supplement containing phytomenadione 250 micrograms daily. A reduction in the anticoagulant effect of **warfarin** was also seen in one healthy subject who ate about 450 g **spinach** daily.[6,7]

In a pharmacokinetic study in healthy subjects, a daily intake of 400 g of **brussels sprouts** for 2 weeks slightly decreased the AUC of **warfarin** by 16% and increased its metabolic clearance by 27%.[8] This is probably because **brussels sprouts** induce the cytochrome P450 isoenzyme CYP1A2, which has a role in the 'metabolism of warfarin', (p.405).

A few cases of this interaction (often described as warfarin resistance) have been reported in patients taking **dicoumarol**,[9] or **warfarin**[10-13] when consuming large amounts of green vegetables (about 300 to 700 g daily),[11,12] such as **spinach**,[9,14] **broccoli**,[11,12] or a weight-loss diet consisting of **lettuce**, **turnip greens**, and **broccoli**.[13] The dietary vitamin K was esti-

mated to be 1.3 g daily in one case,[10] and 6 g daily in another.[13] In two cases, patients suffered a serious thromboembolic event.[12,13] For discussion of a case where a patient had an increase in INR after stopping a herbal preparation, of which spinach, broccoli and cabbage were 3 of 25 ingredients, see 'Coumarins + Vitamin K_1-rich herbal medicines', p.521.

Conversely, a single intake of **spinach** 250 g or **broccoli** 250 g had no effect on thrombotest values over 7 days.[14] Similarly, in another study in healthy subjects stabilised on **acenocoumarol**, a single meal containing either **spinach** 400 g or **broccoli** 400 g with corn oil caused just 0.27 and 0.41 reductions in the mean INR, an effect that was not considered clinically relevant. These reductions were equivalent to that seen with about 200 micrograms of vitamin K_1.[15]

(d) Liver

A patient taking **acenocoumarol** had a soft tissue bleed, and was found to have a very low thrombotest value of about 3%. She had always consumed about 142 g daily of green vegetables, but about 4 months previously had been advised to stop eating liver (750 g weekly) as part of a low-fat diet.[16] In another case, a man taking **warfarin** 5 mg daily had diffuse bruising and an INR of 5.6 two weeks after he was advised to stop eating pork **liver**[12] (1 kg per week). He was eventually restabilised on just 1.5 mg of warfarin daily. Early studies found that liver contained high levels of vitamin K, but more recent studies using more specific detection techniques have shown that liver generally contains very low levels of vitamin K_1 (4 and 7 micrograms in 100 g).[17] However, liver may contain vitamin K_2 substances in sufficient levels to be of possible nutritional relevance.[17,18] The precise role of vitamin K_2 substances in anticoagulation control is less clear, but natto, which is a rich source of these, clearly reduces the effects of coumarins. See 'Coumarins + Food; Soya bean products', p.463.

(e) Seaweed

A patient taking **warfarin** had, on two occasions, reduced INRs of 1.6 and 1.8 (usual range 2 to 3) within 24 hours of eating sushi with **seaweed** (***asakusa-nori***). It was estimated that she had consumed only about 45 micrograms of vitamin K_1, which would not usually interact. However, if her vitamin K stores were low, this amount could have accounted for a large percentage of her vitamin K intake or stores, and might therefore have interacted.[19] Note that **kelp** is a moderate source of vitamin K, see 'Table 12.3', (p.462).

(f) Other foodstuffs

In an early report, a Japanese man recently stabilised on **warfarin** developed bleeding episodes on two occasions shortly after resuming his usual diet of Japanese food (specific foods not mentioned), suggesting increased warfarin effects. However, ingestion of three similar Japanese meals in a 24-hour period had no effect on the prothrombin time in 6 Caucasian patients taking **warfarin**.[20]

B. Overall dietary vitamin K intake

(a) Correlation with INR

Some evidence suggests that the average dietary vitamin K_1 intake is correlated with the efficacy of **warfarin**. In one study, patients consuming a diet containing more than 250 micrograms daily of vitamin K_1 had a lower INR five days after starting **warfarin** than patients consuming less dietary vitamin K_1 (median INR 1.9 versus 3). Also, the high-vitamin K_1 group needed a higher maintenance **warfarin** dose (5.7 mg daily versus 3.5 mg daily).[21] In another study, multiple regression analysis indicated that, in patients taking warfarin, the INR was altered by 1, by a weekly change in the intake of vitamin K of 714 micrograms.[22] Similarly, for each increase in daily dietary vitamin K_1 intake of 100 micrograms, the INR decreased by just 0.2 in another study.[23]

In a randomised, crossover study in patients taking **warfarin** or **phenprocoumon**, increasing the dietary intake of vitamin K_1 by 500% relative to the baseline value (from 118 to 591 micrograms daily) for 4 days only modestly decreased the INR from 3.1 to 2.8 on day 4. Decreasing the dietary intake of vitamin K_1 by 80% (from 118 to 26 micrograms daily) for 4 days increased the INR from just 2.6 to 3.3 on day 7.[24]

(b) Stability of anticoagulant control

There is some evidence that patients with a very low dietary vitamin K_1 intake are more sensitive to alterations in vitamin K_1 intake, and have less stable anticoagulant control. For example, in one study, patients with unstable control of anticoagulation were found to have a much lower dietary intake of vitamin K_1, when compared with another group of patients with stable anticoagulant control (29 micrograms daily versus 76 micrograms daily).[25] In another study in 10 patients with poorly controlled anticoagulation taking **acenocoumarol**, a diet with a low, controlled vitamin K_1 content of 20 to 40 micrograms daily increased the percentage of INR values within the therapeutic range, when compared with a control group of 10 patients not subjected to any dietary restrictions.[26] Supplementation of the diet with small doses of vitamin K_1 has had a similar effect, see 'Coumarins + Vitamin K_1-containing dietary supplements', p.520.

Importance and management

A very well established, well documented and clinically important drug-food interaction, expected to occur with every coumarin or indanedione anticoagulant because they have a common mode of action. The evidence suggests that, in patients with normal vitamin K_1 status, in general, clinically relevant changes in coagulation status require large continued changes in intake of vitamin K_1 from foods. However, there is some evidence to suggest that patients with low dietary vitamin K_1 intake may be sensitive to smaller changes in dietary vitamin K_1. This suggests that patients taking anticoagulants should be advised to eat a normal balanced diet, maintaining a relatively consistent amount of vitamin-K_1 rich foods. They should be told to avoid making major changes to their diet, including starting a weight-loss diet, without increased monitoring of their INR. It is estimated that a normal Western diet contains 300 to 500 micrograms of vitamin K_1 daily. The minimum daily requirement is about 1 micrograms/kg and, in the US, an adequate intake has been determined to be 120 micrograms for adult men and 90 micrograms daily for adult women. 'Table 12.3', (p.462), gives the vitamin K_1 content of some vitamin-K_1 rich foods; however, it is important to note that these are not the bioavailable contents, which may be much lower for green vegetables, particularly if they are eaten in the absence of fat.[18,27] Nevertheless, green leafy vegetables usually contribute 40 to 50% of the total intake, followed by certain vegetable oils and margarines made from these oils.[28] Also, processed foods can have moderate to high vitamin K_1 levels if they contain fats with high vitamin K_1 levels. Note that some foods that have a low vitamin K_1 content can contribute significantly to total intake because of how often they are eaten. Cooking and freezing do not alter the vitamin K_1 content, but vitamin K_1 in oils is degraded by exposure to light.[29] In the US, a chart has been devised to help patients and researchers determine the daily intake of vitamin K_1.[30]

For the effect of multivitamins containing vitamin K_1, see 'Coumarins + Vitamin K_1-containing dietary supplements', p.520, and for the effect of supplements in enteral and parenteral feeds, see 'Coumarins and related drugs + Food; Enteral and parenteral nutrition', p.461.

There is growing evidence that vitamin K_2 substances (menaquinones) may also be important, and in one analysis rich dietary sources of these included goose liver paste, hard and soft cheeses, egg yolk,[18] and natto, the effect of which is already established, see 'Coumarins + Food; Soya bean products', p.463.

Coumarins and related drugs + Garlic

An isolated report described increases in the anticoagulant effects of warfarin in two patients taking garlic supplements. Another report described a decrease in anticoagulant effects of fluindione in a patient taking garlic tablets. Garlic supplements alone have also rarely been associated with bleeding. However, in one study, aged garlic extract did not increase the INR or risk of bleeding in patients taking warfarin.

Clinical evidence

(a) Fluindione

In an 82-year-old man stabilised on fluindione 5 mg (dosage frequency not stated) for chronic atrial fibrillation, the INR dropped to below its usual range (2 to 3) when garlic tablets 600 mg daily were taken, and remained below 2 for 12 consecutive days despite an increase in fluindione dose to 10 mg. The INR returned to normal, with an associated reduction in fluindione dose, when the garlic tablets were stopped. He was also taking enalapril 20 mg, furosemide 40 mg and pravastatin 20 mg (dose frequency not stated).[1]

(b) Warfarin

The INR of a patient stabilised on warfarin more than doubled and haematuria occurred 8 weeks after the patient started to take three *Höfels garlic pearles* daily. The situation resolved when the garlic was stopped. The INR rose on a later occasion while the patient was taking two *Kwai* garlic tablets daily. The INR of another patient was also more than doubled by six *Kwai* garlic tablets daily.[2,3]

In contrast, in a placebo-controlled study in 48 patients stabilised on warfarin, there was no change in INR or evidence of increased bleeding in those receiving 5 mL of aged garlic extract (*Kyolic*) twice daily for 12 weeks.[4] Similarly, in a preliminary report of the use of alternative and complementary medicines in 156 patients taking warfarin, there was no apparent increased risk of bleeding or raised INRs in 57 patients taking potentially interacting complementary medicines (garlic in 10%), compared with 84 who did not.[5]

Mechanism

Garlic has been associated with decreased platelet aggregation, which has on at least two documented occasions led to spontaneous bleeding in the absence of an anticoagulant.[6,7] These effects might therefore increase the risk of bleeding with anticoagulants, see also 'Coumarins + Herbal medicines; Miscellaneous', p.472.

Importance and management

Information about an adverse interaction between warfarin and garlic seems to be limited to two cases from one author. Similarly, the data regarding indanediones is sparse, with just one case reported. Bearing in mind the wide-spread use of garlic and garlic products, and the limited information from the review,[5] and study with aged garlic extract,[4] it seems most unlikely that garlic usually has any generally important interaction with these anticoagulants. Nevertheless, bear the possibility in mind in the event of an unexpected response to treatment.

In addition, garlic may have some antiplatelet effects, and although there appear to be no clinical reports of an adverse interaction between garlic and antiplatelet drugs, it may be prudent to consider the potential for an increase in the severity of bleeding if garlic is given with anticoagulants.
