- A case report describes significantly *raised* efavirenz levels of up to 10 mg/L, with agitation and drowsiness, in a patient taking efavirenz 600 mg daily with rifampicin. The efavirenz dose needed to be reduced to 200 mg daily. However, in this case, genetic testing found that the patient was a poor metaboliser of CYP2B6.[18]

(c) Nevirapine

The concurrent use of nevirapine and rifampicin may result in subtherapeutic levels of nevirapine and possibly treatment failure:

- In a prospective, randomised, controlled study in 71 HIV-positive patients taking rifampicin and given nevirapine 400 mg daily, by week 12, subtherapeutic 12-hour concentrations were found in 21.3% of nevirapine patients. Further analysis reported that low 12-hour concentrations, indicating low exposure to nevirapine, were associated with treatment failure.[2]
- A study in 16 HIV-positive patients taking nevirapine 200 mg twice daily, and rifampicin 450 mg or 600 mg daily found the AUC, and maximum and trough plasma concentrations of nevirapine were increased by 67%, 63%, and 37%, respectively, at least 10 days after rifampicin was stopped. Of the three patients who were reported to have a raised viral load during rifampicin treatment, only one had a subtherapeutic nevirapine trough level of 1.3 mg/L, whereas five other patients with subtherapeutic nevirapine levels (less than 3 mg/L) had viral loads less than 400 copies/mL.[19]
- In another study in 13 patients taking nevirapine 200 mg twice daily, the addition of rifampicin 450 mg or 600 mg daily caused a 46% reduction in the AUC of nevirapine, and a 53% reduction in the minimum levels, with 8 of the patients having a nevirapine trough level below the therapeutic range (3 micrograms/mL). In 7 of the patients who had a reduction in the minimum levels to less than the therapeutic range, increasing the dose of nevirapine to 300 mg twice daily for 2 weeks increased the levels to above the therapeutic range in all patients without increasing adverse effects.[20]
- In a retrospective study, 6 patients taking nevirapine 200 mg twice daily (5 patients) or 300 mg twice daily (one patient) had therapeutic nevirapine levels while taking rifampicin. In the same study, another 4 patients had subtherapeutic nevirapine levels, one patient had levels at the low end of the therapeutic range, whereas one patient was found to have raised nevirapine levels.[7]
- Another retrospective analysis of therapeutic drug monitoring of nevirapine in HIV-positive patients also reported that the concurrent use of rifampicin was associated with about a 40% reduction in nevirapine plasma concentrations.[3] An efficacy study found that the 209 HIV-positive patients taking nevirapine 200 mg daily with rifampicin had a higher risk of raised viral loads at 6 months and had a shorter time to virological failure than 1726 HIV-positive patients taking nevirapine without rifampicin. No pharmacokinetic data for nevirapine were reported in this study.[14]
- The manufacturer states that the AUC of nevirapine was reduced by 58% by rifampicin in 14 subjects, when compared with historical data. There was no change in steady-state rifampicin pharmacokinetics.[21,22]

Some studies suggest the reduction in nevirapine levels does not result in therapeutic failure:

- In a study in HIV-positive patients with tuberculosis found that rifampicin caused a 31% decrease in the AUC of nevirapine and a non-significant 21% decrease in its trough concentration.[23] The authors of this study suggested that there is probably no need to increase the nevirapine dose, since the trough levels were still sufficiently above the level needed for antiviral activity.[23] Moreover, in contrast to the studies reported above, subsequent observational data supported the continued efficacy of standard dose nevirapine when it was used with rifampicin.[24]
- Others have also reported the successful use of nevirapine with twice weekly rifampicin with little effect on trough nevirapine levels.[25]
- In yet another study, the concurrent use of rifampicin and nevirapine reduced nevirapine levels by about 18% with no reduction in virological response, although the proportion of patients with trough levels below the recommended level was much higher (29.7% versus 6.8%) at 8 weeks.[26] When these patients stopped rifampicin treatment, the nevirapine levels were reported to increase from 5.4 mg/L to 6.4 mg/L. No difference in viral load reductions and CD4+ counts were seen between the group treated with rifampicin and the control group.[27]

Mechanism

Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, by which the NNRTIs are metabolised, therefore reducing their levels. Efavirenz is also metabolised by CYP2B6, and this isoenzyme may also be affected by rifampicin.

Importance and management

The interactions between the NNRTIs and rifampicin are clinically significant; however, there is considerable debate regarding optimum dosing of efavirenz with concurrent use of rifampicin.

It has been recommended that the combination of **delavirdine** and rifampicin should be considered as contraindicated because the effects of the interaction are so large.[1] The CDC in the US and the manufacturer recommend that rifampicin should not be used with delavirdine.[28,29]

The manufacturer of **etravirine** predicts that rifampicin will decrease the plasma concentration of etravirine. Due to the risk of therapeutic failure, they therefore contraindicate the concurrent use of etravirine and rifampicin,[30] as do the CDC in the US.[28]

Efavirenz may be taken with rifampicin, however guidance on the appropriate dose adjustments required for efavirenz are conflicting. The CDC in the US suggest that usually no dose alteration of efavirenz is needed when it is taken with rifampicin but note however, that some experts recommend increasing the efavirenz dose to 800 mg daily in patients weighing more than 60 kg.[28] The British HIV Association (BHIVA) recommend increasing the efavirenz dose to 800 mg daily in patients more than 50 kg.[31] This is supported by evidence from some studies.[12,13] The UK manufacturer recommends a dose increase to 800 mg daily regardless of weight.[32] However, one study reported increases in efavirenz levels and adverse effects with the higher dose.[12,13,17] Some patients may be lacking or deficient in CYP2B6, and as one study found, may have raised efavirenz levels despite rifampicin use.[16] In these patients it is likely that a 600 mg dose of efavirenz may be sufficient. Concurrent use should be closely monitored and the efavirenz dose adjusted accordingly.

Based on these pharmacokinetic data, the manufacturers suggests that the concurrent use of rifampicin with **nevirapine** is not recommended, and that rifabutin may be considered instead, with close monitoring of adverse effects.[21,22] In the UK, rifampicin is not recommended for use with nevirapine, but if the combination is used, standard doses and monitoring of nevirapine is advised.[31] The CDC in the US state note that no dose alteration is needed for either nevirapine or rifampicin on concurrent use.[28]

Rifabutin may be used with some NNRTIs as an alternative to rifampicin. For further information and advice on the management of drug interactions between rifabutin and the NNRTIs, see 'NNRTIs + Rifabutin', p.935.

NNRTIs + St John's wort (*Hypericum perforatum*)

There is some evidence to suggest that St John's wort may decrease the levels of nevirapine. Delavirdine, efavirenz and etravirine would be expected to be similarly affected.

Clinical evidence

Nevirapine levels, obtained by routine monitoring, were noted to be lower in 5 men who were also taking St John's wort. Based on a pharmacokinetic modelling analysis, it was estimated that St John's wort increased the oral clearance of **nevirapine** by about 35%.[1]

Mechanism

This finding supports predictions based on the known metabolism of the NNRTIs by the cytochrome P450 isoenzyme CYP3A4 (see 'Table 21.2', (p.914)), of which St John's wort is a known inducer.

Importance and management

The interaction between St John's wort and nevirapine confirms advice issued by the CSM in the UK,[2] that St John's wort may decrease blood levels of the NNRTIs with possible loss of HIV suppression. Therefore concurrent use should be avoided.

NNRTIs + Tenofovir

In general, no pharmacokinetic interaction appears to occur between tenofovir and efavirenz, etravirine, or nevirapine, although raised efavirenz levels have been reported in some patients. Neuropsychiatric adverse effects have been reported with the concurrent use of efavirenz and tenofovir. Some clinical data have shown a high rate of treatment failure when tenofovir is given with enteric-coated didanosine and either efavirenz or nevirapine.

Clinical evidence

(a) Efavirenz

In a pharmacokinetic study in 29 subjects, there was no interaction between efavirenz 600 mg daily and tenofovir disoproxil fumarate 300 mg daily.[1,2] Also, efavirenz plasma levels did not differ between patients taking tenofovir and patients not taking tenofovir. It appeared that efavirenz did not alter tenofovir levels.[3]

Another study also reported no overall difference in efavirenz levels in 18 HIV-positive patients also taking tenofovir, when compared with 151 HIV-positive patients taking efavirenz alone. However, further analysis found that 23 patients who were poor metabolisers of the cytochrome P450 isoenzyme CYP2B6 (those lacking or deficient in CYP2B6) had higher levels of efavirenz than those who were extensive metabolisers of CYP2B6 (that is, those with normal levels of this isoenzyme). Five of the 23 were taking tenofovir with efavirenz and were found to have significantly higher levels of efavirenz than the 18 who were not taking tenofovir. In one case, the addition of tenofovir increased the AUC of efavirenz by about 66% resulting in neuropsychological adverse effects. These adverse effects resolved when the efavirenz dose was reduced to 200 mg daily.[4]

Nine cases of neuropsychiatric adverse effects, such as nightmares, insomnia, and dizziness, have been reported in HIV-positive patients taking efavirenz, in each case developing within 48 hours of starting tenofovir. These patients had previously been taking long-term efavirenz-based HAART with no reports of neurological adverse effects. In 6 of these patients, the symptoms resolved when tenofovir was stopped.[5]

Some clinical data have shown a high rate of treatment failure with a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 200 or 250 mg and efavirenz 600 mg daily.[6]

(b) Etravirine

In a study, healthy subjects were given tenofovir 300 mg daily for 16 days with etravirine 200 mg or 800 mg twice daily on days one to 8 or days 9 to 16. Tenofovir modestly reduced the $AUC_{0\text{-}12}$ of etravirine by 19 to 31%. Etravirine slightly increased the AUC of tenofovir by about 15%.[7]

(c) Nevirapine

In a retrospective analysis, plasma levels of nevirapine 200 mg twice daily or 400 mg once daily did not differ between patients taking tenofovir disoproxil fumarate 300 mg daily and those not taking tenofovir. It appeared that nevirapine did not alter tenofovir levels.[3]

Some clinical data have shown a high rate of treatment failure with a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 200 or 250 mg and nevirapine 400 mg daily.[6]

Mechanism

Efavirenz is metabolised by the cytochrome P450 isoenzyme CYP2B6. Patients lacking or with low levels of this isoenzyme (poor metabolisers) are known to have increased levels of efavirenz, which may increase the risk of adverse effects. However, as tenofovir is not known to have significant inhibitory effects on cytochrome P450 isoenzymes, the mechanism for the raised efavirenz levels reported with tenofovir is unclear. The au-

thors of this study note that tenofovir has been found to weakly inhibit CYP2B6 *in vitro*.[4]

Importance and management

In general, no significant pharmacokinetic interaction appears to occur between efavirenz and tenofovir. However, the study[4] suggesting that patients who are poor metabolisers of CYP2B6 may have higher levels of efavirenz when treated with tenofovir warrants further investigation. Until further information is available, it may be prudent to bear the possibility of an interaction in mind should a patient taking efavirenz develop an increase in adverse effects when tenofovir is started. Note that there are clinical data supporting the use of other tenofovir and efavirenz-based regimens.[1,2]

The modest changes in etravirine and tenofovir pharmacokinetics are not expected to be of clinical significance, so no dose adjustment is needed with concurrent use. No significant pharmacokinetic interaction appears to occur between nevirapine and tenofovir.

The combination of efavirenz or nevirapine with tenofovir and didanosine should probably not be used, and the UK manufacturer specifically advises against the use of tenofovir with didanosine,[1] see 'NRTIs + Tenofovir', p.957.

NNRTIs + Valproate

Efavirenz levels were not altered by valproic acid in one study in HIV-positive patients, and valproic acid levels were not different to those in a control group not taking efavirenz. However, one patient had a marked decrease in valproate levels after starting efavirenz. A case of hepatotoxicity has occurred in a patient taking valproic acid with nevirapine, ritonavir and saquinavir.

Clinical evidence

In a study in 11 HIV-positive patients taking **efavirenz** 600 mg daily with various NRTIs, there was no change in the pharmacokinetics of **efavirenz** after they took valproic acid 250 mg twice daily for 7 days. Valproic acid levels achieved in these patients were not significantly different from those in 11 HIV-positive control patients mainly taking NRTIs, even when the 3 control patients taking a protease inhibitor or NNRTI (amprenavir, indinavir, or nelfinavir with nevirapine) were excluded.[1]

However, a patient with a bipolar disorder and multidrug addiction had a decrease in plasma valproic acid levels of more than 50% shortly after starting an antiretroviral regimen including **efavirenz**. Even though the valproate dose was increased to 4 g daily, it was found difficult to achieve a target plasma level of 50 mg/dL. About 3 months later, following a valproate dose reduction to 1.5 g daily due to adverse effects, his level was unaltered, at 52 mg/dL.[2]

A case of valproate-associated hepatotoxicity occurred in a 51-year-old man about 3 weeks after he started **nevirapine** 200 mg twice daily, ritonavir 400 mg twice daily, saquinavir 400 mg twice daily, and stavudine. Serum valproic acid levels remained therapeutic.[3]

Mechanism

Uncertain.

Importance and management

The findings of the study[1] suggest that valproate can be used with efavirenz-based regimens without any pharmacokinetic drug interaction. However, the case report of reduced valproic acid levels introduces a note of caution. It may be appropriate to monitor valproate levels in patients taking efavirenz. It is unclear whether the case of hepatotoxicity was a result of a drug interaction. Note that there has been some concern about using valproate in HIV infection but there seems to be no established reason to avoid or specifically promote the use of valproate in HIV-infection *per se*.

NNRTIs; Delavirdine + Glutamic acid

Glutamic acid increases the absorption of delavirdine in patients with poor gastric acid production.

Clinical evidence, mechanism, importance and management

When **glutamic acid** 1.36 g three times daily was given with delavirdine 400 mg three times daily to 8 HIV-positive subjects with gastric hypoacidity, the AUC of delavirdine was increased by 50%.[1] Delavirdine is a weak base that is poorly soluble at neutral pH. Therefore, in subjects with gastric hypoacidity, the absorption of delavirdine is reduced, and substances that lower gastric pH increase its absorption. However, the clinical value of using **glutamic acid** with delavirdine to boost its absorption is unknown. The manufacturer recommends that, in patients with achlorhydria, delavirdine should be taken with an **acidic beverage** such as **orange** or **cranberry juice**.[2]

1. Morse GD, Adams JM, Shelton MJ, Hewitt RG, Cox SR, Chambers JH. Gastric acidification increases delavirdine mesylate (DLV) exposure in HIV+ subjects with gastric hypoacidity (GH). *Clin Pharmacol Ther* (1996) 59, 141.
2. Rescriptor (Delavirdine mesylate). Pfizer Inc. US Prescribing information, May 2008.

NNRTIs; Etravirine + Miscellaneous

Etravirine modestly decreases the levels of maraviroc. Etravirine is predicted to decrease the levels of some antiarrhythmics, immunosuppressants (ciclosporin, sirolimus and tacrolimus), and the phosphodiesterase-type-5 inhibitors (sildenafil, tadalafil, and vardenafil).
Etravirine has no clinically significant effect on the pharmacokinetics of digoxin and enfuvirtide. No interaction is expected to occur between etravirine and ribavirin.

Clinical evidence, mechanism, importance and management

(a) Antiarrhythmics

The manufacturers of etravirine predict that it will reduce the levels of **amiodarone**, **disopyramide**, **flecainide**, **lidocaine** (systemic use), **mexiletine**, **propafenone**, and **quinidine**. They therefore recommend caution on concurrent use and to monitor the drug levels of the affected antiarrhythmic, if this is possible.[1,2]

(b) Digoxin

The UK manufacturer reports that etravirine slightly increased the AUC and maximum concentration of digoxin by 18% and 19%, respectively.[1] This minor change in digoxin levels would not be expected to be of clinical significance, and no digoxin dose adjustment is needed on concurrent use. The US manufacturer states that, when starting digoxin in a patient taking etravirine the lowest possible dose of digoxin should be used. If etravirine is started in a patient taking digoxin, they state that no dose adjustments of either drug are necessary.[2] Both the UK and US manufacturer advises monitoring of digoxin levels on the concurrent use of etravirine.[1,2]

(c) Enfuvirtide

The UK manufacturer reports that enfuvirtide 90 mg twice daily had no significant effect on the pharmacokinetics of etravirine. The levels of enfuvirtide are not expected to be affected by etravirine. No dose adjustment is necessary on concurrent use.[1]

(d) Immunosuppressants

The manufacturers predict that etravirine will reduce the levels of **ciclosporin**, **tacrolimus** and **sirolimus**. This is because etravirine is an inducer of the isoenzyme CYP3A4, by which ciclosporin, sirolimus and tacrolimus are metabolised. They therefore recommend caution on concurrent use, and suggest monitoring the drug levels of the affected immunosuppressant to prevent a loss of therapeutic effect.[1,2]

(e) Maraviroc

The UK manufactures reports that concurrent use of etravirine with maraviroc 300 mg twice daily decreases the AUC, maximum concentration, and minimum concentration of maraviroc by 53%, 60%, and 39%, respectively. However, when etravirine was taken with maraviroc and ritonavir-boosted **darunavir** 100/600 mg twice daily, the AUC, maximum concentration and minimum concentration of maraviroc were increased 3-fold, 1.8-fold, and 5.3-fold, respectively. The pharmacokinetics of etravirine were minimally affected and no dose adjustment of etravirine appears to be needed when it is taken with maraviroc and a ritonavir-boosted protease inhibitor. For maraviroc, the manufacturer[1] advises following the dose adjustments given for concurrent use with the protease inhibitors, see 'Maraviroc + Ketoconazole and other CYP3A4 inhibitors', p.922.

(f) Phosphodiesterase type-5 inhibitors

The manufacturers report that etravirine reduces the AUC and maximum concentration of **sildenafil** by 57% and 45%, respectively. Similarly, the AUC and maximum levels of its active metabolite, *N*-desmethylsildenafil, are also reduced, by 41% and 25%, respectively.[1,2] Other phosphodiesterase inhibitors (**tadalafil** and **vardenafil**) are predicted to be similarly affected. This is because etravirine induces the isoenzyme CYP3A4, by which these phosphodiesterase inhibitors are metabolised. An initial dose adjustment of the phosphodiesterase inhibitor is not considered to be necessary on concurrent use. However, given the reductions reported with sildenafil, some patients may require a dose increase, according to clinical effect.[1,2]

(g) Ribavirin

The UK manufacturer states that although the combination has not been studied, an interaction between etravirine and ribavirin is unlikely. Therefore no dose adjustment of either drug is needed with concurrent use.[1]

NRTIs + Aciclovir and related drugs

The concurrent use of zidovudine and aciclovir normally appears to be uneventful, but an isolated report describes overwhelming fatigue in one patient given zidovudine and intravenous aciclovir. No interaction would be expected between zidovudine and valaciclovir. Famciclovir does not alter the pharmacokinetics of zidovudine or emtricitabine.

Clinical evidence, mechanism, importance and management

(a) Emtricitabine

In a study in 12 healthy subjects no important pharmacokinetic interaction was found between single doses of emtricitabine 200 mg and **famciclovir** 500 mg.[1]

(b) Zidovudine

1. Aciclovir or Valaciclovir. A study in 20 HIV-positive men found no pharmacokinetic interaction between zidovudine 100 mg and aciclovir 400 or 800 mg, both given every 4 hours, 5 times a day, and the combination was well tolerated over a 6-month period.[2] When 41 HIV-positive patients taking zidovudine were given aciclovir, no changes in the pharmacokinetics of the zidovudine occurred and the adverse effects were unchanged.[3] In a group of patients with AIDS taking zidovudine, some of whom were also given aciclovir, no obvious problems developed that could be attributed to the use of the aciclovir.[4]

In contrast, a man with herpes who had been treated with intravenous aciclovir 250 mg every 8 hours for 3 days, developed overwhelming fatigue and lethargy within about an hour of starting oral zidovudine 200 mg every 4 hours. This lessened slightly on changing from intravenous to oral aciclovir, which was continued for 3 days, and symptoms resolved when the aciclovir was withdrawn. The symptoms developed again when intravenous aciclovir was given as a test.[5] This isolated case of fatigue is not understood, and no other cases appear to have been reported. It is therefore unlikely to be of general relevance.

Note that as valaciclovir is a prodrug of aciclovir, no interaction would generally be expected when it is given with zidovudine.

2. Famciclovir. Minimal changes in zidovudine pharmacokinetics were seen when 12 HIV-positive patients taking zidovudine 400 mg to 1 g daily were given a single 500-mg dose of famciclovir.[6]

NRTIs + Antacids

Aluminium/magnesium hydroxide modestly reduces the bioavailability of zalcitabine. Antacids would not be expected to have any additional pharmacokinetic effect on buffered didanosine preparations.

Clinical evidence, mechanism, importance and management

(a) Didanosine

Didanosine is acid labile, so to increase its absorption, some didanosine preparations (e.g. buffered tablets) have been formulated with antacids.[1] Additional concurrent antacids would not be expected to have any further clinically relevant effect on didanosine pharmacokinetics, although the US manufacturers of the oral powder for solution[2] suggest that additional antacids may increase the adverse effects of the components of this preparation (presumably both the antacid and didanosine components).

(b) Zalcitabine

A study in 12 HIV-positive patients given a single 1.5-g dose of zalcitabine found that 30 mL of *Maalox* [**aluminium/magnesium hydroxide**] caused a 25% reduction in the bioavailability of zalcitabine.[3] These changes are moderate and of uncertain clinical importance. The manufacturers recommended that zalcitabine should not be taken at the same time as **aluminium/magnesium**-containing antacids.[4,5]

NRTIs + Antiepileptics

Valproate increases the bioavailability of zidovudine, and one case of severe anaemia was attributed to the interaction. A case of liver toxicity has also been reported on the concurrent use of these

drugs. Phenytoin and phenobarbital are predicted to slightly decrease abacavir levels.

Clinical evidence

(a) Abacavir

The UK manufacturer of abacavir says that **phenobarbital** and **phenytoin** may slightly decrease abacavir concentrations by affecting glucuronyltransferases.[1] The US manufacturer however does not mention this potential interaction.[2]

(b) Zidovudine

In a study in 6 HIV-positive subjects, the AUC and mean plasma levels of zidovudine 100 mg every 8 hours were increased by 80% when they were given **valproic acid** 250 mg or 500 mg every 8 hours for 4 days. No adverse reactions, changes in hepatic or renal function, or alterations in the blood picture were reported.[3] A case report describes a patient with AIDS taking zidovudine 100 mg five times daily who had a two- to threefold increase in trough and peak serum zidovudine levels, and a 74% increase in the CSF zidovudine levels while taking **valproic acid** 500 mg three times daily.[4] In another report, a patient taking **carbamazepine**, **clobazam** and **gabapentin** was given zidovudine, **lamivudine** and **abacavir**. Nine months later, **valproic acid** 500 mg twice daily was added because of a seizure frequency of greater than one per month. At this time, his haemoglobin level was normal. About 2 months later, he was found to have severe anaemia, requiring a blood transfusion. **Stavudine** was substituted for zidovudine in his antiretroviral therapy, and 4 months later his haemoglobin was normal. The adverse haematological effects were attributed to an interaction between the **valproate** and zidovudine.[5] Another HIV-positive patient, who had been taking **valproate** for 2 years and zidovudine, developed severe encephalopathy, adult respiratory distress syndrome and liver failure (steatosis). Both valproate and zidovudine were stopped, and the patient gradually recovered.[6]

For the possible effect of zidovudine on phenytoin levels, see 'Phenytoin + Zidovudine', p.648.

Mechanism

The evidence indicates that the metabolism (glucuronidation) of zidovudine is inhibited by valproate so that its bioavailability is increased.[3,4] It was suggested that this caused the zidovudine haematological toxicity in the case reported.[5] The glucuronidation of abacavir is predicted to be increased by drugs that can induce glucuronyltransferases, such as phenobarbital and phenytoin.[1]

Importance and management

Information seems to be limited to the papers cited, but an interaction between zidovudine and valproate would appear to be established. It would therefore seem prudent to monitor for increases in zidovudine adverse effects and possible toxicity if valproate is added. The other NRTIs do not undergo significant glucuronidation (see 'Antivirals', (p.913)), and would therefore not be expected to interact with valproate.

Bear in mind the possibility of an interaction should a patient taking phenytoin or phenobarbital have a reduced response to abacavir.

For a discussion of drug-disease considerations when using valproate in HIV infection, see under Importance and management in 'Protease inhibitors + Valproate', p.988.

NRTIs + Antimycobacterials

Didanosine, stavudine and zalcitabine are not expected to interact with rifabutin, but rifabutin may modestly increase the clearance of zidovudine. An isolated case describes undetectable rifabutin levels in a patient taking antiretrovirals including buffered didanosine.
Rifampicin (rifampin) appears to modestly increase the clearance of zidovudine, and is predicted to interact similarly with abacavir.
Isoniazid, pyrazinamide and ethambutol appear not to interact with zidovudine.
The clearance of isoniazid is increased by zalcitabine, and there is a theoretical increased risk of peripheral neuropathy.

Clinical evidence, mechanism, importance and management

(a) Abacavir

The UK manufacturer of abacavir[1] says that potent enzyme inducers such as **rifampicin** (**rifampin**) may slightly decrease abacavir plasma concentrations due to their ability to induce glucuronyltransferases (see also *Zidovudine*, below). As yet, there appears to be no other information on this.

(b) Didanosine

In a study in 12 patients with AIDS, **rifabutin** 300 to 600 mg daily for 12 days did not significantly affect the pharmacokinetics of [buffered] didanosine 167 to 250 mg twice daily.[2] The steady-state pharmacokinetics of **rifabutin** were not affected by didanosine (buffered sachet preparation),[3] which suggests that the buffer used in the didanosine preparation had no effect on **rifabutin** absorption.[3] However, a case has been reported of a patient taking ritonavir-boosted lopinavir, efavirenz, lamivudine and buffered didanosine who had impaired **rifabutin** absorption. When **rifabutin** was taken 30 minutes after didanosine, **rifabutin** levels were undetectable, but when **rifabutin** was taken 3 hours after didanosine, **rifabutin** levels were apparent.[4]

The controlled study[3] suggests that no special precautions are necessary if both drugs are given. However, the case report[4] introduces an element of caution, especially if other drugs that may affect **rifabutin** pharmacokinetics are used. If indeed **rifabutin** absorption is affected by antacids (there appear to be no clinical data on this), then giving the drugs at least 2 hours apart, or using the enteric-coated didanosine preparation should avoid the interaction.[4]

For a discussion on the effects of antacids contained in buffered didanosine preparations on the absorption of **isoniazid**, see 'Isoniazid + Antacids', p.346.

(c) Stavudine

A study in 10 HIV-positive subjects found that **rifabutin** 300 mg daily had no significant effects on the pharmacokinetics of the stavudine 30 mg or 40 mg twice daily and the incidence of adverse effects did not increase.[5] No special precautions would seem necessary if both drugs are given.

(d) Zalcitabine

A study in 12 HIV-positive patients found that when zalcitabine 1.5 mg three times daily was given with **isoniazid** 300 mg daily the pharmacokinetics of zalcitabine remained unchanged but the clearance of **isoniazid** was approximately doubled.[6] The UK manufacturer of zalcitabine[7] recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy: the US manufacturer recommended that the combination should be avoided where possible.[8]

The UK manufacturer of **rifabutin** suggests that no significant interaction would be expected between **rifabutin** and zalcitabine.[9]

(e) Zidovudine

The pharmacokinetics of **rifabutin** are not affected by the concurrent use of zidovudine in patients with AIDS,[10] and **rifabutin** does not affect the pharmacokinetics of zidovudine in HIV-positive patients,[11] although one analysis found a trend towards increased zidovudine clearance.[12] No increase in adverse effects appears to occur when **rifabutin** is given with zidovudine.[10]

In a retrospective study of healthy subjects and HIV-positive individuals, the clearance of zidovudine was increased by 132% by **rifampicin** (**rifampin**) and by 50% by **rifabutin**, suggesting that the enzyme-inducing effects of **rifabutin** are less than those of **rifampicin**, so less significant interactions would be expected.[13]

A comparative study in HIV-positive patients given zidovudine and antimycobacterials (**isoniazid**, **rifampicin**, **pyrazinamide**, and **ethambutol** initially, then **isoniazid** and **rifampicin**) for 8 months, found no evidence of an adverse interaction. However, marked anaemia occurred in those subjects given both groups of drugs, but it was not necessary to permanently stop zidovudine in any patient. The authors therefore advised care-

ful monitoring for haematological toxicity.[14] Another study in 4 HIV-positive patients found that **rifampicin** lowered the AUC and increased the clearance of zidovudine in all patients, probably due to the enzyme-inducing activity of **rifampicin**, which increases the glucuronidation of zidovudine. When **rifampicin** was stopped in one patient, the zidovudine AUC doubled.[15] A later study of the same interaction in 8 HIV-positive men found that **rifampicin** significantly induced the glucuronidation of zidovudine and suggested that the effect wore off 14 days after stopping **rifampicin**. The authors of this study suggested that dose alterations may not be necessary on concurrent use.[16] The British HIV Association (BHIVA) advise that standard doses of zidovudine may be used.[17]

NRTIs + Atovaquone

Moderate increases in the AUC of zidovudine have been seen with atovaquone. Atovaquone appears to decrease the AUC of didanosine. Didanosine and zidovudine do not affect the pharmacokinetics of atovaquone.

Clinical evidence

(a) Didanosine

The manufacturer of atovaquone notes that it decreased the AUC of didanosine by 24% in a multiple dose interaction study. There was no change in the pharmacokinetics of atovaquone.[1]

(b) Zidovudine

A study in 14 HIV-positive patients given atovaquone 750 mg every 12 hours and zidovudine 200 mg every 8 hours found that under steady-state conditions the zidovudine had no effect on the pharmacokinetics of atovaquone.[2] This confirmed the findings of a previous analysis of pharmacokinetic data from a small number of patients enrolled in clinical studies.[3] However, the AUC of zidovudine was increased by about 30%, and its clearance was reduced by 25% by the concurrent use of atovaquone.[2]

Mechanism

Atovaquone might inhibit the metabolism (glucuronidation) of zidovudine.[2]

Importance and management

The manufacturer of atovaquone notes that the decrease in **didanosine** levels is unlikely to be clinically relevant.[1]

The manufacturer of atovaquone states that the increased plasma levels of **zidovudine** likely with a 3-week course of atovaquone for acute pneumocystis pneumonia are unlikely to increase the adverse effects of zidovudine,[1] and routine dose adjustments are not required.[4] Nevertheless, the manufacturers of atovaquone and zidovudine recommend regular monitoring for zidovudine-associated adverse effects when the drugs are used together, particularly if atovaquone suspension is used, as this achieves higher atovaquone levels, which might have a greater effect.[1,5] The authors of the study with zidovudine[2] suggest that increases could possibly be important in patients also taking other drugs causing bone marrow toxicity (such as ganciclovir, see 'NRTIs + Ganciclovir or Valganciclovir', p.948, and flucytosine, see 'NRTIs; Zidovudine + Myelosuppressive drugs', p.961). If bone marrow toxicity is seen, it is suggested that the zidovudine dose may need to be reduced by a third.[2]

NRTIs + Azoles

Fluconazole has no significant effect on the pharmacokinetics of didanosine or stavudine, but it may modestly increase zidovudine levels. Fluconazole levels are unaffected by these NRTIs.
Itraconazole has no affect on the pharmacokinetics of zidovudine. The levels of itraconazole from capsules are markedly reduced when buffered didanosine is given at the same time, but itraconazole tablets and ketoconazole are not affected if buffered didanosine is given 2 hours later. Enteric-coated didanosine has no clinically relevant effect on the pharmacokinetics of fluconazole, itraconazole or ketoconazole. The frequency of haematological toxicity with zidovudine does not appear to be increased by ketoconazole.

Clinical evidence

(a) Didanosine

1. Buffered preparation. A 35-year-old patient with AIDS was given **itraconazole** capsules 200 mg twice daily following an episode of cryptococcal meningitis. When he relapsed it was noted that he had been taking the **itraconazole** at the same time as his buffered didanosine. Subsequent study in this patient indicated a marked delay in **itraconazole** absorption when it was taken with didanosine. Two hours after the dose, plasma **itraconazole** concentrations of 1.6 micrograms/mL were seen without didanosine, but were undetectable with didanosine. A peak **itraconazole** level of 1.4 micrograms/mL was seen when it was given 8 hours after a dose of didanosine.[1] In a study in 6 healthy subjects when [buffered] didanosine was given with a single 200-mg oral dose of **itraconazole**, the peak levels of **itraconazole** were undetectable; in the absence of didanosine, **itraconazole** levels were 0.9 micrograms/mL.[2] A later study in 12 HIV-positive patients found that the AUC of a single 200-mg dose of **itraconazole** was not significantly different when buffered didanosine 200 mg was given 4 hours before or 2 hours after **itraconazole**.[3]

Twelve HIV-positive patients were given buffered didanosine 375 mg twice daily either alone or 2 hours after **ketoconazole** 200 mg daily, for 4 days. Didanosine maximum plasma levels were slightly reduced by 12% and no significant changes in the pharmacokinetics of **ketoconazole** were seen when dosing was separated in this way.[4]

A group of 12 HIV-positive subjects taking buffered didanosine 100 to 250 mg twice daily were also given **fluconazole** for 7 days (two 200-mg doses on the first day, followed by 200 mg daily). The pharmacokinetics of didanosine remained unchanged in the presence of **fluconazole**, and concurrent use was well tolerated. **Fluconazole** pharmacokinetics were not assessed.[5]

2. Enteric-coated preparation. Enteric-coated didanosine 400 mg had no significant effect on the pharmacokinetics of **fluconazole** 200 mg in 14 healthy subjects, and no clinically relevant effect on the pharmacokinetics of **itraconazole** 200 mg in 25 healthy subjects.[6] Similarly, in a study in 24 healthy subjects, enteric-coated didanosine 400 mg had no clinically relevant effect on the pharmacokinetics of **ketoconazole** 200 mg. Three of the subjects had increased concentrations of **ketoconazole** with didanosine, but their values for **ketoconazole** alone appeared unusually low. When their data were excluded, no effect on AUC was seen in the remaining 21 subjects.[7]

(b) Stavudine

A study in 10 HIV-positive subjects taking stavudine 40 mg twice daily, found that the addition of **fluconazole** 200 mg daily for one week had no significant effect on the pharmacokinetics of the stavudine.[8]

(c) Zidovudine

On two occasions, 12 HIV-positive men were given zidovudine 200 mg every 8 hours with and without **fluconazole** 400 mg daily for 7 days. While taking **fluconazole** the AUC of zidovudine increased by 74%, the maximum serum levels increased by 84%, the terminal half-life was increased by 128% and the clearance was reduced by 43%.[9] In contrast, another study in 10 HIV-positive patients found only a very small change in the pharmacokinetics of a single 500-mg dose of zidovudine given before and after 7 days of treatment with **fluconazole** (e.g. a 7% increase in the AUC of zidovudine). In another 10 patients, zidovudine had no effect on the pharmacokinetics of a single dose of **fluconazole**.[10]

Itraconazole 200 mg daily for 2 weeks was reported to have no effect on the pharmacokinetics of zidovudine in 7 patients, but the serum levels in 2 patients were higher.[11]

A study of zidovudine use in 282 patients with AIDS found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common, but this was not increased by the concurrent use of **ketoconazole** in some of these patients.[12]

Mechanism

Itraconazole and ketoconazole depend on stomach acidity for absorption. A raised gastric pH, caused by the antacids in the buffered didanosine formulation appears to reduce itraconazole absorption from the capsule formulation (consider, 'Azoles + Antacids', p.243). The didanosine itself appears to have no part to play in this interaction. The enteric-coated preparation of didanosine does not contain any antacids and therefore does not interact.

In vitro data suggest that the altered zidovudine pharmacokinetics may, in part, occur because fluconazole inhibits zidovudine glucuronidation.[13]

Importance and management

The most significant interaction occurs between the buffered preparation of **didanosine** and itraconazole *capsules*. Patients should avoid taking both drugs at the same time, but taking itraconazole capsules at least 2 hours before buffered didanosine appears to solve the problem. Any possible interaction with ketoconazole can similarly be avoided by giving ketoconazole at least 2 hours before a buffered didanosine preparation. Alternatively, the interaction may be avoided by using the enteric-coated preparation of didanosine or itraconazole *solution*.

There is no pharmacokinetic interaction between **stavudine** and fluconazole. No interaction would be expected with other similar NRTIs such as **lamivudine** and **zalcitabine** (see 'Antivirals', (p.913)).

There is evidence of a minor interaction between **zidovudine** and fluconazole, but this is unlikely to be clinically significant.

NRTIs + Co-trimoxazole or Trimethoprim

Trimethoprim, both alone and as co-trimoxazole (trimethoprim with sulfamethoxazole) reduces the renal clearance of lamivudine, zalcitabine and zidovudine, and therefore raises their plasma levels. No clinically significant pharmacokinetic interaction occurs if didanosine is given with co-trimoxazole or trimethoprim.

Clinical evidence

(a) Didanosine

A study in 10 HIV-positive subjects investigated the pharmacokinetics of didanosine 200 mg, trimethoprim 200 mg and sulfamethoxazole 1 g in combination. Most pharmacokinetic parameters were unchanged. However, didanosine clearance was reduced by 35%, trimethoprim clearance was decreased by 32%, and sulfamethoxazole clearance was increased by 39%, when all three drugs were given together. When only two of the three drugs were given, trimethoprim caused a 27% decrease in the clearance of didanosine, and didanosine caused an 82% increase in the clearance of sulfamethoxazole.[1] Despite these alterations in clearance, the maximum serum concentration, AUC and half-life of each of the three drugs were minimally affected.[1]

(b) Lamivudine

A study of 14 HIV-positive patients taking co-trimoxazole 960 mg daily for 5 days found that the AUC of a single 300-mg dose of lamivudine given on day 4 was increased by 43% and the renal clearance was decreased by 35%. The pharmacokinetics of trimethoprim and sulfamethoxazole were unaffected.[2] Similarly, in a population pharmacokinetic analysis, the concurrent use of lamivudine and co-trimoxazole was associated with a 31% reduction in the apparent oral clearance of lamivudine, and an estimated 43% increase in steady-state lamivudine levels.[3] The UK manufacturer notes that the interaction is due to trimethoprim, and that sulfamethoxazole did not interact.[4]

(c) Stavudine

The UK manufacturer notes that an interaction with trimethoprim is possible, as both drugs are actively secreted by the renal tubules.[5]

(d) Zalcitabine

In a steady-state study, 8 HIV-positive patients took zalcitabine 1.5 mg three times daily with and without trimethoprim 200 mg twice daily. Trimethoprim increased the AUC and decreased the clearance of zalcitabine by about 35%.[6]

(e) Zidovudine

A study in 9 HIV-positive patients given zidovudine 3 mg/kg by infusion over one hour found that trimethoprim 150 mg or co-trimoxazole 960 mg did not affect the metabolic clearance of the zidovudine. However, the renal clearances of zidovudine were reduced by 48% by trimethoprim and by 58% by co-trimoxazole, and the renal clearances of its glucuronide metabolite were reduced by 20% and 27%, respectively.[7] Another study also found that co-trimoxazole did not alter zidovudine pharmacokinetics.[8] A further 5 HIV-positive patients had a 30% increase in the AUC of zidovudine when they were given trimethoprim (doses not stated).[9] Zidovudine renal clearance was reduced by 58% in 8 HIV-positive subjects when they were also given trimethoprim 200 mg, but the $AUC_{0\text{-}6}$ of the zidovudine glucuronide to zidovudine ratio was unchanged, suggesting that the metabolism was unaffected.[10]

Increases in the half-lives of trimethoprim, sulfamethoxazole and

N-acetyl sulfamethoxazole of 72%, 39%, and 115%, respectively, were seen when co-trimoxazole was given to 4 patients with AIDS taking zidovudine 250 mg every 8 hours for 8 days.[11]

A study of zidovudine use in 282 patients with AIDS found that haematological abnormalities (anaemia, leucopenia, neutropenia) were common. However, the frequency was not increased in the patients (number unknown) also taking co-trimoxazole.[12] However, a later study in a sub-Saharan population taking co-trimoxazole and zidovudine reported a higher than expected level of blood disorders.[13]

Mechanism

It is suggested that trimethoprim inhibits the secretion of both zidovudine and its glucuronide by the kidney tubules. It is not known why the half-life of co-trimoxazole is increased. The other NRTIs that interact are likely to do so by the same mechanism.

Importance and management

Established interactions. With the NRTIs that are actively excreted via the kidneys (e.g. **lamivudine**, **stavudine**, and **zalcitabine**), it is unlikely that dose alterations are necessary unless the patient has renal impairment. However, when both drugs are needed, patients should be closely monitored for signs of toxicity. However, the UK manufacturer of lamivudine recommends that the use of lamivudine with high-dose co-trimoxazole for the treatment of pneumocystis pneumonia and toxoplasmosis should be avoided.[4]

As renal clearance represents only 20 to 30% of the total clearance of **zidovudine**, the authors of two of these reports[7,10] suggest that this interaction is unlikely to be clinically important for zidovudine unless the glucuronidation by the liver is impaired by liver disease or by other drugs, see 'NRTIs; Zidovudine + Drugs that inhibit glucuronidation', p.960. The possible increased risk of haematological adverse effects requires confirmation. The manufacturer[14] of zidovudine advises that although limited data suggest that there is no significant increased risk of adverse effects when zidovudine is taken with *prophylactic* co-trimoxazole, in general the concurrent use of zidovudine with drugs that are known to cause myelosuppression, such as co-trimoxazole, should be closely monitored, see also 'NRTIs; Zidovudine + Myelosuppressive drugs', p.961.

Didanosine also does not appear to interact with co-trimoxazole or trimethoprim to a clinically relevant extent. Nevertheless concurrent use should be well monitored, especially because co-trimoxazole alone has been associated with a high incidence of adverse effects in patients with AIDS.[15]

NRTIs + Cytokines

Interferon alfa does not alter the pharmacokinetics of didanosine or lamivudine to a clinically relevant extent. Interferon alfa and, particularly, interferon beta can cause an increase in the levels of zidovudine. HIV-positive patients infected with hepatitis C and given interferon alfa and ribavirin may be at special risk of NRTI-associated lactic acidosis.
Interleukin-2 does not appear to interact significantly with zidovudine.

Clinical evidence

(a) Didanosine

Interferon alfa 1 million to 15 million units daily was given to 26 HIV-positive patients taking didanosine sachets 100 to 375 mg twice daily. Interferon appeared to have no clinically significant effects on the pharmacokinetics of didanosine.[1]

(b) Lamivudine

In a study in 19 healthy subjects, a single subcutaneous injection of **interferon alfa** 10 million units had no clinically significant effects on the pharmacokinetics of lamivudine 100 mg daily for 7 days. Lamivudine did not appear to alter the pharmacokinetics of **interferon alfa**.[2]

(c) Zidovudine

In a study, patients with AIDS who had been taking zidovudine 200 mg every 4 hours for 8 weeks were also given subcutaneous **recombinant beta interferon** 45 million units daily. After 3 days and 15 days the zidovudine metabolism was reduced by 75% and 97%, respectively. By day 15, the zidovudine half-life was increased by about twofold.[3] Another study in 6 children aged 3 months to 17 years found that 5 weeks of the concurrent use of **interferon alfa** increased the AUC of zidovudine by 36%, increased its maximum serum level by 69% and reduced its clearance by 20%.[4]

A study found that a 4-week course of **interleukin-2** (0.25 million units/m^2 daily) by continuous infusion had no clinically significant effect on the pharmacokinetics of a 100-mg intravenous dose of zidovudine.[5] Another study in 8 HIV-positive men given oral zidovudine 200 mg every 4 hours found similar results.[1]

Mechanism

Interferon beta appears to inhibit the metabolism (glucuronidation) of zidovudine by the liver.

Importance and management

Information seems to be limited to these reports. The results of the first report suggest that the **zidovudine** dose may need to be reduced if interferon beta is added in order to avoid increased zidovudine toxicity. A dose reduction of two-thirds, or even more, may be necessary. More study is needed to confirm these observations. Interferon alfa appears to interact to a lesser extent. The manufacturers warn that the risk of haematological toxicity may be increased if zidovudine and interferon are used together, and that concurrent use in hepatitis C may increase the risk of NRTI-associated lactic acidosis. Patients at risk should be carefully monitored.[6,7]

No significant pharmacokinetic interaction appears to occur between interferon alfa and **didanosine** or **lamivudine**. Nevertheless, all manufacturers note that, because of the risk of NRTI-associated lactic acidosis, caution should be exercised when giving NRTIs (**abacavir**, didanosine, **emtricitabine**, lamivudine, **stavudine**, zidovudine) to any patient with hepatomegaly, hepatitis or other known risk factors for liver disease and hepatic steatosis. They also state that HIV-positive patients infected with hepatitis C and treated with interferon alfa and ribavirin may constitute a special risk. Patients at increased risk should be monitored closely.

No clinically significant interaction appears to occur between zidovudine and interleukin-2.

For the discussion of the effects of ribavirin, both alone and when used in combination with interferons, on NRTIs, see 'NRTIs + Ribavirin', p.956.

NRTIs + Dapsone

Buffered didanosine does not alter the pharmacokinetics of dapsone, but there is some circumstantial evidence to suggest that it may reduce the prophylactic effects of dapsone in preventing pneumocystis pneumonia. Dapsone has no effect on the pharmacokinetics of zalcitabine, whereas zalcitabine causes a small rise in the levels of dapsone, and there is a theoretical increased risk of peripheral neuropathy with the combination. Dapsone appears not to affect the pharmacokinetics of zidovudine, although concurrent use may be associated with an increased risk of blood dyscrasias.

Clinical evidence, mechanism, importance and management

(a) Didanosine

An early report of the use of buffered didanosine described the development of pneumocystis pneumonia in 11 out of 28 HIV-positive patients taking dapsone prophylaxis, compared with only one of 12 patients taking aerosolised pentamidine, and none of 17 patients taking co-trimoxazole (trimethoprim with sulfamethoxazole). Of the 11 patients where prophylaxis failed, 4 died from respiratory failure.[1] The authors suggested that the most likely explanation of the high failure rate of dapsone with didanosine, was reduced dapsone absorption due to the citrate-phosphate buffer in the didanosine formulation.[1] This has led to some recommending that the drugs be taken at least 2 hours apart. However, in a controlled study in 6 HIV-positive subjects, dapsone pharmacokinetics were not altered when a dose of buffered didanosine was taken within 5 minutes.[2] Similarly, in 6 healthy subjects, dapsone pharmacokinetics were not altered by the aluminium/magnesium antacids and other excipients contained in didanosine tablets.[2] Another study in healthy subjects similarly did not find that a marked rise in gastric pH affects the absorption of dapsone, see 'Dapsone + Antacids', p.341. Furthermore, low dapsone levels have been found in patients receiving a weekly dapsone regimen who took dapsone at least 2 hours before or 6 hours after didanosine, and in patients taking zidovudine or no antiretrovirals (although this study did not look at whether dapsone levels were correlated with efficacy).[3] In a retrospective analysis, other authors found no evidence to confirm a correlation between failure of pneumocystis pneumonia prophylaxis with dapsone and use of drugs that increase gastric pH (didanosine, H_2-receptor antagonists, antacids).[4]

It has therefore been adequately demonstrated that the buffered preparation of didanosine and antacids do not affect dapsone absorption. The explanation for the apparent failure of pneumocystis pneumonia prophylaxis in the original report[1] is unresolved. Despite the use of both didanosine and dapsone in the management of HIV and opportunistic infections there do not appear to be any further reports of problems with the combination.

(b) Zalcitabine

A pharmacokinetic study in 12 HIV-positive patients who were given zalcitabine 1.5 mg three times daily and dapsone 100 mg daily, alone or together, found that dapsone did not significantly affect the pharmacokinetics of zalcitabine. However, zalcitabine decreased the clearance of dapsone by 21%, increased its maximum serum levels by 19% and increased its half-life by 34%.[5] These changes are relatively small and seem unlikely to have much clinical relevance, but until this is confirmed it would seem prudent to monitor the concurrent use of these two drugs. The UK manufacturer[6] recommended caution with the combination because of the possibility of an increased risk of peripheral neuropathy: the US manufacturer advised avoiding the combination where possible.[7]

(c) Zidovudine

In a study in 8 HIV-positive subjects, dapsone 100 mg daily had no effect on the pharmacokinetics of a single 200-mg dose of zidovudine.[8] In a further study, which considered the safety of dapsone in combination with zidovudine, dapsone was shown to increase the risk of zidovudine-related blood dyscrasias.[9] Therefore it would seem that dapsone and zidovudine can be given concurrently, but monitoring for an increase in adverse events would seem advisable.

NRTIs + Drugs that cause pancreatitis

An isolated case of additive pancreatic toxicity has been described with zalcitabine and intravenous pentamidine, and is expected when didanosine or stavudine, and possibly lamivudine, are given with other drugs that can cause pancreatitis. An isolated case describes pancreatitis with lamivudine and azathioprine.

Clinical evidence

A single case report describes a 51-year-old woman with a kidney transplant who developed pancreatitis after starting **lamivudine**. **Azathioprine** had been discontinued only 3 days before and it is possible (although the evidence is weak) that the residual serum **azathioprine** had interacted with **lamivudine** to cause the pancreatitis.[1] Note that **lamivudine** alone may cause pancreatitis.[2,3]

Fatal fulminant pancreatitis occurred in a patient given **zalcitabine** and intravenous **pentamidine**.[4]

A case of pancreatitis has been reported in a patient taking **stavudine** 30 mg twice daily and **lamivudine** 150 mg twice daily with nevirapine 200 mg twice daily. Stavudine was stopped and the patient recovered.[5]

A retrospective, case-control study in HIV-positive patients found that use of **stavudine** was associated with an increased risk of developing acute pancreatitis (adjusted odds ratio 2.19). Further, nebulised **pentamidine** was associated with an increased risk of developing pancreatitis (adjusted odds ratio 6.27). The use of **co-trimoxazole**, **dapsone**, **didanosine**, and **hydroxycarbamide** appeared to be associated with an increased risk for developing pancreatitis, but after adjustments for factors such as race, no statistically significant increased risk was found. No increased risk of pancreatitis was found with **abacavir**.[6] However, note that the use of hydroxycarbamide, stavudine and didanosine is associated with an increased risk of pancreatitis, see 'NRTIs + Hydroxycarbamide', p.949.

Mechanism

The specific mechanism for NRTI-associated pancreatitis is not known but may be due to mitochondrial toxicity caused by inhibition of host mitochondrial DNA polymerise gamma.[6] Concurrent use of NRTIs with other drugs known to cause pancreatitis may increase the risk.

Importance and management

Of the NRTIs, didanosine, stavudine and zalcitabine have been associated with fatal pancreatitis.[4,7-11] Pancreatitis has occurred in patients taking

lamivudine.[2,3] Concurrent use of other drugs known to cause pancreatitis may possibly increase the risk of pancreatitis occurring.

The manufacturers of **didanosine** recommend that if another drug that has the potential to cause pancreatitis is required, treatment with didanosine should be stopped. However, if concurrent use is unavoidable, patients should be closely monitored.[7,8] Similarly, other authors recommend temporarily discontinuing didanosine in patients needing systemic pentamidine or sulfonamide-containing regimens.[12]

The UK manufacturer of **stavudine** recommends that patients receiving concurrent treatment with drugs known to cause pancreatitis should be carefully observed,[9] and the US manufacturer specifically recommends caution and close monitoring with the concurrent use of didanosine and stavudine,[10] see 'NRTIs + NRTIs', p.950. The manufacturers of **zalcitabine** recommended that if a drug that has the potential to cause pancreatitis is required, treatment with zalcitabine should be interrupted.[4,11] They specifically applied this to the use of pentamidine to treat pneumocystis pneumonia.[4,11]

Note that hydroxycarbamide (hydroxyurea) may increase the risk of pancreatitis with didanosine and stavudine, and the combination should probably be avoided, see 'NRTIs + Hydroxycarbamide', p.949.

The UK manufacturer states that **lamivudine** is rarely associated with pancreatitis, but recommend that treatment with lamivudine should be stopped if there is any suspicion of pancreatitis.[2] No firm conclusions can be drawn from the case discussed above. However, as other isolated reports have attributed pancreatitis to lamivudine use alone, it would be prudent to exercise caution with concurrent use of lamivudine with other drugs known to cause pancreatitis.

NRTIs + Food

Food can reduce the extent of absorption of didanosine, possibly causing a loss in efficacy. The extent of absorption of zalcitabine and zidovudine is reduced slightly by food. Food does not affect the extent of absorption of abacavir, emtricitabine, lamivudine, and stavudine.

Clinical evidence, mechanism, importance and management

(a) Abacavir

The manufacturer of abacavir notes that food delayed the rate, but not the extent, of abacavir absorption. Therefore, abacavir can be taken with or without food.[1,2]

(b) Didanosine

1. Buffered preparations. Didanosine (as two 150-mg chewable tablets) was given to 10 HIV-positive subjects on four occasions: 30 minutes before breakfast, one hour before breakfast, one hour after breakfast, and 2 hours after breakfast. When the dose was given before breakfast the results were very similar to those obtained for subjects in the fasting state. When given after breakfast, the didanosine AUC and maximum plasma concentration were both decreased by about 50%.[3] Similar results were found in another study.[4] A further study[5] using sachets containing didanosine, sucrose and citrate-phosphate buffer, similarly found that food reduced the bioavailability of didanosine by 41% (a reduction from 29% to 17%). The reason for this effect would appear to be that food delays gastric emptying so that didanosine is exposed to prolonged contact with gastric acid, which causes decomposition (see 'Antivirals', (p.913)), with a resultant fall in bioavailability. To achieve maximum bioavailability, didanosine buffered preparations should be taken on an empty stomach at least 30 minutes before food[6,7] or 2 hours after food.[7]

2. Enteric-coated preparation. In a study in 20 healthy subjects, a high-fat meal reduced the AUC and maximum concentration of a single 400-mg dose of didanosine (from an enteric-coated bead formulation) by 19% and 46%, respectively, and increased the time to maximum concentration by 3 hours. A light meal also reduced the maximum concentration and AUC of didanosine by 22% and 27%, respectively, and delayed the time to maximum concentration by about 2.5 hours. Modest reductions in the AUC and maximum concentration were also seen when the same enteric-coated bead didanosine was taken either after fasting, one hour before and 2 hours after a light meal, or sprinkled over yoghurt or apple sauce; however, these changes were not statistically significant.[8]

Based on these results, the manufacturer recommends that didanosine gastro-resistant capsules are taken intact on an empty stomach,[9,10] at least 2 hours before or 2 hours after a meal.[9] However, a study in 668 patients found that in those patients who adhered to their HAART regimen taking enteric-coated didanosine with food did not lead to an increase in therapeutic failure.[11] An open-label study in 21 HIV-positive patients also found that taking enteric-coated didanosine with food had no effect on its virological efficacy.[12]

(c) Emtricitabine

The manufacturer says that giving emtricitabine hard capsules with a high-fat meal did not affect the AUC of emtricitabine[13,14] but slightly reduced the maximum level by 29%.[14] Similarly, giving emtricitabine oral solution with a low-fat or high-fat meal did not affect the AUC or maximum level of emtricitabine. Therefore, both these formulations of emtricitabine may be given with or without food.[13,14]

(d) Lamivudine

In a study in 24 healthy subjects, food slightly reduced the maximum concentration of lamivudine (from a combined tablet with zidovudine) by 15% when compared with fasting subjects, but did not significantly affect the extent of absorption.[15] The US manufacturer reports that, in a study in 12 HIV-positive patients, food delayed the absorption of lamivudine and decreased the maximum concentration by 40% when compared with the fasting patients. However, the AUC of lamivudine was unaffected.[16] The UK manufacturer notes that food delayed the rate and reduced the maximum plasma concentration (by about 47%), but not the extent (AUC) of lamivudine absorption.[17] Therefore, lamivudine can be taken with or without food.[16,17]

(e) Stavudine

The UK manufacturer of stavudine notes that a standardised high-fat meal delayed the absorption and reduced the maximum plasma concentration (specific details not given), but did not alter the extent of systemic exposure of stavudine, when compared with the fasting state. Nevertheless, they recommend that, for optimal absorption, stavudine should be taken on an empty stomach at least one hour before meals. However, if this is not possible, they suggest giving stavudine with a light meal; in addition, the contents of the capsule may be mixed with food.[18] The US manufacturer states that stavudine can be taken with food or on an empty stomach.[19]

(f) Zalcitabine

The manufacturers of zalcitabine[20,21] noted that food decreased the maximum plasma concentration by 39% and prolonged the time to achieve maximum concentrations from 0.8 hours to 1.6 hours, when compared with the fasting state. The extent of absorption was decreased by 14%. The UK manufacturer stated that zalcitabine could be taken with or without food.[20]

(g) Zidovudine

Zidovudine was given to 13 patients with AIDS either with breakfast or when fasting. The maximum plasma level of zidovudine was 2.8-fold greater in the fasted patients, and the AUC was reduced by 22% when zidovudine was given with food.[22] Zidovudine rate and extent of absorption was reduced in another study by a standard breakfast (14% decrease in AUC with a 200-mg dose and 33% with a 100-mg dose).[23] In a study[24] of 8 patients, a high-fat meal reduced the maximum zidovudine serum levels by about 50%. In all these cases inter-individual variation in zidovudine

absorption was high.[22-24] However, when a sustained-release formulation of zidovudine was used, the absorption was delayed, but the AUC was increased by 28% by a high-fat meal.[25] In contrast, the AUC of zidovudine was not affected by 25 g of a protein supplement.[26] In a study in 24 healthy subjects, although food reduced the maximum concentration of zidovudine (from a combined tablet with lamivudine) by 45% when compared with fasting subjects, it had no significant effect on the extent of absorption of zidovudine.[15]

Inter-individual variation in zidovudine absorption appears high and the practical consequences of the changes caused are uncertain. Some have suggested that zidovudine should be taken on an empty stomach;[23,24] the US manufacturer states that zidovudine can be taken with or without food,[27] but the UK manufacturer gives no specific recommendations regarding its administration in relation to food.[28]

NRTIs + Ganciclovir or Valganciclovir

The concurrent use of zidovudine and ganciclovir produces a very marked increase in haematological toxicity, without any apparent increase in efficacy. Didanosine levels are raised by ganciclovir, but there is some evidence suggesting that the efficacy of ganciclovir prophylaxis is reduced. Ganciclovir does not appear to interact with stavudine, and there is no clinically important pharmacokinetic interaction between ganciclovir and zalcitabine. Valganciclovir is a prodrug of ganciclovir and expected to interact similarly.

Clinical evidence

(a) Didanosine

In a study, buffered didanosine 200 mg twice daily was given to 12 HIV-positive patients with oral ganciclovir 1 g three times daily. When didanosine was given 2 hours before ganciclovir, the maximum serum levels and AUC of didanosine were raised by about 47% and 83%, respectively, and those of ganciclovir were decreased by about 26% and 22%, respectively. When didanosine was given simultaneously with ganciclovir, the maximum serum levels and AUC of didanosine were similarly raised, by about 53% and 77%, respectively, but those of ganciclovir were unchanged. The renal clearance of didanosine was not significantly changed by ganciclovir.[1] Similar increases in didanosine levels with intravenous ganciclovir[2] and high-dose oral ganciclovir 2 g every 8 hours have also been reported.[3] However, in contrast, an earlier study found that the pharmacokinetics of didanosine (sachet preparation) were not altered by intravenous ganciclovir.[4]

Rates of dose-limiting intolerance to the combination of didanosine and ganciclovir were reported to be similar to those seen with didanosine alone in one small study (15 of 32 patients tolerated usual doses of didanosine with the ganciclovir).[5] However, analysis of the results of a large randomised study unexpectedly suggested that there was an increased risk of cytomegalovirus infection in those patients taking ganciclovir and didanosine, when compared with those not taking didanosine.[6]

There is a case report[7] of a persistently low CD4+ cell count, but with complete viral suppression, in a patient taking buffered didanosine 200 mg twice daily with valganciclovir 900 mg twice daily. When didanosine was replaced with abacavir, the CD4+ count increased from about 80 cells/m^2 to 323 cells/m^2.

(b) Stavudine

In a study of 11 HIV-positive patients, oral ganciclovir 1 g three times daily had no significant effect on the pharmacokinetics of stavudine 40 mg twice daily, nor were the pharmacokinetics of ganciclovir affected by the stavudine.[8] There were no serious or severe adverse events attributed to the combination.

(c) Zalcitabine

In a study in 10 HIV-positive patients, zalcitabine 750 micrograms every 8 hours increased the AUC of oral ganciclovir 1 g three times daily by 22%. There was no change in zalcitabine pharmacokinetics. There were no serious or severe adverse events attributed to the combination.[8]

(d) Zidovudine

The efficacy of zidovudine 100 or 200 mg every 4 hours, given alone or with intravenous ganciclovir 5 mg/kg twice daily for 14 days, then daily for 5 days of each week, was assessed in 40 patients for the treatment of cytomegalovirus (CMV). Severe haematological toxicity occurred in all of the first 10 patients given zidovudine 1.2 g daily and ganciclovir. Consequently the dose of zidovudine was reduced to 600 mg daily. Overall 82% of the 40 patients enrolled experienced profound and rapid toxicity (anaemia, neutropenia, leucopenia, gastrointestinal disturbances). Zidovudine dose reductions to 300 mg daily were needed in many patients. No change in the pharmacokinetics of zidovudine or ganciclovir was noted.[9]

Another study in 6 patients with AIDS and CMV retinitis, given zidovudine and ganciclovir, found increased bone marrow toxicity but no improved efficacy over ganciclovir alone.[10] Increased toxicity (myelotoxicity and pancytopenia) following the use of both drugs has also been reported elsewhere.[11,12]

In contrast to the first study,[9] a specific study on the pharmacokinetics of zidovudine and ganciclovir in HIV-positive subjects reported that oral ganciclovir increased the maximum levels and AUC of zidovudine by 38% and 15%, respectively, without altering renal clearance. Zidovudine did not alter ganciclovir pharmacokinetics.[1]

Mechanism

Ganciclovir inhibits purine nucleoside phosphorylase-4, the enzyme involved in the breakdown of didanosine, and this may result in an increase in its levels. Valganciclovir is rapidly metabolised to ganciclovir and would be expected to interact similarly.[7]

The toxicity resulting from the concurrent use of zidovudine and ganciclovir may be simply additive,[9] but *in vitro* studies with three human cell lines found synergistic cytotoxicity when both drugs were used.[13]

There is some *in vitro* evidence to suggest that ganciclovir antagonises the anti-HIV activity of zidovudine and didanosine.[14]

Importance and management

The interactions between ganciclovir and **didanosine** or **zidovudine** would appear to be established, but the clinical importance is uncertain. Zidovudine seems to be associated with greater toxicity than didanosine. However, there is also some evidence suggesting reduced ganciclovir efficacy in the presence of didanosine, and this requires further study. Close and careful monitoring is required if either combination is used.

Ganciclovir does not appear to alter the pharmacokinetics of **stavudine** or **zalcitabine**. Zalcitabine increased ganciclovir levels to a minor extent, although this is probably not clinically important.

As valganciclovir is a prodrug of ganciclovir, it would be prudent to use similar precaution when prescribing valganciclovir with these NRTIs.

NRTIs + H_2-receptor antagonists

The concurrent use of buffered didanosine and ranitidine results in a minor increase in the levels of didanosine, and a minor decrease in the levels of ranitidine. Cimetidine raises zalcitabine levels. Cimetidine and ranitidine do not have a clinically significant effect on zidovudine or lamivudine levels.

Clinical evidence, mechanism, importance and management

(a) Didanosine

Didanosine 375 mg (buffered sachet preparation) was given to 12 HIV-positive patients either alone, or 2 hours after a single 150-mg dose of **ranitidine**. The didanosine AUC was increased by 14% by **ranitidine**.[1] The reason for this effect is not known but the **ranitidine** possibly enhanced the effects of the citrate-phosphate buffer with which the didanosine was formulated. The **ranitidine** AUC was reduced by 16% for reasons that are not understood, but it is possible that antacids (such as the citrate-phosphate buffer) that are formulated with didanosine reduce the absorption of **ranitidine**[1] (see 'H_2-receptor antagonists + Antacids', p.1147).

These bioavailability changes appear to be too small to matter clinically, and no particular precautions would seem necessary if the drugs are taken in this way.

(b) Lamivudine

Lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system; however, the manufacturer states that **cimetidine** and **ranitidine**, which are partially eliminated by this mechanism, do not interact with lamivudine.[2]

(c) Zalcitabine

A study in 12 HIV-positive patients given a single 1.5-mg dose of zalcitabine found that **cimetidine** 800 mg caused a 24% reduction in the renal clearance of zalcitabine (assumed to be due to a reduction in renal tubular secretion) and a 36% increase in the AUC of zalcitabine.[3] These changes are relatively moderate but it would seem prudent to be alert for possible toxicity on concurrent use.

(d) Zidovudine

In a randomised crossover study, zidovudine 600 mg daily was given to 5 HIV-positive men and one man with AIDS. Zidovudine was given either alone, with **cimetidine** 300 mg four times daily, or with **ranitidine** 150 mg twice daily, each for 7 days. **Cimetidine** reduced the renal elimination of zidovudine by 56%, but had no effect on its AUC. It was suggested that the reduction in clearance was due to inhibition of tubular secretion. **Ranitidine** had no effect on zidovudine pharmacokinetics. No clinical toxicity occurred and the immunological parameters measured (CD4 and CD8) were not significantly altered. The authors concluded that no change in the dose of zidovudine is needed if either of these H_2-receptor antagonists is given concurrently.[4] Information about other H_2-receptor antagonists seems to be lacking.

NRTIs + Hydroxycarbamide

Hydroxycarbamide appears to increase the antiviral activity of NRTIs, particularly didanosine. However, the concurrent use of hydroxycarbamide and didanosine may carry a higher risk of adverse effects including neuropathy and pancreatitis, especially if stavudine is also given.

Clinical evidence, mechanism, importance and management

Data from *in vitro* studies have shown that hydroxycarbamide increases the antiviral activity of NRTIs, particularly **didanosine**, possibly by increasing their intracellular activation (phosphorylation).[1,2] The combination is therefore under clinical investigation. Some randomised studies[3-5] have shown that the addition of hydroxycarbamide to reverse transcriptase inhibitors improves virologic response, whereas others have not found this.[6] One of these studies in patients taking **efavirenz** and **abacavir** found no increased rate of adverse effects in patients taking hydroxycarbamide 500 mg twice daily compared with patients not taking hydroxycarbamide, but more subjects in the hydroxycarbamide group withdrew from the study because of adverse effects 23% versus 4%). There was no increase in the incidence of blood dyscrasias with the concurrent use of hydroxycarbamide.[5]

However, a number of studies have found increased toxicity, particularly with **didanosine** and **stavudine**. One study reported that the relative risk of neuropathy when **didanosine** was given with hydroxycarbamide was 2.35, compared with **didanosine** alone, and increased to 7.8 when **stavudine** was also added.[7] Another study reported an increased incidence of neuropathy, and an increased incidence of fatigue and nausea and vomiting.[8] The risk of pancreatitis may also be increased. In one study, 3 patients randomised to receive indinavir, **didanosine**, **stavudine** and hydroxycarbamide developed pancreatitis and died, compared with no deaths in those receiving the same antivirals without hydroxycarbamide.[9] Another case of pancreatitis (non-fatal) has been reported when hydroxycarbamide was given with **stavudine**, **didanosine** and nevirapine.[10] Fatal hepatotoxicity and hepatic failure have also been reported in patients given hydroxycarbamide with **didanosine** and **stavudine**.[11,12] In response to these data, the manufacturers of **didanosine** and **stavudine** specifically

state that use of these two NRTIs with hydroxycarbamide should be avoided.[11-14] Moreover, the UK manufacturers go as far as to say that hydroxycarbamide should not be used in the treatment of HIV infection.[14]

NRTIs + Macrolides

Clarithromycin causes some reduction in the bioavailability of zidovudine. Clarithromycin does not appear to interact with didanosine, stavudine or zalcitabine, and azithromycin does not interact with didanosine or zidovudine.

Clinical evidence

(a) Didanosine

When **azithromycin** 1.2 g daily for 14 days was given to 12 HIV-positive subjects with didanosine 200 mg twice daily there was no significant change in the pharmacokinetics of either drug.[1]

Clarithromycin 1 g twice daily for 7 days was given to 4 HIV-positive patients and 8 patients with AIDS taking oral didanosine. For the group as a whole the pharmacokinetics of didanosine remained unchanged, but there were large differences in the AUC between subjects that could have hidden an interaction.[2]

(b) Stavudine

A study in 10 HIV-positive subjects found that the addition of **clarithromycin** 500 mg twice daily to stavudine 30 or 40 mg twice daily had no significant effects on the pharmacokinetics of stavudine and the incidence of adverse effects did not increase.[3]

(c) Zalcitabine

A 7-day course of **clarithromycin** 500 mg twice daily was given to 12 HIV-positive subjects taking zalcitabine. The addition of **clarithromycin** caused no change to the pharmacokinetics of zalcitabine.[4]

(d) Zidovudine

In a study in 12 HIV-positive subjects, **azithromycin** 600 mg to 1.2 g daily for 14 days did not affect the pharmacokinetics of zidovudine 100 mg five times daily.[1] Similarly, **azithromycin** 1 g, given weekly to 9 HIV-positive subjects, caused no change in the pharmacokinetics of zidovudine 10 mg/kg daily. The **azithromycin** pharmacokinetics also remained unchanged.[5]

Fifteen HIV-positive patients were given zidovudine 100 mg every 4 hours five times a day and oral **clarithromycin** 500 mg, 1 g or 2 g every 12 hours, both together and alone. The pharmacokinetics of **clarithromycin** were not substantially changed by zidovudine, but the zidovudine levels and AUCs were reduced by 23 to 58% and 12 to 36%, respectively, by **clarithromycin**. However, these effects were not seen in all patients.[6,7] Another study similarly found that **clarithromycin** caused a moderate reduction in the AUC of oral zidovudine (by up to 27%). No changes were seen when zidovudine was given 4 or more hours after **clarithromycin**.[8] In a study in 16 patients with AIDS, zidovudine and **clarithromycin** were given 2 hours apart for 4 days. The maximum plasma levels of zidovudine rose by about 50%, but the minimum levels and the AUC over 8 hours did not change.[9]

Mechanism

Not understood but the interaction between clarithromycin and zidovudine may possibly be due to some changes in absorption.

Importance and management

The overall picture is slightly confusing, but it seems that some reductions in **zidovudine** levels are likely if clarithromycin is taken at the same time, but no important changes seem to occur if the administration of the drugs is separated. The authors of one study recommend that the clarithromycin is given at least 2 hours before or after zidovudine.[7] The UK manufacturer of zidovudine includes this recommendation,[10] but the US manufacturer does not include any information on its use with clarithromycin.[11] Azithromycin appears to be a potential non-interacting alternative.

The authors of the report on **didanosine** conclude that clarithromycin may safely be given with didanosine,[2] and it also seems likely that didanosine and azithromycin can be used safely together. Similarly, **stavudine** and **zalcitabine** may safely be used with clarithromycin.

NRTIs + NRTIs

Some combinations of NRTIs are potentially antagonistic (stavudine with zidovudine, lamivudine with zalcitabine) and some are expected to result in additive toxicity (didanosine with stavudine or zalcitabine, and possibly stavudine with zalcitabine). Some do not appear to result in additional benefits (emtricitabine with lamivudine or zalcitabine), and some are considered inferior to other combinations (stavudine with lamivudine, zidovudine with zalcitabine or didanosine). Sole use of all triple NRTI regimens should generally be avoided.

Clinical evidence, mechanism, importance and management

A. Abacavir

(a) Lamivudine

In a study, 13 HIV-positive subjects were given a single 150-mg dose of lamivudine with abacavir 600 mg. The pharmacokinetics of abacavir were not significantly affected, but the lamivudine maximum plasma levels and AUC were decreased by 35% and 15%, respectively. These changes were considered to be consistent with a change in absorption. The extent of the

change is not thought to be clinically significant and so no dose alteration would seem necessary on concurrent use.[1] In UK and US guidelines, the combination of abacavir and lamivudine is currently a recommended dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment naïve patients.[2,3] The triple NRTI combination of abacavir, lamivudine and **zidovudine** is generally not recommended as it is less efficacious than other recommended regimens. US guidelines recommend that it should only be used when another NNRTI- or protease inhibitor-based regimen cannot be used.[3]

(b) Zidovudine

In a study in 13 HIV-positive patients, a single 300-mg dose of zidovudine had no significant effect on the pharmacokinetics of abacavir 600 mg. The maximum plasma level of zidovudine was decreased by 20%, but the AUC was unchanged. These results were confirmed in a steady-state study in which 79 HIV-positive subjects received 8 weeks of treatment with abacavir 600 mg to 1.8 g daily, in divided doses, and zidovudine 600 mg daily, in divided doses.[4] This change is not thought to be clinically significant, and so no dose alteration would seem necessary on the concurrent use of abacavir and zidovudine.[1] The triple NRTI combination of abacavir, **lamivudine** and zidovudine is generally not recommended as it is less efficacious than other recommended regimens. US guidelines recommend that it should only be used when another NNRTI- or protease inhibitor-based regimen cannot be used.[3]

B. Didanosine

(a) Emtricitabine

In UK and US guidelines, the combination of didanosine and emtricitabine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.[2,3]

(b) Lamivudine

The manufacturer notes that as lamivudine is cleared predominantly from the body by the kidneys using the organic cationic transport system and didanosine is not cleared in this way, an interaction between these two drugs by this mechanism is unlikely.[5] Didanosine does not affect the intracellular activation of lamivudine *in vitro*.[6] In UK and US guidelines, the combination of didanosine and lamivudine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor, for the treatment of HIV-infection in treatment naïve patients.[2,3]

(c) Stavudine

In a study in 10 HIV-positive patients, stavudine 40 mg twice daily, taken for 9 doses, had no significant effect on the pharmacokinetics of didanosine 100 mg taken twice daily. The half-life of the stavudine increased from 1.56 hours to 1.96 hours, but the AUC was unchanged and adverse effects were minimal. The authors of the report concluded that no clinically significant pharmacokinetic interaction is likely to occur on concurrent use and that no change in acute safety and tolerance would be expected.[7] Didanosine does not interfere with the intracellular activation of stavudine *in vitro*.[8] However, both didanosine and stavudine can cause peripheral neuropathy and pancreatitis, and there is some evidence that this risk may be additive. In one early study, stavudine and didanosine were given to 13 HIV-positive subjects for 8 weeks. Neuropathy occurred in 3 patients, with only 2 restarting treatment.[9] In another study, the relative risk of neuropathy was 1.39 for stavudine alone, relative to didanosine alone, and 3.5 for the concurrent use of both drugs.[10] In 1999, the manufacturer of didanosine issued a stronger warning about the risk of pancreatitis with didanosine, and noted this risk was higher in patients also taking stavudine.[11] Concurrent use should be therefore be closely monitored. A case of symptomatic hyperlactataemia occurred in a patient after changing his antiretroviral therapy to didanosine, stavudine and nevirapine.[12] The concurrent use of stavudine and didanosine has been associated with a high incidence of toxicity, particularly peripheral neuropathy, pancreatitis, and lactic acidosis. The development of lactic acidosis has resulted in fatalities in pregnant women.[3] It has been suggested that this combination of NRTIs is associated with the greatest toxicity.[12] US guidelines say that the combination of didanosine and stavudine should not be recommended at any time, with the exception of when no other antiretroviral options are available, and only if the potential benefits outweigh the risks.[3] UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.[2]

See also 'NRTIs + Drugs that cause pancreatitis', p.946.

(d) Zalcitabine

A 29-year-old man with persistent mild neuropathy due to zalcitabine developed severe neuropathy when given didanosine 3 weeks after discontinuing zalcitabine. As the didanosine neuropathy developed so rapidly it was suggested that it was caused by additive toxicity with zalcitabine.[13] Note also that both drugs are associated with pancreatitis. The US manufacturer advised against use of the combination,[14] whereas the UK manufacturers advised caution and careful monitoring if drugs that share these serious adverse effects are used concurrently.[15] See also 'NRTIs + Drugs that cause pancreatitis', p.946.

In vitro, didanosine had no significant effect on the intracellular activation of zalcitabine.[15]

(e) Zidovudine

A study in 8 HIV-positive patients found that when they were given zidovudine 250 mg with didanosine 250 mg (buffered sachet formulation), the pharmacokinetics of didanosine were unaltered but the zidovudine AUC was raised by 35%, possibly due to altered absorption.[16] Conversely, in another study zidovudine plasma levels were lower in 4 out of 5 HIV-positive patients when given didanosine (chewable tablets) and there was an average 14% reduction in the zidovudine AUC. Zidovudine clearance was increased by 29% but didanosine pharmacokinetics were unchanged.[17] A study in over 50 young subjects ranging in age from 3 months to 21 years found that, when compared with day 3 (start of concurrent use), no significant changes in AUCs occurred after 4 or 12 weeks of them taking zidovudine 60 to 180 mg/m^2 every 6 hours with didanosine 60 to 180 mg/m^2 every 12 hours (given 2 minutes after an antacid).[18] Several other studies have not found a pharmacokinetic interaction or evidence of increased toxicity when didanosine and zidovudine were used concurrently.[19-21] The UK manufacturer of didanosine states that there is no evidence that concurrent use increases the myelosuppressive effects of zidovudine.[22]

The reports are slightly contradictory, but the weight of evidence seems to be that no clinically relevant interaction occurs. UK guidelines say there are no data on the use of zidovudine with enteric-coated didanosine as part of HAART, and that the combination cannot be recommended.[2]

C. Emtricitabine

(a) Lamivudine

The manufacturer of emtricitabine states that there is no information on the concurrent use of cytidine analogues such as emtricitabine and lamivudine, and the combination should not be used.[23] The US guidelines also state that the combination of emtricitabine and lamivudine should not be offered at any time because of the similar resistance profile of the two drugs and there being no potential benefit.[3]

(b) Stavudine

In a single-dose study in 6 healthy subjects, no important pharmacokinetic interaction occurred between emtricitabine 200 mg and stavudine 40 mg.[24] UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.[2]

(c) Zalcitabine

The manufacturer of emtricitabine states that there is no information on the concurrent use of cytidine analogues, such as emtricitabine and zalcitabine, and therefore, the combination should not be used.[23]

(d) Zidovudine

In a single-dose study in 6 healthy subjects, the AUC and maximum level of zidovudine 300 mg were increased by 26% and 66%, respectively, by emtricitabine 200 mg. The pharmacokinetics of emtricitabine were not altered.[24] The authors suggest that these increases in zidovudine levels are unlikely to be clinically relevant based on experience of using the two drugs together for 48 weeks in a phase III clinical study.[24] Further experience is needed.

D. Lamivudine

(a) Stavudine

Nucleoside reverse transcriptase inhibitors such as lamivudine need to be activated by phosphorylation within the cells to a triphosphate anabolite. Because stavudine does not affect this phosphorylation *in vitro*[6] it is predicted that no interaction is likely to occur by this mechanism. The manufacturer briefly states that no clinically relevant pharmacokinetic interaction was noted between stavudine 40 mg and lamivudine 150 mg in a single-dose study.[25,26] Nevertheless, current US guidelines state that the combination of stavudine and lamivudine is not a preferred or alternative dual NRTI combination for use in initial antiretroviral regimens because

of significant toxicities including lipoatrophy, peripheral neuropathy and serious, life-threatening lactic acidosis with hepatic steatosis, with or without pancreatitis, and rapidly progressive neuromuscular weakness.[3] Similarly, UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.[2]

(b) Zalcitabine

The manufacturers say that lamivudine is not recommended to be used with zalcitabine, because lamivudine may inhibit the intracellular activation of zalcitabine.[14,15,27]

(c) Zidovudine

In a study, lamivudine 300 mg twice daily was given to 12 HIV-positive patients for 5 doses, with a 200-mg dose of zidovudine with the last dose. No major changes in the pharmacokinetics of the zidovudine occurred and it was concluded that dose adjustments are not needed if these two drugs are given concurrently.[28] Another study found the same results,[1] and an extensive study in over 200 patients has shown that concurrent use can be safe and effective.[29]

However, there are case reports of blood dyscrasias occurring with concurrent use. Zidovudine 500 to 600 mg daily was given with lamivudine 300 mg daily to 13 HIV-positive patients. Zidovudine or lamivudine alone had previously been given to 9 of these 13 without problem. However, when both drugs were given, blood dyscrasias occurred in all patients within 7 weeks. Significant anaemia occurred in all patients, with precipitous declines in haemoglobin levels and one patient developed leucopenia and thrombocytopenia. Both drugs were stopped, blood transfusions were given, and all patients improved or recovered. Zidovudine or lamivudine alone was later started in 8 patients and 2 patients tolerated the combination (with the zidovudine dose halved in one patient and the drugs added sequentially in the other) without further haematological problems.[30] Similar precipitous falls in haemoglobin occurred in another 2 patients when lamivudine 300 mg daily was added to their long-term zidovudine treatment. Again both recovered when the drugs were stopped and blood was given.[31] Anaemia is a common adverse effect of zidovudine, but these patients had no problems until the lamivudine was added. However, the available evidence indicates that concurrent use can be safe and effective, with the adverse interactions cited here being uncommon. It has been suggested that a complete baseline blood count should be done, both when concurrent use is started, and every month for the first 3 months of treatment.[31] The manufacturers[5,27] state that no clinically significant interaction occurs on concurrent use, and a combination product is available. In the UK and US guidelines, the combination of zidovudine and lamivudine is currently a recommended alternative dual NRTI option for use with an NNRTI or a protease inhibitor for the treatment of HIV-infection in treatment naïve patients.[2,3] The US guidelines state that the triple NRTI combination of **abacavir**, lamivudine and zidovudine is generally not recommended as it is less efficacious than other recommended regimens. They advise that it should only be used when another NNRTI- or protease inhibitor-based regimen cannot be used.[3]

E. Stavudine

(a) Zalcitabine

In vitro, stavudine had no significant effect on the intracellular activation of zalcitabine.[15,25] Both stavudine and zalcitabine have the potential to cause peripheral neuropathy and pancreatitis. The concurrent use of drugs causing these serious adverse effects should be closely monitored (see also 'NRTIs + Drugs that cause pancreatitis', p.946).

(b) Zidovudine

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within the cells to a triphosphate anabolite before they become effective. *In vitro* studies using mononucleated blood cells found that zidovudine significantly inhibited this phosphorylation.[8] Antagonism between zidovudine and stavudine has also been seen in a clinical study.[32] Therefore, the manufacturers[25,26] and the US guidelines[3] currently do not recommend the combination. Similarly, UK guidelines say that stavudine is not recommended for use as one of the NRTIs for initial therapy of HIV because of its toxicity.[2]

F. Zalcitabine

In vitro, zalcitabine had no significant effect on the intracellular activation of **zidovudine**.[15] In a study in 56 patients with advanced HIV infection, taking zidovudine 50 to 200 mg every 8 hours and zalcitabine 5 to 10 micrograms/kg every 8 hours, neither drug affected the pharmacokinetics of the other nor was toxicity increased.[33] No special precautions would appear to be necessary. Note that zalcitabine is now rarely used and the licensed product has been withdrawn in many countries.

NRTIs + Paracetamol (Acetaminophen)

Limited and unconfirmed evidence suggests that paracetamol possibly increases the bone marrow suppressant effects of zidovu-

dine. Single case reports describe severe liver toxicity when patients were given paracetamol with either zidovudine or didanosine.

Clinical evidence

(a) Didanosine

Increasing abdominal pain occurred in a 47-year-old HIV-positive man one month after he started didanosine (his other medications included nevirapine, hydroxycarbamide, aciclovir and lorazepam). He had been treating the pain with paracetamol, and had taken 4 g over 3 days. Severe hepatitis and pancreatitis were diagnosed, which slowly resolved over the following 3 weeks.[1]

(b) Zidovudine

An early study of zidovudine use in 282 patients with AIDS found that haematological abnormalities (anaemia, leucopenia, neutropenia) were very common and 21% needed multiple red cell transfusions. Some of the patients also received paracetamol, which increased the haematological toxicity (neutropenia) by an unstated amount.[2]

Short-term clinical studies using paracetamol 650 mg up to every 4 hours found that it had no clinically significant effects on the pharmacokinetics of zidovudine,[3-6] although in one case zidovudine clearance was slightly increased.[7] An 8-month study in a single patient suggested that long-term concurrent use did not affect the pharmacokinetics of either drug. However, in this individual, very rapid absorption and a high peak serum level of zidovudine were seen, so as a precaution the zidovudine dose was reduced from 200 mg every 4 hours to 100 mg every 6 hours.[8]

A patient taking zidovudine and co-trimoxazole took 3.3 g of paracetamol over 36 hours. Within 2 days he developed severe hepatotoxicity, and as other causes were excluded, the reaction was attributed to the paracetamol. The authors suggested that zidovudine may have augmented the paracetamol toxicity.[9] However, in a single-dose study, reduced paracetamol glucuronidation and increased formation of hepatotoxic metabolites were seen in patients with advanced HIV infection compared with healthy HIV-positive subjects and those without HIV, and this effect was independent of zidovudine use.[10] In contrast, in another study, disease state (AIDS versus healthy HIV-positive subjects) was not found to alter paracetamol metabolism, and zidovudine was found to *increase* paracetamol glucuronidation in some patients.[11]

Mechanism

Not understood. Paracetamol does not increase the serum levels of zidovudine,[3-5,7] which might have provided an explanation for the apparent increased toxicity. One *in vitro* study found that paracetamol does not affect the glucuronidation of zidovudine,[12] whereas another found that paracetamol did inhibit zidovudine glucuronidation.[13] The effect of zidovudine on paracetamol metabolism is also unclear.

Didanosine may cause pancreatitis or hepatic disease, and zidovudine may also rarely cause hepatic disease. It has been suggested that the hepatotoxicity of these drugs are augmented when they are given together.[1]

Importance and management

Paracetamol is a widely used non-prescription analgesic, and this appears to be an isolated report of potential combined toxicity with **didanosine**, although the authors suggest extreme caution when potentially hepatotoxic drugs such as paracetamol are used with didanosine.[1] Both drugs may cause hepatotoxicity alone, and didanosine itself may cause severe pancreatitis, and there is limited evidence that hepatotoxicity may increased by the concurrent use of these drugs. Consider stopping paracetamol and didanosine in any patient who develops signs or symptoms of hepatotoxicity or pancreatitis.

The short-term use of **zidovudine** and paracetamol does not appear to alter the pharmacokinetics of either drug. Whether paracetamol can increase the haematological toxicity of zidovudine and whether the drugs have combined hepatotoxicity is unclear from the available data. More study is needed.

NRTIs + Probenecid

Probenecid reduces the loss of zalcitabine and zidovudine, increasing their levels. The concurrent use of zalcitabine and probenecid is well tolerated, but the incidence of adverse effects appears to be greatly increased with the concurrent use of probenecid and zidovudine.

Clinical evidence

(a) Zalcitabine

In a single-dose study, 12 HIV-positive or AIDS patients were given zalcitabine 1.5 mg alone or with probenecid 500 mg, given 8 and 2 hours before then 4 hours after zalcitabine. The renal clearance of the zalcitabine was decreased by 42% by probenecid, its half-life was increased by 47% and its AUC was increased by 54%.[1]

(b) Zidovudine

In 12 patients with AIDS or AIDS-related complex the concurrent use of zidovudine and probenecid 500 mg every 8 hours for 3 days increased the AUC of zidovudine by an average of 80% (range 14 to 192%).[2] Other studies in patients[3-5] and healthy subjects[6] found that probenecid roughly doubled the AUC of zidovudine when given in a variety of dosing schedules.[3,4] However, the effects on zidovudine pharmacokinetics were minimal if the two drugs were given 6 hours apart.[5] Another report describes a very high incidence of rashes in 6 out of 8 HIV-positive men given zidovudine with probenecid 500 mg every 6 hours. The rash and other symptoms (such as malaise, fever and myalgia) were sufficiently severe for the probenecid to be withdrawn in 4 patients.[7] A later study found that when using only 250 mg of probenecid every 8 hours the AUC of zidovudine was increased by 70% but the adverse effects still occurred, although the incidence was possibly somewhat lower.[8] Conversely, others reported the successful use of probenecid 500 mg three times daily with a reduced dose of zidovudine (600 mg daily) in 7 patients without any occurrence of rash.[9]

Mechanism

Experimental clinical evidence indicates that probenecid reduces the metabolism (glucuronidation) of zidovudine by liver enzymes, and inhibits the renal secretion of the zidovudine glucuronide metabolite.[2-4,6,10,11] The interaction with zalcitabine is presumably due to inhibition of zalcitabine secretion in the renal tubules.[1]

Importance and management

The concurrent use of **zidovudine** and probenecid should be well monitored to ensure that zidovudine levels do not rise excessively. Reduce the zidovudine dose as necessary. However, the apparent increase in adverse effects during concurrent use seen by one group of researchers[7,8] should be borne in mind.

Note that *cidofovir* should be given with probenecid, and if these drugs

are given to a patient taking zidovudine caution is particularly recommended.[12,13] The US manufacturer of cidofovir advises that zidovudine should be temporarily discontinued or the dose halved when cidofovir with probenecid is given.[13]

The concurrent use of **zalcitabine** and probenecid was well tolerated, and because the zalcitabine half-life is short compared to its dosing schedule significant accumulation would not be expected.

It would seem prudent to monitor for any signs of toxicity if either drug combination is used long-term. The safety of concurrent use needs further assessment.

NRTIs + Protease inhibitors

Buffered didanosine decreases the AUC of indinavir and interacts similarly with atazanavir. Ritonavir-boosted atazanavir, lopinavir and tipranavir appear to reduce the AUC of abacavir. Ritonavir-boosted tipranavir reduces the AUC of zidovudine. The changes in pharmacokinetics seen when giving other combinations of protease inhibitors with NRTIs do not appear to be clinically significant. Protease inhibitors do not affect the intracellular activation of NRTIs.

Clinical evidence, mechanism, importance and management

The protease inhibitors **indinavir**, **ritonavir**, and **saquinavir** had no effect on intracellular activation of various NRTIs (**didanosine**, **lamivudine**, **stavudine**, **zalcitabine** and **zidovudine**).[1] No interaction would be expected by this mechanism. Other potential interactions are discussed below.

Current local and national guidelines should be consulted when choosing protease inhibitor and NRTI combinations, and they recommend the use of two NRTIs and a ritonavir-boosted protease inhibitor as an alternative to using two NRTIs and an NNRTI such as efavirenz.[2,3] See also 'NRTIs + NRTIs', p.950, for information on the choice of NRTI combinations.

(a) Abacavir

1. Amprenavir or Fosamprenavir. A phase I study in HIV-positive patients given amprenavir 900 mg twice daily with abacavir 300 mg twice daily for 3 weeks found that neither drug had any clinically significant effect on the pharmacokinetics of the other.[4] The manufacturer of amprenavir notes that its AUC, minimum levels and maximum levels were increased by 29%, 27%, and 47%, respectively, by abacavir,[5,6] without any change in abacavir pharmacokinetics, but no dose adjustments are considered necessary on concurrent use.[5] The manufacturer of fosamprenavir states that, based on data with amprenavir, no significant interaction is expected with abacavir.[7]

2. Atazanavir with Ritonavir. In a study in 24 HIV-positive patients, ritonavir-boosted atazanavir 100/300 mg daily slightly reduced the AUC of abacavir 600 mg daily by 17% but had no significant effect on the maximum or minimum plasma concentrations of abacavir. The pharmacokinetics of ritonavir-boosted atazanavir were not significantly affected by abacavir. The reduction in abacavir levels is thought to be due to induction of abacavir glucuronidation by ritonavir.[8-10]

The authors of this study state that the clinical significance of this interaction remains unclear, however, they note that even though a larger reduction in abacavir levels was seen with ritonavir-boosted **lopinavir** (see *Lopinavir with Ritonavir*, below) a regimen containing abacavir and ritonavir-boosted lopinavir with lamivudine has been shown to be effective in the management of HIV infection. The authors[10] suggest that further study is needed, and it would seem prudent to monitor concurrent use to ensure antiviral efficacy, until further data is available. Note that the concurrent use of abacavir and lamivudine with ritonavir-boosted atazanavir is one of the recommended regimens for treatment-naive patients.[2,3]

3. Darunavir with Ritonavir. The manufacturers of darunavir state that no interaction is expected between abacavir and ritonavir-boosted darunavir.[11,12]

4. Lopinavir with Ritonavir. In a study in 24 HIV-positive patients, ritonavir-boosted lopinavir 100/400 mg twice daily reduced the AUC, maximum plasma concentration and minimum plasma concentration of abacavir 600 mg daily by 31%, 34%, and 64%, respectively. The pharmacokinetics of ritonavir-boosted lopinavir were not significantly affected by abacavir.[10] The reduction in abacavir levels is thought to be due to induction of abacavir glucuronidation by ritonavir, and possibly also lopinavir.[8-10]

The authors of this study state that the clinical significance of this interaction remains unclear, however, a regimen containing abacavir, lamivudine and ritonavir-boosted lopinavir has been shown to be effective in the management of HIV infection. The authors[10] suggest that further study is needed, and it would seem prudent to monitor concurrent use to ensure antiviral efficacy, until further data is available. Note that the concurrent use of abacavir and lamivudine with ritonavir-boosted lopinavir is one of the recommended regimens for treatment-naïve patients.[2,3]

5. Tipranavir with Ritonavir. Ritonavir-boosted tipranavir given decreased the AUC of abacavir by approximately 40%. The clinical relevance of this reduction has not been established,[13,14] but it may decrease the efficacy of abacavir.[13] Therefore the UK manufacturer states that the concurrent use of ritonavir-boosted tipranavir and abacavir is not recommended unless there are no other available NRTIs suitable for patient management.[13]

(b) Didanosine

1. Amprenavir or Fosamprenavir. The AUC and the minimum level of amprenavir 600 mg twice daily were not altered to a clinically relevant extent when it was given simultaneously with, or one hour before, buffered didanosine; or simultaneously with the enteric-coated preparation of didanosine. The only notable change was a 15% decrease in the maximum levels of amprenavir when it was given with buffered didanosine, which was not considered clinically significant.[15] Nevertheless, the manufacturers of amprenavir suggested that it should be given at least one hour apart from didanosine,[5,6] and this has also be recommended for regimens containing amprenavir and ritonavir.[15] However, the manufacturer of fosamprenavir, a prodrug of amprenavir, state that, although no specific study has been done, a clinically relevant interaction due to the antacid content of didanosine would not be expected. Enteric-coated didanosine is not expected to interact with fosamprenavir.[7]

2. Atazanavir. The manufacturer of atazanavir found that buffered didanosine markedly decreased atazanavir plasma levels, with little change in didanosine levels,[16] and they recommend that administration should be separated.[16,17] Conversely, although enteric-coated didanosine did not alter atazanavir levels, simultaneous administration with food reduced didanosine levels.[16,17] Therefore, the UK manufacturer[17] recommends that ritonavir-boosted atazanavir should be taken with food, 2 hours before didanosine (both the buffered tablets and enteric-coated formulations), whereas the US manufacturer[16] advises taking atazanavir 2 hours before or one hour after didanosine. Note that 'didanosine', (p.947), is preferably taken on an empty stomach, whereas 'atazanavir', (p.971), should be taken with food.

3. Darunavir with Ritonavir. Didanosine 400 mg daily, given on an empty stomach 2 hours before ritonavir-boosted darunavir 100/600 mg twice daily, did not affect the pharmacokinetics of darunavir. Therefore, the manufacturer of darunavir advises that no dose adjustments are required when these drugs are given together.[11] However, note that 'didanosine', (p.947), is preferably taken on an empty stomach, whereas 'darunavir', (p.971), should be taken with food. Therefore, the US manufacturer advis-

es taking didanosine one hour before or 2 hours after ritonavir-boosted darunavir, which is taken with food.[12]

4. Indinavir. The concurrent use of [buffered] didanosine and indinavir reduced the AUC of indinavir by 80%, but when indinavir was given one hour before didanosine its pharmacokinetics were not significantly affected.[18] Similarly, another study found that the pharmacokinetics of indinavir 800 mg were unchanged when it was given one hour after buffered didanosine 400 mg.[19] In a single-dose study in 23 healthy subjects, an enteric-coated preparation of didanosine had no effect on the pharmacokinetics of indinavir.[20] Indinavir may require a normal acidic gastric pH for optimal absorption, whereas some didanosine preparations are formulated with buffering agents to raise gastric pH. Any increase in pH would therefore be expected to reduce indinavir absorption.[21] The manufacturers of indinavir recommend that indinavir and didanosine should be given at least one hour apart.[21,22] This recommendation does not apply to the enteric-coated preparation of didanosine.[20,21,23] Note that both 'didanosine', (p.947), and 'indinavir', (p.971), are preferably taken on an empty stomach.

5. Lopinavir with Ritonavir. The manufacturers advise that ritonavir-boosted lopinavir *tablets* may be taken at the same time as didanosine, on an empty stomach. However, didanosine must be taken one hour before or 2 hours after ritonavir-boosted lopinavir *oral solution*, which should be taken with food.[8,9]

6. Nelfinavir. The pharmacokinetics of nelfinavir were not significantly altered after concurrent use with didanosine.[24] Note that 'nelfinavir', (p.971), should preferably be taken with food, and all 'didanosine preparations', (p.947), without food. The US manufacturer states that no interaction occurred when nelfinavir was taken one hour after didanosine and therefore recommends that nelfinavir is therefore taken one hour after didanosine enteric-coated preparations.[23]

7. Ritonavir. In a study in 13 HIV-positive subjects, buffered didanosine 200 mg twice daily was given with ritonavir 600 mg twice daily. Administration of the two drugs was separated by 2.5 hours, and treatment was given for 4 days. Treatment was staggered in this way, because 'ritonavir', (p.971), should be given with food, and 'didanosine', (p.947), without food. There was little or no change in the pharmacokinetics of ritonavir, and the maximum serum levels and AUC of didanosine were reduced by 16% and 13%, respectively, which was not considered to be clinically significant. It was suggested that these changes may have been due to altered absorption in the presence of ritonavir.[25] The manufacturer of ritonavir therefore recommends that ritonavir and didanosine should be taken 2.5 hours apart and suggest that dose alterations should not be necessary.[26]

8. Saquinavir. In a study in 8 healthy subjects, a single 400-mg dose of didanosine decreased the AUC and maximum plasma concentration of saquinavir (taken as ritonavir-boosted saquinavir 100/1600 mg soft capsules) by about 30% and 25%, respectively, but did not significantly affect the minimum plasma concentration of saquinavir. The manufacturer considers these changes are of doubtful clinical significance, and state that no dose adjustment is needed on concurrent use.[27] Note also that 'saquinavir', (p.971), should preferably be taken with food, and all 'didanosine preparations', (p.947), should be taken on an empty stomach.

9. Tipranavir with Ritonavir. Ritonavir-boosted tipranavir caused a 33% reduction in the AUC of didanosine in one of three studies,[14] but the clinical relevance of this has not been established.[13,14] Consequently, the manufacturer recommends that dosing of enteric-coated didanosine and ritonavir-boosted tipranavir should be separated by at least 2 hours to avoid formulation incompatibility.[13,14]

(c) Emtricitabine

The manufacturers of **darunavir** state that no interaction is expected between emtricitabine and ritonavir-boosted darunavir.[11,12]

The manufacturer of emtricitabine also states that no clinically significant interaction occurs with the concurrent use of **indinavir**.[28]

(d) Lamivudine

Lamivudine metabolism does not involve the cytochrome P450 isoenzyme CYP3A4. Therefore it is unlikely that it will interact with drugs, such as the protease inhibitors, that are metabolised by this system.[29] No pharmacokinetic interaction appears to occur between lamivudine and **amprenavir**,[5,6] **atazanavir**,[16,17] **fosamprenavir**,[7] **indinavir**,[21,22] ritonavir-boosted **lopinavir**[8,9] and **nelfinavir**,[30,31] and no interaction is expected with ritonavir-boosted **darunavir**.[11,12] Ritonavir-boosted **tipranavir** does not appear to cause a significant change in the AUC of lamivudine.[13,14]

(e) Stavudine

The manufacturer of **atazanavir**[16,17] notes that there was no pharmacokinetic interaction with stavudine.

The manufacturers of darunavir state that no interaction is expected between stavudine and ritonavir-boosted **darunavir**.[11,12]

The AUC of stavudine was increased by 25% when stavudine 40 mg twice daily was given with **indinavir** 800 mg every 8 hours for a week, which was not considered to be clinically significant. The serum levels of **indinavir** were unchanged.[32] Similarly, in a study in 24 healthy subjects, ritonavir-boosted **indinavir** 200/800 mg twice daily increased the AUC of stavudine by 24%, but this change was not considered clinically relevant.[33] No dose adjustments are needed on concurrent use.[21]

The manufacturer of ritonavir-boosted **lopinavir** notes that no significant interaction occurs with stavudine.[8,9]

In an early pilot study, the concurrent use of **nelfinavir** and stavudine was well tolerated, and the adverse effects were similar to those seen when stavudine was given alone, although the incidence of diarrhoea did increase.[34] The manufacturer of **nelfinavir** notes that no clinically significant interactions have been seen with stavudine.[30,31]

In a study in HIV-positive children, **ritonavir** oral clearance was about 50% slower and the AUC about 2.5-fold higher in 6 children who received stavudine than in 7 who received zidovudine and lamivudine, although these differences did not reach statistical significance.[35]

Ritonavir-boosted **tipranavir** does not appear to cause a significant change in the AUC of stavudine.[13,14] Therefore, no dose adjustment is needed on concurrent use.[13]

(f) Zalcitabine

The manufacturer of zalcitabine noted that there is no pharmacokinetic interaction with **saquinavir**.[36,37] They stated that pharmacokinetic interactions with protease inhibitors would not be expected because zalcitabine is mainly excreted unchanged in the urine.[36] The manufacturers of **darunavir** similarly state that no interaction is expected between zalcitabine and ritonavir-boosted darunavir.[11,12]

(g) Zidovudine

1. Amprenavir or Fosamprenavir. The manufacturer of amprenavir noted that the AUC and maximum levels of zidovudine were increased by 31% and 40%, respectively, when given with amprenavir. However, the pharmacokinetics of amprenavir were unchanged.[5,6] The UK manufacturer of amprenavir stated that no dose adjustment of either drug is necessary when amprenavir and zidovudine are used together.[5] The manufacturer of fosamprenavir advises that, based on data with amprenavir, no significant interaction is expected with zidovudine.[7]

2. Atazanavir. The manufacturer of atazanavir notes that there was no clinically relevant pharmacokinetic interaction with zidovudine.[17]

3. Darunavir with Ritonavir. The manufacturers of darunavir state that no interaction is expected between zidovudine and ritonavir-boosted darunavir.[11,12]

4. Indinavir. A study found that when zidovudine 200 mg every 8 hours and indinavir 1 g every 8 hours were given together for a week the AUC of zidovudine was increased by 17% and the AUC of indinavir was increased by 13%.[32] In another study, the concurrent use of indinavir and zidovudine with lamivudine increased the zidovudine AUC by 39% but did not change indinavir pharmacokinetics.[22] The manufacturer of indinavir also reports that the concurrent use of zidovudine 200 mg three times daily with indinavir 1 g three times daily, both taken for 7 days, had no effect on the pharmacokinetics of indinavir and on the AUC of zidovudine, although the minimum level of zidovudine was increased by 51%.[21,22] These changes are not clinically relevant, and the UK manufacturer of indinavir states that no dose adjustment is needed with concurrent use.[21]

5. Lopinavir with Ritonavir. The manufacturer of ritonavir-boosted lopinavir notes that it induces glucuronidation and therefore has the potential to reduce zidovudine levels. However this, and its clinical relevance, have yet to be studied.[8,9]

6. Nelfinavir. The manufacturer of nelfinavir notes that clinically significant interactions have not been observed with zidovudine, and no dose adjustments are needed.[30,31]

7. Ritonavir. A crossover study in 18 HIV-positive subjects found that the pharmacokinetics of ritonavir 300 mg every 6 hours were unchanged by zidovudine 200 mg every 8 hours. However, the maximum plasma levels and AUC of zidovudine were both reduced by about 25%. The lack of change in the other pharmacokinetic parameters suggested that these

changes were not due to altered metabolism,[38] although the manufacturer of ritonavir suggests that ritonavir may have induced the glucuronidation of zidovudine.[26] Nevertheless, dose alterations are not considered necessary.[26]

8. Saquinavir. The UK manufacturer of saquinavir notes that there was no pharmacokinetic interaction with zidovudine.[27]

9. Tipranavir with Ritonavir. Ritonavir-boosted tipranavir decreased the AUC of zidovudine by about 35%, without affecting glucuronidated-zidovudine levels. The clinical relevance of this reduction has not been established,[13,14] but it may decrease the efficacy of zidovudine.[13] Therefore, the UK manufacturer states that concurrent use of ritonavir-boosted tipranavir with zidovudine is not recommended unless there are no other available NRTIs suitable for patient management.[13]

NRTIs + Ribavirin

The use of ribavirin with the NRTIs may result in increased toxicity (lactic acidosis, blood dyscrasias and hepatotoxicity), which may be more frequent with didanosine than other NRTIs. These effects may also be exacerbated by the additional use of interferon for hepatitis C. Early *in vitro* data suggested that ribavirin may reduce the antiretroviral effects of some NRTIs but this does not appear to have been demonstrated in practice.

Clinical evidence and mechanism

(a) Abacavir

In a retrospective study in HIV-positive patients with hepatitis C, the use of abacavir was reported to increase the risk of therapeutic failure with interferon alfa and ribavirin, particularly in patients with ribavirin levels of less than 2.3 micrograms/mL.[1] Similarly, another study found abacavir reduced the response to ribavirin.[2]

(b) Didanosine

In two studies, ribavirin did not alter the pharmacokinetics of didanosine in HIV-positive adults or children.[3,4] However, *in vitro*, ribavirin increases the intracellular activation of didanosine, and the manufacturers note that this could result in increased adverse effects.[5-7] In one early study, no increase in adverse effects was seen when ribavirin 600 mg daily was given to 16 HIV-positive patients who had already been taking didanosine 125 to 200 mg twice daily for 4 weeks. Ribavirin was given 6 hours after the morning dose of didanosine. Over the 8 or 20 weeks of the study the combination was well tolerated.[3] Nevertheless, cases of mitochondrial toxicity (hepatotoxicity, pancreatitis, lactic acidaemia) have been reported when ribavirin was added to didanosine-containing antiretroviral regimens,[8-10] and fatalities have occurred.[8,11] In an analysis of data from the adverse event reporting system of the FDA in the US, 31 patients were identified who had adverse events suggestive of mitochondrial toxicity while taking ribavirin with an NRTI. Of these, nearly 90% had received didanosine, 71% stavudine, and 65% both didanosine and stavudine. Five patients died; all of who were taking didanosine, with stavudine in three of these cases. The use of ribavirin with didanosine was associated with an increased risk of mitochondrial toxicity (odds ratio 12.4) compared with patients receiving ribavirin with other NRTIs (odds ratios: didanosine with stavudine, 8; stavudine, 3.3; abacavir, 1.1; lamivudine, 0.2; zidovudine, 0.06).[11] Some other studies have shown an increased risk of mitochondrial toxicity when ribavirin was given with didanosine.[12,13]

(c) Lamivudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of lamivudine.[14] However, in a study in 22 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of lamivudine (a 27% increase in AUC), and no effect on the intracellular activation of lamivudine, when compared with 24 similar patients who received placebo.[15]

(d) Stavudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of stavudine.[6,16] However, in a study in 5 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of stavudine (a 45% increase in AUC), and no effect on intracellular activation of stavudine, when compared with similar patients who received placebo.[15] Similarly, no decrease in the antiviral activity of stavudine (as assessed by plasma HIV-RNA levels) has been seen when ribavirin was given with interferon for hepatitis C infection in patients with HIV.[17,18]

(e) Zidovudine

In vitro, ribavirin reduced the intracellular activation and antiretroviral activity of zidovudine.[6,19] However, in a study in 14 patients with hepatitis C

and HIV infections, the addition of ribavirin to treatment with zidovudine 300 mg twice daily had no significant effect on the pharmacokinetics of zidovudine.[20] Similarly, an earlier study in a study in 7 HIV-positive patients with hepatitis C, ribavirin 800 mg daily had no statistically significant effect on the pharmacokinetics of zidovudine (a 22% decrease in AUC), and no effect on the intracellular activation of zidovudine, when compared with similar patients who received placebo.[15] Moreover, in a study in 8 patients taking zidovudine, there was no significant variation in HIV viral load or CD4 counts after 3 or 6 months of ribavirin treatment, compared with baseline values.[18] One US manufacturer of ribavirin includes details of a study in which patients treated with zidovudine, interferon alfa and ribavirin had a higher incidence of severe neutropenia (15% versus 9%) and severe anaemia (5% versus 1%) than other similar patients not receiving zidovudine.[21]

Importance and management

In the UK, the manufacturers of all NRTIs state that patients co-infected with hepatitis C and treated with 'interferon alfa', (p.945), and ribavirin may be at increased risk of lactic acidosis. Patients at increased risk should be closely monitored.

The UK manufacturer of **didanosine**[5] advises that treatment with nucleoside analogues [such as didanosine] should be discontinued in the setting of symptomatic hyperlactataemia and metabolic/lactic acidosis, progressive hepatomegaly, or rapidly elevating aminotransferase levels. Others consider that didanosine should not be systematically replaced in patients requiring treatment for hepatitis C because the risk of lactic acidosis is only small.[22] Nevertheless, they suggest that if a modification of antiretroviral treatment is needed then it is best to avoid didanosine.[22] As a result of the increased risk of mitochondrial toxicity, the manufacturers say that the concurrent use of ribavirin and didanosine is not recommended,[5,6,21,23,24] and the US manufacturer of didanosine[7] and the British HIV Association (BHIVA) contraindicates concurrent use.[25]

Similarly, the British HIV Association recommends avoiding the concurrent use of **abacavir** with ribavirin for hepatitis C infection if possible, as concurrent use may reduce intracellular levels of ribavirin and possibly reduce the response to treatment.

The US manufacturer of **stavudine** states that patients also receiving 'interferon', (p.945), with or without ribavirin, should be closely monitored for treatment-associated toxicities, particularly hepatic decompensation.[26] Based on an analysis of data from the adverse event reporting system of the FDA in the US, the UK manufacturers[6,23] of ribavirin consider that concurrent use of stavudine should be avoided to limit the risk of mitochondrial toxicity. The British HIV Association (BHIVA) also recommends avoiding concurrent use, if possible.[25] However, one manufacturer of ribavirin also advises that plasma HIV-RNA levels are closely monitored in patients taking ribavirin with stavudine to ensure continued efficacy.[6]

The manufacturer of **lamivudine** advises caution if NRTIs are given to patients with risk factors for liver disease and notes that patients with hepatitis C treated with interferon and ribavirin may be a special risk category.[27]

The US manufacturer of **zidovudine** advises that patients also receiving interferon alfa, with or without ribavirin, should be closely monitored for treatment-associated toxicities, especially hepatic decompensation, neutropenia, and anaemia. They also recommend that nucleoside analogues that antagonise the antiretroviral activity of zidovudine, such as ribavirin, should be avoided.[28] The British HIV Association (BHIVA) recommends avoiding the concurrent use of ribavirin with zidovudine, if possible.[25] However, one manufacturer of ribavirin also advises that plasma HIV-RNA levels are closely monitored in patients taking ribavirin with zidovudine to ensure continued efficacy.[6] Both UK manufacturers[6,23] of ribavirin also note that patients treated with zidovudine are at increased risk of developing anaemia, and one does not recommend concurrent use.[23] They advise that an alternative choice to zidovudine should be considered in patients requiring treatment with ribavirin, particularly those with a previous history of zidovudine-induced anaemia.[23] The US manufacturer of zidovudine gives similar advice.[28]

NRTIs + Tenofovir

Tenofovir increases the levels of didanosine: an increased risk of pancreatitis and peripheral neuropathy has been reported, and a high level of treatment failure. There is no pharmacokinetic interaction between tenofovir and abacavir, emtricitabine, lamivudine or stavudine. However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high level of treatment failure. Triple-NRTI regimens involving tenofovir are not recommended, with the possible exception of tenofovir, lamivudine and zidovudine.

Clinical evidence, mechanism, importance and management

Note that tenofovir is a nucleotide (nucleoside monophosphate) analogue and is often classed as an NRTI.

(a) Abacavir

In a study in HIV-positive patients taking ritonavir-boosted lopinavir, no significant pharmacokinetic interaction was reported between tenofovir, and abacavir or lamivudine.[1] Similarly, in a study in 8 healthy subjects, no clinically relevant pharmacokinetic interaction was found between tenofo-

vir and abacavir.[2,3] However, the combination of tenofovir, lamivudine and abacavir was unexpectedly associated with a high rate of treatment failure (early virological non-response) in clinical studies.[4] Consequently, in July 2003 the manufacturer and others recommended that this triple therapy should not be used alone, and if these three drugs are used with other antiretrovirals, virological response should be closely monitored.[4] US guidelines (November 2008) for the treatment of HIV-1 infection state that triple NRTI regimens like this should not be used routinely (with two specific exceptions) because of suboptimal virological activity or lack of data.[5] Similarly, UK guidelines (2008) state that triple NRTI regimens such as tenofovir, abacavir and lamivudine should not be used because of unacceptably high rates of virological failure.[6]

(b) Didanosine

The AUC of buffered didanosine 250 mg or 400 mg was increased by 44% when it was given one hour before tenofovir.[2] Similarly the AUC of enteric-coated didanosine 400 mg was increased by 48% and 60% when didanosine was given 2 hours before or at the same time as tenofovir disoproxil fumarate 300 mg, respectively.[7] The pharmacokinetics of tenofovir were unchanged.[2,7] Another study found that the AUC of enteric-coated didanosine 250 mg (simultaneously or 2 hours apart, fasted or with food) was about equivalent to that seen with didanosine 400 mg alone when tenofovir was given.[7]

The main concern with raised didanosine levels is the increased risk of adverse effects, particularly pancreatitis and peripheral neuropathy. One retrospective analysis found that 5 of 185 patients receiving didanosine with tenofovir developed pancreatitis compared with one of 182 taking didanosine without tenofovir and none of 208 taking tenofovir without didanosine, suggesting an increased risk of pancreatitis with the combination. All 6 cases of pancreatitis were in women without renal impairment, who weighed less than 60 kg. Five had received a reduced dose of didanosine (250 mg) and one had received didanosine 400 mg. Pancreatitis developed after 12 to 24 weeks.[8] Similarly, another analysis found that the use of tenofovir with didanosine (400 mg daily or 250 mg daily if weight less than 60 kg) was associated with a higher incidence of peripheral neuropathy (12% versus 4%) and pancreatitis (4% versus 0%) than use with lower doses of didanosine (100 mg to 250 mg daily).[9] However, another analysis failed to find an enhanced risk of toxicity with the combination of didanosine and tenofovir at full dose during the first 6 months of use.[10] Tenofovir is rarely associated with acute renal failure, and in one study[11], the concurrent use of didanosine with tenofovir was found to be associated with an increased risk of developing renal impairment (odds ratio 3.1). In an analysis of 5 HIV-positive patients with acute renal failure and 22 cases reported in the literature, all of whom were taking tenofovir, 9 patients were also taking didanosine, and it was suggested that tenofovir-associated renal failure, might be due to an interaction,[12] although others contend that this does not necessarily infer an association.[13] Cases of pancreatitis[14,15] or lactic acidosis and renal failure[16-18] have been reported (the use of ritonavir may be a factor in at least one of these cases[18]).

Furthermore, a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 250 mg and lamivudine 300 mg was unexpectedly associated with a high rate of treatment failure (early virological non-response) in a clinical study in treatment-naïve patients.[19] Similarly, other studies have shown a high rate of treatment failure with a once daily combination of tenofovir disoproxil fumarate 300 mg, enteric-coated didanosine 250 mg and either efavirenz or nevirapine in treatment-naïve patients with high baseline viral loads and low CD4 counts.[20] A poor immune response (lack of increase in CD4 cell counts) has also been seen with full-dose didanosine with tenofovir regimens in treatment-experienced patients.[21]

The pharmacokinetic interaction is established, and raised didanosine levels would be expected when it is given with tenofovir. The US manufacturers recommend that the dose of didanosine should be reduced to 250 mg daily when given with tenofovir in patients weighing more than 60 kg with a creatinine clearance of at least 60 mL/minute,[2,22] and 200 mg daily in patients weighing less than 60 kg and with a creatinine clearance of at least 60 mL/minute; the dose in patients with a creatinine clearance of less than 60 mL/minute has not been established.[22] However, the UK manufacturer of tenofovir notes that reducing the didanosine dose to 250 mg has been associated with a high rate of virological failure.[23] Nevertheless, because of the high rates of treatment failure seen with didanosine in combination with tenofovir and an NNRTI or lamivudine, and the potential for tenofovir to potentiate didanosine-related toxicity, the EMEA,[24] the MHRA in the UK[25] and UK guidelines[6] now recommend that didanosine should not be used with tenofovir in any antiretroviral combination. Similarly, the 2008 US guidelines also say that didanosine should not be used with tenofovir as part of initial therapy because of a high rate of early virological failure, rapid selection of resistant mutations, and the potential for immunological non-response/CD4 decline.[5] If the combination is considered necessary, the dose should be adjusted as recommended and the patient should be carefully monitored for didanosine-related adverse effects (e.g. pancreatitis, peripheral neuropathy) and for antiviral efficacy.

(c) Emtricitabine

In a study in 16 healthy subjects, no pharmacokinetic interaction was reported between tenofovir disoproxil fumarate 300 mg daily and emtricitabine 200 mg daily, both for 7 days.[26] The 2008 UK and US guidelines for treatment of HIV infections recommend the combination of tenofovir and emtricitabine with either an NNRTI or a protease inhibitor.[5,6] Tenofovir and emtricitabine are available in a fixed dose combination product.

(d) Lamivudine

In a study in HIV-positive patients, no significant pharmacokinetic interaction was reported between tenofovir and abacavir or lamivudine.[1] The manufacturer also briefly notes that there was no pharmacokinetic interaction between tenofovir and lamivudine.[23] The 2008 UK guidelines for treatment of HIV infections recommend the combination of tenofovir and lamivudine with either an NNRTI or a protease inhibitor.[6]

However, for studies showing a high rate of virological failure with the combination of tenofovir, lamivudine and one other NRTI, see *Abacavir*, and *Didanosine*, above. UK and US guidelines say to avoid sole use of all regimens of tenofovir plus two NRTIs (triple-NRTI regimens), with the possible exception of tenofovir plus lamivudine and zidovudine when a protease inhibitor or NNRTI-based regimen cannot be used.[5,6]

(e) Stavudine

There is information to suggest that tenofovir disoproxil fumarate 300 mg does not alter levels of stavudine 100 mg.[27]

NRTIs; Didanosine + Allopurinol

Allopurinol markedly raises didanosine levels.

Clinical evidence, mechanism, importance and management

In a study, buffered didanosine 400 mg was given to 14 healthy subjects, with and without allopurinol 300 mg daily for 7 days. Allopurinol significantly increased didanosine absorption, shown by a twofold increase in the AUC of didanosine and a 69% rise in its maximum serum levels.[1] Similar findings were seen in HIV-positive subjects.[2] Moreover, the addition of allopurinol 300 mg daily allowed the dose of didanosine to be halved from 400 mg daily to 200 mg daily in 4 patients taking buffered didanosine, hydroxycarbamide and chloroquine. Didanosine plasma levels and antiviral efficacy were unchanged when compared with pre-treatment levels in patients taking didanosine 400 mg daily without allopurinol.[3] The US manufacturer notes that, in subjects with renal impairment, allopurinol 300 mg increased the AUC and maximum plasma concentration of a single 200-mg dose of didanosine 3.1-fold and 2.3-fold, respectively.[4] The manufacturer notes that allopurinol may increase the exposure to didanosine by inhibiting xanthine oxidase, an enzyme involved in didanosine metabolism.[5] This interaction has been studied for its therapeutic benefit.[3] However, if the dose of didanosine is not reduced, there is the potential for an increase in didanosine adverse effects. The manufacturers state that concurrent use of allopurinol with didanosine is contraindicated,[4,5] and that patients requiring allopurinol should be changed from didanosine to an alternative antiretroviral regimen.[5]

NRTIs; Didanosine + Loperamide or Metoclopramide

Loperamide and metoclopramide do not appear to alter the pharmacokinetics of didanosine.

Clinical evidence, mechanism, importance and management

In a study in 6 men and 6 women who were HIV-positive, the pharmacokinetics of oral buffered didanosine 300 mg were not altered to a clinically relevant extent by 4 mg of loperamide, given 19, 13, 7 and one hour before the didanosine. The rate of didanosine absorption was slightly decreased but the extent of absorption was unchanged. Similarly, the pharmacokinetics of oral buffered didanosine 300 mg were found to be unaffected by 10 mg of intravenous metoclopramide.[1] It appears that neither delaying nor accelerating gastrointestinal transit time appreciably alters the pharmacokinetics of didanosine, which is acid labile. On the basis of this study the authors conclude that neither the dose nor the frequency of didanosine administration need to be altered if either loperamide or metoclopramide is given concurrently.[1]

NRTIs; Stavudine + Doxorubicin

***In vitro* evidence suggests that doxorubicin may inhibit the activation of stavudine.**

Clinical evidence, mechanism, importance and management

Nucleoside reverse transcriptase inhibitors such as stavudine need to be phosphorylated within cells before they become effective. *In vitro* studies using mononucleated blood cells found that doxorubicin may interfere with stavudine phosphorylation at clinically relevant concentrations.[1] The clinical importance of this interaction awaits assessment. However, caution is recommended on concurrent use.

1. Hoggard PG, Kewn S, Barry MG, Khoo SH, Back DJ. Effects of drugs on 2',3'-dideoxy-2',3'-didehydrothymidine phosphorylation in vitro. *Antimicrob Agents Chemother* (1997) 41, 1231–6.

NRTIs; Zidovudine + Aspirin or NSAIDs

***In vitro* evidence suggests that indometacin and naproxen inhibit the glucuronidation of zidovudine. However, in subsequent clinical studies, indometacin and naproxen did not affect zidovudine pharmacokinetics. The concurrent use of ibuprofen and zidovudine appears to increase the risk of bleeding in patients with haemophilia.**

Clinical evidence, mechanism, importance and management

An *in vitro* study using human liver microsomes found that **indometacin** and **naproxen** inhibited the glucuronidation of zidovudine by 50% or more, and aspirin also had some inhibitory effect.[1] This suggested that these drugs might possibly increase the effects and the toxicity of zidovudine. However, clinical studies have found no changes in the pharmacokinetics of zidovudine given with **indometacin** 25 mg twice daily for 3 days[2] or **naproxen** 500 mg to 1 g daily for 3 or 4 days.[2,3] Many drugs that were reported to inhibit the glucuronidation of zidovudine *in vitro* appear to have only modest effects on zidovudine levels in clinical studies, which are unlikely to be clinically important in most patients (see 'NRTIs; Zidovudine + Drugs that inhibit glucuronidation', p.960). No clinically relevant pharmacokinetic interaction appears to occur between zidovudine and NSAIDs. However, in 2007, the MHRA in the UK issued minimum requirements to manufacturers regarding the content of licensed product characteristics for systemic NSAIDs. This included a statement that the concurrent use of NSAIDs increased the risk of haematological toxicity with zidovudine, and that there is evidence of an increased risk of haemarthroses and haematoma in HIV-positive patients with haemophilia taking zidovudine and ibuprofen.[4,5] This appears to be based on data from a study in 10 HIV-positive patients with haemophilia taking zidovudine 100 or 200 mg five times daily, which found a reduction in platelet adhesion and an increase in bleeding times in those patients given **ibuprofen** 400 mg four times daily for at least 2 weeks. Three patients had an excess bleeding tendency on concurrent use, although this did not correlate with platelet function defects. Neither the clearance of zidovudine or **ibuprofen** was affected by concurrent use.[6] A patient with AIDS and haemophilia taking **ibuprofen** had a fourfold increase in spontaneous haemorrhages of the joints after starting zidovudine. This eventually resolved when zidovudine was stopped and restarted at a reduced dose of zidovudine 100 mg three times daily with once-daily **ibuprofen**.[7] Another case has also been reported of a prolonged bleeding time with bleeding from a venous ulcer in a patient taking zidovudine who self-medicated with **ibuprofen** 800 mg tablets. His bleeding time had returned to normal 4 weeks after stopping **ibuprofen**.[8] An earlier study of zidovudine use in 282 patients with AIDS

found that haematological abnormalities were not increased by the concurrent use of aspirin in 47 patients.[9]

Although there is limited published evidence, the increased risk of bleeding reported in HIV-positive patients with haemophilia taking **ibuprofen** with zidovudine appears to be of clinical significance, and these patients require close monitoring if they are also prescribed NSAIDs. Whether this increased risk is restricted to those patients with haemophilia is unclear.

NRTIs; Zidovudine + Benzodiazepines

Oxazepam causes a modest increase in the bioavailability of zidovudine, and concurrent use can increase the incidence of headaches. Lorazepam is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

A pharmacokinetic study in 6 HIV-positive patients found that **oxazepam** did not significantly affect the bioavailability of zidovudine. All of the patients were sleepy and fatigued while taking **oxazepam** (as expected), but 5 of the 6 complained of headaches while taking both drugs, compared with only one of 6 while taking zidovudine alone and none while taking **oxazepam** alone. The authors of the report suggest that if headaches occur during concurrent use, the benzodiazepine should be stopped.[1] A previous *in vitro* study using human liver microsomes confirmed that **oxazepam** inhibits the metabolism of zidovudine to its glucuronide, and **lorazepam** behaves in the same way.[2] The same precautions suggested for **oxazepam** would therefore also appear to apply to **lorazepam**.

NRTIs; Zidovudine + Drugs that inhibit glucuronidation

***In vitro* evidence suggests that chloramphenicol inhibits the glucuronidation of zidovudine. Dipyridamole does not appear to alter the pharmacokinetics of zidovudine.**

Clinical evidence and mechanism

(a) Chloramphenicol

An *in vitro* study using human liver microsomes found that chloramphenicol inhibited the glucuronidation of zidovudine by 50% or more, suggesting that the effects and toxicity of zidovudine may be increased.[1] The effect of concurrent use in patients awaits assessment.

(b) Dipyridamole

Theoretically, dipyridamole and zidovudine might inhibit the metabolism of each other by competing for glucuronidation, the major clearance mechanism for both drugs. However, a study in 11 asymptomatic HIV-positive patients found that dipyridamole 75 to 100 mg every 4 hours for 5 days caused no significant changes in the pharmacokinetics of zidovudine 500 mg daily, but the dipyridamole adverse effects (headaches, nausea) when taking the higher dose were found to be intolerable.[2]

Importance and management

Many drugs that have been reported to inhibit the glucuronidation of zidovudine *in vitro* (such as naproxen and indometacin, see 'NRTIs; Zidovudine + Aspirin or NSAIDs', p.959) appear to have only modest or no significant effects on zidovudine pharmacokinetics in *clinical* studies. In general, these minor pharmacokinetic interactions are unlikely to be of clinically importance in most patients. No significant interaction appears to occur between dipyridamole and zidovudine, and therefore no special precautions appear to be necessary.

Based on data from studies with other drugs that affect the glucuronidation of zidovudine and the lack of a reported clinical interaction, it seems unlikely that a clinically relevant pharmacokinetic interaction will occur between chloramphenicol and zidovudine. However bear the possibility in mind should a patient develop zidovudine adverse effects, particularly as both drugs can cause haematological toxicity.

1. Sim SM, Back DJ, Breckenridge AM. The effect of various drugs on the glucuronidation of zidovudine (azidothymidine; AZT) by human liver microsomes. *Br J Clin Pharmacol* (1991) 32, 17–21.

NRTIs; Zidovudine + Lithium

Lithium can apparently oppose the neutropenic effects of zidovudine in some patients.

Clinical evidence, mechanism, importance and management

A study in 5 patients with AIDS found that serum lithium carbonate levels of 0.6 to 1.2 mmol/L increased their neutrophil counts sufficiently to allow the re-introduction of zidovudine, which had previously been withdrawn due to neutropenia. Withdrawal of the lithium resulted in a rapid fall in neutrophil levels in 2 patients.[1] Improvement in neutropenia occurred in another patient with AIDS taking zidovudine 1.2 g daily when lithium carbonate 300 mg three times daily was also given.[2] Lithium has been found to induce granulopoiesis, and these reports suggest that no adverse reaction appears to occur in patients taking zidovudine and lithium, and that there may be some advantages to their use. However, lithium has a narrow therapeutic range and its toxic symptoms might be difficult to distinguish from any neurological complications caused by the disease. The addition of lithium could also increase the risk of interactions with other drugs.[3,4] A study of 3 further patients found a lack of a beneficial effect with lithium in 2 of the patients and only a short-term improvement in the neutrophil count in the third. In addition, one patient experienced severe diarrhoea necessitating discontinuation of the lithium.[5]

1. Roberts DE, Berman SM, Nakasato S, Wyle FA, Wishnow RM, Segal GP. Effect of lithium carbonate on zidovudine-associated neutropenia in the acquired immunodeficiency syndrome. *Am J Med* (1988) 85, 428–31.

NRTIs; Zidovudine + Megestrol

Megestrol acetate does not affect the pharmacokinetics of zidovudine.

Clinical evidence, mechanism, importance and management

In a study in 12 asymptomatic HIV-positive patients, megestrol acetate 800 mg daily for 13 days had no effect on the steady-state pharmacokinetics of zidovudine or its glucuronide metabolite.[1] As megestrol does not appear to affect the metabolism of zidovudine, no dose adjustment of zidovudine appears to be necessary on concurrent use.

1. Van Harken DR, Pei JC, Wagner J, Pike IM. Pharmacokinetic interaction of megestrol acetate with zidovudine in human immunodeficiency virus-infected patients. *Antimicrob Agents Chemother* (1997) 41, 2480–3.

NRTIs; Zidovudine + Myelosuppressive drugs

There have been reports of serious myelotoxicity when zidovudine was given with vancomycin or cytotoxic antineoplastics, and, on theoretical grounds, any drug causing bone marrow suppression might be additive with the effects of zidovudine. Moderate pharmacokinetic changes have been seen when zidovudine was given with chemotherapy regimens used for Kaposi's sarcoma, Hodgkin's disease, and non-Hodgkin's lymphoma.

Clinical evidence and mechanism

(a) Antineoplastics

In one preliminary report, the addition of **vinblastine** to zidovudine resulted in severe bone marrow depression.[1] Similarly, 9 of 21 patients could not tolerate zidovudine while receiving a chemotherapy regimen (**cyclophosphamide**, **doxorubicin**, **teniposide**, **prednisone**, **vincristine** and **bleomycin**) because of haematological toxicity.[2] However, a small retrospective case review in patients with Kaposi's sarcoma who were given **vincristine** 2 mg and **bleomycin** 30 mg or **vinblastine** 2.5 mg to 5 mg (every 3 to 4 weeks) found no significant increased risk of relapse or effect on survival in those also taking zidovudine. Of the patients taking zidovudine, 11 (24%) developed anaemia. Peripheral neuropathy was reported in 13 (28%) of all patients treated.[3] Similarly, another group have reported that the concurrent use of zidovudine 400 mg to 1 g daily with **vincristine** 2 mg and **bleomycin** 30 units (both given once every 2 weeks) in 19 HIV-positive patients with Kaposi's sarcoma was well-tolerated. Neutropenia occurred in 4 patients (21%) and neuropathy occurred in one patient (5%).[4] The pharmacokinetic interaction of chemotherapy with zidovudine was assessed in HIV-positive patients being treated for Kaposi's sarcoma, non-Hodgkin's lymphoma or Hodgkin's disease. The antineoplastics used were **bleomycin**, **cyclophosphamide**, **doxorubicin**, **epirubicin**, **etoposide**, **vinblastine**, **vincristine**, **vindesine** and **vinorelbine**. Zidovudine metabolism was unchanged, but a 43% decrease was noted in the maximum plasma levels of zidovudine and the time to peak level was prolonged by 51%, which was independent of the chemotherapy given.[5] The authors concluded that dose changes of zidovudine were not needed with the antineoplastics used, based on these pharmacokinetic changes alone, as the zidovudine AUC remained unchanged and maximum plasma levels have not been shown to clearly correlate with its activity.[5] Thus it appears that any interaction is likely to be attributable to additive myelosuppressive effects.

(b) Vancomycin

A report describes marked neutropenia in 4 HIV-positive patients receiving zidovudine when they were given vancomycin (which can also, rarely, have neutropenic effects).[6]

Importance and management

On theoretical grounds any drug causing bone marrow suppression might be additive with the effects of zidovudine. The manufacturers recommend that extra care be taken in monitoring haematological parameters if concurrent treatment with any myelosuppressive drug and zidovudine is required.[7,8] The UK manufacturer specifically mention systemic **pentamidine**, '**dapsone**', (p.946), '**pyrimethamine**', (p.269), '**co-trimoxazole**', (p.944), **amphotericin** (myelotoxicity and nephrotoxicity seen in a study in *dogs*[9]), **flucytosine**, '**ganciclovir**', (p.948), '**interferon**', (p.945), **vinblastine**, and **doxorubicin**,[7] whereas the US manufacturer advises caution with '**ganciclovir**', (p.948), '**interferon alfa**', (p.945), and '**ribavirin**', (p.956).[8] However, the UK manufacturer[7] also states that limited clinical data do not indicate a significantly increased risk of adverse reactions to zidovudine if it is given with prophylactic doses of '**co-trimoxazole**', (p.944), aerosolised **pentamidine**, pyrimethamine, and '**aciclovir**', (p.941).

Note that the UK manufacturer[7] also states that the use of **vincristine** with zidovudine may lead to additive myelosuppression, although vincristine is much less commonly associated with blood dyscrasias and anaemia than vinblastine.

NRTIs; Zidovudine + Nimodipine

***Animal* studies suggest that nimodipine may increase the bioavailability of zidovudine.**

Clinical evidence, mechanism, importance and management

Studies in *animals* have shown that the AUC of zidovudine is increased and its volume of distribution and clearance rate decreased when it is given with nimodipine.[1] The clinical relevance of the interaction is not known, but as the adverse effects of zidovudine are dose related, the manufacturer of nimodipine suggests that this interaction should be considered in patients given both drugs.[2]

Oseltamivir + Drugs that affect renal clearance

Probenecid inhibits the renal secretion of the active metabolite of oseltamivir and markedly raises its plasma levels. No pharmacokinetic interaction occurs between amoxicillin and oseltamivir, and cimetidine does not appear to alter oseltamivir pharmacokinetics.

Clinical evidence

(a) Amoxicillin

In a study in healthy subjects, oseltamivir 75 mg twice daily for 4.5 days had no effect on the pharmacokinetics of a single 500-mg dose of amoxicillin given with the last dose of oseltamivir. Similarly, amoxicillin had no effect on the pharmacokinetics of the active metabolite of oseltamivir.[1]

(b) Cimetidine

In a crossover study[1] in 18 healthy subjects, cimetidine 400 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 150-mg dose of oseltamivir given on day 2.

(c) Probenecid

In a crossover study in 18 healthy subjects, probenecid 500 mg every 6 hours for 4 days approximately halved the renal clearance of the active metabolite of oseltamivir, and increased its AUC about 2.5-fold when a single 150-mg dose of oseltamivir was given on day 2. Population pharmacokinetic data have been used to assess the possibility of using a lower dose of oseltamivir in combination with probenecid. Oseltamivir 45 mg twice daily, but not oseltamivir 30 mg twice daily, with probenecid 500 mg every 6 hours resulted in the same plasma levels of active metabolite as oseltamivir 75 mg twice daily alone.[2]

Mechanism

Probenecid appears to completely inhibit the renal tubular secretion of the active metabolite of oseltamivir via the anionic renal transporter process. Oseltamivir does not alter amoxicillin pharmacokinetics, suggesting minimal potential to inhibit the renal anionic transport process.[1] Cimetidine, which inhibits the renal tubular secretion of drugs via the cationic secretion transport process, had no effect on oseltamivir.

Importance and management

Probenecid markedly increased the AUC of the active metabolite of oseltamivir, but because of the large safety margin of oseltamivir, this increase is not considered to be clinically relevant.[1,3,4] Although one study found that a reduced dose of oseltamivir with probenecid produced therapeutic oseltamivir metabolite levels, it was suggested that the use of the combination may compromise tolerability, increase the potential for interactions, and the increased dosing requirements of the oseltamivir with probenecid regimen may reduce compliance.[2]

Oseltamivir did not alter **amoxicillin** pharmacokinetics, and is therefore unlikely to interact with other renally secreted organic acids. Other drugs that are involved in the active anionic tubular secretion mechanism are also unlikely to interact. **Cimetidine** does not interact with oseltamivir, and other drugs that are inhibitors of the renal cationic secretion transport process are unlikely to interact.[1]

Although the UK manufacturer states that clinically important drug interactions involving competition for renal tubular secretion are unlikely, they recommend care should be taken when giving oseltamivir to patients taking other similarly excreted drugs with a narrow therapeutic margin, and they give **chlorpropamide**, **methotrexate**, and **phenylbutazone** as examples.[3]

Oseltamivir and Zanamivir + Miscellaneous

Antacids do not affect the pharmacokinetics of oseltamivir, and there is no pharmacokinetic interaction between amantadine, aspirin or paracetamol (acetaminophen) and oseltamivir. Aspirin and a variety of other drugs used for influenza management do not affect the antiviral activity of zanamivir *in vitro*.

Clinical evidence, mechanism, importance and management

(a) Oseltamivir

1. Amantadine. In a crossover study, 17 healthy subjects were given oseltamivir 75 mg twice daily alone or with amantadine 100 mg twice daily for 5 days. Amantadine did not significantly affect the pharmacokinetics of oseltamivir or its active metabolite, oseltamivir carboxylate, and the pharmacokinetics of amantadine were not significantly affected by oseltamivir.[1] Therefore, no dose adjustment of either drug appears to be necessary on concurrent use.

2. Antacids. In a single-dose study, the pharmacokinetics of oseltamivir 150 mg and its active carboxylate metabolite were not affected by antacids. The antacids used were an **aluminium/magnesium hydroxide** suspension (*Maalox*) and **calcium carbonate** tablet (*Titralac*).[2] No dose adjustment of oseltamivir appears to be necessary on concurrent use.

3. Aspirin. A pharmacokinetic interaction between oseltamivir and aspirin was predicted to occur, because both drugs are hydrolysed by esterases and secreted by anionic tubular secretion.[3] However, in a study in 12 healthy subjects given a single 900-mg dose of aspirin before, during and/or after oseltamivir 75 mg twice daily for 9 doses, no pharmacokinetic interaction occurred between aspirin and oseltamivir.[3] Therefore, no dose adjustment of either drug appears to be necessary on concurrent use.

4. Paracetamol (Acetaminophen). The manufacturer notes that no pharmacokinetic interaction occurs between paracetamol and oseltamivir.[4,5] Therefore, no dose adjustment of either drug appears to be necessary with concurrent use.

(b) Zanamivir

The *in vitro* antiviral potency of zanamivir was not affected by **aspirin**, **paracetamol**, **ibuprofen**, **phenylephrine**, **oxymetazoline**, **promethazine**, or **co-amoxiclav** (amoxicillin with clavulanic acid).[6] Zanamivir is used as an inhalation, and has a low systemic bioavailability, so interactions would not generally be expected.

Protease inhibitors + Aciclovir and related drugs

No significant pharmacokinetic interaction occurs between valaciclovir or aciclovir and tipranavir or ritonavir.

Clinical evidence, mechanism, importance and management

In a study, 26 healthy subjects were given ritonavir-boosted tipranavir 200/500 mg twice daily, with a single 500-mg dose of **valaciclovir**, a prodrug of aciclovir. Steady-state ritonavir-boosted tipranavir increased the AUC and trough level of aciclovir by 7% and 19%, respectively, and decreased its peak concentration by 5%. **Valaciclovir** had no significant effects on the pharmacokinetics of tipranavir, although the AUC, maximum concentration and minimum concentration of ritonavir were slightly reduced by 14%, 19% and 6%, respectively. The most common adverse effects were gastrointestinal disorders, although 3 subjects stopped taking ritonavir-boosted tipranavir as a result of increases in liver enzymes.[1]

The slight increase in aciclovir levels are not of significance as aciclovir has a wide therapeutic margin. The slight reduction in ritonavir levels is also not considered clinically significant. No dose adjustment is therefore needed when **valaciclovir**, and therefore probably aciclovir, are given with tipranavir or ritonavir.

1. Sabo JP, Cong XJ, Haas D, Eskoetter H, Kraft M, Mauss S. Lack of a pharmacokinetic effect between steady-state tipranavir/ritonavir (TPV/r) and single-dose valacyclovir in healthy volunteers. 48th Interscience Conference on Antimicrobial Agents and Chemotherapy, Washington, October 2008. Abstract A-967.

Protease inhibitors + Antiepileptics; Miscellaneous

Stiripentol did not alter single-dose saquinavir pharmacokinetics in a controlled study. In one case report, ritonavir did not alter zonisamide levels. Ritonavir is predicted to increase ethosuximide levels.

Clinical evidence, mechanism, importance and management

(a) Ethosuximide

The US manufacturer advises that **ritonavir** may increase the levels of ethosuximide, and that a dose reduction of ethosuximide may be needed with concurrent use and monitoring is advised.[1] However, the UK manufacturer[2] does not mention this interaction, and there appear to be no published clinical data regarding this.

(b) Stiripentol

In a crossover study in 12 healthy subjects,[3] stiripentol 1 g twice daily for 8 days had no effect on the pharmacokinetics of a single 400-mg dose of **saquinavir** given on day 8. No dose adjustment of unboosted saquinavir [now not recommended] appears to be needed with the concurrent use of

stiripentol. However, the effects of using ritonavir-boosted saquinavir with stiripentol have not been reported. Further study is needed.

(c) Zonisamide

A 20-year-old HIV-positive man with epilepsy, who had his seizures controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking **ritonavir**, and after the first 200-mg dose his zonisamide levels remained unchanged.[4] However, his levels of carbamazepine were almost doubled.

Protease inhibitors + Atovaquone

Atovaquone modestly reduces the minimum level of indinavir. Ritonavir alone, or used as a pharmacological booster for other protease inhibitors, is predicted to decrease atovaquone levels.

Clinical evidence, mechanism, importance and management

(a) Indinavir

Preliminary results from a study in healthy subjects suggest that the concurrent use of atovaquone 750 mg twice daily and indinavir 800 mg three times daily results in a minor 5% decrease in the AUC of indinavir, and a 13% increase in the AUC of atovaquone.[1] The UK manufacturer of atovaquone notes that concurrent use decreased the minimum level and AUC of indinavir by 23% and 9%, respectively. They recommend that caution should be exercised on concurrent use because of the potential risk of indinavir treatment failure.[2] However, note that the effect on indinavir was small and it is often used with other antiretrovirals, which might modify the interaction by affecting indinavir levels. The UK manufacturer of indinavir states that as **ritonavir** is predicted to affect atovaquone glucuronidation, caution and careful monitoring is needed when ritonavir-boosted indinavir is taken with atovaquone.[3] See also *Ritonavir*, below.

(b) Ritonavir

The manufacturer of ritonavir predicts that it will decrease the plasma levels of atovaquone,[4,5] by inducing atovaquone glucuronidation.[5] They say that the clinical significance of this prediction is unknown, but that an increase in the atovaquone dose might be needed.[4] However, the manufacturer of atovaquone[2] states that there are no data regarding an interaction between atovaquone and protease inhibitors other than indinavir (see above). Careful monitoring of serum levels and/or therapeutic effects is recommended when atovaquone is given with ritonavir, either as a pharmacokinetic enhancer or as an antiretroviral.[5] This predicted interaction would therefore apply to ritonavir-boosted **lopinavir**[6] and any other ritonavir-boosted protease inhibitor. However, there does not appear to be any data to confirm that the interaction occurs or is clinically relevant.

Protease inhibitors + Azoles; Fluconazole

Fluconazole may modestly increase the levels of amprenavir, saquinavir and tipranavir, but does not significantly affect atazanavir, indinavir, lopinavir, nelfinavir, or ritonavir levels.

Clinical evidence

A study in 9 HIV-positive patients taking **amprenavir** 600 mg to 750 mg, **lopinavir** 400 mg to 533 mg and **ritonavir** 100 mg to 233 mg, all twice daily, found that the addition of fluconazole 100 mg daily increased the trough plasma levels of **amprenavir**, **lopinavir** and **ritonavir** by 66%, 18%, and 35%, respectively.[1]

The manufacturer of **atazanavir** reports that fluconazole 200 mg daily had no significant effect on the pharmacokinetics of ritonavir-boosted atazanavir 100/300 mg daily. Fluconazole concentrations were unaffected by ritonavir-boosted **atazanavir**.[2]

A study in 8 healthy subjects found that fluconazole 400 mg on day one, followed by 200 mg daily for 4 days did not alter any of the pharmacokinetic parameters of **ritonavir** 200 mg every 6 hours by more than 15%.[3] Similarly, fluconazole had no effect on the pharmacokinetics of **ritonavir** in 3 HIV-positive subjects.[4]

The pharmacokinetics of both **indinavir** 1 g every 8 hours and fluconazole 400 mg daily were not significantly affected by concurrent use in 11 HIV-positive patients.[5] Another study also found no significant interaction between **indinavir** and fluconazole.[6]

A population pharmacokinetic analysis estimated that fluconazole decreased **nelfinavir** clearance by 26 to 30%, but this was not considered clinically significant.[7] The effects of concurrent ritonavir on the interaction of fluconazole with nelfinavir in 3 patients has been reported. In one patient taking **nelfinavir** 1.25 g twice daily with ritonavir-boosted **lopinavir** 133.3/533.3 mg twice daily, the addition of fluconazole 100 mg twice daily for 4 weeks significantly increased the AUC, maximum plasma concentration and trough plasma concentration of **nelfinavir** by 2.44-fold, 2,12-fold, and 2.6-fold, respectively. The levels of the M8 metabolite of nelfinavir were barely detected in the presence of fluconazole. In two other patients taking **nelfinavir** 1.25 g twice daily with stavudine 40 mg twice daily and either efavirenz 800 mg daily or abacavir 300 mg twice daily, the same fluconazole course had no significant effect on the pharmacokinetics of **nelfinavir** or its metabolite.[8]

In a study in 5 HIV-positive subjects, fluconazole 400 mg on day 2, followed by 200 mg daily for 6 days increased the median AUC of **saquinavir** by 50%, and the maximum level by 56%.[4]

In a study in 20 healthy subjects, fluconazole 100 mg daily increased the AUC, maximum plasma levels and minimum plasma levels of ritonavir-boosted **tipranavir** 200/500 mg twice daily by 50%, 32%, and 69%, respectively. Fluconazole levels were not affected.[9]

Mechanism

Fluconazole is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4 by which the protease inhibitors are metabolised.[3,5] Fluconazole also inhibits CYP2C9 and CYP2C19; one study[1] suggested that in the presence of ritonavir (an inhibitor of CYP3A4) fluconazole will have a more significant inhibitory effect on CYP2C9 than CYP3A4. This is supported by the study of the effects of fluconazole on nelfinavir pharmacokinetics in the absence or presence of ritonavir which suggested that the effect of fluconazole on CYP2C19 may be increased by ritonavir.[8]

Importance and management

Fluconazole appears to have no clinically significant effects on the pharmacokinetics of atazanavir, indinavir, and ritonavir. The small to modest changes in the pharmacokinetics of saquinavir seen with fluconazole are unlikely to be of clinical significance. Similarly, the modest effects of fluconazole on nelfinavir pharmacokinetics found in the population analysis are not expected to be of clinical relevance.[10] However, the case of significantly raised nelfinavir levels suggests that in some cases a clinically relevant interaction may occur in patients taking also taking ritonavir. Bear the potential for an interaction in mind should a patient develop raised nelfinavir levels and/or adverse effects.

Because fluconazole causes a more significant increase in tipranavir levels, the manufacturer of tipranavir states that fluconazole, in doses of greater than 200 mg daily, is not recommended. No dose adjustments are recommended for lower doses of fluconazole.[11,12]

Protease inhibitors + Azoles; Itraconazole

Itraconazole increases the levels of fosamprenavir, indinavir, ritonavir-boosted lopinavir, and saquinavir, and may theoretically increase the levels of other protease inhibitors. Similarly, some protease inhibitors may also increase itraconazole levels, and cases of raised itraconazole levels and adverse effects have been reported. No significant interaction is predicted to occur between itraconazole and nelfinavir.

Clinical evidence

Two patients taking **indinavir**, and another taking **ritonavir**-boosted **saquinavir**, who were also given itraconazole, developed eczematous eruptions and raised serum transaminases. These effects may be seen with protease inhibitors alone, and were attributed to raised levels of both medications, arising from concurrent use. The patient taking **ritonavir**-boosted **saquinavir** had a very prolonged itraconazole half-life.[1] In another patient, the itraconazole dose was halved when ritonavir-boosted **lopinavir** was started, and after 5 weeks of concurrent use the itraconazole half-life had increased about tenfold, although no signs of itraconazole toxicity were seen.[2] In a study in 17 HIV-positive patients, itraconazole caused a median fivefold increase in the AUC of **saquinavir**, and it was considered that itraconazole may be an alternative to **ritonavir** for boosting **saquinavir** levels;[3] another study has investigated this potential use.[4] The UK manufacturer says that giving **indinavir** 600 mg every 8 hours with itraconazole 200 mg twice daily produces an AUC similar to that achieved when **indinavir** 800 mg every 8 hours is given alone.[5] The manufacturers report that in a study in 12 subjects, itraconazole 200 mg twice daily for 7 days increased the trough level of **indinavir** 600 mg three times daily for 7 days by 49%.[5,6]

Mechanism

Itraconazole is a known substrate and potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism. Thus enzyme inhibition and competition for metabolism results in raised serum levels of both drugs.

Importance and management

Information about the interactions of protease inhibitors with itraconazole is limited. The UK manufacturer of itraconazole states that protease inhibitors (such as **indinavir**, **ritonavir**, and **saquinavir**) should be used with caution with itraconazole. They advise close monitoring of concurrent use and note that a dose reduction of the protease inhibitor may be required.[7] The US manufacturer specifically states that the levels of indinavir, ritonavir, and saquinavir may be increased by itraconazole, and also note that indinavir and ritonavir may increase itraconazole levels.[8] On the basis of the available data, it is possible that itraconazole has greater effects than ketoconazole on protease inhibitor levels, consider 'Protease inhibitors + Azoles; Ketoconazole', p.964. The manufacturers of indinavir advise reducing the indinavir dose to 600 mg every 8 hours if it is to be given with itraconazole.[5,6] As both indinavir and ritonavir can inhibit CYP3A4, and as the use of ritonavir-boosted indinavir with itraconazole has not been specifically studied, the manufacturers advise close monitoring for itraconazole adverse effects.[5] The UK manufacturer of saquinavir recommends monitoring for saquinavir toxicity if itraconazole is used but states that no data are available for ritonavir-boosted saquinavir.[9]

Some protease inhibitors, especially ritonavir and possibly indinavir, may increase itraconazole levels and most manufacturers say that doses of itraconazole greater than 200 mg a day are not recommended. The US manufacturers[10] of **fosamprenavir** recommend increased monitoring for adverse effects and state that the dose of itraconazole may need to be reduced if it is greater than 400 mg daily. However, both manufacturers advise against the use of itraconazole doses greater than 200 mg daily when fosamprenavir is taken with ritonavir.[10,11]

The US manufacturer[12] of **nelfinavir** suggests that, based on the known pharmacokinetics of both nelfinavir and itraconazole, no significant interaction is likely to occur; the modest changes in nelfinavir pharmacokinetics seen with ketoconazole, another potent inhibitor of CYP3A4, support this prediction. Consider also 'Protease inhibitors + Azoles; Ketoconazole', p.964.

Protease inhibitors + Azoles; Ketoconazole

Most protease inhibitors increase the levels of ketoconazole. Ketoconazole may increase the levels of the protease inhibitors.

Clinical evidence

(a) Amprenavir or Fosamprenavir

In a single-dose study, amprenavir 1.2 g caused a modest 44% increase in the AUC of ketoconazole 400 mg. The AUC of amprenavir was also increased by 32%.[1] In a study in 15 healthy subjects, ritonavir-boosted fosamprenavir 100/700 mg twice daily taken for 10 days increased the AUC and maximum plasma concentration of ketoconazole 200 mg daily (taken from days 6 to 10) 2.69-fold and by 25%, respectively. However, in this study, the pharmacokinetics of amprenavir were unaffected by ketoconazole, and the AUC and maximum plasma concentration of ritonavir were slightly increased by 13% and 17%, respectively.[2]

(b) Atazanavir

The pharmacokinetics of atazanavir 400 mg daily were not affected by the concurrent use of ketoconazole 200 mg daily for 7 days.[3]

(c) Darunavir

In a study in healthy subjects, ketoconazole 200 mg twice daily for 13 doses increased the $AUC_{0\text{-}12}$, maximum plasma level and minimum plasma level of darunavir by 155%, 78%, and 179%, respectively. However, when ritonavir 100 mg twice daily was added to darunavir 400 mg twice daily, the same dose of ketoconazole had a much less pronounced effect on darunavir levels: the $AUC_{0\text{-}12}$, maximum plasma level and minimum plasma level of darunavir were increased by 42%, 21%, and 73%, respectively. Darunavir alone had no significant effect on the pharmacokinetics of ketoconazole; however, ritonavir-boosted darunavir increased the $AUC_{0\text{-}12}$, maximum plasma level and minimum plasma level of ketoconazole 3.1-fold, 2.1-fold, and 9.7-fold, respectively. Ketoconazole had no signif-

icant effects on the pharmacokinetics of ritonavir. The incidence of adverse effects was similar for all the treatment regimens.[4]

(d) Indinavir

In a study in 10 healthy subjects, ketoconazole 400 mg daily for 4 doses increased the AUC of a single 400-mg dose of indinavir by 62%. The maximum concentration was increased by 14%, which is not clinically significant.[5]

(e) Lopinavir

A single 200-mg dose of ketoconazole had no effect on the pharmacokinetics of lopinavir (taken as ritonavir-boosted lopinavir 100/400 mg twice daily). However, the AUC of ketoconazole was increased threefold by ritonavir-boosted lopinavir.[6] In contrast, in an HIV-positive patient, ketoconazole 200 mg daily for 14 days was associated with a 68% increase in trough lopinavir levels and a 33% increase in ritonavir levels.[7]

(f) Nelfinavir

In a study in healthy subjects, ketoconazole increased the AUC of nelfinavir by 35%. Nelfinavir had no significant effect on the pharmacokinetics of ketoconazole. The doses and duration of treatment with ketoconazole and nelfinavir were not reported.[8]

(g) Ritonavir

The manufacturers report that, in a study in 12 subjects, ritonavir 500 mg twice daily for 10 days increased the AUC of ketoconazole 200 mg daily for 7 days 3.4-fold and increased the maximum plasma level by 60%.[9,10] The pharmacokinetics of ritonavir were minimally affected.[10]

(h) Saquinavir

In one early clinical study, patients who received ketoconazole with saquinavir had a greater drop in viral load after 3 months than those not receiving ketoconazole.[11] However, in one pharmacokinetic study in 7 HIV-positive patients, ketoconazole 200 mg daily for 7 days then 400 mg daily for 7 days had no consistent effect on saquinavir peak and trough plasma levels, although inter-individual variability was great. Saquinavir (as hard gelatin capsules[12]) was given at the low dose of 600 mg three times daily.[13] Conversely, when saquinavir (soft gel capsule) 1.2 g three times daily was given to 12 healthy subjects with ketoconazole 400 mg daily for 7 days, the saquinavir AUC and maximum plasma levels were raised by 190% and 171%, respectively.[12] A similar study in 22 HIV-positive patients, using ketoconazole 200 mg daily, found that the saquinavir AUC and maximum plasma levels were raised by 69% and 36%, respectively.[12]

In 12 HIV-positive patients, ketoconazole 200 mg or 400 mg increased the AUC of saquinavir and ritonavir in combination (both 400 mg twice daily) by 37% and 29%, respectively. The distribution of ritonavir was also affected, with disproportionate rises seen in CSF concentrations. All these changes appeared to be unrelated to the dose of ketoconazole used.[14]

The peak plasma level of ketoconazole 400 mg daily was similar to that usually seen with ketoconazole 800 mg alone when ritonavir-boosted saquinavir were given.[14] Moreover, in this study, dose escalation to higher doses of ketoconazole was discontinued as the first patient given ketoconazole 600 mg daily stopped treatment early because of adverse gastrointestinal effects.[14] However, saquinavir alone did not affect ketoconazole pharmacokinetics.[12] A further study in 25 stable HIV-positive patients investigated the potential for using ketoconazole rather than ritonavir as a pharmacological booster for saquinavir. Patients were given ritonavir-boosted saquinavir 100/2000 mg daily for at least 4 weeks before ritonavir was changed to ketoconazole 400 mg daily for 2 weeks. The AUC, maximum plasma level and minimum plasma level of saquinavir were 80%, 69%, and 67% lower, respectively, in the ketoconazole-boosted regimen than in the ritonavir-boosted regimen. Thirteen patients given ketoconazole compared with 2 patients given ritonavir had saquinavir levels below the minimum recommended level. A positive correlation between the AUC of ketoconazole and saquinavir was noted.[15] In another study in 32 healthy subjects, ketoconazole 200 mg daily had no significant effect on the pharmacokinetics of ritonavir-boosted saquinavir 100/1000 mg twice daily. However, the $AUC_{0\text{-}12}$ and maximum plasma concentration of ketoconazole were increased by 168% and 45%, respectively. No significant increase in adverse effects was reported.[16]

Mechanism

Ketoconazole is a known substrate and inhibitor of the cytochrome P450 isoenzyme CYP3A4, and the protease inhibitors also inhibit and share this pathway of metabolism.[1,12,14] Thus enzyme inhibition, and competition for metabolism results in raised serum levels of both drugs. Ketoconazole may also inhibit the P-glycoprotein transport of saquinavir and ritonavir, causing a decrease in their clearance, and raising serum levels.[12,14] Inhibition of P-glycoprotein may reduce the transport of protease inhibitors out of the CSF, so increasing CSF levels.[14]

Importance and management

The magnitude of the changes in the pharmacokinetics of the protease inhibitors seen with ketoconazole are unlikely to warrant dose changes of the protease inhibitors or cause significant increase in their adverse effects, although the manufacturer of ketoconazole advises that a protease inhibitor dose reduction may be needed.

The manufacturers of **indinavir** recommend considering reducing the dose of indinavir to 600 mg every 8 hours in the presence of ketoconazole.[17,18]

The significant increase seen with unboosted **darunavir** is unlikely to be of significance in clinical practice, as it is usually combined with low-dose ritonavir, and the interaction between ritonavir-boosted darunavir and ketoconazole is modest in comparison.

The data on the effect of protease inhibitors on ketoconazole are more limited. A marked effect was seen for ritonavir alone, and for ritonavir-boosted **darunavir**, **fosamprenavir**, **lopinavir**, **saquinavir**, and theoretically **tipranavir**. This may increase the adverse effects of ketoconazole. Most protease inhibitor manufacturers say that ketoconazole in doses of greater than 200 mg daily is not recommended. The US manufacturer of **fosamprenavir** states that if unboosted fosamprenavir is given with a dose of ketoconazole greater than 400 mg daily, the ketoconazole dose may need to be reduced: increased monitoring for ketoconazole adverse effects is advised.[19] However, both the UK and US manufacturers advise against the use of ketoconazole doses greater than 200 mg daily when fosamprenavir is taken with ritonavir.[19,20] Similarly, the UK manufacturers of ketoconazole and **ritonavir** say that, due to an increase in gastrointestinal and hepatic adverse effects, a dose reduction of ketoconazole should be considered when it is given with ritonavir (either at full dose or when it is used to boost the effects of other protease inhibitors).[9,21]

Protease inhibitors + Azoles; Miscellaneous

Systemic clotrimazole is predicted to increase the levels of darunavir, and miconazole is predicted to increase the levels of the protease inhibitors, such as saquinavir. An interaction between the protease inhibitors and topical or intravaginal azoles is unlikely.

Clinical evidence, mechanism, importance and management

The extent of absorption from many topical or intravaginal azole antifungals is low, and therefore the likelihood of an interaction with the protease inhibitors is small, see 'Azoles; Topical + Miscellaneous', p.251. More specific information on individual azoles that are most commonly used topically is given below

(a) Clotrimazole

The UK manufacturer of **darunavir** reports that the concurrent use of systemic clotrimazole increased the AUC of **darunavir** (from ritonavir-boosted darunavir) by a mean of 33% (using a population pharmacokinetic model). They suggest that clotrimazole may inhibit **darunavir** metabolism by the cytochrome P450 isoenzyme CYP3A4, and therefore advise close monitoring when clotrimazole is taken with ritonavir-boosted darunavir.[1] However, this modest increase in darunavir levels is unlikely to be of clinical significance and there appears to be no published data to support the suggestion that clotrimazole has a clinically relevant effect on darunavir levels. The US manufacturers give no specific advice regarding this interaction.[2]

(b) Miconazole

The UK manufacturer of miconazole oral gel states that it may inhibit the metabolism of drugs by CYP3A4 and they specifically name **saquinavir**.[3] However, the UK manufacturer of **saquinavir** states that an interaction between ritonavir-boosted **saquinavir** and miconazole has not been studied.[4] The US manufacturers make no specific comment regarding the possibility of an interaction between miconazole and saquinavir.[5] Note that a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction.

Protease inhibitors + Azoles; Posaconazole

Posaconazole appears to increase the AUC of both atazanavir and ritonavir-boosted atazanavir. Other protease inhibitors are predicted to be similarly affected.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, oral posaconazole 400 mg twice daily given with **atazanavir** 300 mg daily for 7 days, increased the maximum serum levels and AUC of **atazanavir** about 2.6-fold and 3.7-fold, respectively. When the study was repeated with **ritonavir**-boosted **atazanavir** 100/300 mg daily, the maximum serum levels and AUC of **atazanavir** were increased by about 50%, and 2.5-fold, respectively, and plasma bilirubin levels were increased.

These effects probably occur because posaconazole, a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, decreases the metabolism of **atazanavir** by this isoenzyme, leading to an increase in both its levels and adverse effects. The manufacturer of posaconazole recommends that patients should be carefully monitored for **atazanavir** adverse effects and toxicity during concurrent use.[1] Other protease inhibitors are predicted to interact similarly, and the same precautions are advisable.

1. Noxafil (Posaconazole). Schering-Plough Ltd. UK Summary of product characteristics, November 2009.

Protease inhibitors + Azoles; Voriconazole

The current use of protease inhibitors and voriconazole is predicted to interfere with the metabolism of both drugs. Ritonavir appears to decrease voriconazole levels in most patients, although some individuals may conversely have increased voriconazole levels. No interaction appears to occur between indinavir and voriconazole.

Clinical evidence

(a) Indinavir

The manufacturers note that *in vitro* studies suggest that the metabolism of protease inhibitors may be inhibited by voriconazole, and the metabolism of voriconazole may be inhibited by protease inhibitors.[1,2] However, in a study in 18 healthy subjects, the pharmacokinetics of both indinavir 800 mg three times daily and voriconazole 200 mg twice daily were unaffected by at least one week of concurrent use.[3]

(b) Ritonavir

In a study in 29 healthy subjects, ritonavir 400 mg twice daily for 10 days decreased the mean steady-state maximum plasma levels and $AUC_{0\text{-}12}$ of oral voriconazole (400 mg twice daily for one day, then 200 mg twice daily for 9 days) by 68% and 83%, respectively, although one subject had a 2.5-fold *increase* in the steady-state maximum levels and $AUC_{0\text{-}12}$ of voriconazole. Large intersubject variability in ritonavir levels were reported with some subjects having a 50% decrease and others a twofold increase during voriconazole exposure. Overall these changes were not considered statistically significant. Low-dose ritonavir (100 mg daily) decreased the mean $AUC_{0\text{-}12}$ and the maximum plasma concentration of voriconazole by 39% and 24%, respectively. However 4 subjects had increases in voriconazole exposure, which was modest in 3 of them (increases of between 10% and 42%) but in one subject threefold increases occurred.[4]

In contrast, a study in 20 healthy subjects also found that ritonavir 300 mg twice daily for 2 days significantly reduced the oral clearance of a single 400-mg dose of voriconazole, given with the first dose of ritonavir. This effect was much greater in those patients who were poor metabolisers of CYP2C19 (those lacking or deficient in this isoenzyme) than those who had normal levels of CYP2C19 (i.e. extensive metabolisers).[5]

Mechanism

Voriconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4: protease inhibitors are also metabolised by this route, and can, to varying degrees, also inhibit this isoenzyme. Voriconazole is primarily metabolised by CYP2C9 and CYP2C19, with some minor involvement from CYP3A4. Ritonavir is known to induce the CYP2C9 and CYP2C19 isoenzymes, leading to a reduction in voriconazole levels.[4] Some individuals may have low levels or lack the isoenzyme CYP2C19 (poor metabolisers), an isoenzyme subject to 'genetic polymorphism', (p.4), and other routes of metabolism may take precedence. In this case, CYP3A4 may have developed a more prominent role in voriconazole metabolism. As ritonavir has an overall inhibitory effect on CYP3A4, it is possible that the individuals with significantly raised voriconazole levels were poor metabolisers of CYP2C19. However the authors do note that these subjects were not phenotyped.[4]

Importance and management

Based on the evidence of significantly reduced voriconazole levels and the possible risk of voriconazole treatment failure, the manufacturers say that the concurrent use of **ritonavir** (at doses of 400 mg and above twice daily) is contraindicated.[1,6] The manufacturers also recommend that when ritonavir is used as a pharmacokinetic enhancer (usually 100 mg twice daily) voriconazole should only be given if the benefits outweigh the risks.[1,2,6] Conversely, it should be borne in mind that voriconazole levels may be *increased* by ritonavir in some individuals should voriconazole adverse effects develop.

Most protease inhibitors are given with ritonavir as a pharmacokinetic

enhancer; however, caution is also warranted if they are given alone, as all protease inhibitors can inhibit CYP3A4 to some extent and may therefore also increase voriconazole levels. Voriconazole may also affect protease inhibitor levels, but other than ritonavir and **indinavir**, which are not significantly affected, this does not appear to have been studied. Be aware that some increase in their levels is theoretically possible if voriconazole is given. The manufacturer of voriconazole suggests that patients should be carefully monitored for evidence of drug toxicity and/or loss of efficacy during concurrent use of other HIV-protease inhibitors (**amprenavir**, **nelfinavir** and **saquinavir** are specifically mentioned).[1]

Protease inhibitors + Barbiturates

Phenobarbital and other barbiturates are predicted to increase the metabolism of the protease inhibitors, thereby reducing their levels and possibly resulting in failure of the antiretrovirals. However, one case suggested that this may not have occurred with primidone and ritonavir with saquinavir. Another case reported unchanged phenobarbital levels when a patient was changed from indinavir to ritonavir and saquinavir.

Clinical evidence, mechanism, importance and management

The manufacturers of many of the protease inhibitors predict that their levels may be reduced by **phenobarbital**, due to induction of the cytochrome P450 isoenzyme CYP3A4 by which they are metabolised. The UK manufacturer of **darunavir** notes that when it is boosted with ritonavir, concurrent phenobarbital is not recommended as it may significantly reduce darunavir levels.[1] In contrast, the US manufacturer of **darunavir** notes that its levels are not affected by **phenobarbital**, although **phenobarbital** levels may be decreased by **ritonavir**-boosted **darunavir**.[2]

There do not appear to be any controlled studies to demonstrate the extent of the pharmacokinetic interaction between **phenobarbital** and different protease inhibitors. Data from one case report of carbamazepine toxicity with ritonavir-boosted saquinavir provides indirect evidence to suggest that the interaction with **primidone** is not clinically important. In this report, a patient taking an antiretroviral regimen including **ritonavir** and **saquinavir** had his antiepileptic medication changed from carbamazepine to **primidone** 500 mg daily, due to raised carbamazepine levels and toxicity. The authors noted that during follow-up (duration not stated), viral load was still undetectable and seizures remained under control.[3] **Primidone** is metabolised to **phenobarbital**, and might have been expected to cause antiretroviral therapy failure. Alternatively, the effect of **ritonavir**, which is a potent inhibitor of CYP3A4, may have been sufficient to offset any increased clearance associated with **phenobarbital**.

Another patient taking **phenobarbital**, phenytoin and carbamazepine was found to have unchanged phenobarbital levels 2 days after switching from an antiretroviral regimen including **indinavir** to one containing **ritonavir** 300 mg twice daily and **saquinavir**. His plasma levels of carbamazepine had doubled, and there was a 33% drop in the levels of phenytoin.[4] For further discussion about the interaction of carbamazepine or phenytoin with the protease inhibitors, see 'Protease inhibitors + Carbamazepine', p.967, and 'Protease inhibitors + Phenytoin', p.977.

The combination of protease inhibitors and barbiturates should be used with caution, with increased monitoring of antiviral efficacy.

Protease inhibitors + Cannabinoids

The short-term use of cannabis cigarettes or dronabinol (Δ^9-tetrahydrocannabinol) did not appear to adversely affect indinavir or nelfinavir levels or viral loads in HIV-positive patients.

Clinical evidence

In 9 HIV-positive patients on a stable regimen containing **indinavir** (mostly 800 mg every 8 hours), smoking a **cannabis cigarette** (3.95% tetrahydrocannabinol) three times daily before meals for 14 days resulted in a median 14% decrease in AUC and maximum level and a 34% decrease in minimum indinavir level. However, only the change in maximum level was statistically significant.[1] Similarly, **dronabinol** (Δ^9-tetrahydrocannabinol) 2.5 mg three times daily for 14 days had no significant effect on **indinavir** pharmacokinetics.[1]

In another 11 patients on a stable regimen containing **nelfinavir** 750 mg three times daily, there was a non-significant 10% decrease in the AUC, a 17% decrease in maximum level, and a 12% decrease in minimum nelfinavir level after 14 days of **cannabis cigarettes.**[1] Similarly, **dronabinol** 2.5 mg three times daily for 14 days had no significant effect on **nelfinavir** pharmacokinetics.[1]

There was no adverse effect on viral load or CD4 count in the patients receiving cannabis cigarettes or dronabinol.[2]

Mechanism

Unknown.

Importance and management

Short-term use of cannabis cigarettes or dronabinol does not appear to have any important effect on levels of indinavir or nelfinavir, nor on markers of HIV infection.

Protease inhibitors + Carbamazepine

Case reports suggest that ritonavir markedly increases carbamazepine levels and toxicity. Cases have also been reported with ritonavir-boosted lopinavir, and nelfinavir. Ritonavir-boosted darunavir also appears to increase the levels of carbamazepine. Carbamazepine reduces indinavir levels and efficacy, reduces tipranavir levels, and would also be expected to decrease the levels of other protease inhibitors.

Clinical evidence

(a) Darunavir

The manufacturer reports that ritonavir-boosted darunavir 100/600 mg twice daily increased the $AUC_{0\text{-}12}$ and trough level of carbamazepine 200 mg twice daily by 45% and 54%, respectively. The $AUC_{0\text{-}12}$ of ritonavir was reduced by 49%. The pharmacokinetics of darunavir were unaffected by carbamazepine.[1]

(b) Indinavir

A report describes a 48-year-old man whose antiretrovirals (indinavir 800 mg every 8 hours, lamivudine 150 mg twice daily and zidovudine 200 mg three times daily) became ineffective after a 10-week course of carbamazepine for postherpetic neuralgia. Over this time indinavir levels were up to 16 times lower than those measured in the absence of carbamazepine.[2] In two further cases, patients taking carbamazepine had partial failure of indinavir-containing antiretroviral regimens, which prompted a change in their therapy to include ritonavir rather than indinavir.[3,4]

In 3 of the case reports described under *Ritonavir*, below, in which ritonavir increased carbamazepine levels,[3-5] patients had previously received indinavir (800 mg three times daily[3,5]) and carbamazepine (600 mg daily[3,4] or 400 mg three times daily[5]) without experiencing carbamazepine

toxicity (therapeutic carbamazepine levels were reported in 2 of the cases[3,4]). This suggests that indinavir does not increase carbamazepine levels. However, in the case described above,[2] carbamazepine levels reached the therapeutic range for epilepsy even though the dose of carbamazepine was only 200 mg daily, suggesting indinavir may increase carbamazepine levels in some patients.

(c) Lopinavir

An HIV-positive patient who had a serum carbamazepine level of 10.3 mg/L while taking carbamazepine 400 mg three times daily reported feeling very drowsy within 9 days of starting to take tenofovir, lamivudine and ritonavir-boosted lopinavir 100/400 mg twice daily. His carbamazepine serum level was found to have increased by 46%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 7.4 mg/L.[6]

(d) Nelfinavir

An HIV-positive patient who had a serum carbamazepine level of 9.8 mg/L while taking carbamazepine 400 mg three times daily started feeling more tired and unsteady on his feet 3 days after starting to take tenofovir, lamivudine and nelfinavir 1.25 g twice daily. His carbamazepine level was found to have increased by 53%, to 15 mg/L. The carbamazepine dose was reduced to 400 mg twice daily, and 2 days later the carbamazepine level was 9.3 mg/L.[6]

(e) Ritonavir

An 20-year-old HIV-positive man with epilepsy, whose seizures had been controlled with carbamazepine 350 mg twice daily and zonisamide 140 mg twice daily, was admitted to hospital for review of his antiretrovirals. He started taking ritonavir 200 mg three times daily, but after the first dose of ritonavir his serum carbamazepine levels rose from 9.5 mg/L to 17.8 mg/L. This was accompanied by intractable vomiting and vertigo, so after 2 days the ritonavir was stopped. Symptoms resolved over the next few days. Subsequently ritonavir 200 mg daily was started, with the same effect, so the carbamazepine dose was reduced by two-thirds, which resulted in carbamazepine levels of 6.2 micrograms/mL. Levels of ritonavir were not measured.[7] Three other cases also document two- to threefold rises in carbamazepine levels with associated toxicity caused by the addition of ritonavir 300 mg, 400 mg or 600 mg twice daily and **saquinavir** 400 mg twice daily.[3-5] In one case, an increase in carbamazepine levels was not expected as the effects of '**efavirenz**', (p.925), an inducer of CYP3A4, which can reduce carbamazepine levels, were expected to balance the inhibitory effects of ritonavir and saquinavir. However, the patient needed a carbamazepine dose reduction from 600 mg daily to 100 mg daily to keep the levels within the therapeutic range, before ritonavir was discontinued.[4]

(f) Tipranavir

Carbamazepine 200 mg twice daily reduces the minimum levels of tipranavir (dose not stated) by 61%, when compared with historical controls. This may result in reduced tipranavir effectiveness. The minimum levels of carbamazepine and its active metabolite were increased by 23%, which is not expected to be clinically significant.[8] In a multiple dose study, 17 subjects were given carbamazepine 200 mg twice daily for 43 doses and ritonavir-boosted tipranavir 200/500 mg [twice daily] for 15 doses. The minimum levels of carbamazepine were increased by 35% and the AUC was increased by 26%. A similar study, in which carbamazepine was given at a dose of 100 mg twice daily, found no clinically significant interaction.[9]

Mechanism

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly increases the levels of carbamazepine, which is metabolised by this isoenzyme. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also 'Antivirals', (p.913)). Moreover, carbamazepine is an inducer of CYP3A4, and therefore can increase the metabolism of protease inhibitors causing the levels to become subtherapeutic. The use of ritonavir-boosted protease inhibitors could theoretically offset this effect, but it may lead to increased carbamazepine toxicity.

Importance and management

Although the evidence is limited, these interactions seem to be established. It would therefore appear that the use of carbamazepine with protease inhibitors should be avoided where possible (mainly because of the risk of antiviral treatment failure). If both must be used then extremely close monitoring of both antiviral efficacy and carbamazepine levels/toxicity is warranted. Symptoms of carbamazepine toxicity include nausea, vomiting, ataxia and drowsiness.

The UK manufacturer of darunavir suggests that the dose of carbamazepine may need to be reduced by 25 to 50%, according to clinical effect, if it is given with ritonavir-boosted darunavir; no dose adjustment of ritonavir-boosted darunavir is required.[1] The US manufacturer advises that no initial dose adjustment of carbamazepine is needed but that the dose should then be adjusted according to clinical response and carbamazepine levels.[10] The authors of one report suggest that amitriptyline or gabapentin would be possible alternatives for carbamazepine used for pain, or valproic acid or lamotrigine for carbamazepine used for seizures.[2] However, note that ritonavir is predicted to increase the levels of amitriptyline, so caution is needed on concurrent use, see 'Tricyclic and related antidepressants + Protease inhibitors', p.1511. Furthermore, reduced lamotrigine and valproate levels have also been reported with ritonavir-boosted protease inhibitors, see 'Protease inhibitors + Lamotrigine', p.974, and 'Protease inhibitors + Valproate', p.988.

Protease inhibitors + Cat's claw (*Uncaria tomentosa*)

An isolated case report describes raised atazanavir, ritonavir and saquinavir levels following the use of cat's claw.

Clinical evidence

An HIV-positive woman awaiting liver transplantation, taking **atazanavir** 300 mg daily, **ritonavir** 100 mg daily and **saquinavir** 1 g daily, in combination with abacavir 600 mg daily and lamivudine 300 mg daily, was found to have an increased trough level of all three protease inhibitors. **Atazanavir** trough levels were 1.22 micrograms/mL (expected range of 0.15 to 0.18 micrograms/mL), **ritonavir** trough levels were 6.13 micrograms/mL (expected level of 2.1 micrograms/mL), and **saquinavir** trough levels were 3.4 micrograms/mL (expected range 0.1 to 0.25 micrograms/mL). On further questioning, the patient reported no change in her compliance with the medication but reported that she been taking a herbal supplement containing cat's claw for the previous 2 months. No evidence of protease inhibitor related toxicity was found and the patient reported no adverse effects. The supplement was stopped and by day 15 the levels of all three drugs had returned to within normal limits.[1]

Mechanism

In vitro studies suggested that cat's claw may inhibit the cytochrome P450 isoenzyme CYP3A4, the main isoenzyme responsible for the metabolism of atazanavir, ritonavir and saquinavir; however, the results of this study are questionable.

Importance and management

Evidence appears to be limited to one case report from which it is difficult to draw general conclusions. What it illustrates is that more research is needed into the use of cat's claw with protease inhibitors. Patients taking drugs for serious conditions such as HIV-infection should carefully con-

sider the risks and benefits of adding herbal medicines to their existing regimen, where the outcome of concurrent use is unknown.

Protease inhibitors + Co-trimoxazole

Minor pharmacokinetic changes have been seen when co-trimoxazole is given with the protease inhibitors.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given **indinavir** 400 mg every 6 hours with co-trimoxazole 960 mg every 12 hours found that there was no change in the AUC of **indinavir**, but a small 17% decrease in **indinavir** trough levels occurred. In addition, there was an 18% increase in the AUC of **trimethoprim**, and a 5% increase in the AUC of **sulfamethoxazole**. None of these changes were considered to be clinically important.[1] A retrospective cohort study in 781 patients taking **indinavir** reported that the concurrent use of prophylactic co-trimoxazole in 362 patients was not associated with an increased risk of developing **indinavir**-related renal toxicity.[2]

In a study in 15 healthy subjects, **ritonavir** 500 mg twice daily caused a 20% increase in the AUC of **trimethoprim** and a 20% decrease in the AUC of **sulfamethoxazole** from a single 960-mg dose of co-trimoxazole. These changes were considered too small to be of clinical relevance.[3] The pharmacokinetics of **ritonavir** were not assessed.

The combination of **saquinavir** 600 mg three times daily and co-trimoxazole 960 mg three times weekly caused no changes in the pharmacokinetics of **saquinavir**.[4]

There would seem to be no reason for avoiding the use of co-trimoxazole with any of the protease inhibitors.

Protease inhibitors + Drugs that affect gastric pH

Proton pump inhibitors and H_2-receptor antagonists significantly reduce atazanavir levels. Other drugs that increase gastric pH are also predicted to reduce the plasma levels of atazanavir. Fosamprenavir may be similarly affected (moderate effects seen with ranitidine), although antacids and esomeprazole had little effect in one study. Omeprazole decreases indinavir levels and an antacid modestly decreased tipranavir levels. Neither ranitidine nor omeprazole had any effect on the levels of ritonavir-boosted darunavir or lopinavir. In contrast, cimetidine, ranitidine and omeprazole have been shown to increase saquinavir levels.

Clinical evidence

(a) Atazanavir

1. H_2-receptor antagonists. In a study in 40 healthy subjects, **famotidine** 40 mg daily, as either a single dose or in two divided doses, for 7 days minimally reduced the AUC and maximum level of ritonavir-boosted atazanavir 100/300 mg by 4 to 12% and reduced the minimum concentration by about 20%. No significant difference in this effect was seen when **famotidine** was taken at the same time as atazanavir or when it was taken 2 or 12 hours later. When ritonavir-boosted atazanavir was given 2 hours before the morning dose of **famotidine** 40 mg twice daily, the atazanavir AUC, maximum levels and minimum levels were reduced by 21%, 26%, and 28% respectively.[1] The manufacturers report that, in another study in healthy subjects, **famotidine** 40 mg twice daily reduced the atazanavir AUC, maximum levels and minimum levels by 18%, 14%, and 28%, respectively, when given simultaneously with ritonavir-boosted atazanavir 100/300 mg once daily.[2,3] A greater effect (41% reduction in AUC) was seen when the drugs were given without ritonavir.[3] In a randomised study in healthy subjects, **ranitidine** 150 mg one hour before breakfast reduced the atazanavir AUC, maximum level and minimum level by 48%, 52%, and 43%, respectively, when ritonavir-boosted atazanavir 100/300 mg daily was taken 30 minutes after breakfast.[4]

2. Proton pump inhibitors. In a study in 19 healthy subjects, the addition of **omeprazole** 20 mg daily for 7 days reduced the AUC and minimum plasma concentration of ritonavir-boosted atazanavir 100/300 mg daily by 27%, and reduced the maximum concentration by 33%. A large degree of interindividual variability was reported and in 4 subjects, the reduction in AUC and minimum plasma levels was greater than 50%. No significant increase in adverse effects occurred with omeprazole.[5]

In another study in healthy subjects, a higher dose of **omeprazole** 40 mg daily for 10 days significantly reduced the AUC, maximum concentration and minimum concentration of ritonavir-boosted atazanavir 100/300 mg daily by 76%, 72%, and 79%, respectively. Giving the protease inhibitors with cola or increasing the atazanavir dose by 100 mg daily only slightly improved these values.[6] Similar results were found in another study in healthy subjects,[4] and an even greater effect (94% reduction in AUC) was seen when atazanavir 400 mg alone was given with omeprazole 40 mg,[3] and the same effect was seen with **lansoprazole** 60 mg.[7] In one study, ritonavir levels were not affected by **omeprazole**.[4]

Atazanavir trough levels were significantly lower in patients taking proton pump inhibitors than in those taking H_2-receptor antagonists in another study.[8] A 65-year-old HIV-positive man had a marked reduction in atazanavir trough levels and AUC in a 12-hour study while receiving **esomeprazole** and ritonavir-boosted atazanavir.[9] However, 9 of 12 subjects had a successful virological outcome while taking atazanavir with or without ritonavir together with a proton pump inhibitor (**esomeprazole**, **lansoprazole**, **omeprazole**, **pantoprazole**, **rabeprazole**) in a retrospective analysis of concurrent use.[10] Another retrospective analysis also found no difference in virological outcome in 10 patients taking ritonavir-boosted atazanavir with proton pump inhibitors (**rabeprazole**, **omeprazole**) and 66 patients not taking proton pump inhibitors.[11] In a retrospective review, 10 patients were found to be taking atazanavir with a proton pump inhibitor (**esomeprazole**, **lansoprazole**, **omeprazole** or **pantoprazole**). Only 2 patients did not maintain adequate viral suppression. Omeprazole was stopped in one of these patients; however, this did not result in an improvement in viral load.[12] Another study in HIV-positive patients reported that the concurrent use of omeprazole 20 mg or 40 mg daily or rabeprazole 20 mg daily had no significant effect on the pharmacokinetics of ritonavir-boosted atazanavir.[13] Similarly, in one patient taking ritonavir-boosted atazanavir 100/300 mg daily, tenofovir and lamivudine, and **lansoprazole** 30 mg twice daily, the AUC, maximum level and minimum level of atazanavir were higher than those seen historically with ritonavir-boosted atazanavir and tenofovir.[14] Another two patients maintained virological suppression when **omeprazole** 20 mg to 40 mg daily was taken with ritonavir-boosted atazanavir 150 mg twice daily and 300 mg daily, respectively.[15,16]

(b) Darunavir

In a crossover study in 16 healthy subjects, **omeprazole** 20 mg daily and **ranitidine** 150 mg twice daily had no significant effect on the AUC or minimum level of darunavir after ritonavir-boosted darunavir 100/400 mg was given twice daily for 5 days.[17]

(c) Fosamprenavir

In a crossover study in healthy subjects, the AUC of amprenavir (derived from a single 1.4-g dose of fosamprenavir) was decreased by 18% and the maximum plasma level was decreased by 35%, but the minimum level was not significantly altered by the concurrent use of 30 mL of an **aluminium**/**magnesium hydroxide antacid** *(Maalox TC)*.[18] In the same study, **ranitidine** 300 mg, given one hour before fosamprenavir 1.4 g, decreased the AUC of amprenavir by 30% and decreased its maximum level by 51% without altering the minimum level.[18]

In contrast, in studies in healthy subjects, **esomeprazole** 20 mg daily had no effect on the steady-state pharmacokinetics of amprenavir after either fosamprenavir 1.4 g twice daily or ritonavir-boosted fosamprenavir 100/700 mg twice daily. However, fosamprenavir 1.4 g twice daily increased the **esomeprazole** AUC by 55%. In this study, the daily dose of **esomeprazole** was given simultaneously with the first dose of protease inhibitor.[19] Another study in healthy subjects given ritonavir-boosted fosamprenavir 100/1400 mg daily for 7 days found that **omeprazole**

20 mg in the evening had no significant effect on the pharmacokinetics of amprenavir.[5] Similarly, no pharmacokinetic interaction was apparent in an 8-hour study in a 65-year-old HIV-positive patient who was given ritonavir-boosted fosamprenavir with **esomeprazole**.[9]

(d) Indinavir

The manufacturer notes that, in a study in 12 healthy subjects, **cimetidine** 600 mg twice daily for 6 days had no clinically significant effect on the pharmacokinetics of a single 400-mg dose of indinavir.[20]

In a study in 8 healthy subjects given **omeprazole** 40 mg daily with a single 800-mg dose of indinavir, half of the subjects had a clinically significant decrease in the plasma levels of indinavir; no significant pharmacokinetic changes occurred in the others.[21] In a review by the same authors, 4 of 9 patients taking **omeprazole** with indinavir had lower plasma levels of indinavir than expected. In 2 patients, increasing the indinavir dose from 800 mg to 1 g, three times daily, resulted in acceptable plasma levels.[22] In a later randomised controlled study in 14 healthy subjects, **omeprazole** 40 mg daily for 7 days reduced the AUC of a single 800-mg dose of indinavir by 47%. However, the addition of ritonavir 200 mg to indinavir negated the effect of **omeprazole**.[23]

Note that 'buffered didanosine', (p.954), has also been shown to reduce indinavir levels.

(e) Lopinavir

In a randomised study in healthy subjects, **omeprazole** 40 mg daily or **ranitidine** 150 mg one hour before breakfast had no effect on the relative bioavailability of either lopinavir or ritonavir when ritonavir-boosted lopinavir 200/800 mg daily was taken 30 minutes after breakfast, or when ritonavir-boosted lopinavir 100/400 mg twice daily (30 minutes after a meal, as tablets) was given 1.5 hours after the acid-reducing drug.[4]

In a clinical study of ritonavir-boosted lopinavir daily (8 study patients, 86 control patients) or twice daily (7 study patients, 45 control patients) given with tenofovir and emtricitabine, the trough levels of lopinavir were assessed at 4, 8, 16, 24 and 48 weeks: patients taking acid-reducing drugs (**proton pump inhibitors** 67%, **H_2-receptor antagonists** or **antacids**) were then compared with control patients not using acid-reducing drugs. There was no significant difference in trough lopinavir levels between the patients taking acid-reducing drugs and the controls, except that at 24 weeks the trough level of lopinavir was 50% higher, and at 48 weeks it was 73% higher, in users of acid-reducing drugs taking ritonavir-boosted lopinavir daily. No difference was seen in the group taking ritonavir-boosted lopinavir twice daily.[24]

(f) Nelfinavir

In a study, 19 healthy subjects were given **omeprazole** 40 mg daily for 4 days with 1.25 g nelfinavir twice daily for 7 doses. **Omeprazole** reduced the AUC and maximum plasma concentration of nelfinavir by almost 40%, although in 3 patients the AUC of nelfinavir was actually *increased* by **omeprazole**. The pharmacokinetics of the active metabolite of nelfinavir, M8, were also affected, with a reduction in AUC and maximum plasma concentration of 92% and 89%, respectively. Four subjects had undetectable nelfinavir metabolite levels.[25]

(g) Saquinavir

When **cimetidine** 400 mg twice daily was given with saquinavir, the AUC of saquinavir 1.2 g twice daily was 120% greater when compared with saquinavir 1.2 g three times daily alone.[26] In a study in 12 healthy subjects, the AUC of saquinavir given with food was 67% higher when it was given after two 150-mg doses of **ranitidine** given 12 hours apart, and one hour before the saquinavir.[27]

In a study in 18 healthy subjects, **omeprazole** 40 mg daily increased the AUC of saquinavir by 82% when ritonavir-boosted saquinavir 100/1000 mg was given twice daily.[28] In another study in 12 HIV-positive patients taking ritonavir-boosted saquinavir 100/1000 mg twice daily, **omeprazole** 40 mg taken for one week at the same time as saquinavir, significantly increased the AUC, maximum plasma concentration and minimum plasma concentration of saquinavir by 54%, 55% and 73%, respectively. Taking **omeprazole** 2 hours before ritonavir-boosted saquinavir resulted in slightly larger increases of 67%, 65%, and 97%, in the AUC, maximum plasma concentration and minimum plasma concentration of saquinavir, respectively. The pharmacokinetics of ritonavir were not affected by **omeprazole**. Increases in saquinavir bioavailability did not result in an increase in adverse effects.[29]

(h) Tipranavir

In a single-dose study in healthy subjects, 20 mL of an **aluminium**/**magnesium hydroxide** antacid *(Maalox Plus)* decreased the AUC, minimum level and maximum level of tipranavir by 25 to 29%, after ritonavir-boosted tipranavir 500/200 mg was taken at the same time as the antacid.[30-32]

The manufacturer notes that when **omeprazole** 40 mg daily was given with ritonavir-boosted tipranavir there were no changes in the pharmacokinetics of either protease inhibitor, but the AUC and maximum plasma concentration of **omeprazole** were reduced by 71% and 73%, respectively.[32] Similar effects were found with **esomeprazole**.[32]

Mechanism

The UK manufacturer of indinavir states that a normal (acidic) gastric pH may be necessary for optimum absorption of indinavir.[33] Any drug that increases the gastric pH could therefore potentially reduce absorption. Altered gastric pH may also account for the interaction with atazanavir[34] and nelfinavir.[25] In addition, omeprazole may inhibit the metabolism of nelfinavir to its M8 metabolite by the cytochrome P450 isoenzyme CYP2C19.[25] Cimetidine probably boosts saquinavir levels by inhibiting its first-pass metabolism.[26] It is not understood why ranitidine and omeprazole increase saquinavir levels.

Importance and management

Atazanavir

Proton pump inhibitors. The marked pharmacokinetic interaction of omeprazole with atazanavir (with or without ritonavir) is established; lansoprazole appears to act similarly. Based on the available data, advice in Europe[34] and the US[35] is that atazanavir or ritonavir-boosted atazanavir should not be given with omeprazole or other proton pump inhibitors. However, the UK manufacturer[2] advises that if the concurrent use of a proton pump inhibitor is necessary, the dose of ritonavir-boosted atazanavir should be increased to 400 mg daily and both the UK and US manufacturers advise that a maximum dose of 20 mg of omeprazole (or the equivalent in other proton pump inhibitors) should be used.[2,3] The US manufacturers limit this advice to treatment-naive patients, and advise that the dose of the proton pump inhibitor should be taken 12 hours before atazanavir.[3]

H_2-receptor antagonists. Modest effects were seen with atazanavir and the simultaneous use of famotidine, whereas ranitidine taken 1.5 hours before ritonavir-boosted atazanavir had a more marked effect. The manufacturers state that **ritonavir-boosted atazanavir** 100/300 mg (with food) should be given with or 10 hours after famotidine 20 mg twice daily (or the comparable dose of another H_2-receptor antagonist).[2,3] In the US, famotidine up to 40 g twice daily may be given to treatment-naive patients, with the same dose, and dose interval as the lower famotidine dose.[3] In the UK, if famotidine 40 mg twice daily or more is required, then the manufacturers suggest considering increasing the dose of ritonavir-boosted atazanavir to 100/400 mg.[2]

In the presence of **tenofovir** the UK manufacturer suggests that concurrent use of ritonavir-boosted atazanavir with an H_2-receptor antagonist should be avoided unless the combination is considered essential. If the combination is given, both the US and UK manufacturers advise that the dose of atazanavir may be increased to 400 mg, but this has not been fully evaluated.[2,3] The US manufacturer limits this advice to treatment-experienced patients, and suggests no dose alteration for treatment-naive patients.

For **unboosted atazanavir**, in treatment-naive patients, the US manufacturer recommends a dose of 400 mg daily with food, which should be given 2 hours before or 10 hours after the H_2-receptor antagonist. The dose of famotidine (or equivalent) should not exceed 20 mg in any single dose or 40 mg in a day.[3]

Buffered medicinal products. The manufacturers recommend atazanavir should be given 2 hours before or one hour after buffered medicinal products.[2,3] This would include didanosine buffered tablets (see 'NRTIs + Protease inhibitors', p.954).

Other protease inhibitors

Based on the limited data with other protease inhibitors, the manufacturers of **amprenavir** recommended that it should not be given within one hour of antacids.[36,37] However, the decrease in amprenavir levels seen when **fosamprenavir** is given with an antacid are not considered clinically relevant, and no fosamprenavir dose adjustments are considered to be necessary.[38] Greater decreases were seen with ranitidine, although the minimum

levels were unchanged. The UK manufacturer[38] states that no fosamprenavir dose adjustment is needed with ranitidine or other H_2-receptor antagonists, whereas the US manufacturer[39] says the combination should be used with caution as fosamprenavir may become less effective. However, no interaction occurred with esomeprazole, and this, or other proton pump inhibitors may be given at the same time as fosamprenavir.[38,39]

The interaction between omeprazole and **indinavir** would appear to be established. Omeprazole should probably not be used with indinavir unless ritonavir is used to boost the indinavir levels.[23] This would be likely apply to other proton pump inhibitors used with indinavir as well. No significant interaction occurs between **indinavir** and cimetidine, and based on this result, the other H_2-receptor antagonists would not be expected to interact.

The reduction in the levels of **nelfinavir** and its active metabolite may lead to loss of virological activity, and therefore the UK manufacturer contraindicates the concurrent use of omeprazole and recommends caution if other proton pump inhibitors are used with nelfinavir.[40] The manufacturer of esomeprazole similarly contraindicates concurrent use with nelfinavir.[41] However the US manufacturer recommends that no proton pump inhibitors should be given with nelfinavir.[42]

Cimetidine very markedly increases **saquinavir** levels, and further study is required to discover whether this is clinically useful.[26] Ranitidine causes a fairly marked increase in saquinavir levels, although this is probably not clinically relevant. If omeprazole or other proton pump inhibitors are taken with ritonavir-boosted saquinavir, the manufacturer of saquinavir recommends monitoring for potential saquinavir toxicity.[43] Separating the dose of omeprazole from saquinavir does not appear to minimise the interaction.

Antacids modestly decreased **tipranavir** levels, and administration should be separated by at least 2 hours.[32] The use of tipranavir with omeprazole or esomeprazole is not recommended,[32] but if both drugs are given consider increasing the dose of the proton pump inhibitor,[31,32] according to response.

Omeprazole and ranitidine do not appear to alter the pharmacokinetics of ritonavir-boosted **darunavir** or **lopinavir**.

Protease inhibitors + Food

Food increases the bioavailability of atazanavir, darunavir, ritonavir-boosted lopinavir soft capsules and solution, nelfinavir and saquinavir (all formulations), but decreases that of indinavir. A high-fat meal increases the bioavailability of tipranavir, but food also improves its tolerability. Food only minimally affects the bioavailability of amprenavir, fosamprenavir, ritonavir-boosted lopinavir tablets and ritonavir. Mixing ritonavir with enteral feeds does not affect the pharmacokinetics of ritonavir.

Clinical evidence, mechanism, importance and management

(a) Absorption decreased

A single 600-mg dose of **indinavir** was given to 7 HIV-positive subjects immediately after various types of meal. The protein, carbohydrate, fat and high-viscosity meals reduced the AUC of **indinavir** by 68%, 45%, 34% and 30%, respectively. The fat meal was associated with the largest inter-subject variation in bioavailability. The effect of the protein meal was attributed to the fact that it raised gastric pH and therefore impaired the absorption of **indinavir** (a weak base). The impairment of **indinavir** absorption caused by the other meals, which did not alter gastric pH, may have been due to delayed gastric emptying.[1] A similar study comparing a full breakfast with light breakfasts (toast or cereal) on indinavir absorption found that the full breakfast reduced the absorption of **indinavir** by 78% and reduced its maximum serum levels by 86%, while the light breakfasts had no significant effect.[2] The manufacturers[3,4] advise that **indinavir** is taken one hour before or 2 hours after meals, or with low-fat light meals only, although the UK manufacturers also state that when indinavir is tak-

en with ritonavir it may be taken with or without food.[3] The US manufacturer gives examples of a light meal, such as dry toast with jam, juice, and coffee with skimmed milk and sugar; or corn flakes, skimmed milk and sugar.[4]

(b) Absorption increased

1. Atazanavir. The manufacturers of atazanavir report that a light meal increased the AUC and maximum concentration of a single 300-mg dose of ritonavir-boosted atazanavir by 33% and 40%, respectively, compared with the fasting state, whereas a high-fat meal did not significantly increase the absorption of atazanavir.[5,6] The US manufacturer also notes that a light meal increased the AUC and maximum concentration of atazanavir 400 mg by 70% and 57%, respectively.[6] Administration with a light meal or a high-fat meal also decreased the wide variation in plasma levels. The manufacturers therefore recommend that atazanavir should be taken with food to enhance bioavailability and minimise variability.[5,6]

2. Darunavir. In a study in 22 healthy subjects, the relative bioavailability of ritonavir-boosted darunavir was found to be 30% lower when it is taken on an empty stomach, compared with intake immediately after food. In this study, no significant difference in the affects of food on darunavir were seen between the different meals tested (a high-fat breakfast, a standard breakfast, a protein-rich drink, or a croissant and coffee). Taking darunavir with food did not affect interindividual variability in darunavir absorption.[7] Therefore, the manufacturers advise that ritonavir-boosted darunavir tablets should be taken with food.[8,9]

3. Lopinavir. A moderate-fat meal increased the AUC and maximum level of lopinavir capsules by 48% and 23%, respectively, and a high-fat meal increased the AUC and maximum level of lopinavir capsules by 96% and 43%, respectively. The corresponding increases for lopinavir solution were 80% and 54% for the moderate-fat meal, and 130% and 56% for the high-fat meal.[10] The manufacturers of ritonavir-boosted lopinavir *soft capsules* and *oral solution* say that it should be taken with food.[10,11]
No clinically significant difference was seen in the bioavailability of ritonavir-boosted lopinavir *tablets* between fasting and fed subjects, therefore the manufacturers say that it can be taken with or without food.[11,12]

4. Nelfinavir. When nelfinavir 400 mg or 800 mg was given to 12 healthy subjects in the fasted state, the AUC was only 27% to 50% of that observed when nelfinavir was taken with a meal.[13] The US manufacturer reports that in two studies in healthy subjects, food significantly increased the exposure to a 1.25-g dose of nelfinavir two- to threefold when compared with the fasting state, with the highest increase in the AUC and maximum concentration of nelfinavir occurring with the high-calorie, high-fat meal (1000 kcal and 50% fat).[14] A small study in healthy subjects also found a similar effect.[15] The UK manufacturer reports that this effect appears to be less in multiple-dose studies where a high-fat meal (800 kcal and 50% fat) increased the AUC and maximum concentration by a modest 20% compared with a lighter meal (250 kcal and 33% fat).[16] Another study in 24 healthy subjects found that the AUC of nelfinavir 1.25 g taken twice daily for 17 days, was only reduced by 13% when it was taken with a light breakfast (250 kcal and 13 g fat) compared with a standard breakfast (800 kcal and 35 g fat).[17] As food significantly increases the absorption of nelfinavir the manufacturers recommend that it should be taken with food.[14,18]

5. Saquinavir. The manufacturer of saquinavir hard capsules and tablets notes that, in a crossover study in 22 HIV-positive patients taking ritonavir-boosted saquinavir 100/1000 mg twice daily and receiving three consecutive doses under fasting conditions or after a high-fat, high-calorie meal, the AUC, maximum and minimum levels of saquinavir under fasting conditions were about 70% lower than with a high-fat meal. There were no clinically significant differences in the pharmacokinetic profile of ritonavir in fasting and fed conditions but the ritonavir minimum level was about 30% lower in the fasting state, when compared with its administration with a meal.[16,19] Ritonavir-boosted saquinavir should be given with, or up to 2 hours after, a meal.[16,19,20]

6. Tipranavir. The US manufacturer states that, in a study, the pharmacokinetics of tipranavir were unaffected when it was taken with food (500 to 682 kcal, 23 to 25% of the calories from fat), compared with fasting conditions. They therefore state that tipranavir can be taken with or without food.[21] The UK manufacturer states that food improves the tolerability of ritonavir-boosted tipranavir, and recommends that it should be taken with food.[22]

(c) Absorption minimally affected

1. Amprenavir. The manufacturers reported that food resulted in a 25% reduction in the AUC of amprenavir, but no change in its steady-state trough level. Consequently, the manufacturers stated it can be taken with or without food,[23,24] but the US manufacturer said that it should not be taken with a high-fat meal.[24]

2. Fosamprenavir. In a study in 24 healthy subjects, food had no clinically significant effects on the bioavailability of a 1.73 g dose of fosamprenavir from a tablet formulation.[25] Fosamprenavir *tablets* may be taken without regard to food intake.[26,27]
A high-fat meal modestly reduced the AUC and maximum concentration of a 1.73-g dose of fosamprenavir *suspension* by 20% and 41%, respectively.[25] The manufacturers advise that adults should take the oral *suspension* without food and on an empty stomach. However, they advise that in order to improve palatability and ensure compliance, children may take the *suspension* with food.[27,28]

3. Ritonavir. The US manufacturer notes that a meal increased the absorption of ritonavir capsules by 13%, when compared with the fasting state, whereas the absorption of the oral solution was decreased by 7%.[29] See also *Lopinavir* and *Saquinavir*, above. Although these changes are modest, the manufacturers state that ritonavir capsules and solution are preferably taken with food.[29-31]
There is also some evidence that mixing ritonavir with **enteral feeds** does not affect ritonavir pharmacokinetics. A 600-mg dose of ritonavir oral solution was mixed with 240 mL of **enteral feeds** (either *Advera* or *Ensure*), **chocolate milk** or water within one hour of dosing. When given up to 15 minutes after a low-fat meal, the pharmacokinetics of ritonavir in either of the **enteral feeds** or the **milk** were almost identical to those when ritonavir was given in water.[32]

Protease inhibitors + Garlic

A garlic supplement reduced the plasma levels of saquinavir by 50% in one study, but had little effect in another. Another garlic supplement did not significantly affect the pharmacokinetics of a single dose of ritonavir.

Clinical evidence

In a study in 9 healthy subjects garlic reduced the AUC, and maximum and minimum plasma levels of **saquinavir** by about 50%. The garlic was taken in the form of a dietary supplement (*GarliPure, Maximum Allicin Formula* caplets) twice daily for 20 days. **Saquinavir** 1.2 g three times daily was given for 4-day periods before, during, and after the garlic supplement. Fourteen days after the garlic supplement was stopped the **saquinavir** pharmacokinetics had still not returned to baseline values. Of the 9 subjects, 6 had a substantial drop in the AUC of **saquinavir** while taking garlic, then a rise when garlic was stopped. The remaining 3 had no change in the AUC of **saquinavir** while taking garlic, but had a drop when garlic was stopped.[1] However, in another study, garlic extract (*Garlipure*) 1.2 g daily for 3 weeks had no significant effect on the pharmacokinetics of a single 1.2-g dose of **saquinavir** (a slight decrease in AUC in 7 subjects and a slight increase in 3).[2]

In a study in 10 healthy subjects the use of a garlic extract (10 mg, equivalent to 1 g of fresh garlic) twice daily for 4 days did not significantly affect the pharmacokinetics of a single 400-mg dose of **ritonavir**. There was a non-significant 17% decrease in the AUC of **ritonavir**. The garlic was given in the form of capsules (*Natural Source Odourless Garlic Life Brand*).[3] Gastrointestinal toxicity was noted in 2 patients taking garlic or garlic supplements when they started to take **ritonavir**-containing regimens.[4]

Mechanism

The mechanism of this interaction is uncertain, but it is thought that garlic reduced the bioavailability of saquinavir by increasing its metabolism in the intestine.[1] Why there was a disparity in the effect of garlic on saquinavir between patients is unclear.

Allicin is thought to have inhibited the activity of P-glycoprotein *in vitro*, which caused the build-up of ritonavir within the cell.[5]

Importance and management

Although information is limited, a reduction in saquinavir plasma levels of the magnitude seen in the first study could diminish its antiviral efficacy. All garlic supplements should probably be avoided in those taking saquinavir as the sole protease inhibitor, but note that this is no longer generally recommended. The effect of garlic on saquinavir levels in the presence of ritonavir (as a pharmacokinetic enhancer) does not appear to have been studied. The pharmacokinetic effect on single-dose ritonavir was not clinically important, but this requires confirmation in a multiple-dose study.

Protease inhibitors + Ginkgo (*Ginkgo biloba*)

Ginkgo does not appear to affect the pharmacokinetics of ritonavir-boosted lopinavir.

Clinical evidence

In a study in 14 healthy subjects, ginkgo 120 mg twice daily for 2 weeks had no significant effect on the pharmacokinetics of ritonavir-boosted **lopinavir** 100/400 mg twice daily (given for 2 weeks alone before adding the ginkgo). The ginkgo extract was assayed and contained 29% flavonol glycosides and 5% terpene lactones.[1]

Mechanism

The authors suggest that without ritonavir, the levels of lopinavir would have been reduced by ginkgo because they also found that ginkgo modestly reduced the levels of midazolam, probably by inducing the cytochrome P450 isoenzyme CYP3A4. As ritonavir is an inhibitor of CYP3A4, they suggest that it attenuates the action of ginkgo on lopinavir metabolism. However, note that all protease inhibitors are inhibitors of CYP3A4 to varying extents, and note also that in other studies with midazolam, ginkgo had no effect on midazolam levels, or even caused a minor increase in levels, which suggests that ginkgo does not have a clinically relevant effect on CYP3A4 activity.

Importance and management

The study here shows that ginkgo does not alter the pharmacokinetics of ritonavir-boosted lopinavir, and no special precautions are required on concurrent use. This would apply to all other ritonavir-boosted protease inhibitors. As regards protease inhibitors that are not boosted by ritonavir, the authors of this study recommend avoiding ginkgo.[1] This seems an over-cautious approach, given that the sum of studies available show that ginkgo does not have a clinically relevant effect on the probe CYP3A4 substrate midazolam.

Protease inhibitors + Grapefruit and other fruit juices

Grapefruit juice does not have any clinically significant effects on the pharmacokinetics of either amprenavir or indinavir, but may double the AUC of saquinavir. Seville orange juice did not alter indinavir pharmacokinetics in one study.

Clinical evidence, mechanism, importance and management

(a) Amprenavir and Fosamprenavir

In a study in 12 healthy subjects, 200 mL of grapefruit juice (given on two occasions) slightly delayed the rate but not the extent of absorption of a single 1.2-g dose of amprenavir and modestly reduced the maximum plasma concentration of by 22%. These effects were not clinically significant. No adverse effects were reported in this study.[1] The manufacturer of fosamprenavir notes that taking amprenavir with grapefruit juice was not associated with clinically significant changes in plasma amprenavir pharmacokinetics.[2] Note that fosamprenavir is metabolised to amprenavir in the gut. No special precautions appear to be necessary with concurrent use.

(b) Indinavir

In a single-dose study in 10 healthy subjects, grapefruit juice (8 oz, about 200 mL) reduced the AUC of indinavir 400 mg by 27%, although this was not considered clinically significant.[3] In another study in 13 healthy subjects, grapefruit juice or **Seville orange juice** (both about 200 mL) had no effect on the pharmacokinetics of indinavir. In this study indinavir 800 mg was given every 8 hours for 4 doses; with water, grapefruit juice, or Seville orange juice given with the last 2 doses.[4] Similarly, in 14 HIV-positive subjects, grapefruit juice (180 mL of double strength) had no effect on the steady-state pharmacokinetics of indinavir (a non-significant 5% increase in AUC was seen and a slight delay in the rate of absorption).[5]

(c) Saquinavir

In a study of the effects of the concurrent use of grapefruit juice 400 mL and saquinavir (*Invirase*; hard capsules) 600 mg, grapefruit juice was found to increase the AUC of saquinavir by 50%, possibly by affecting the cytochrome P450 isoenzyme CYP3A4 in the intestine.[6] The manufacturer notes that the increase was 100% when double-strength grapefruit juice was used.[7] They say that these increases are unlikely to be clinically relevant, and no saquinavir dose adjustment is necessary, although they note that ritonavir-boosted saquinavir has not been specifically studied.[7]

Protease inhibitors + Lamotrigine

Ritonavir-boosted atazanavir and lopinavir appear to reduce lamotrigine plasma levels, whereas the protease inhibitor levels do not appear to be altered. An increased dose of lamotrigine was required in a patient who was also taking ritonavir-boosted saquinavir. Atazanavir alone does not appear to have any significant effect on the pharmacokinetics of lamotrigine.

Clinical evidence

(a) Atazanavir

In a study, 17 healthy subjects were given a single 100-mg dose of lamotrigine alone, after 6 days of atazanavir 400 mg daily, and after 10 days of ritonavir-boosted atazanavir 100 mg/300 mg daily. Atazanavir alone had no significant effect on the pharmacokinetics of lamotrigine. However ritonavir-boosted atazanavir reduced the AUC and maximum plasma concentration of lamotrigine by 32% and 6%, respectively. Formation of lamotrigine-2N-glucuronide was also increased by ritonavir-boosted atazanavir.[1]

(b) Lopinavir

In a study in 18 healthy subjects taking lamotrigine 100 mg twice daily, ritonavir-boosted lopinavir 100/400 mg twice daily for 10 days decreased the steady-state minimum plasma level of lamotrigine by 55%, decreased the AUC of lamotrigine by 46%, and increased its clearance by 85%. Doubling the dose of lamotrigine to 200 mg twice daily increased the AUC to a similar level to that seen with the lower dose without ritonavir-boosted lopinavir. Pharmacokinetic parameters for lopinavir and ritonavir were similar to those in historical controls.[2] The authors of a review describe a patient taking lamotrigine 25 mg twice daily who had a favourable decline in viral load 2 months after starting to take ritonavir-boosted lopinavir, lamivudine and stavudine. There was no toxicity and no recurrence of seizures.[3]

(c) Saquinavir and Ritonavir

A 30-year-old woman taking nevirapine, saquinavir 1.2 g daily, and ritonavir 600 mg daily with an undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of an increased frequency and severity of seizures. The lamotrigine dose was eventually increased to 1.8 g daily to achieve serum levels of 5 to 8 mg/L. The ritonavir dose was doubled and the saquinavir dose increased to 2 g daily to compensate for the enzyme-inducing effects of phenytoin (consider also 'Protease inhibitors + Phenytoin', p.977). The patient's viral load remained undetectable, and her seizures decreased over the next 6 months, but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).[4]

Mechanism

Ritonavir decreases lamotrigine levels by induction of glucuronidation,[5] although an effect of lopinavir cannot be ruled out.[2] Atazanavir is known to inhibit glucuronidation by UGT1A1, and would therefore have been expected to have a significant effect on lamotrigine pharmacokinetics; however. this was not seen in the study above.

Importance and management

The pharmacokinetic interaction between lamotrigine and ritonavir would appear to be established; however, as the relationship between lamotrigine levels and efficacy is not clear, the clinical relevance of the decrease is uncertain.[2] Lamotrigine efficacy should be monitored in patients taking ritonavir or any ritonavir-boosted antiretroviral regimen. Anticipate the need to increase the lamotrigine dose.

Protease inhibitors + Macrolides

Nelfinavir approximately doubles the levels of azithromycin. Single doses of azithromycin have no effect on the levels of indinavir and nelfinavir. Atazanavir, darunavir, ritonavir and tipranavir increase clarithromycin levels, whereas amprenavir, indinavir and saquinavir do not have a clinically significant effect on clarithromycin pharmacokinetics. Clarithromycin has no important effect on the pharmacokinetics of amprenavir, atazanavir, darunavir, indinavir or ritonavir, but it increases tipranavir levels, and may markedly raise saquinavir levels (from soft capsules). Erythromycin may also increase the levels of saquinavir from soft capsules. Additive QT prolongation is predicted to occur if ritonavir-boosted lopinavir is taken with clarithromycin or erythromycin.

Clinical evidence

(a) Azithromycin

1. Indinavir. A single 1.2-g dose of azithromycin had no effect on the pharmacokinetics of indinavir in healthy subjects who had taken indinavir 800 mg three times daily for 5 days. The pharmacokinetics of azithromycin were not assessed[1]

2. Nelfinavir. A single 1.2-g dose of azithromycin was given to 12 healthy subjects who had taken nelfinavir 750 mg every 8 hours for 8 days. The pharmacokinetics of nelfinavir were minimally affected, but the AUC and maximum serum levels of azithromycin were about doubled.[2]

(b) Clarithromycin

1. Amprenavir. In a study in 12 healthy adults, amprenavir 1.2 g twice daily was given with clarithromycin 500 mg twice daily, for 4 days. The AUC and maximum serum levels of amprenavir were slightly increased, by 18% and 15%, respectively, whereas the pharmacokinetics of clarithromycin were not significantly altered. None of these changes were considered to be clinically significant.[3]

2. Atazanavir. The concurrent use of atazanavir 400 mg daily and clarithromycin 500 mg twice daily for 4 days increased the AUC of clarithromycin by 94%, and reduced the AUC of the metabolite 14-hydroxyclarithromycin by 70%. In addition, there was a minor 28% increase in the AUC of atazanavir.[4]

3. Darunavir. In a study, 17 healthy subjects were given ritonavir-boosted darunavir 100/400 mg twice daily, clarithromycin 500 mg twice daily or both drugs together, all for 13 doses. Clarithromycin had no significant effect on the pharmacokinetics of darunavir: the maximum plasma concentration and AUC of darunavir were reduced by 17% and 13%, respectively, and the minimum plasma concentration was unchanged.

However, the AUC, peak plasma levels and trough plasma levels of clarithromycin were increased by 57%, 26% and 174%, respectively. The metabolite, 14-hydroxyclarithromycin, was not detectable.[5]

4. Indinavir. In 11 healthy subjects clarithromycin 500 mg every 12 hours, given with indinavir 800 mg every 8 hours, caused no clinically important alterations in the pharmacokinetics of indinavir: the only significant change was a 52% increase in the trough level. The AUC of clarithromycin was increased by about 50%, and that of 14-hydroxyclarithromycin reduced by about 50%, but neither of these changes were considered clinically important because of the wide safety margin of clarithromycin.[6]

5. Lopinavir. A case of rhabdomyolysis has been reported in an HIV-positive patient taking clarithromycin, ritonavir-boosted lopinavir, and atorvastatin, see 'Statins + Macrolides', p.1337.

6. Ritonavir. When ritonavir 200 mg every 8 hours was given with clarithromycin 500 mg every 12 hours there were only minimal changes in ritonavir pharmacokinetics (13% increase in AUC and 15% increase in maximum plasma level). However, the AUC of clarithromycin increased by 77% with an almost total inhibition of 14-hydroxyclarithromycin formation (99.7% decrease in AUC).[7]

7. Saquinavir. In a study in healthy subjects the concurrent use of saquinavir soft capsules *(Fortovase)* [no longer available] 1.2 g three times daily and clarithromycin 500 mg twice daily increased the AUC and maximum serum levels of saquinavir by 177% and 187%, respectively. The AUC and maximum serum levels of clarithromycin were about 40% higher than when it was given alone.[8,9] The manufacturer notes that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (*Invirase*).[8,9]

8. Tipranavir. In a study in 21 healthy subjects, clarithromycin 500 mg twice daily was taken for 13 days with ritonavir-boosted tipranavir 200/500 mg twice daily from day 6 to 13. Ritonavir-boosted tipranavir increased the minimum plasma level of clarithromycin by 68%, although the AUC and maximum concentration were minimally affected. The $AUC_{0\text{-}12}$ and maximum plasma concentration of the 14-hydroxy metabolite of clarithromycin were also reduced by 97%, and its minimum level reduced by 95%. No increase in adverse effects was reported, although one subject taking ritonavir-boosted tipranavir and clarithromycin had a significant grade 3 increase in ALT. Clarithromycin increased the AUC, maximum and minimum concentration of tipranavir by 66%, 40%, and 100%, respectively.[10]

(c) Erythromycin

The concurrent use of saquinavir soft capsules (*Fortovase*) [no longer available] 1.2 g three times daily and erythromycin 250 mg four times daily doubled the AUC and maximum serum levels of saquinavir in HIV-infected subjects.[11] The manufacturers note that there are no data on the interaction using ritonavir-boosted saquinavir hard capsules or tablets (*Invirase*).[8,9]

Mechanism

Ritonavir is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 and consequently markedly inhibits the 14-hydroxylation of clarithromycin by this isoenzyme. Other protease inhibitors would be expected to interact similarly, although to a lesser degree (see also 'Antivirals', (p.913)). The effect of ritonavir-boosted darunavir on clarithromycin may also possibly be due to P-glycoprotein inhibition.[12] Clarithromycin is a moderate inhibitor of CYP3A4, but generally has only a small effect on the protease inhibitors, except for saquinavir. The effect of clarithromycin on saquinavir, and nelfinavir on azithromycin may involve inhibition of P-glycoprotein.[2,3]

Importance and management

The interaction of amprenavir or indinavir with **clarithromycin** does not appear to be clinically significant. Similarly, although large increases in saquinavir levels have been seen, the manufacturers say that for short courses no dose adjustment is needed.[8,9] However, with ritonavir, because the hepatic metabolism of clarithromycin is so strongly inhibited it becomes more dependent on renal clearance, therefore the interaction may be significant in patients with renal failure.[7] The manufacturers of ritonavir and clarithromycin suggest that no dose reductions should be needed in those with normal renal function, but they recommend a 50% reduction in the dose of clarithromycin for those with a creatinine clearance of 30 to 60 mL/minute and a 75% reduction for clearances of less than 30 mL/minute.[13-16] Some advise avoiding clarithromycin in doses exceeding 1 g daily.[13,14] Similar clarithromycin dose reductions in renal impairment are recommended for ritonavir-boosted darunavir,[17] fosamprenavir,[18] and ritonavir-boosted tipranavir.[19,20] The UK manufacturer of tipranavir also advises that patients taking a dose of clarithromycin of more than 500 mg twice daily should be monitored for clarithromycin adverse effects. They also note that the low levels of 14-hydroxyclarithromycin due to the interaction with ritonavir-boosted tipranavir may be of clinical relevance in the treatment of *Haemophilus influenzae*.[20] Although there are no formal studies or specific dose recommendations for other ritonavir-boosted protease inhibitors (lopinavir and saquinavir), similar precautions would seem prudent. Atazanavir also reduces the conversion of clarithromycin to its 14-hydroxy metabolite, and it is usually given with ritonavir. The US manufacturer of atazanavir suggest that if the combination is used the clarithromycin dose should be reduced by 50%, as clarithromycin may prolong the QT interval. As the levels of 14-hydroxyclarithromycin are also significantly reduced, they advise that for most infections an alternative to clarithromycin should be considered with the exception of *Mycobacterium avium* complex infections, where this metabolite is inactive.[21] However, the UK manufacturer cautions that reducing the dose of clarithromycin to avoid high levels of the parent drug may result in subtherapeutic levels of the 14-hydroxy metabolite, which is active against *Haemophilus influenzae*.[22] The US manufacturer states that the concurrent use of ritonavir-boosted atazanavir with clarithromycin has not been studied.[21]

The increase in **azithromycin** levels with nelfinavir is likely to be of clinical significance,[2] and, although the outcome is presumed to be positive, this has yet to be assessed in practice. If concurrent use is necessary, monitor for azithromycin adverse effects (e.g. hepatic adverse effects, hearing impairment).[23] The manufacturers of ritonavir-boosted lopinavir do not expect a clinically significant interaction with azithromycin.[24,25]

Despite the increases in saquinavir levels, the UK manufacturer says that no dose adjustment is needed when saquinavir is given with **erythromycin**.[8] The UK manufacturer of ritonavir suggests that because erythromycin levels may rise, due to inhibition of its metabolism by ritonavir, care should be taken if both drugs are given.[13] It would seem prudent to monitor for erythromycin adverse effects. A similar warning has been issued by the UK manufacturer of fosamprenavir about the use of erythromycin.[18] The US manufacturer of atazanavir does not expect a clinically significant interaction with erythromycin.[21]

Note that clarithromycin and erythromycin have been associated with QT prolongation, and rises in their levels may increase this risk. The US manufacturer[25] of ritonavir-boosted lopinavir states that a clinically significant interaction with erythromycin is not expected. However, the UK manufacturer states that both **erythromycin** and **clarithromycin** can prolong the QT interval and that cardiac adverse effects have also been reported with ritonavir-boosted lopinavir. As ritonavir-boosted lopinavir may also increase the levels of these macrolides, they advise caution with concurrent use.[24] For more information about the risks of QT prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

The UK manufacturer of **telithromycin** predicts that the protease inhibitors will increase its levels and, as telithromycin has been reported to cause QT prolongation, they advise caution on concurrent use, and contraindicate concurrent use in patients with severe renal or hepatic impairment.[26]

Protease inhibitors + Mefloquine

No pharmacokinetic interaction appears to occur between mefloquine and indinavir or nelfinavir. Ritonavir does not appear to alter mefloquine pharmacokinetics, but mefloquine may modestly decrease steady-state ritonavir levels.

Clinical evidence

Two HIV-positive patients receiving HAART, one taking **indinavir** 800 mg three times daily, the other taking **nelfinavir** 1.25 g twice daily were given mefloquine 250 mg weekly, before a trip to Africa. Mefloquine therapeutic levels were achieved, and its half-life was similar to that found in healthy subjects. In addition, no consistent changes in the plasma levels of the protease inhibitors were found.[1]

In 12 healthy subjects **ritonavir** 200 mg twice daily for one week had no significant effect on the pharmacokinetics of mefloquine.[2] Conversely, mefloquine (250 mg daily for 3 days, then 250 mg weekly) significantly reduced the steady-state AUC, maximum plasma levels and minimum plasma levels of **ritonavir** 200 mg twice daily by 31%, 36%, and 43%, respectively, but had no effect on the pharmacokinetics of single-dose **ritonavir**.[2]

Mechanism

Despite being inhibitors of the cytochrome P450 isoenzyme CYP3A4, the protease inhibitors do not appear to alter mefloquine pharmacokinetics.[1,2] It was suggested that the decrease in ritonavir levels was due to decreased absorption, perhaps due to mefloquine-induced inhibition of bile acid production or induction of P-glycoprotein.[2]

Importance and management

The limited evidence suggests that protease inhibitors do not affect mefloquine pharmacokinetics. The data on the effect of mefloquine on ritonavir are less clear. Until further evidence is available, if concurrent use is necessary, it may be prudent to closely monitor ritonavir levels/efficacy.

Protease inhibitors + Minocycline

Minocycline appears to reduce the levels of ritonavir-boosted atazanavir, but does not appear to significantly affect the levels of ritonavir.

Clinical evidence, mechanism, importance and management

In a study, 12 HIV-positive subjects who had been taking **ritonavir-boosted atazanavir** 100/300 mg daily for at least 4 weeks as part of a HAART regimen were given minocycline 100 mg twice daily for 14 days. Minocycline reduced the AUC, maximum concentration and minimum concentration of **atazanavir** by 33%, 25%, and 50%, respectively. The addition of valproic acid 250 mg twice daily for a further 14 days did not significantly change the outcome of the interaction. Minocycline had no statistically significant effect on the pharmacokinetics of **ritonavir** in the subset of 9 subjects analysed (10% and 5% reduction in the AUC and maximum concentration respectively, with a 23% increase in the minimum concentration).[1]

The possible mechanism and clinical significance of this interaction are unclear. Note that this was a small study and patients were allowed to continue their regular medication during the study, which may have influenced the outcome. However, the possibility of a clinically relevant interaction cannot be excluded. The authors suggest that further study is needed to establish the pharmacokinetic interaction, as well as its likely treatment outcomes. They also advise that although no significant interaction was seen with **ritonavir**, an interaction cannot be excluded due to the small sample size.[1]

Effects of minocycline and valproic acid coadministration on atazanavir plasma concentrations in human immunodeficiency virus-infected adults receiving atazanavir-ritonavir. Antimicrob Agents Chemother (2008) 52, 3035–9.

Protease inhibitors + Miscellaneous

Indinavir levels are raised by interleukin-2, but not affected by influenza vaccination. Nelfinavir does not appear to interact with pancreatic enzyme supplements. In one case report, the combination of ritonavir and saquinavir with fusidic acid raised the plasma levels of all three drugs.

Clinical evidence, mechanism, importance and management

(a) Fusidic acid

A 32-year-old HIV-positive man was admitted with suspected fusidic acid toxicity after taking fusidic acid 500 mg three times daily for one week, with his usual treatment of **ritonavir** 400 mg twice daily, **saquinavir** 400 mg twice daily and stavudine 40 mg twice daily. His plasma fusidic acid level was found to be twice the expected level, and his **ritonavir** and **saquinavir** levels were also elevated. He improved spontaneously, but 4 days later he returned with jaundice, nausea and vomiting. All medications were stopped, but after 6 days his fusidic acid level was still 30% greater than expected, his **saquinavir** level was 16.3 micrograms/mL (reference range 1 to 4 micrograms/mL) and his **ritonavir** level was 43.4 micrograms/mL (reference range 4 to 12 micrograms/mL). He was later able to restart his antiretrovirals without problem. It is possible that there was mutual inhibition of drug metabolism. The authors recommend avoiding this drug combination.[1] This appears to be the only published report, and further study is needed to confirm this interaction. However, bear this case in mind should a patient taking fusidic acid with antiretrovirals developing fusidic acid toxicity.

(b) Influenza vaccine

In a study, influenza whole virus vaccine was given to 9 patients taking **indinavir** containing HAART. No significant changes were found in **indinavir** pharmacokinetics.[2] Therefore, no special precautions appear to be necessary on concurrent use.

(c) Interleukins

In a pharmacokinetic study in 9 HIV-positive patients, the subjects continued taking their usual antiretrovirals and were given a 4-week course of **indinavir** 800 mg three times daily followed by infusions of 3 to 12 million units of interleukin-2, daily for 5 days. The AUC of **indinavir** increased in 8 of the 9 subjects (average increase 88%). During this time interleukin-6 was also elevated, so it was thought that the increased **indinavir** concentrations were due to the inhibitory effects of interleukin-6 on the cytochrome P450 isoenzyme CYP3A4. Increased **indinavir** trough

levels were also seen in a further 8 patients not participating in the pharmacokinetic study.[3]

(d) Pancreatic enzymes

In a study in 9 HIV-positive subjects, the concurrent use of pancreatic enzymes (pancrelipase 20,000 USP units, amylase 65,000 USP units and protease 65,000 USP units) and **nelfinavir** 1.25 g twice daily for 14 days resulted in no significant changes in the pharmacokinetics of **nelfinavir**.[4]

Protease inhibitors + Phenytoin

Nelfinavir, and ritonavir-boosted fosamprenavir and lopinavir appear to modestly reduce phenytoin levels. In case reports, ritonavir has decreased, increased or not altered phenytoin levels. Phenytoin decreased lopinavir levels, and possibly also indinavir and ritonavir levels, had only had a minor effect on the levels of amprenavir (given as ritonavir-boosted fosamprenavir), but did not alter nelfinavir levels. Phenytoin is predicted to reduce the levels of atazanavir, darunavir, saquinavir, and tipranavir.

Clinical evidence

(a) Fosamprenavir

In a randomised crossover study, healthy subjects were given ritonavir-boosted fosamprenavir 100/700 mg daily with phenytoin 300 mg daily for 10 days. The AUC and maximum plasma concentration of amprenavir were increased by 20% and 7%, respectively, and the AUC and maximum plasma concentration of phenytoin were decreased by 22% and 20%, respectively.[1]

(b) Indinavir

A 39-year-old HIV-positive man, taking phenytoin 300 mg daily, started to take indinavir 800 mg three times daily. When the phenytoin dose was reduced to 200 mg daily, the viral load dropped by almost half and his CD4 count doubled.[2]

(c) Lopinavir

In studies in healthy subjects, the concurrent use of phenytoin 300 mg daily and ritonavir-boosted lopinavir 100/400 mg twice daily resulted in a 30% decrease in the AUC of lopinavir and a 23% decrease in the AUC of phenytoin.[3]

(d) Nelfinavir

An HIV-positive man taking phenytoin and phenobarbital for epilepsy had been taking nelfinavir 750 mg three times daily and stavudine 30 mg twice daily for nearly 3 months when he had a tonic-clonic seizure. After starting nelfinavir and stavudine, serum phenytoin levels were found to have dropped from around 10 mg/L to around 5 mg/L.[4] Similarly, in healthy subjects, nelfinavir 1.25 g twice daily for 7 days decreased the AUC of phenytoin by about 30% and the maximum serum level by 21%, whereas the nelfinavir levels were not altered.[5]

(e) Ritonavir

A case report describes the intentional use of ritonavir 600 mg twice daily to boost phenytoin levels in a 14-year-old boy who had been having seizures for 28 days, despite the use of several antiepileptics. Phenytoin at 20 mg/kg daily had originally failed to produce satisfactory plasma levels, although it did reduce the rate of seizures. After starting ritonavir his seizures were controlled and the phenytoin level became therapeutic. Seizures started again after the ritonavir was stopped.[6] Conversely, an HIV-positive patient taking carbamazepine and phenytoin had little change in his phenytoin levels, which remained at around 15 mg/L, 2 months after switching from an antiretroviral regimen including **indinavir** to one containing ritonavir 600 mg twice daily and **saquinavir**.[7] Another patient taking phenobarbital, phenytoin and carbamazepine had a 33% drop in his phenytoin level 2 days after switching from an antiretroviral regimen including **indinavir** to one containing ritonavir 300 mg twice daily and **saquinavir**. The level of carbamazepine had doubled, and the level of phenobarbital was unchanged.[8]

A 30-year-old woman taking nevirapine, **saquinavir** 1.2 g daily and ritonavir 600 mg daily with undetectable viral load had her epilepsy medication changed from gabapentin and lorazepam to lamotrigine and phenytoin because of increased frequency and severity of seizures. She required phenytoin 8 mg/kg daily to maintain therapeutic serum levels. The ritonavir dose was doubled and the saquinavir dose increased to 2 g daily to compensate for the enzyme-inducing effects of phenytoin. The patient's viral load remained undetectable, and her seizures decreased over the next 6 months but she died suddenly of unexplained causes following a tonic-clonic seizure (autopsy not performed).[9]

Mechanism

Phenytoin is an inducer of the cytochrome P450 isoenzyme CYP3A4, and would be expected to increase the metabolism of the protease inhibitors, although nelfinavir levels were not altered, possibly because it is a substrate for several other isoenzymes.

Phenytoin is principally metabolised by CYP2C9 and CYP2C19, and would therefore, not be expected to be substantially affected by most protease inhibitors. However, both increases and modest decreases in phenytoin levels have been seen.

Importance and management

Although information is limited, some of these interactions are expected. Phenytoin may decrease the plasma levels of indinavir, lopinavir, and possibly ritonavir. The manufacturers of **saquinavir**[10,11] and **tipranavir**[12,13] also predict that their levels may be reduced by phenytoin, although they note that the effect on ritonavir-boosted saquinavir has not been assessed.[10,11]

The UK manufacturer of **darunavir** states that phenytoin may significantly decrease darunavir levels and advises against concurrent use,[14] whereas the US manufacturer notes that darunavir levels are not affected by phenytoin.[15] The manufacturers of **atazanavir** also predict that its levels may be reduced by inducers of CYP3A4.[16,17] The UK manufacturer specifically advises against the concurrent use of ritonavir-boosted **atazanavir** with drugs that induce CYP3A4 [not named].[16]

Phenytoin appears not to alter nelfinavir levels, and have only a minor, probably clinically unimportant effect on the levels of amprenavir (given as ritonavir-boosted fosamprenavir).

In addition, protease inhibitors appear to alter phenytoin levels. Therefore an alternative antiepileptic, such as sodium valproate, which does not affect cytochrome P450 isoenzymes, may be more appropriate in patients taking protease inhibitors. See 'Protease inhibitors + Valproate', p.988, for further comment on the use of valproate with protease inhibitors. However, if there is no option but to use phenytoin, close monitoring of antiviral efficacy and phenytoin levels is essential.

Protease inhibitors + Protease inhibitors

Various dual combinations of protease inhibitors have been tried, or are used, to boost the levels and consequently the efficacy of one of the protease inhibitors. Ritonavir is the most potent at boosting levels of the other protease inhibitors. Some protease inhibitor combinations may result in additive toxicity (indinavir and ritonavir or atazanavir).

Clinical evidence

A. Amprenavir or Fosamprenavir

(a) Atazanavir

The concurrent use of fosamprenavir 1.4 g daily with atazanavir 400 mg daily decreases the AUC and minimum level of atazanavir by 33% and 57%, respectively, and increases the AUC and minimum concentration of amprenavir by 78% and 283%, respectively. The use of ritonavir-boosted fosamprenavir 100/700 mg twice daily with atazanavir 300 mg daily reduces the AUC and maximum concentration of atazanavir by 22% and 24%, respectively, with no effect on the pharmacokinetics of amprenavir.[1] The US manufacturer states that the appropriate dose for concurrent use has not been established.[2] The US guidelines say there is insufficient data to make a dose recommendation with concurrent use.[1]

- The appropriate dose of fosamprenavir with atazanavir is not established.[1,2]

(b) Indinavir

The manufacturer of indinavir reports that indinavir 1.2 g twice daily increased the AUC of amprenavir 1.2 g twice daily by 90%. The pharmacokinetics of indinavir were unaffected. They state that there are no data on the concurrent use of ritonavir-boosted indinavir with amprenavir.[3] Similarly, the manufacturers of fosamprenavir state that there are no interaction studies on the concurrent use of indinavir with ritonavir-boosted fosamprenavir.[4] The steady-state AUC of amprenavir was 33% higher when amprenavir 750 or 800 mg three times daily was given with indinavir 800 mg three times daily. In this study, the AUC of indinavir was 38% lower than historical control data.[5] Similarly, in a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was reduced by 54% by indinavir.[6] This agrees with *in vitro* data.[7] It was suggested[5] that the effect of amprenavir on indinavir was due to the lipid-like formulation of amprenavir reducing the absorption of indinavir (analogous to 'food', (p.971)). The changes in amprenavir levels were not considered to be clinically relevant.[5]

- The appropriate dose of amprenavir or fosamprenavir with indinavir is not established.[1-3] No drug interaction studies have been performed with ritonavir-boosted fosamprenavir.[4]

(c) Lopinavir

Preliminary data suggest that giving amprenavir 600 mg twice daily with ritonavir-boosted lopinavir 100/400 mg twice daily resulted in amprenavir trough plasma levels that were lower than with ritonavir-boosted amprenavir at the same doses. Similarly the lopinavir levels were lower than those without amprenavir.[8] Others have reported similar findings,[9] and increasing the dose of ritonavir did not prevent a decrease in amprenavir levels with lopinavir.[10] Similar findings were also reported for fosamprenavir with ritonavir-boosted lopinavir,[11] and further study showed that separation of doses reduced the effect of amprenavir on ritonavir-boosted lopinavir levels, but increased the effect on amprenavir levels.[12] However, the manufacturer of ritonavir-boosted lopinavir reports that concurrent use of ritonavir-boosted lopinavir/ritonavir 100/400 mg twice daily with amprenavir 750 mg twice daily for 10 days resulted in an increase in the amprenavir AUC, maximum level and minimum level of 72%, 12% and 457%, respectively, when compared with amprenavir 1200 mg twice daily alone.[13]

The manufacturer of fosamprenavir notes that giving ritonavir-boosted lopinavir 100/400 mg with ritonavir-boosted fosamprenavir 100/700 mg, both twice daily for 2 weeks, increased the AUC and minimum level of lopinavir by 37% and 52%, respectively, whereas the AUC and minimum level of amprenavir were decreased by 63% and 65%, respectively.[2] In addition, they say that the rate of adverse effects, in particular gastrointestinal adverse effects and increases in triglyceride levels, was higher with this combination.[2,4]

- The US manufacturer of ritonavir-boosted lopinavir advises against the concurrent use of once daily ritonavir-boosted lopinavir with fosamprenavir,[13] whereas the UK manufacturer of ritonavir-boosted lopinavir advises against the concurrent use of fosamprenavir.[14]
- An optimum dose for the concurrent use of ritonavir-boosted fosamprenavir with lopinavir has not been established.[2,13] Avoid once daily regimens.[13]
- The US guidelines[1] and the UK manufacturer[14] advise against the concurrent use of ritonavir-boosted lopinavir with fosamprenavir. However, the US manufacturer of lopinavir recommends a dose increase of ritonavir-boosted lopinavir *tablets* to 125/500 mg twice daily may be needed if amprenavir or fosamprenavir is given. The manufacturer recommends a dose increase of ritonavir-boosted lopinavir *oral solution* to 133/533 mg twice daily (dose rounded to 6.5 mL) if fosamprenavir is given; once daily regimens should be avoided.[13]

(d) Nelfinavir

The trough concentration of amprenavir 750 or 800 mg three times daily was increased by 189% by nelfinavir 750 mg three times daily, but the AUC and maximum level of amprenavir were not significantly altered. In this study, the pharmacokinetics of nelfinavir were not altered, when compared with historical control data.[5] In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was reduced by about 40% by nelfinavir,[6] which agrees with *in vitro* data.[7] The increase in amprenavir trough concentration could result in improved antiviral efficacy, but further study is needed.[5]

- The manufacturer of amprenavir recommended that no dose adjustment of either drug is needed when amprenavir is given with nelfinavir.[15]
- The appropriate dose of fosamprenavir with nelfinavir is not established.[1,2] No drug interaction studies have been performed with fosamprenavir.[4]

(e) Ritonavir

The AUC, minimum levels, and maximum levels of amprenavir 1.2 g twice daily were increased by 131%, 484%, and 33%, respectively, by ritonavir 200 mg twice daily.[16] This agrees with *in vitro* data.[7] The manufacturer recommends that doses of both protease inhibitors be reduced when they are used together.[16,17] Based on modelling of pharmacokinetic data, a dose of amprenavir 600 mg with ritonavir 100 mg, both twice daily, has been suggested.[18] This combination has shown good clinical efficacy in at least one study,[19] and resulted in satisfactory amprenavir levels when efavirenz was also used[20] (see also 'NNRTIs + Protease inhibitors', p.931). Amprenavir levels with ritonavir-boosted fosamprenavir 100/700 mg twice daily were similar to those achieved with ritonavir-boosted amprenavir 100/600 mg twice daily.[21] The manufacturers advise that ritonavir oral solution should not be given with amprenavir oral solution to children due to the risk of toxicity from excipients in the two formulations.[22]

- Ritonavir may be given as a pharmacokinetic booster with fosamprenavir in the following doses, depending on the patients previous antiretroviral treatment: ritonavir 100 mg or 200 mg daily with fosamprenavir 1400 mg daily, or ritonavir 100 mg twice daily with fosamprenavir 700 mg twice daily.[1,2,4]

(f) Saquinavir

The steady-state AUC of amprenavir was reduced by 32% when amprenavir 750 or 800 mg three times daily was given with saquinavir (soft gel capsule) 800 mg three times daily, and the maximum plasma level was reduced by 37%. In this study, the pharmacokinetics of saquinavir were not changed when compared with historical control data.[5] In a model-based pharmacokinetic analysis of data from a clinical study, amprenavir intrinsic clearance was not altered by saquinavir,[6] which confirms *in vitro* data.[7] It was suggested that, as amprenavir was given with 'food', (p.971), in the first study, this may have accounted for the reduced amprenavir levels.[5]

- No dose adjustment of amprenavir or ritonavir-boosted saquinavir is needed when they are given together.[23]
- Appropriate dose of fosamprenavir with saquinavir not established.[1,2] No drug interaction studies have been performed with saquinavir and fosamprenavir.[4]

(g) Tipranavir

In a clinical study of dual-boosted protease inhibitors in multiple-treatment experienced HIV-positive adults there was a 55% reduction in minimum amprenavir levels when ritonavir-boosted tipranavir 200/500 mg twice daily was added to ritonavir-boosted amprenavir 100/600 mg twice daily.[24,25] Therefore the use of ritonavir-boosted tipranavir with ritonavir-boosted amprenavir or fosamprenavir is not recommended, as the clinical relevance of the reduction in amprenavir levels has not been established.[1] If the combination is nevertheless considered necessary, close monitoring of the plasma levels of the protease inhibitors is strongly encouraged.[24,25]

- Concurrent use is not recommended.[1,24,25]

B. Atazanavir

(a) Darunavir

The manufacturer notes that giving atazanavir 300 mg daily with ritonavir-boosted darunavir 100/400 mg twice daily did not significantly alter the AUC and minimum level of darunavir. In addition, the AUC and minimum level of atazanavir were not significantly changed, when compared with ritonavir-boosted atazanavir 100/300 mg daily alone, although the minimum level of atazanavir was increased by 52%.[26,27]

- No dose adjustment of either drug is needed.[1,26,27]

(b) Indinavir

There are no pharmacokinetic data on the use of atazanavir with indinavir, but it is predicted that there may be an additive risk of unconjugated hyperbilirubinaemia.

- Concurrent use is not recommended.[1,28,29]

(c) Ritonavir

In a study in 61 HIV-positive patients, the addition of ritonavir 100 mg to atazanavir 300 mg increased the AUC of atazanavir about 3.5-fold, and increased its trough plasma level about eightfold, when compared with atazanavir 400 mg alone.[28] The manufacturer of atazanavir recommends that a dose of atazanavir 300 mg daily is given with ritonavir 100 mg daily.[28,29]

- Ritonavir is recommended as a pharmacokinetic booster with atazanavir.[28,29]

(d) Saquinavir

In a study in 7 subjects, the addition of atazanavir 400 mg daily to saquinavir soft capsules 1.2 g daily increased the AUC of saquinavir about 5.5-fold, and increased its trough plasma level about sevenfold.[29] In another study in 18 HIV-positive patients, atazanavir 300 mg daily increased the AUC and maximum concentration of ritonavir-boosted saquinavir 100/1600 mg daily by 60% and 42%, respectively.[23,30] The AUC and maximum concentration of ritonavir was also increased by 41% and 34%, respectively, with no change in atazanavir pharmacokinetics. The manufacturer notes that there is no clinical data available for the concurrent use of atazanavir with ritonavir-boosted saquinavir 100/1000 mg twice daily.[23,30] However, the US manufacturer of atazanavir notes that a regimen including this combination, as well as tenofovir, did not provide adequate efficacy.[29]

- Not an effective combination. The appropriate dose of atazanavir with ritonavir-boosted or unboosted saquinavir not established.[1,29]

(e) Tipranavir

The manufacturer notes that, in a study in healthy subjects, the concurrent use of atazanavir 300 mg daily with ritonavir-boosted tipranavir 100/500 mg twice daily increased tipranavir exposure (minimum plasma level increased by 75%) and ritonavir exposure (AUC increased by 51%) while markedly reducing atazanavir exposure (AUC reduced by 68%, and minimum level reduced by 81%).

- Concurrent use is not recommended.[24,25]

C. Darunavir

(a) Indinavir

The manufacturers note that, in a study in 9 subjects, giving indinavir 800 mg twice daily with ritonavir-boosted darunavir 100/400 mg twice daily increased the AUC and minimum level of darunavir by 24% and 44%, respectively. In addition, the AUC and minimum level of indinavir were increased by 23% and 125%, respectively, when compared with ritonavir-boosted indinavir 100/800 mg twice daily alone.[26,27] The US manufacturer[27] states that the appropriate dose of indinavir with ritonavir-boosted darunavir has not been established; however, the UK manufacturer[26] suggests that the dose of indinavir may need reducing from 800 mg twice daily to 600 mg twice daily if adverse effects occur.

- No dose adjustment is usually needed. Decreasing the dose of indinavir to 600 mg twice daily may be necessary if the combination is poorly tolerated.[26]

(b) Lopinavir

The manufacturers note that, in a study in 14 subjects, giving ritonavir-boosted lopinavir 100/400 mg with ritonavir-boosted darunavir 100/1200 mg, both twice daily, decreased the AUC and minimum level of darunavir by 38% and 51%, respectively. When ritonavir-boosted lopinavir 133.3/533 mg was given with unboosted darunavir 1200 mg, both twice daily, the AUC and minimum level of darunavir were decreased by 41% and 55%, respectively. The pharmacokinetics of lopinavir were unaffected in both studies.[26,27] The manufacturers and the US guidelines state that the appropriate doses for concurrent use have not been established.

- The manufacturers contraindicate concurrent use.[1,26,27]

(c) Saquinavir

The manufacturer notes that giving saquinavir hard capsules 1 g twice daily with ritonavir-boosted darunavir 100/400 mg twice daily decreased the AUC and minimum level of darunavir by 26% and 42%, respectively. The levels of saquinavir were not changed, when compared with using ritonavir-boosted saquinavir 100/1000 mg twice daily alone.[26,27] The US manufacturer and US guidelines state that the appropriate doses for concurrent use have not been established.[1,27]

- Concurrent use is not recommended.[1,26,27]

(d) Other protease inhibitors

The combination of darunavir with other protease inhibitors, other than atazanavir, indinavir, ritonavir-boosted lopinavir and saquinavir, or with ritonavir as a pharmacological booster, has not been studied. Therefore, the manufacturer does not recommended concurrent use.[26,27]

D. Indinavir

(a) Lopinavir

In a study in 13 subjects, indinavir 600 mg twice daily for 10 days with ritonavir-boosted lopinavir 100/400 mg twice daily produced a similar indinavir AUC, a 3.5-fold higher indinavir minimum level and 29% lower indinavir maximum level when compared with indinavir 800 mg three times daily alone.[13,14] Based on historical comparisons, lopinavir levels were similar to those seen without indinavir.[14]

- Reduce the dose to indinavir 600 mg twice daily if a ritonavir-boosted lopinavir twice daily dosing regimen is given.[1,13] Ritonavir-boosted lopinavir given once daily has not been studied with indinavir.[13]

(b) Nelfinavir

The concurrent use of indinavir 1.2 g every 12 hours with nelfinavir 1.25 g every 12 hours produced plasma levels that were equivalent to the standard dose of indinavir 800 mg every 8 hours in HIV-positive subjects. This suggests that nelfinavir only modestly inhibits indinavir metabolism. In this multiple-dose study, indinavir did not affect the pharmacokinetics of nelfinavir.[31] In contrast, a single 750-mg dose of nelfinavir, given after indinavir 800 mg every 8 hours for 7 days to 6 subjects resulted in an 83% increase in the AUC of nelfinavir and a 31% increase in its maximum concentration. In addition, giving a single 800-mg dose of indinavir after nelfinavir 750 mg three times daily for 7 days to 6 subjects resulted in a 51% increase in the indinavir plasma AUC, but no significant effect on the maximum or minimum concentration of indinavir.[15,32] The US guidelines note that there is limited data for giving indinavir 1.2 g twice daily with nelfinavir 1.25 g twice daily.[1]

- The appropriate dose of indinavir with nelfinavir has not been established.[32,33]

(c) Ritonavir

The effects of a range of doses of ritonavir (200, 300, or 400 mg every 12 hours) on indinavir pharmacokinetics were assessed in 39 healthy subjects. The AUC of indinavir 400 or 600 mg was increased two- to fivefold by ritonavir. It is suggested that the combination of indinavir 400 mg every 12 hours with ritonavir 400 mg every 12 hours will result in an AUC of indinavir roughly equivalent to that of indinavir 800 mg every 8 hours, without any effect on the pharmacokinetics of ritonavir.[34] In another similar study, when compared with historical data for indinavir 800 mg every 8 hours, the AUC of indinavir was at least 1.4-fold, 2.3-fold, and 3.3-fold

higher when ritonavir-boosted indinavir was given in twice daily doses of 400/400 mg, 100/800 mg, and 200/800 mg, respectively. The regimens also produced markedly higher trough indinavir levels. The 100/800 mg regimen was the best tolerated.[35] In another study, indinavir 800 mg twice daily for 14 days increased the AUC, maximum concentration and minimum concentration of ritonavir 100 mg twice daily, also taken for 14 days, by 72%, 61% and 62%, respectively. Increasing the dose of ritonavir to 200 mg twice daily had a lesser effect on the maximum concentration (increase of 19%) and had a similar effect on the AUC, increasing it by 96%. However, this produced a more significant increase in the trough level of ritonavir, of 4.7-fold.[33] The US manufacturer states that the appropriate doses for concurrent use have not been established.[33]

- If ritonavir is given as a pharmacokinetic booster, the manufacturers recommended dose is ritonavir-boosted indinavir 100/400 mg twice daily.[3] The US guidelines advise giving indinavir 800 mg with ritonavir 100 or 200 mg, both twice daily, or indinavir 400 mg with ritonavir 400 mg twice daily.[1]
- Caution is needed when indinavir is used at a dose of 800 mg twice daily with ritonavir, because of the possibility of an increased risk of nephrolithiasis. Appropriate hydration is strongly recommended.[3,33]
- The US guidelines state that concurrent use is not recommended as part of initial therapy because of the risk of nephrolithiasis.[1]

(d) Saquinavir

In a single-dose study in 6 subjects, the concurrent use of indinavir and saquinavir 600 mg (hard capsule), or 800 mg or 1.2 g (soft capsule), increased the AUC of saquinavir 6-fold, 7.2-fold and 4.6-fold, respectively. Large increases in both the minimum and maximum concentrations of saquinavir were also reported.[3,33] Concurrent use with ritonavir-boosted saquinavir has not been studied.[30]

- The appropriate dose of indinavir with saquinavir is not established.[1,3,33]

(e) Tipranavir

The concurrent use of tipranavir with indinavir is not recommended as there is insufficient data and doses are not established.[1]

E. Lopinavir

(a) Nelfinavir

The US manufacturer notes that, in a study in 13 subjects, the concurrent use of nelfinavir 1 g twice daily with ritonavir-boosted lopinavir 100/400 mg twice daily resulted in similar nelfinavir pharmacokinetics to nelfinavir 1.25 g twice daily alone, but with markedly increased levels of the M8 metabolite of nelfinavir. Lopinavir levels were modestly reduced (27% decrease in the AUC and 38% decrease in the minimum level).[13] The US guidelines state that there are no dosing recommendations.[1]

- A dose increase of ritonavir-boosted lopinavir *oral solution* to 133/533 mg twice daily or ritonavir-boosted lopinavir *tablets* to 125/500 mg twice daily may be needed. In children, the dose of ritonavir-boosted lopinavir should be increased to 75/300 mg/m^2. Avoid once daily regimens.[13,14]

(b) Ritonavir

Ritonavir is used to increase the plasma levels of lopinavir. The marketed combination is lopinavir 400 mg twice daily with ritonavir 100 mg twice daily.[13,14] When an additional 100 mg of ritonavir twice daily was added to this combination, the AUC of lopinavir was increased by 33% and its trough concentration was increased by 64%.[14]

- The use of lopinavir with ritonavir as a pharmacokinetic enhancer is established. The dose of additional ritonavir is not established, and is generally not recommended.[1]

(c) Saquinavir

Saquinavir 800 mg twice daily given with ritonavir-boosted lopinavir produced a 9.6-fold increase in saquinavir AUC relative to saquinavir 1.2 g three times daily given alone. When compared with ritonavir-boosted saquinavir 100/1000 mg twice daily, the increase in saquinavir AUC was about 30%, and was similar to that reported after ritonavir-boosted saquinavir 400/400 mg twice daily alone. When saquinavir 1.2 g twice daily was given with ritonavir-boosted lopinavir, no further increase in concentrations was noted. Lopinavir levels did not appear to be affected by saquinavir, based on historical comparison with ritonavir-boosted lopinavir alone.[14]

- In the US, the manufacturer recommends that saquinavir 1 g twice daily be used with ritonavir-boosted lopinavir 100/400 mg twice daily.[1,13]

(d) Tipranavir

In a clinical study of dual-boosted protease inhibitors in multiple-treatment experienced HIV-positive adults there was a 70% reduction in minimum lopinavir levels when ritonavir-boosted tipranavir 200/500 mg twice daily was added to ritonavir-boosted lopinavir 100/400 mg twice daily.[24,25] The clinical relevance of the reduction in lopinavir levels has not been established.

- Concurrent use is not recommended.[1,24,25] Appropriate doses are not established.[1]

F. Nelfinavir

(a) Ritonavir

Single-dose data indicate that ritonavir increases the AUC of nelfinavir by 1.8- to 2.5-fold, whereas the AUC of ritonavir is unchanged.[36] In a multiple-dose study in healthy subjects, ritonavir 100 or 200 mg twice daily increased the steady-state AUC of nelfinavir 1.25 g twice daily by 20% and 39%, after morning and evening doses, respectively. The AUC of the M8 metabolite of nelfinavir was increased by 74% and 86%, respectively. There was no difference in the effect of the two doses of ritonavir on nelfinavir AUC.[37]

- The appropriate dose of nelfinavir with ritonavir is not established.[1,32]

(b) Saquinavir

A single 1.2-g dose of saquinavir (soft gel capsules), given after 3 days of nelfinavir 750 mg every 8 hours had no effect on the pharmacokinetics of nelfinavir, but the nelfinavir caused a fourfold increase in the AUC of saquinavir.[38] Similar two- to twelvefold increases have been found in other studies in HIV-positive subjects.[39-42] A study in which 157 patients received 12 weeks of saquinavir with nelfinavir (doses unstated) found that concurrent use was well tolerated.[43] The US manufacturer states that saquinavir 1.2 g with nelfinavir 1.25 g, both taken twice daily, gives adequate plasma concentrations of both drugs.[30]

- No dose adjustment is needed for ritonavir-boosted saquinavir 100/1200 mg with nelfinavir 1.25 g taken twice daily.[23]

G. Ritonavir

(a) Saquinavir

A study in 6 patients with advanced HIV infection found that while taking saquinavir 600 mg three times daily the addition of ritonavir 300 mg twice daily increased the maximum saquinavir plasma levels 33-fold, and increased the AUC 58-fold at steady state.[44] A pilot study in HIV-positive patients given both drugs together (saquinavir 800 mg daily, ritonavir 400 to 600 mg daily) found that the ritonavir serum levels were unaffected. However, the saquinavir levels were substantially higher than those achieved with saquinavir alone in daily doses of 3.6 to 7.2 g.[45] A study in 57 healthy subjects covering a range of ritonavir and saquinavir *(Invirase)* doses (200 to 600 mg) found that saquinavir did not affect ritonavir pharmacokinetics, but ritonavir increased the AUC of saquinavir 50 to 132-fold. The authors suggested that giving both drugs in a dose of 400 mg every 12 hours might be optimal.[46] Subsequent study has revealed that the effect of ritonavir on saquinavir is not related to the ritonavir dose in the range of 100 to 400 mg twice daily,[47-49] and that the use of a combination with a higher dose of saquinavir and a lower dose of ritonavir may be preferable, as the lower doses of ritonavir are associated with fewer adverse effects.[49] A dose of saquinavir 1 g twice daily with ritonavir 100 mg twice daily is recommended by the manufacturers of saquinavir.[23,30] The UK manufacturer of ritonavir also states that doses of ritonavir higher than 100 mg twice daily should not be used in combination with saquinavir.[50] The manufacturers of ritonavir note that higher doses of ritonavir have been associated with an increased incidence of adverse events, including a significant increase in total triglycerides and cholesterol.[50,51] The concurrent use of saquinavir and ritonavir has led to severe adverse events, mainly diabetic ketoacidosis and liver disorders, especially in patients with pre-existing liver disease.[50]

- When ritonavir is given as a pharmacokinetic booster, the recommended dose is saquinavir 1000 mg with ritonavir 100 mg twice daily.[1,23,30,50,51] Higher ritonavir doses are associated with increased adverse effects and should not be used.[50]

H. Saquinavir

(a) Tipranavir

In a clinical study of dual-boosted protease inhibitors in multiple-treatment experienced HIV-positive adults there was a marked, approximately

80%, reduction in minimum saquinavir levels when ritonavir-boosted tipranavir 200/500 mg twice daily was added to ritonavir-boosted saquinavir 100/600 mg twice daily.[24,25] The clinical relevance of the reduction in saquinavir levels has not been established.

- Concurrent use is not recommended.[1,24,25] Appropriate doses are not established.[1] However, the combination is given, close monitoring the plasma levels of the protease inhibitors is strongly encouraged.[25]

Mechanism

Protease inhibitors are inhibitors and substrates of the cytochrome P450 isoenzyme CYP3A4, with ritonavir being the most potent inhibitor and saquinavir one of the least (see 'Antivirals', (p.913)). They probably interact by inhibiting each other's gut (pre-absorption) and hepatic (post-absorption) metabolism, so resulting in increased absorption and decreased elimination.[46,52] A mechanism involving inhibition of P-glycoprotein may also be involved.[52]

Importance and management

Ritonavir inhibits the metabolism of amprenavir (and amprenavir derived from fosamprenavir), atazanavir, darunavir, indinavir, lopinavir, nelfinavir, tipranavir, and particularly saquinavir. Low-dose ritonavir is therefore used in combination with other protease inhibitors to boost their levels, and allow a reduction in the protease inhibitor dose and the frequency of dosing. The US guidelines state that ritonavir-boosted atazanavir, darunavir, fosamprenavir or lopinavir are the protease inhibitors preferred as alternative options to efavirenz for use with dual NRTIs for the treatment of HIV-infection in treatment naïve patients. Ritonavir-boosted saquinavir is considered inferior to these.[1] The 2009 UK guidelines recommend dual NRTIs with a boosted protease inhibitor as an alternative option to dual NRTIs with efavirenz. The preferred ritonavir-boosted protease inhibitors are atazanavir, fosamprenavir, lopinavir and saquinavir: unboosted atazanavir may be used as an alternative regimen for patients with cardiovascular risk factors (dyslipidaemia).[53] The US guidelines state that indinavir should be avoided as initial therapy because of a high incidence of nephrolithiasis, and that atazanavir with indinavir should never be used because of potential additive hyperbilirubinaemia. They also state that darunavir, saquinavir and tipranavir must not be used without low-dose ritonavir.[1] There appears to be no clinically important pharmacokinetic interactions between amprenavir with indinavir, nelfinavir, or saquinavir, between atazanavir with darunavir and ritonavir, and probably also indinavir with nelfinavir. Various dual ritonavir-boosted protease inhibitor combinations act to lower the levels of one of the protease inhibitors and should therefore probably be avoided. When considering appropriate protease inhibitor combinations, in addition to pharmacokinetic interactions, cross resistance patterns and adverse effects should also be considered. Current local and national guidelines should be consulted when choosing protease inhibitor combinations.

Protease inhibitors + Rifampicin (Rifampin)

Rifampicin markedly reduces the bioavailability of amprenavir, atazanavir, indinavir, indinavir, ritonavir-boosted lopinavir, nelfinavir and both saquinavir and ritonavir-boosted saquinavir, but only modestly reduces the bioavailability of ritonavir. It is also predicted to reduce the levels of ritonavir-boosted darunavir and tipranavir. Some protease inhibitors increase the levels of rifampicin.

Clinical evidence

(a) Amprenavir or Fosamprenavir

When 11 healthy subjects were given amprenavir 1.2 g twice daily with rifampicin 600 mg daily for 4 days the pharmacokinetics of rifampicin were not affected, but the AUC of amprenavir was reduced by 82%. The maximum plasma level of amprenavir was also reduced by 70%, from 9.2 to 2.78 micrograms/mL, and its minimum level was reduced by 94%, from 0.32 to 0.02 micrograms/mL.[1]

It is expected that the concurrent use of fosamprenavir or ritonavir-boosted fosamprenavir with rifampicin will also result in large decreases in the plasma concentrations of the metabolite, amprenavir.[2,3]

(b) Atazanavir

In a study, 52 healthy subjects were given atazanavir 400 mg daily for 6 days, followed by ritonavir-boosted atazanavir 100/300 mg daily for 10 days. They were then given rifampicin 600 mg daily for the next 10 days with either the same dose of ritonavir-boosted atazanavir or with of ritonavir-boosted atazanavir in higher doses of either 200/300 mg daily or 200/400 mg daily. The addition of rifampicin to ritonavir-boosted atazanavir 100/300 mg daily reduced the AUC, maximum plasma concentration and minimum plasma concentration of atazanavir by 72%, 49% and 97%, respectively. However, increasing the ritonavir dose by just 100 mg daily resulted in smaller although still clinically significant reduction in the AUC, maximum concentration and minimum concentration of atazanavir (53%, 35% and 93%, respectively). Similarly, increasing both the atazanavir and ritonavir doses by 100 mg again slightly reduced the effects of rifampicin; however, the AUC and minimum plasma level of atazanavir were still reduced, by 46% and 92%, respectively. The AUC and maximum plasma levels of rifampicin were increased by ritonavir-boosted atazanavir by 49 to 64% and 32 to 36%, respectively, with the effects slightly increasing with the increase in atazanavir and ritonavir doses, as before.[4]

In another study in 10 healthy subjects, the effects of rifampicin 600 mg daily on the pharmacokinetics of atazanavir 300 mg or 400 mg twice daily for between 8 and 11 days were investigated. Rifampicin reduced the mean AUC of atazanavir 300 mg by 79% and that of atazanavir 400 mg by 59%. The mean maximum and minimum plasma concentrations of atazanavir were reduced by 63% and 94% and 40% and 87% for atazanavir 300 mg and 400 mg twice daily, respectively. No significant increases in rifampicin exposure were reported.[5] A small study in 3 HIV-positive patients also reported subtherapeutic levels of atazanavir (given as ritonavir-boosted atazanavir 100/300 mg daily) with rifampicin 600 mg daily , and the study was stopped prematurely.[6] None of these studies reported significant increase in adverse effects with the concurrent use of atazanavir or ritonavir-boosted atazanavir and rifampicin.[4-6] However, a subsequent pharmacokinetic study in 15 healthy subjects who received rifampicin 600 mg daily with ritonavir-boosted atazanavir 100/300 mg daily was stopped prematurely due to nausea and vomiting, and significant increases in hepatic transaminases.[7]

(c) Indinavir

A study in 11 patients with AIDS given indinavir 800 mg every 8 hours and rifampicin 600 mg daily for 14 days found that the AUC of rifampicin was increased by 73%.[8] In a similar study looking at the effects of rifampicin on indinavir, the indinavir AUC and maximum serum levels were decreased by 92% and 86%, respectively.[9] In another study, in 6 HIV-positive patients taking ritonavir-boosted indinavir 100/800 mg twice daily, rifampicin 300 mg daily for 4 days decreased the median indinavir plasma levels (measured 12 hours after the last dose) by 87% and the median ritonavir levels by 94%.[10]

(d) Lopinavir

In a study in healthy subjects, rifampicin 600 mg daily for 10 days decreased the AUC of lopinavir (given as ritonavir-boosted lopinavir 100/400 mg twice daily) by 75%.[11] In another study, a dose titration of ritonavir-boosted lopinavir was carried out in healthy subjects to try to overcome the interaction with rifampicin.[12] In 10 evaluable subjects, rifampicin 600 mg daily with ritonavir-boosted lopinavir 200/800 mg twice daily decreased the minimum lopinavir level by 57% without affecting the maximum level, when compared with ritonavir-boosted lopinavir 100/400 mg twice daily without rifampicin. In another 9 evaluable subjects, rifampicin 600 mg daily with ritonavir-boosted lopinavir 400/400 mg twice daily did not alter the maximum or minimum level of lopinavir, but markedly *increased* ritonavir levels, when compared with ritonavir-boosted lopinavir 100/400 mg twice daily without rifampicin. Of 29 subjects who received the adjusted doses of ritonavir-boosted lopinavir with rifampicin, 9 subjects had grade 2 to 3 elevations in liver enzymes, and this was more common in the 400/400 mg group than the 200/800 mg group.[12] In a subsequent study, healthy subjects were given rifampicin 600 mg daily for 5 days and then also given ritonavir-boosted lopinavir at standard doses. However, on day 8, the study was stopped prematurely due to a high incidence of adverse effects, including nausea, vomiting and hepatotoxicity.[13]

A study in children investigated the difference between a control group taking ritonavir-boosted lopinavir in the standard ratio of 1:4 and a group taking rifampicin with ritonavir-boosted lopinavir in a ratio of 1:1. The AUC, maximum plasma concentration and minimum plasma concentration of lopinavir were 31%, 26% and 15% lower in the rifampicin group, when compared with the control group. However the minimum levels in 13 of the 15 children were still above the minimum recommended levels of lopinavir (greater than 1 mg/L).[14]

(e) Nelfinavir

Rifampicin 600 mg daily for 7 days decreased the AUC of nelfinavir 750 mg every 8 hours for 6 days by 82%.[15] A 7-month-old infant with HIV and tuberculosis was given a rifampicin-based antimycobacterial regimen with nelfinavir-based HAART. Nelfinavir plasma levels were found to be very low, so ritonavir was added. This improved nelfinavir levels, and also greatly increased those of the principal active metabolite of nelfinavir. The regimen was well tolerated and had a good clinical response.[16]

(f) Ritonavir

When ritonavir 500 mg every 12 hours was given with rifampicin 300 mg or 600 mg daily for 10 days, the AUC of ritonavir was 35% lower and the maximum level 25% lower than in subjects receiving ritonavir alone.[17]

(g) Saquinavir

In a pharmacokinetic study in HIV-positive patients, the concurrent use of rifampicin and isoniazid reduced the AUC, maximum serum concentration and minimum serum concentration of saquinavir by 40%, 35%, and 49%, respectively. Similarly, the AUC, maximum serum concentration and minimum serum concentration of ritonavir were also reduced, by 43%, 50%, and 64%, respectively. The ritonavir trough level was undetectable in most of the patients. Ritonavir-boosted saquinavir had no significant effect on the pharmacokinetics of rifampicin or isoniazid.[18] Rifampicin 600 mg daily decreased the AUC of saquinavir (soft capsules, *Fortovase*) 1.2 g three times daily by 70%.[19] It was suggested that the combination of ritonavir and saquinavir (both 400 mg twice daily) could cancel out the effects of rifampicin on saquinavir, so therapeutic levels of all three drugs could be achieved. This assumption has been confirmed in HIV-positive patients.[20,21] Five of 20 patients originally given the combination developed hepatotoxicity, 2 of whom had co-morbidities.[21] However, in a further study in healthy subjects, severe hepatotoxicity with transaminase elevations about 20 times the upper limit of normal occurred in 11 of 17 subjects after they took ritonavir-boosted saquinavir 100/1000 mg twice daily with rifampicin 600 mg daily for one to 5 days.[22]

Mechanism

Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, by which the protease inhibitors are at least partially metabolised, and therefore it markedly reduces protease inhibitor levels.

The mechanism for the increase in rifampicin levels seen with ritonavir-boosted atazanavir is unknown. As rifampicin and its metabolite are not substrates for CYP3A4, which atazanavir inhibits, and atazanavir is only a weak inhibitor of P-glycoprotein, the authors of one study suggest that other mechanisms, such as competition for biliary excretion or other transport systems may be involved.[4]

Importance and management

Rifampicin markedly reduces the levels of many of the protease inhibitors, and its use with unboosted protease inhibitors should be avoided, because of the risk of reduced antiviral efficacy and emergence of resistant viral strains. There are limited data to suggest that ritonavir as the sole protease inhibitor, or ritonavir used as a pharmacokinetic enhancer with other protease inhibitors such as saquinavir, can be used with rifampicin.[23] However, further study has shown a high incidence of hepatotoxicity with ritonavir-boosted saquinavir 100/1000 mg twice daily and rifampicin, and therefore the manufacturers of both ritonavir and saquinavir contraindicate the concurrent use of rifampicin.[17,24-26] The manufacturers of atazanavir, **darunavir**, fosamprenavir, indinavir, nelfinavir, **tipranavir**, and ritonavir-boosted lopinavir also contraindicate the concurrent use of rifampicin.[2,3,27-37]

UK guidelines from 2009 state that, until more data are available, ritonavir-boosted protease inhibitors should not be used with rifampicin. They recommend that rifampicin should be switched to rifabutin for use with protease inhibitors, or that the protease inhibitor should be changed to an alternative antiretroviral if this is possible.[38] Similarly, the US guidelines state that all unboosted protease inhibitors should not be given with rifampicin or **rifapentine**, and that rifabutin should be used instead.[39] They also advise against the use of higher doses of ritonavir with lopinavir or saquinavir due to the high rate of hepatic adverse effects. The UK manufacturer of ritonavir-boosted lopinavir and also notes that high rates of hepatic adverse effects have been reported when a dose of ritonavir-boosted lopinavir 400/400 mg twice daily was used to overcome the inductive effects of rifampicin. They advise that if use of this regimen is unavoidable, the dose of lopinavir should be only be increased after rifampicin has been started and patients should be very closely monitored for adverse effects and efficacy.[40]

Both the UK and US guidelines[23,38,39] state that rifampicin may only be used with full-dose ritonavir (600 mg to 1.2 g daily) and advise caution on concurrent use; the UK guidelines note that this combination is poorly tolerated.[38]

'Table 21.5', (p.984), summarises the clinical recommendations for the concurrent use of protease inhibitors and rifampicin.

For further guidance on the use of rifabutin with the protease inhibitors, see 'Protease inhibitors + Rifabutin', p.983.

Protease inhibitors + Rifabutin

Rifabutin bioavailability is significantly increased by the protease inhibitors, in particular ritonavir, with an increased risk of toxicity. Rifabutin modestly decreases the bioavailability of indinavir, nelfinavir, and particularly saquinavir (with an increased risk of therapeutic failure), and appears to increase ritonavir-boosted darunavir, but has no significant effect on amprenavir, atazanavir, and ritonavir-boosted fosamprenavir or ritonavir-boosted tipranavir.

Clinical evidence

(a) Amprenavir or Fosamprenavir

When amprenavir 1.2 g twice daily was given with rifabutin 300 mg daily to 11 healthy subjects for 10 days there was an almost threefold increase in the AUC of rifabutin, but the pharmacokinetics of amprenavir were not significantly altered. The combination was poorly tolerated, with 5 of 11 subjects stopping treatment between days one and 9 due to adverse events.[1] When reduced doses of rifabutin (150 mg every other day) were given with ritonavir-boosted fosamprenavir 100/700 mg twice daily for 2 weeks to healthy subjects the rifabutin $AUC_{0\text{-}48}$ was unchanged and the maximum level was decreased by 14%, when compared with rifabutin 300 mg daily given alone. However, the $AUC_{0\text{-}48}$ and maximum level of the 25-*O*-desacetylrifabutin metabolite were increased by 11-fold and nearly sixfold,

Table 21.5 Summary of the recommendations for the use of protease inhibitors with rifamycins

Protease inhibitor	*Rifabutin*	*Rifampicin (Rifampin)*	*Refs*
Protease inhibitors			
Amprenavir	Rifabutin dose reduced to 150 mg daily or every other day. Amprenavir dose unchanged.	Not recommended (amprenavir levels markedly reduced).	1
Atazanavir	Rifabutin dose reduced to 150 mg daily.	Not recommended (atazanavir levels markedly reduced).	1
Fosamprenavir	Rifabutin dose reduced to 150 mg daily or 300 mg three times per week. Fosamprenavir dose unchanged.	Not recommended (amprenavir levels markedly reduced).	1-4
Indinavir	Rifabutin dose reduced to 150 mg daily or 300 mg three times per week. Indinavir dose increased to 1 g every 8 hours. Not recommended in UK Guidelines or by UK manufacturer.	Not recommended (indinavir levels markedly reduced, rifampicin levels raised).	1, 2, 4-7
Nelfinavir	Rifabutin dose reduced to 150 mg once daily or 300 mg three times per week. Nelfinavir dose unchanged (1.25 g twice daily preferred).	Not recommended (nelfinavir levels markedly reduced).	1, 2, 4, 8, 9
Ritonavir	Rifabutin dose reduced to 150 mg every other day or three times per week. Further dose reductions may be necessary.* Ritonavir dose unchanged.	May be used at usual doses, although limited data (ritonavir levels reduced). May lead to loss of virologic response.	2, 10
Saquinavir	Not recommended (saquinavir levels reduced).	Not recommended (saquinavir levels markedly reduced).	1, 2
Ritonavir-boosted protease inhibitors			
Atazanavir	Rifabutin dose reduced by up to 75% (150 mg every other day or three times per week). Ritonavir-boosted atazanavir dose unchanged.	Not recommended (atazanavir levels markedly reduced).	2, 11, 12
Darunavir	Rifabutin dose reduced to 150 mg every other day. Ritonavir-boosted darunavir dose unchanged.	Not recommended (darunavir levels predicted to be markedly reduced).	13, 14
Fosamprenavir	Rifabutin dose reduced by at least 75% (150 mg every other day or three times per week). Ritonavir-boosted fosamprenavir dose unchanged.	Not recommended (amprenavir levels predicted to be markedly reduced).	1, 3, 4, 15
Indinavir	Rifabutin dose reduced to 150 mg every other day or three times per week. Ritonavir-boosted indinavir dose unchanged. Not recommended in UK guidelines or by UK manufacturer	Not recommended (indinavir levels markedly reduced).	1, 2, 4, 16
Lopinavir	Rifabutin dose reduced to 150 mg every other day or three times per week. Ritonavir-boosted lopinavir dose unchanged.	Not recommended (lopinavir levels markedly reduced). However, adjusted doses of ritonavir-boosted lopinavir (200/800 mg or 400/400 mg twice daily) may overcome the pharmacokinetic interaction, but have a high incidence of elevated liver enzymes, and so if used, close monitoring is needed.	1, 2, 4, 17-19
Saquinavir	Rifabutin dose reduced to 150 mg every other day or three times per week. Appropriate ritonavir-boosted saquinavir dose not established. Consider usual dose (100/1000 mg twice daily).	Rifampicin dose unchanged. Ritonavir-boosted saquinavir 400/400 mg twice daily. Note that a regimen of 100/1000 mg twice daily with rifampicin was associated with severe hepatotoxicity, and the combination is contraindicated.	1, 2, 4, 20, 21
Tipranavir	Rifabutin dose reduced to 150 mg every other day or three times per week. Further dose reductions may be necessary. Ritonavir-boosted tipranavir dose unchanged.	Not recommended (tipranavir levels predicted to be markedly reduced).	1, 4, 22, 23

*Formerly considered contraindicated (rifabutin levels markedly increased with risk of toxicity)

respectively, which could potentially lead to an increase of rifabutin-related adverse effects such as uveitis. The AUC, maximum plasma concentration and minimum plasma concentration of amprenavir were modestly increased by 36%, 35% and 17%, respectively, compared with historical data.[2] No additional increase in significant adverse effects was reported on concurrent use.[2]

(b) Atazanavir

The manufacturers report that in a study in 7 subjects, atazanavir 400 mg daily given with rifabutin 150 mg daily for 14 days did not have any important effect on the pharmacokinetics of atazanavir. However, in 3 subjects, the AUC and minimum level of rifabutin 150 mg were 2.1-fold and 3.4-fold higher, respectively, than historical data for a standard 300-mg dose of rifabutin when given with atazanavir 600 mg daily. The AUC and minimum levels of the rifabutin 25-*O*-desacetyl metabolite were significantly increased, by 22-fold and 75-fold, respectively.[3,4]

(c) Darunavir

In a study in healthy subjects, either ritonavir-boosted darunavir 100/600 mg twice daily, rifabutin 150 mg on alternate days, or both drugs were taken for 13 days. The AUC of rifabutin was not significantly changed compared with rifabutin 300 mg daily alone. However, the AUC and minimum plasma level of its 25-*O*-desacetyl metabolite was increased almost 10-fold and 27-fold, respectively. Rifabutin increased the AUC of both darunavir and ritonavir by 57% and 66%, respectively. In addition, rifabutin increased the AUC and minimum plasma level of darunavir by 57% and 75%, respectively. A higher rate of adverse effects (headache, diarrhoea, back pain, dizziness and vomiting) was reported with concurrent use.[5]

(d) Indinavir

When 10 healthy subjects were given rifabutin 300 mg daily with indinavir 800 mg every 8 hours to for 10 days, the indinavir maximum serum levels and AUC were reduced by about one-third, whereas the rifabutin maximum serum levels and AUC were increased two- to three-fold.[6] When the same dose of indinavir (800 mg every 8 hours) was given with half the dose of rifabutin (150 mg daily), the AUC of indinavir was similarly reduced (by 32%), but the increase in the AUC of rifabutin was less (54% increase).[6] In a further study, the pharmacokinetics of indinavir 1 g every 8 hours (increased dose) and rifabutin 150 mg daily (reduced dose) were investigated in healthy and HIV-positive subjects. The AUC of indinavir was the same with this increased dose as with indinavir 800 mg every 8 hours alone. However, despite halving the rifabutin dose, the AUC was still up to 70% higher than with the 300-mg dose alone.[7] When the combination was used in practice, there were no treatment failures in 25 patients taking rifabutin and HAART (containing indinavir and/or nelfinavir). Rifabutin was given as 300 mg twice weekly and the indinavir dose was increased from 800 mg to 1.2 g every 8 hours to achieve satisfactory levels.[8]

(e) Lopinavir

When healthy subjects were given ritonavir-boosted lopinavir 100/400 mg twice daily with rifabutin 150 or 300 mg daily for 10 days the AUC of rifabutin was increased threefold and the AUC of lopinavir was increased by 17%.[9] A case of rifabutin-induced uveitis has been reported in an HIV-positive patient taking rifabutin 300 mg daily and also taking ritonavir-boosted lopinavir 100/400 mg twice daily.[10]

(f) Nelfinavir

When rifabutin 300 mg daily for 8 days was given with nelfinavir 750 mg every 8 hours for 7 to 8 days, the nelfinavir AUC and minimum concentration were reduced by 32% and 53%, respectively. Nelfinavir increased the rifabutin AUC, maximum concentration and minimum concentration by 207%, 146%, and 305%, respectively.[11,12] When the same dose of nelfinavir was given with half the dose of rifabutin (150 mg daily) for 8 days, the nelfinavir AUC was reduced by a similar amount (23%), although the minimum concentration was only reduced by 25%. The rifabutin AUC and minimum concentration were increased by nelfinavir but by a lower amount (83% and 177%, respectively), and the maximum concentration of rifabutin was minimally affected.[12,13] A study in 7 HIV-positive patients taking rifabutin 300 mg twice weekly with nelfinavir 1.25 g twice daily reported a small increase of 22% in the AUC of rifabutin and a larger increase of 246% in the AUC of its 25-*O*-desacetyl metabolite. The pharmacokinetics of nelfinavir and its M8 metabolite were unaffected. However, the sample size in this study was too small to establish or exclude statistical significance.[14]

(g) Ritonavir

In a study in 5 healthy subjects when ritonavir 500 mg twice daily was given with rifabutin 150 mg daily for 8 days, the maximum serum level of rifabutin was increased threefold and the AUC was increased fourfold. The AUC of the rifabutin active metabolite, 25-*O*-desacetylrifabutin, was increased 35-fold. Seven subjects had to be withdrawn due to adverse effects, primarily leucopenia.[15] Retrospective analysis of regimens containing ritonavir found that the concurrent use of rifabutin was associated with a higher incidence of rifabutin-related adverse effects including arthralgia, joint stiffness, uveitis and leucopenia.[16]

(h) Saquinavir

In 12 HIV-positive subjects, the AUC of saquinavir 600 mg three times daily was reduced by about 40% by rifabutin 300 mg daily.[17] Similarly, in 14 HIV-positive patients, the AUC of saquinavir (soft capsules) 1.2 g three times daily was decreased by 47% by rifabutin 300 mg daily. In addition, the rifabutin AUC was increased by 44% by saquinavir.[18] However, the concurrent use of ritonavir and saquinavir (hard capsules), both 400 mg twice daily, with intermittent rifabutin dosing (300 mg weekly or 150 mg every 3 days) for 8 weeks was reported to be safe and manageable. Rifabutin did not significantly alter the protease inhibitor levels, and the rifabutin pharmacokinetics were similar to those usually seen with rifabutin 300 mg daily alone.[19]

A case of anterior uveitis has been reported in an HIV-positive patient taking ritonavir-boosted saquinavir 200/1000 mg daily and rifabutin 300 mg daily. The patient was also taking abacavir, lamivudine, tenofovir, atovaquone, omeprazole, isoniazid and pyridoxine. Rifabutin was stopped, and the patient's vision improved when treated with topical prednisolone.[20]

(i) Tipranavir

In a study in 20 healthy subjects, a single 150-mg dose of rifabutin was taken on day 8 of a 13-day course of ritonavir-boosted tipranavir 200/500 mg twice daily. The single dose of rifabutin had no significant effect on the pharmacokinetics of tipranavir. However, ritonavir-boosted tipranavir significantly increased the AUC, maximum serum concentration and minimum serum concentration of rifabutin 2.9-fold, 1.7-fold and

2.14-fold, respectively. In addition, the AUC, maximum concentration and minimum concentration of 25-*O*-desacetylrifabutin were increased 20.7-fold, 3.2-fold and 7.8-fold, respectively. The effects of the single dose of rifabutin on the pharmacokinetics of ritonavir were not reported.[21]

Mechanism

The protease inhibitors are metabolised by the cytochrome P450 isoenzyme CYP3A4, and as rifabutin is a weak inducer of this isoenzyme, it may reduce the levels of the protease inhibitors.

Rifabutin itself is partially metabolised by CYP3A4 whereas 25-*O*-desacetyl rifabutin is completely metabolised by CYP3A4. Therefore inhibition of CYP3A4 by the protease inhibitors, and in particular ritonavir, can increase the levels of rifabutin and greatly increase the levels of its 25-*O*-des-acetyl metabolite.[21]

Importance and management

Established interactions of clinical importance. The protease inhibitors increase the levels of rifabutin and its active 25-*O*-desacetyl metabolite, with a consequent increase in adverse effects unless the rifabutin dose is reduced. **Ritonavir** is the most potent protease inhibitor in this regard, and the combination has been considered contraindicated. However, rifampicin is contraindicated for use with the protease inhibitors (see 'Protease inhibitors + Rifampicin (Rifampin)', p.982), and both the CDC in the US and the British HIV Association (BHIVA) advise that rifabutin is used instead of rifampicin, but only if the dose of rifabutin is markedly reduced.[22-24]

For patients taking **ritonavir-boosted protease inhibitors**, the US guidelines recommend that the dose of rifabutin is reduced to 150 mg every other day or three times per week whereas the British HIV Association (BHIVA) just recommend using a rifabutin dose of 150 mg three times weekly.[22-24] The BHIVA in the UK also advise against using rifabutin with unboosted indinavir or saquinavir, and they suggest that the dose of rifabutin is reduced to 150 mg daily with other unboosted protease inhibitors.[23] 'Table 21.5', (p.984), summarises the clinical recommendations for the concurrent use of protease inhibitors and rifabutin.

In addition, rifabutin decreases the levels of some protease inhibitors, particularly **saquinavir**, increasing the risk of HIV treatment failure. Rifabutin should not be used when saquinavir is the sole protease inhibitor (no longer recommended). However, there is some evidence that rifabutin can be used with ritonavir-boosted saquinavir. In this case the manufacturer recommends that patients should be closely monitored for hepatic adverse effects.[25]

The US manufacturer of **indinavir** advises that the dose of indinavir is increased to 1 g every 8 hours and the dose of rifabutin halved if both drugs are given,[26] whereas the UK manufacturer does not recommend concurrent use and suggests an alternative HIV regimen is considered.[27]

Therapy should be closely monitored to minimise the occurrence of rifabutin-related adverse effects, in particular uveitis and blood dyscrasias. Patients should also be closely monitored for adherence to the protease inhibitor regimen, as non-compliance could lead to subtherapeutic rifabutin levels and tuberculosis treatment failure. Note that, in one analysis, the use of rifabutin 150 mg twice weekly with low-dose ritonavir and a second protease inhibitor was associated with low rifabutin levels.[28] Further rifamycin-resistant *Mycobacterium tuberculosis* may occur in HIV-positive patients resulting in relapse.[29]

Protease inhibitors + St John's wort (*Hypericum perforatum*)

St John's wort causes a marked reduction in the serum levels of indinavir, which may result in HIV treatment failure. Other protease inhibitors, whether used alone or boosted by ritonavir, are predicted to interact similarly.

Clinical evidence

In a single-drug pharmacokinetic study, 8 healthy subjects were given three 800-mg doses of **indinavir** on day 1 of to achieve steady-state serum levels, and then an 800-mg dose on day 2. For the next 14 days they were given St John's wort extract 300 mg three times daily. Starting on day 16, the indinavir dosing was repeated. It was found that St John's wort reduced the mean AUC of **indinavir** by 54% and decreased the 8-hour **indinavir** trough serum level by 81%.[1]

Mechanism

Not fully understood, but it seems highly likely that the St John's wort induces the activity of the cytochrome P450 isoenzyme CYP3A4, thereby increasing the metabolism of indinavir and therefore reducing its levels.

Importance and management

Direct information seems to be limited to this study, but the interaction would appear to be established. Such a large reduction in the serum levels

of indinavir is likely to result in treatment failures and the development of viral resistance. Therefore St John's wort should be avoided. There seems to be no direct information about other protease inhibitors, but since they are also metabolised by CYP3A4 it is reasonable to expect that they will be similarly affected by St John's wort. The FDA in the US has suggested that concurrent use of St John's wort and protease inhibitors is not recommended.[2] Similarly, the CSM in the UK has advised that patients taking protease inhibitors should avoid St John's wort and that anyone already taking both should stop the St John's wort and have their HIV RNA viral load measured.[3] The levels of the protease inhibitors are likely to increase as the induction effects of St John's wort diminish, usually over one to two weeks.[4] Therefore the dose of the protease inhibitor will probably need adjusting. The US and UK manufacturers of all protease inhibitors (**amprenavir**, **atazanavir**, **darunavir**, **fosamprenavir**, **lopinavir/ritonavir**, **nelfinavir**, **ritonavir**, **saquinavir**, **tipranavir**) either contraindicate or advise against the use of St John's wort.

Protease inhibitors + Tenofovir

Ritonavir-boosted atazanavir, darunavir and lopinavir modestly increase the levels of tenofovir, and there is at least one case report of nephrotoxicity with the combination of tenofovir, didanosine, and ritonavir-boosted lopinavir. Ritonavir-boosted saquinavir, tipranavir, and probably also fosamprenavir, have little effect on tenofovir levels. Tenofovir modestly decreases atazanavir levels. Tenofovir has no important effect on ritonavir-boosted darunavir, lopinavir, and tipranavir levels, and modestly increased those of ritonavir-boosted saquinavir in one of two studies. No pharmacokinetic interaction occurs between tenofovir and indinavir or nelfinavir.

Clinical evidence

(a) Atazanavir

In a study in 33 subjects, tenofovir disoproxil fumarate 300 mg daily decreased the AUC and trough level of unboosted atazanavir 400 mg daily, taken for 14 days, by 25% and 40%, respectively. Atazanavir increased the AUC and trough level of tenofovir by 24% and 22%, respectively.[1-3] Similar results were seen when administration was separated by 12 hours.[2]

When atazanavir 300 mg daily was given with ritonavir 100 mg daily (as a pharmacokinetic booster) to 10 subjects for 42 days, the addition of tenofovir disoproxil fumarate 300 mg daily reduced the AUC of atazanavir by a similar amount (25%), but had less of an effect on the trough level (23% reduction), when compared with ritonavir-boosted atazanavir alone.[4] Similarly, in two studies in HIV-positive patients, the pharmacokinetics of ritonavir-boosted atazanavir did not differ significantly between patients taking tenofovir and those not taking tenofovir.[5,6] Other studies have suggested that the concurrent use of ritonavir-boosted atazanavir increases the AUC of tenofovir by 37% and increases its minimum level by 29%.[1,2,7]

(b) Darunavir

In a study in 12 healthy subjects, the concurrent use of ritonavir-boosted darunavir 100/300 mg twice daily with tenofovir disoproxil fumarate 300 mg daily for 14 days modestly increased the tenofovir AUC and minimum level by 22% and 37%, respectively. The pharmacokinetics of darunavir were not significantly changed (minimum level increased by 24% and AUC increased by 21%). Tenofovir had no significant effect on the pharmacokinetics of ritonavir. No significant increase in adverse effects was reported with concurrent use.[8]

(c) Fosamprenavir

The US manufacturer notes that, in a phase III clinical study in 45 subjects, amprenavir trough plasma levels (derived from fosamprenavir) were similar in subjects receiving tenofovir 300 mg daily with ritonavir-boosted fosamprenavir 100/700 mg twice daily for 4 to 48 weeks to those in subjects not receiving tenofovir.[9] Similarly, in a pharmacokinetic study in 30 healthy subjects given ritonavir-boosted fosamprenavir 100/1400 mg daily or 200/1400 mg daily for 28 days, tenofovir disoproxil fumarate 300 mg daily (taken on days 15 to 28) had no significant effect on the pharmacokinetics of amprenavir.[10]

An observational cohort study[11] in 445 HIV-positive patients taking tenofovir reported that the concurrent use of amprenavir was associated with an increased risk of tenofovir-induced renal failure (odds ratio 3.6), whereas another cohort study of 1428 HIV-positive patients including 105 patients taking tenofovir and fosamprenavir found no statistically significant decline in renal function with concurrent use and the use of ritonavir-boosted protease inhibitors did not increase the risk of renal adverse effects.[12]

(d) Indinavir

The manufacturer of tenofovir notes that, in a study in 13 subjects, there was no clinically significant pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg daily and indinavir 800 mg three times daily, taken for 7 days.[3,7]

(e) Lopinavir

In a study in 24 healthy subjects, the concurrent use of ritonavir-boosted lopinavir 100/400 mg twice daily with tenofovir 300 mg daily for 14 days, resulted in a 32% increase in the AUC and a 51% increase in the trough level of tenofovir, but no change in the clearance of tenofovir. The pharmacokinetics of lopinavir and ritonavir were unaffected by tenofovir. No serious adverse effects were reported in this short-term study, and no subjects had changes in creatinine clearance or developed renal failure.[13] Another study in 30 HIV-positive patients found that ritonavir-boosted lopinavir reduced tenofovir clearance by 18%.[14]

A study in 20 HIV-positive subjects found that concurrent use of tenofovir reduced the AUC and maximum concentration of lopinavir by 26% and 28%, respectively. The AUC and maximum concentration of ritonavir were also similarly affected by tenofovir, with a reduction of 37% and 45%, respectively. However, the minimum concentrations of either drug were not significantly reduced by tenofovir.[15] There is one case report of Fanconi syndrome with nephrogenic diabetes insipidus, which developed in a patient taking ritonavir-boosted lopinavir 200/800 mg daily, tenofovir disoproxil fumarate 300 mg daily, didanosine and lamivudine (for an interaction between tenofovir and didanosine, see 'NRTIs + Tenofovir', p.957). The tenofovir level was 3.7-fold higher than expected and the didanosine level was eightfold higher than it had been before tenofovir was started. Lopinavir levels were unchanged.[16]

(f) Nelfinavir

In a study in 29 healthy subjects, there was no significant pharmacokinetic interaction between tenofovir disoproxil fumarate 300 mg daily and unboosted nelfinavir 1.25 g twice daily, taken for 14 days. No serious adverse effects were reported with concurrent use in this study.[7,17]

(g) Saquinavir

In a study in 35 healthy subjects, tenofovir disoproxil fumarate 300 mg daily modestly increased the AUC and minimum level of saquinavir by 29% and 47%, respectively, after administration of ritonavir-boosted saquinavir 100/1000 mg twice daily taken for 14 days. The minimum level of ritonavir was also increased by 23%. The only change in tenofovir pharmacokinetics was a slight mean 23% increase in minimum level.[18] In another study,[19] in 18 HIV-positive patients taking ritonavir-boosted saquinavir 100/1000 mg twice daily and tenofovir disoproxil fumarate 300 mg daily, the AUC and maximum values of saquinavir were just 1% and 7% lower, respectively, than those seen with ritonavir-boosted saquinavir alone.

(h) Tipranavir

In a study in 22 subjects, ritonavir-boosted tipranavir 100/500 mg twice daily had no effect on the AUC and minimum level of a single 300-mg dose of tenofovir disoproxil fumarate, but it decreased the tenofovir maximum level by 23%. The tipranavir AUC and minimum level were decreased by 18% and 21%, respectively. With an increased dose of ritonavir-boosted tipranavir 200/750 mg twice daily, taken for 23 doses, the maximum level of tenofovir was reduced by 38% with no significant change in AUC and a slight 14% increase in the minimum level, and the decreases in tipranavir AUC and minimum levels were less (decreases of 9% in the AUC and 12% in the minimum level).[20]

Mechanism

It has been suggested that ritonavir increases tenofovir levels via its effect on drug transporter proteins, such as P-glycoprotein in the renal tubuli.[16,21] However, an *in vitro* study found that most protease inhibitors have low or minimal effects on the renal excretion of tenofovir. They suggest instead that an interaction may occur in the intestine, as tenofovir and most protease inhibitors are substrates for intestinal P-glycoprotein.[22] Another *in vitro* study reported that the overall increase in tenofovir levels by some protease inhibitors was due to a combination of different mechanisms including inhibition of tenofovir hydrolysis in intestinal tissue, inhibition of P-glycoprotein-mediated tenofovir efflux and induction of P-glycoprotein expression by the protease inhibitors.[23]

Importance and management

The modest increase in tenofovir levels with ritonavir-boosted **atazanavir**, **darunavir** and **lopinavir** is of uncertain clinical relevance. However, it has been suggested that higher tenofovir levels could potentiate tenofovir-associated adverse events, including renal disorders.[1,2,7,24] For this reason, the UK manufacturer of tenofovir says that renal function should be closely monitored when these three ritonavir-boosted protease inhibitors are given with tenofovir. Particular care should be taken with patients who have underlying systemic or renal disease, or with patients taking nephrotoxic drugs.[3,7] The manufacturers of atazanavir, darunavir and ritonavir-boosted lopinavir also recommend close monitoring of renal function,[1,21,25] and this seems a prudent precaution. The US manufacturer recommends a dose of ritonavir-boosted atazanavir of 100/300 mg daily when it is given with tenofovir.[2] The US manufacturers of atazanavir and tenofovir state that unboosted atazanavir should not be given[2,3] with tenofovir because of the potential for reduced efficacy and development of resistance.

The decrease in atazanavir levels with tenofovir is not of clinical importance if ritonavir is also used, and this combination has been used successfully as part of antiretroviral therapy in clinical studies.[1,7]

The increase in ritonavir-boosted **saquinavir** levels are not likely to be clinically relevant, and the UK manufacturer of saquinavir states that no saquinavir dose adjustment is needed with concurrent use.[26]

The slight interaction between tenofovir and ritonavir-boosted **tipranavir** is unlikely to be clinically relevant. The UK manufacturer of tipranavir states that no tenofovir dose adjustment is needed on concurrent use.[27]

There is no clinically relevant interaction between **nelfinavir** or **indinavir** and tenofovir.

The 2009 UK guidelines give tenofovir as one of the preferred drugs as part of a dual NRTI regimen, to be used with ritonavir-boosted atazanavir, fosamprenavir, lopinavir or saquinavir, for the treatment of HIV infection in treatment naïve patients.[28] The US guidelines also give similar recommendations.[29] When considering appropriate antiretroviral combinations, in addition to pharmacokinetic interactions, cross resistance patterns and adverse effects should be considered. Current local and national guidelines should be consulted when choosing antiretroviral regimens.

Protease inhibitors + Valproate

Lopinavir levels appeared to be raised by valproic acid in one study in HIV-positive patients, whereas valproic acid levels were not significantly different to those in a control group not taking ritonavir-boosted lopinavir. However, in one case, starting an antiretroviral regimen including ritonavir-boosted lopinavir decrease the valproic acid level, which resulted in an exacerbation of mania. A case of hepatotoxicity has occurred in a patient taking valproic acid with nevirapine and ritonavir-boosted saquinavir.

Clinical evidence

(a) Lopinavir

In a study in 8 HIV-positive patients taking ritonavir-boosted lopinavir 100/400 mg twice daily with various NRTIs, the median AUC of lopinavir increased by 75% without any change in the estimated half-life after they took valproic acid 250 mg twice daily for 7 days. Although the maximum and minimum lopinavir levels were also higher, the difference was not statistically significant. Ritonavir levels were not assessed. Valproic acid levels achieved in the patients taking ritonavir-boosted lopinavir were not significantly different from those in 11 HIV-positive control patients mainly taking NRTIs, even when the 3 patients taking a protease inhibitor or NNRTI (amprenavir, indinavir, or nelfinavir with nevirapine) were excluded.[1] However, one report describes a decrease in valproate levels in a 30-year-old man after he started taking ritonavir-boosted lopinavir.[2] This patient, who had been taking valproic acid 375 mg daily as divalproex sodium for 7 months after an episode of mania, had a subtherapeutic valproic acid level of 197 micromol/L. The dose was increased to 250 mg three times daily and after 25 days his trough valproic acid level had increased to 495 micromol/L. He was then started on an antiretroviral regimen of lamivudine, zidovudine, ritonavir-boosted lopinavir and paroxetine for depression. Four days later he was hypomanic and the paroxetine was replaced with sertraline, which the patient discontinued. Twenty-one days later he had become increasingly manic, and the valproic acid level was

found to be 238 micromol/L, about 50% lower than the previous level. An increase in the valproic acid dose to 1.5 g daily was eventually required to achieve a therapeutic level of 392 micromol/L.

(b) Saquinavir

A case of valproate-associated hepatotoxicity occurred in a 51-year-old man about 3 weeks after he started taking nevirapine 200 mg twice daily, saquinavir 400 mg twice daily, ritonavir 400 mg twice daily, and stavudine. Serum valproic acid levels remained therapeutic.[3]

Mechanism

Ritonavir, and possibly lopinavir, might decrease the plasma levels of valproic acid by induction of glucuronidation. See also 'Protease inhibitors + Lamotrigine', p.974, which is similarly affected.

Importance and management

It has been predicted that ritonavir might reduce valproate levels,[4,5] but the case report[2] appears to be the first clinical evidence of this occurring. Other evidence from the earlier study[1] suggested valproate levels were not affected to a statistically significant extent by ritonavir, although there was a downward trend in valproic acid levels. However, the authors subsequently noted that this study used a low-dose of valproate and that a more clinically significant interaction may occur with higher doses of valproate.[6] In addition, this study unexpectedly found that lopinavir levels appeared to be higher in patients taking valproic acid, although the increase is probably not clinically relevant.[1] If possible, monitor valproate levels when any antiretroviral regimen that includes ritonavir is used. Further study is needed. Note that there has been some concern about using valproate in HIV infection but there seems to be no established reason to avoid or specifically promote the use of valproate in HIV-infection *per se*.

Protease inhibitors; Fosamprenavir + Miscellaneous

Fosamprenavir is a prodrug of amprenavir, and is rapidly and almost completely hydrolysed to amprenavir and inorganic phosphate primarily in the lining of the gut.[1,2] The interactions of fosamprenavir are therefore primarily those of amprenavir.

Protease inhibitors; Indinavir + Ascorbic acid (Vitamin C)

Ascorbic acid (vitamin C) 1 g daily caused a minor decrease in indinavir levels in healthy subjects.

Clinical evidence, mechanism, importance and management

In a study[1] in healthy subjects, high-dose vitamin C 1 g daily for 7 days caused a 14% reduction in the AUC of indinavir 800 mg taken every 8 hours (4 doses beginning on day 6) and a 20% reduction in its maximum plasma level. However, whether this is a real effect needs further study as a similar reduction in plasma levels after a similar indinavir regimen was thought to be a time-dependent effect, see 'Protease inhibitors; Indinavir + Milk thistle', p.989. No recommendations can therefore be made based on this isolated report.

Protease inhibitors; Indinavir + Goldenseal (*Hydrastis*)

Goldenseal root had no effect on the pharmacokinetics of a single dose of indinavir in one study.

Clinical evidence

In a study in 10 healthy subjects, the peak plasma level and oral clearance of indinavir after a single 800-mg dose was not changed by goldenseal root (*Nature's Way*) 1.14 g twice daily for 2 weeks. In addition, there was no change in the indinavir half-life. Eight of the subjects had less than a 20% change in oral clearance, but one subject had a 46% increase and one a 46% decrease.[1]

Mechanism

Goldenseal (*Hydrastis canadensis*) was found to be an inhibitor of cytochrome P450 isoenzyme CYP3A4 *in vitro*.[2] This was confirmed in a clinical study using oral midazolam as a probe substrate for CYP3A4, which found a decrease of about 40% in the metabolism of midazolam to hydroxymidazolam.[3] Goldenseal root might therefore be expected to inhibit the metabolism of indinavir.

Importance and management

This study suggests that goldenseal root has no effect on indinavir levels, and may be taken without any undue concern in patients on this protease inhibitor. However, confirmation may be required in light of the midazolam probe study and the two subjects who experienced a relatively greater change in indinavir oral clearance. Further study is needed before firm clinical recommendations can be made

Protease inhibitors; Indinavir + Milk thistle

Although some studies have found that milk thistle slightly lowers indinavir levels, it appears that this is a time-dependent effect rather than a drug interaction, as it also occurred in a control group in one study. The balance of evidence suggests that no important pharmacokinetic interaction occurs.

Clinical evidence

Milk thistle (*Silybum marianum*) 175 mg three times daily (*Thisilyn; Nature's Way,* standardised for 80% silymarin content) for 3 weeks caused a 9% reduction in the AUC of indinavir and a 25% reduction its trough plasma level after four doses of indinavir 800 mg every 8 hours, but only the value for the trough level reached statistical significance.[1] The authors suggested that the effect on the trough level could represent a time-dependent effect of indinavir pharmacokinetics, as the plasma levels without milk thistle were found to be similarly lowered after a washout phase.[1] In another similar study, in 10 healthy subjects, milk thistle standardised for silymarin 160 mg (*General Nutrition Corp.*) three times daily for 13 days and then with indinavir 800 mg every 8 hours for 4 doses did not cause any statistically significant changes in the indinavir pharmacokinetics (6% reduction in AUC and 32% reduction in minimum level).[2] In yet another similar study, in 8 healthy subjects, milk thistle extract 456 mg, standardised for silymarins (*Kare and Hope Ltd*) three times daily for 28 days had no effect on the pharmacokinetics of indinavir 800 mg every 8 hours for four doses when compared with 6 subjects in a control group

not receiving milk thistle extract. Both the control and indinavir group had a lower indinavir AUC after the second and third time of administration compared with the first, and this decline was greater in the control group.[3] A meta-analysis of these 3 studies showed no effect of milk thistle on indinavir levels.[3]

Mechanism

Based on *animal* data, milk thistle might be expected to increase indinavir levels by inhibiting its metabolism,[1] or to have effects via P-glycoprotein.[2]

Importance and management

The available data suggest that milk thistle extract does not have an effect on the pharmacokinetics of indinavir, although it is not totally conclusive. The reduction in indinavir levels appears to be just a time-dependent effect rather than an effect of the milk thistle, and further study is needed with longer exposure to indinavir than just four doses. Evidence appears to be too slim to prohibit concurrent use, but until more is known it may be prudent to give milk thistle cautiously to patients taking indinavir.

Protease inhibitors; Indinavir + Venlafaxine

In a single-dose study, venlafaxine lowered indinavir levels.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given a single dose of indinavir before and after 10 days of venlafaxine 150 mg daily in divided doses. Indinavir did not affect the pharmacokinetics of venlafaxine, but venlafaxine reduced the AUC and maximum plasma levels of indinavir by 28% and 36%, respectively. This is possibly enough to reduce the efficacy of indinavir.[1] The reason for this effect is not clear. More study is needed to establish the effects of multiple doses. Until more is known it would seem prudent to monitor closely to ensure that the antiviral effects of indinavir are not compromised.

1. Levin GM, Nelson LA, DeVane CL, Preston SL, Eisele G, Carson SW. A pharmacokinetic drug-drug interaction study of venlafaxine and indinavir. *Psychopharmacol Bull* (2001) 35, 62–71.

Protease inhibitors; Nelfinavir + Calcium compounds

Calcium supplements do not affect the levels of nelfinavir.

Clinical evidence, mechanism, importance and management

Calcium supplements had no effect on plasma levels of nelfinavir or its M8 metabolite in 15 patients receiving nelfinavir 1.25 g twice daily as part of a HAART regimen. Calcium was given as calcium carbonate 1.35 g twice daily to 9 patients, and calcium gluconate/calcium carbonate 2.95 g/300 mg twice daily to 6 patients, both for 14 days. The plasma levels of nelfinavir were measured before a dose and 3 hours after a dose.[1] Similar results were reported in another study.[2] No nelfinavir dose adjustments appear necessary if calcium supplements are given.

1. Jensen-Fangel S, Justesen US, Black FT, Pedersen C, Obel N. The use of calcium carbonate in nelfinavir-associated diarrhoea in HIV-1-infected patients. *HIV Med* (2003) 4, 48–52.
2. Kopp Hutzler B, Perez-Rodriguez E, Norton S, Hsyu PH. Pharmacokinetics (PK) interactions between nelfinavir (NFV) and calcium supplements (P277). *AIDS* (2000) 14 (Suppl 4), S96.

Raltegravir + Miscellaneous

Rifampicin (rifampin) reduces raltegravir levels. Drugs that affect gastric pH, such as omeprazole, may increase raltegravir levels. Raltegravir does not significantly affect the pharmacokinetics of combined hormonal contraceptives, lamotrigine, and midazolam. Reduced plasma levels of both raltegravir and maraviroc may occur on their concurrent use.

Clinical evidence, mechanism, importance and management

(a) Drugs that affect gastric pH

In a study in 14 healthy subjects, **omeprazole** 20 mg daily for 5 days increased the AUC and maximum plasma levels of raltegravir 3.1-fold and 4.1-fold, respectively. However, HIV-positive patients may have an increased baseline gastric pH and the effect of drugs such as **omeprazole** on raltegravir may be less in patients than in healthy subjects.[1] The UK manufacturer advises that as the effects of raised gastric pH on raltegravir are unclear, raltegravir should not be used with drugs that increase gastric pH (they name **proton pump inhibitors** and **H_2-receptor antagonists**) unless this is unavoidable.[2] In contrast, the US manufacturer states that, although drugs that increase gastric pH may be expected to increase raltegravir levels, the use of raltegravir with **proton pump inhibitors** and **H_2-receptor antagonists** in phase III studies did not result in significant adverse outcomes. Therefore no raltegravir dose adjustment is required.[3]

(b) Hormonal contraceptives

The manufacturers[2,3] report that, in drug interaction studies, raltegravir 400 mg twice daily had no clinically significant effects on the pharmacokinetics of hormonal contraceptives (**ethinylestradiol** and **norelgestromin** are specifically mentioned).[2] No dose adjustment is needed with concurrent use.[2] However, note that whatever other methods of contraception are being used, barrier methods are always advisable to reduce the risk of HIV transmission.

(c) Lamotrigine

In a study in 24 healthy subjects, raltegravir 400 mg twice daily for 5 days had no significant effects on the pharmacokinetics of a single 100-mg dose of lamotrigine given on day 4. Therefore, raltegravir appears not to affect the glucuronidation of lamotrigine. No serious adverse effects were reported.[4] From this study, it appears that no lamotrigine dose adjustments are usually needed in patients also taking raltegravir.

(d) Maraviroc

In a study in 17 healthy subjects, the pharmacokinetics of raltegravir and maraviroc were analysed when taken separately (raltegravir 400 mg twice daily for 3 days and maraviroc 300 mg twice daily for 5 days) or taken together for 3 days. Raltegravir reduced the AUC and maximum plasma concentration of maraviroc by 14% and 21%, respectively. Similarly, maraviroc reduced the AUC, the maximum plasma concentration and the trough plasma concentration of raltegravir by 37%, 30%, and 28%, respectively. The average plasma concentration of maraviroc did not fall below the predicted therapeutic levels of greater than 100 nanograms/mL. The reductions in raltegravir and maraviroc levels are unlikely to be clinically significant and no dose adjustment of either drug appears to be needed on concurrent use.[5]

(e) Midazolam

A study[6] in 10 healthy subjects found that raltegravir 400 mg twice daily for 14 days had no significant effects on a single 2-mg dose of oral midazolam taken on day 14. Midazolam is used as a probe substrate for the cytochrome P450 isoenzyme CYP3A4. This suggests that raltegravir is unlikely to affect the metabolism of other substrates of CYP3A4.

(f) Rifampicin (Rifampin)

In a study in 9 healthy subjects, rifampicin 600 mg daily for 15 days reduced the AUC, the peak plasma levels and the trough plasma levels of a single 400-mg dose of raltegravir given on day 14 by 40%, 38% and 61%, respectively. In a subsequent study, 17 healthy subjects were given an increased dose of raltegravir 800 mg twice daily (to try to overcome the effects of rifampicin) with rifampicin 600 mg daily for 14 days. The AUC and maximum concentration of raltegravir were *increased* by 27% and 62%, respectively. However, doubling the raltegravir dose still resulted in a decrease in the trough level of raltegravir by 53%, when compared with raltegravir alone. No significant increase in adverse effects was reported on concurrent use, and all adverse effects reported were transient.[7]

Raltegravir is primarily metabolised by glucuronyltransferases (UGT1A1), which may be induced by rifampicin. The clinical significance of this is unknown, but the UK manufacturer suggests that a doubling of the raltegravir dose may be considered if the concurrent use of rifampicin cannot be avoided;[2] this dose is also recommended by the US

manufacturers.[3] Although evidence from the second study suggests that this may overcome the reduction in the AUC, the likely clinical significance of the low raltegravir trough level (despite the increase in raltegravir dose) is as yet unclear and should be borne in mind.[7]

(g) Other drugs

The UK manufacturer also advises that no dose adjustment of raltegravir is needed with **glucocorticoids**, **phenytoin**, **phenobarbital**, **rifabutin**, and **St John's wort**). These are said to be less potent inducers of glucuronyltransferases than rifampicin (see under *Rifampicin*, above).[2]

Raltegravir + NNRTIs

Efavirenz and etravirine modestly reduce the AUC of raltegravir. Nevirapine is predicted to interact similarly. However, four cases of significantly reduced raltegravir levels have been reported in patients taking antiretroviral drugs including etravirine.

Clinical evidence, mechanism, importance and management

(a) Efavirenz

In a study in 9 healthy subjects, efavirenz 600 mg daily for 14 days modestly reduced the AUC and maximum plasma levels of a single 400-mg dose of raltegravir (taken on day 12) by 36%.[1]

Raltegravir is metabolised by glucuronosyltransferases (primarily UGT1A1). Efavirenz is thought to induce UGT1A1 thereby modestly reducing raltegravir levels.[1,2]

The reduction in raltegravir levels is not expected to be clinically relevant, and the UK manufacturer advises that no dose adjustments are required on the concurrent use of efavirenz.[2] However, note that the US manufacturer makes no recommendation and advises that the clinical relevance of this reduction has not been directly studied.[3]

(b) Etravirine

In a study in 19 healthy subjects, etravirine 200 mg twice daily for 12 days was taken with raltegravir 400 mg twice daily from day 8 to day 12. Etravirine modestly reduced the trough levels of raltegravir by 34%; however, this was not statistically significant. No change in etravirine pharmacokinetics was reported with raltegravir and no serious adverse effects were reported.[4]

A patient taking enfuvirtide, ritonavir-boosted darunavir and raltegravir was found to have subtherapeutic trough plasma levels of raltegravir one month after enfuvirtide was replaced with etravirine. Three other cases of reduced raltegravir trough plasma levels have also been reported in patients taking antiretroviral drugs including etravirine.[5]

No raltegravir dose adjustment is likely to be needed if it is taken with etravirine.[2,4] However, the US manufacturer advises that this reduction in raltegravir has not been directly assessed.[3] Given the isolated case reports of reduced raltegravir levels in patients also taking etravirine, until further information is available, it may be prudent to consider the potential for an interaction during concurrent use.

(c) Nevirapine

The UK manufacturer predicts that nevirapine will induce the glucuronidation of raltegravir (primarily by UGT1A1). However, they advise that no dose adjustment is needed on concurrent use.[2]

Raltegravir + NRTIs

No clinically significant interaction occurs between raltegravir and lamivudine or tenofovir.

Clinical evidence, mechanism, importance and management

In a study, 9 healthy subjects were given **tenofovir** 300 mg daily with raltegravir 400 mg twice daily for 4 days. The AUC_{0-12} and maximum plasma concentration of raltegravir were increased by 49% and 64%, respectively, and a minor reduction in the AUC_{0-24} and maximum plasma concentration of **tenofovir** was also reported. In a subsequent study by the same authors, 25 HIV-positive patients taking **tenofovir** 300 mg daily and **lamivudine** 300 mg daily were given raltegravir 100 mg to 600 mg twice daily. The raltegravir AUC_{0-12} and maximum concentration were increased by 41% and 33%, respectively.[1] No serious adverse effects were reported on the concurrent use of **tenofovir** and raltegravir. The mechanism for this interaction is unknown. However, the modest increases in raltegravir levels and minor reduction in **tenofovir** levels seen in these studies are not expected to be of clinical relevance. The manufacturer of raltegravir recommends that no dose adjustment of either raltegravir or **tenofovir** is needed.[2]

The US manufacturer also reports that, in drug interaction studies, the pharmacokinetics of **lamivudine** were not affected to a clinically significant extent by raltegravir.[3] There appears to be no information about other NRTIs and raltegravir.

2. Isentress (Raltegravir potassium). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, September 2009.
3. Isentress (Raltegravir potassium). Merck & Co. US Prescribing information, October 2009.

Raltegravir + Protease inhibitors

Atazanavir may modestly increase the levels of raltegravir. Indinavir and saquinavir are predicted to increase raltegravir levels, but to a lesser extent than atazanavir. Low-dose ritonavir and ritonavir-boosted tipranavir appear to have no clinically relevant effect on the pharmacokinetics of raltegravir.

Clinical evidence

(a) Atazanavir

In a study in 19 healthy subjects, raltegravir 400 mg twice daily was taken with atazanavir 300 mg twice daily for 14 days. The concurrent use of atazanavir and raltegravir resulted in a decrease in the AUC and maximum concentration of atazanavir by 17% and 11%, respectively, and an increase in the AUC and maximum concentration of raltegravir by 54% and 39%, respectively. The incidence of adverse effects was not increased with concurrent use.[1] In another study in 12 healthy subjects, atazanavir 400 mg daily for 9 days increased the AUC and maximum concentration of a single 100-mg dose of raltegravir (taken on day 7) by 72% and 53%, respectively.[2] In another study by the same authors in 10 healthy subjects, raltegravir 400 mg twice daily was taken alone or with ritonavir-boosted atazanavir 300 mg daily for 10 days. Ritonavir-boosted atazanavir increased the AUC of raltegravir by 41%; a slight increase of 24% in the maximum concentration was also reported; however, this was not statistically significant. Atazanavir levels were not assessed in this study. No serious adverse effects or clinically relevant ECG changes were reported.[2] A

case series in 3 HIV-positive patients taking unboosted atazanavir 300 mg twice daily with raltegravir 400 mg twice daily reported no increase in adverse effects with this combination and no loss of therapeutic efficacy. Three other patients taking the same regimen but with additional antiretrovirals (one taking lamivudine, another patient taking abacavir with **saquinavir**, and another patient taking lamivudine and tenofovir) similarly had viral loads less than 50 copies/mL and no increase in adverse effects.[3]

(b) Darunavir

In a small study in 18 healthy subjects, only 6 subjects finished the course of ritonavir-boosted darunavir 100/600 mg twice daily with raltegravir 400 mg twice daily for 12 days. Eight cases of a rash occurred; seven were mild to moderate in nature; however, one case progressed to a severe maculopapular rash. As insufficient subjects completed the study, no clear interpretations can be made from the data. However, the data from the remaining 6 subjects suggested that ritonavir-boosted darunavir reduced the AUC and maximum concentration of raltegravir by 29% and 33%, respectively, when compared with raltegravir taken alone for 4 days. No difference was found with ritonavir-boosted darunavir pharmacokinetics when compared with historical data in healthy subjects.[4]

(c) Ritonavir

In a study in 10 healthy subjects, ritonavir 100 mg twice daily was taken for 16 days with a single 400-mg dose of raltegravir taken on day 14. The AUC and maximum plasma concentration of raltegravir were reduced by 16% and 24%, respectively, but this was not statistically significant.[5]

(d) Tipranavir

In a study, 15 healthy subjects were given ritonavir-boosted tipranavir 200/500 mg twice daily for 11 days with raltegravir 400 mg twice daily from day 8 to day 11. Ritonavir-boosted tipranavir reduced the trough plasma level of raltegravir by 55%; the AUC and peak plasma levels of raltegravir were also reduced by 24% and 18%, respectively, but this was not statistically significant.[6]

Mechanism

The main route of metabolism for raltegravir is by glucuronosyltransferases (primarily UGT1A1), and atazanavir is a known inhibitor of this pathway.[7,8] The manufacturers also suggest that less potent inhibitors of UGT1A1, such as indinavir and saquinavir, may interact to a lesser extent than atazanavir. The US manufacturer of ritonavir reports that it may induce glucuronyltransferases.[9]

Importance and management

Although only a modest pharmacokinetic interaction appears to occur between raltegravir and ritonavir-boosted **darunavir**, the high incidence of rash reported in the study above suggests a note of caution is warranted on concurrent use.

The interaction between **atazanavir** and raltegravir appears to be established. However the modest increases reported are not expected to be clinically concurrent use of atazanavir and raltegravir appear to support this. The manufacturers therefore advise that no dose adjustment is needed when raltegravir is given with atazanavir alone or with ritonavir-boosted atazanavir. They also suggest that no dose adjustment is likely to be needed for less potent inhibitors of UGT1A1 such as **indinavir** and **saquinavir**.[7,8]

Although ritonavir may be predicted to have some effect on the pharmacokinetics of raltegravir, as it is a known inducer of glucuronyltransferases, the limited data above suggests that the impact of low doses of **ritonavir**, such as those used for pharmacological boosting of other protease inhibitors, on the pharmacokinetics of raltegravir is unlikely to be clinically significant. No dose adjustment appears to be needed with low-dose ritonavir specifically; however, until further data is available, it may be prudent to monitor concurrent use in patients taking higher doses of ritonavir. Further study is needed.

As the efficacy of raltegravir was not affected by ritonavir-boosted **tipranavir**, the manufacturers advise that no dose adjustment is needed.[7,8]

Ribavirin + Antacids

The manufacturers of ribavirin note that there was a minor 14% decrease in the AUC of ribavirin 600 mg when it was given with an antacid containing aluminium, magnesium, and simeticone,[1-3] but this is not considered clinically relevant.[1,2] No ribavirin dose adjustment is needed on concurrent use.

3. Rebetol (Ribavirin). Schering Corporation. US Prescribing information, November 2009.

Rimantadine + Aspirin or Paracetamol (Acetaminophen)

Both aspirin and paracetamol slightly reduce the levels of rimantadine, but this is unlikely to be clinically relevant.

Clinical evidence, mechanism, importance and management

(a) Aspirin

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, aspirin 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 10% in the presence of aspirin.[1] This reduction is unlikely to be clinically relevant.

(b) Paracetamol

In a study in healthy subjects, rimantadine 100 mg twice daily was given for 13 days. On day 11, paracetamol 650 mg four times daily was started and continued for 8 days. The peak plasma levels and AUC of rimantadine were reduced by about 11% in the presence of paracetamol.[1] This reduction is unlikely to be clinically relevant.

1. Flumadine (Rimantadine hydrochloride). Forest Pharmaceuticals, Inc. US Prescribing information, April 2007.

Rimantadine + Cimetidine

Cimetidine causes a small but probably clinically unimportant rise in the plasma levels of rimantadine.

Clinical evidence, mechanism, importance and management

In 23 healthy subjects the AUC of a single 100-mg dose of rimantadine was increased by 20% and the apparent total clearance reduced by 18% when it was taken one hour after the first dose of cimetidine 300 mg four times daily for 6 days. The authors of the study suggest that these changes are likely to have little, if any, clinical consequences.[1] The effects of multiple-dose concurrent use are not known.

1. Holazo AA, Choma N, Brown SY, Lee LF, Wills RJ. Effect of cimetidine on the disposition of rimantadine in healthy subjects. *Antimicrob Agents Chemother* (1989) 33, 820–3.

Rimantadine + Food

In a study in 12 healthy subjects, the rate and extent of absorption of a single 100-mg dose of rimantadine was not altered by the absence or presence of food.[1] Therefore rimantadine may be taken without regard to food.

1. Wills RJ, Rodriguez LC, Choma N, Oakes M. Influence of a meal on the bioavailability of rimantadine HCl. *J Clin Pharmacol* (1987) 27, 821–3.

Telbivudine + Miscellaneous

Drugs affecting renal function may alter the plasma concentration of telbivudine. It is unknown whether the risk of myopathy with telbivudine is increased by the concurrent use of other drugs that can cause myopathy. Peginterferon-alfa 2a does not alter telbivudine pharmacokinetics; however, the incidence of neuropathy with telbivudine may be increased. Food does not affect telbivudine pharmacokinetics. No pharmacokinetic interaction appears to occur between telbivudine and adefovir, ciclosporin, lamivudine, or tenofovir. No cytochrome P450-mediated interactions are expected to occur with telbivudine.

Clinical evidence, mechanism, importance and management

(a) Adefovir

In a study in healthy subjects the concurrent use of telbivudine 600 mg daily and adefovir 10 mg daily for 7 days did not alter the pharmacokinetics of either drug, when compared with their use alone.[1] No dose adjustment of either drug appears to be needed on concurrent use.

(b) Ciclosporin

The manufacturers of telbivudine note that no pharmacokinetic interaction occurs between ciclosporin and telbivudine.[2,3] However, there is a possibility that additive myopathy may occur, see under *Drugs causing myopathy*, below.

(c) Cytochrome P450-mediated interactions

The manufacturers note that telbivudine is not metabolised by cytochrome P450 and is principally excreted unchanged by the kidneys. It is therefore unlikely to be affected by drugs that induce or inhibit cytochrome P450 isoenzymes.[2,3] Furthermore, *in vitro* studies suggest that telbivudine does not inhibit or induce cytochrome P450 isoenzymes, and is therefore unlikely to interact with drugs that are substrates for these isoenzymes.[2,3]

(d) Drugs affecting renal function

The manufacturers note that telbivudine is eliminated primarily by renal excretion.[2,3] Therefore, the concurrent use of drugs that affect renal function (the manufacturers name **aminoglycosides**, **loop diuretics**, **platinum compounds**, **vancomycin**, **amphotericin B**,[3] and **ciclosporin** and **tacrolimus**[2]) may affect the plasma concentrations of telbivudine. Caution is advised[3] and it would be sensible to closely monitor renal function during concurrent use.

(e) Drugs causing myopathy

The manufacturers of telbivudine note that it is unknown whether the risk of myopathy during treatment is increased by the concurrent use of other drugs associated with myopathy (such as **statins**, **fibrates**, and **ciclosporin**).[2,3] The US manufacturer also lists **corticosteroids**, **chloroquine**, **hydroxychloroquine**, **penicillamine**, **zidovudine**, **erythromycin**, **nicotinic acid**, and certain **azoles**.[2] Monitor concurrent use closely. Patients should be told to report any signs of myopathy and possible rhabdomyolysis (i.e. otherwise unexplained muscle pain, tenderness or weakness or dark coloured urine).[2,3] If myopathy does occur, telbivudine should be stopped.[3]

(f) Food

In a study in healthy subjects, when a single 600-mg dose of telbivudine was given immediately after a high-fat/high-calorie meal there was no effect on the pharmacokinetics of telbivudine, when compared with the fasting state.[4] Telbivudine may be taken with or without food.

(g) Interferons

The manufacturers note that peginterferon-alfa 2a did not alter the pharmacokinetics of telbivudine, although no conclusion can be made about the effect of telbivudine on peginterferon-alfa 2a because of high interindividual variability in its levels.[2,3] However, telbivudine causes neuropathy, and the incidence and possibly severity of this appears to be increased by peginterferon-alfa 2a. The MHRA and CHM in the UK therefore advise that the combination cannot be recommended. If both drugs are given, patients should be closely monitored for peripheral neuropathy. If peripheral neuropathy develops, telbivudine and peginterferon should be stopped.[5] The UK manufacturers advise that the increased risk of neuropathy cannot be excluded if telbivudine is used with other interferon alfa products.[3]

(h) Lamivudine

In a study in healthy subjects, when telbivudine 200 mg daily and lamivudine 100 mg daily were given concurrently for 7 days the pharmacokinetics of both drugs were unchanged.[1] No dose adjustment of either drug appears to be needed if they are used together.

(i) Tenofovir

The manufacturers note that there was no pharmacokinetic interaction between tenofovir disoproxil fumarate and telbivudine.[2,3] Therefore, no dose adjustment of either drug appears to be needed if they are used together.

Tenofovir + Miscellaneous

Tenofovir absorption is increased by high-fat food. Cases of additive nephrotoxicity have been reported with tenofovir and NSAIDs or vancomycin, and the concurrent use of drugs that may cause renal toxicity is not recommended. Tenofovir does not appear to alter the pharmacokinetics of ribavirin, and there was no clinically significant pharmacokinetic interaction with rifampicin (rifampin) or tacrolimus.

Clinical evidence, mechanism, importance and management

(a) Cidofovir

Tenofovir is actively secreted by human organic anion transporter 1 (hOAT1) in the kidneys. Therefore, the manufacturers suggest that if it is given with other drugs that are also secreted by this renal transporter, such as cidofovir, increased levels of tenofovir or the other drug could result. In the UK, they specifically recommend that tenofovir and cidofovir are not given together, unless clearly necessary, when renal function should be monitored weekly.[1]

(b) Food

Administration of tenofovir with a high-fat meal increased its AUC by about 40%, and its maximum level by about 14%, when compared with the fasted state, whereas administration with a light meal had no effect.[1,2] The UK manufacturer recommends that tenofovir is taken with food,[1] whereas the US manufacturer states that it can be taken without regard to food.[2]

(c) NSAIDs

A case of acute tubular necrosis has been reported in an HIV-positive patient taking tenofovir 300 mg daily, ritonavir-boosted lopinavir 33/133 mg daily and lamivudine 300 mg daily when **diclofenac** was started 5 days earlier for limb pain. The patient had been stable on tenofovir for several years with no adverse effects on renal function, and the authors suggests that **diclofenac** affected the renal clearance of tenofovir leading to nephrotoxicity.[3] There is another report of three cases of renal failure with tenofovir. In all cases, the patients had multiple risk factors for developing

renal failure secondary to tenofovir; however, the addition of an NSAID (**indometacin** suppositories in one case, **naproxen** in the other two) lead to the development of acute renal failure. In one of these cases the patient died and another developed end stage renal failure requiring regular dialysis.[4] Ten cases[5] of nephrotoxicity with tenofovir (including 2 of the 3 cases noted above[4] as well as details of a patient who had recently started taking valdecoxib) have been reported to Health Canada between March 2003 and December 2005. Another report describes a possible exacerbation of tenofovir-induced renal failure by NSAIDs: **diclofenac** in one case, and **ibuprofen** and **rofecoxib** in the other.[6]

Tenofovir has the potential to cause nephrotoxicity, and renal function should be routinely monitored during use.[1] NSAIDs reduce renal blood flow and may also cause renal failure. From the cases reported above, it seems that NSAIDs may precipitate renal failure in patients taking tenofovir, particularly these with pre-existing risk factors or mild renal impairment. The manufacturers do not recommend the concurrent use of tenofovir with other drugs that cause renal failure. They also recommend avoiding the use of tenofovir in patients who have recently taken a nephrotoxic drug.[1,2] If concurrent use is unavoidable, they advise increasing the monitoring of renal function to weekly.[1]

(d) Other nephrotoxic drugs

Two cases of acute renal failure, which developed after intravenous **vancomycin** was given, have been reported in patients previously stable on tenofovir for 6 to 10 months.[7] Tenofovir has the potential to cause nephrotoxicity, and the manufacturer recommends monthly monitoring of renal function. Although the concurrent use of other nephrotoxic drugs has not been studied, the manufacturer suggests that renal function should be monitored more frequently (weekly) if concurrent use is unavoidable. The UK manufacturer specifically names **aminoglycosides**, **amphotericin B**, **cidofovir** (see above), **foscarnet**, **ganciclovir**, **interleukin-2**, **pentamidine** and **vancomycin**.[1] The US manufacturer specifically names **cidofovir**, **aciclovir**, **valaciclovir**, **ganciclovir**, and **valganciclovir**.[2] **NSAIDs** may also cause renal failure and cases of nephrotoxicity with tenofovir have been reported, see under *NSAIDs*, above.

(e) Ribavirin

Tenofovir disoproxil fumarate 300 mg daily did not alter the pharmacokinetics of a single 600-mg dose of ribavirin in 22 subjects, and the pharmacokinetics of tenofovir did not appear to be changed by ribavirin when compared with historical data.[8] Note that, there is evidence that HIV-positive patients co-infected with hepatitis C and treated with interferon alfa and ribavirin may be at increased risk of lactic acidosis and hepatic decompensation when receiving any 'NRTI', (p.956), including tenofovir, and increased monitoring is recommended.[1]

(f) Rifampicin (Rifampin)

In a study in 23 subjects, when rifampicin 600 mg daily was given with tenofovir disoproxil fumarate 300 mg daily, the pharmacokinetics of both drugs were not significantly changed (tenofovir compared with historical data). One subject who was withdrawn from the study had raised liver enzyme values.[9] The UK manufacturer notes that no clinically significant interaction occurs between rifampicin and tenofovir. Therefore no special precautions appear to be necessary on concurrent use.[1]

(g) Tacrolimus

In a study in healthy subjects taking a combination of **emtricitabine** 200 mg daily and tenofovir 300 mg daily alone or with tacrolimus 100 micrograms/kg daily, no clinically significant change in the pharmacokinetics of all three drugs was reported.[10] However, both tacrolimus and tenofovir have the potential to cause nephrotoxicity. The manufacturer of tenofovir recommends that renal function should be monitored more frequently (weekly) if concurrent use of other nephrotoxic drugs, such as tacrolimus, is unavoidable.[1]

Vidarabine + Allopurinol

There is some evidence to suggest that if allopurinol and vidarabine (adenine arabinoside) are given together the toxicity of vidarabine may be increased.

Clinical evidence

Two patients with chronic lymphocytic leukaemia taking allopurinol 300 mg daily developed severe neurotoxicity (coarse rhythmic tremors of the extremities and facial muscles, and impaired mentation) 4 days after vidarabine was added for the treatment of viral infections.[1] A retrospective search to find other patients who had taken both drugs for 4 days revealed a total of 17 patients, 5 of whom had experienced adverse reactions including tremors, nausea, pain, itching and anaemia.[1] Another possible case report describes neurological toxicity in a patient taking both drugs.[2]

Mechanism

Uncertain. One suggestion is that the allopurinol causes hypoxanthine arabinoside, the major metabolite of vidarabine, to accumulate by inhibiting xanthine oxidase. A study with *rat* liver cytosol found that allopurinol greatly increased the half-life of this metabolite.[3]

Importance and management

Information seems to be limited to these reports, and so the general clinical importance of this possible interaction is uncertain, but it would be prudent to exercise particular care if these drugs are used together.

Beta blockers

The adrenoceptors of the sympathetic nervous system are of two main types, namely alpha and beta. Drugs that block the beta adrenoceptors (better known as the beta blockers) are therapeutically exploited to reduce, for example, the normal sympathetic stimulation of the heart. The activity of the heart in response to stress and exercise is reduced, its consumption of oxygen is diminished, and in this way exercise-induced angina can be managed. Beta blockers given orally can also be used in the management of cardiac arrhythmias, hypertension, myocardial infarction, and heart failure. They may also be used for some symptoms of anxiety and for migraine prophylaxis. Some beta blockers are used in the form of eye drops for glaucoma and ocular hypertension.

Not all beta receptors are identical but can be further subdivided into two groups, $beta_1$ and $beta_2$. The former are found in the heart and the latter in the bronchi. Since one of the unwanted adverse effects of generalised beta blockade can be the loss of the normal noradrenaline-stimulated bronchodilation (leading to bronchospasm), cardioselective $beta_1$-blocking drugs (e.g. atenolol, metoprolol) were developed, which have less effect on $beta_2$ receptors. However, it should be emphasised that the selectivity is not absolute because bronchospasm can still occur with these drugs, particularly at high doses. 'Table 22.1', (below) includes an indication of the cardioselectivity of commonly used systemic beta blockers. Some beta blockers also have $alpha_1$-blocking activity, which causes vasodilatation, and this is also indicated in 'Table 22.1', (below). Some beta blockers, such as celiprolol and nebivolol, also have vasodilator activity but produce this by mechanisms other than blocking $alpha_1$ receptors. Other beta blockers also possess intrinsic sympathomimetic activity in that they can *activate* beta receptors and are therefore partial agonists. Sotalol has additional class III antiarrhythmic activity, and therefore it has a range of interactions not shared by most other beta blockers.

Beta blockers may be lipophilic drugs (such as metoprolol) or hydrophilic (such as atenolol). The lipophilic beta blockers are more likely to be involved in pharmacokinetic interactions than the hydrophilic drugs. Many of the lipophilic beta blockers are principally metabolised by the cytochrome P450 isoenzyme CYP2D6 (see 'Table 22.1', (below)), and drugs that are inhibitors or inducers of this isoenzyme (see 'Table 1.3', (p.6)) increase or decrease their levels. Propranolol is also metabolised in part by CYP1A2 (see 'Beta blockers + SSRIs', p.1019).

Beta blockers may also be involved in pharmacodynamic interactions with other drugs that are based on enhancement or antagonism of pharmacological effects (such as additive blood pressure reduction).

This section is generally concerned with those drugs that affect the activity of the beta blockers. Where the beta blocker is the affecting drug, the interaction is dealt with elsewhere.

Table 22.1 The actions and metabolism of widely used systemic beta blockers

Drug	*$Beta_1$-receptor selectivity*	*Alpha-blocking activity?*	*ISA**	*Lipophilicity*	*Bioavailability*	*First pass metabolism*	*Metabolism*
Acebutolol	Selective	No	Yes (weak)	Hydrophilic	50 to 70%	30 to 50%	Rapidly metabolised to an active metabolite after which about 50% is excreted by the liver and 50% excreted in the urine.
Atenolol	Selective	No	No	Hydrophilic	40 to 50%	Less than 10%	Largely excreted unchanged in the urine.
Bisoprolol	Selective	No	No	Intermediate	88%	Less than 10%	50% hepatic metabolism and 50% excreted unchanged in the urine.
Carvedilol	Non-selective	Yes ($alpha_1$)	No	Lipophilic	25 to 35%	60 to 80%	Primarily metabolised by CYP2D6, although other isoenzymes do contribute.
Celiprolol	Selective	Yes (weak $alpha_2$)	Yes	Hydrophilic	30 to 70%	Little	Mostly excreted unchanged (only 1-3% metabolised) with 50% excreted in the bile and 50% excreted in the urine.
Esmolol	Selective	No	No	Relatively hydrophilic	N/A	Extensive	Rapidly hydrolysed in red blood cells (half-life 9 minutes).
Labetalol	Non-selective	Yes (postsynaptic $alpha_2$)	No	Moderately lipophilic	25 to 40%	Extensive	Conjugated in the liver.
Metoprolol	Selective	No	No	Lipophilic	50%	About 40 to 60%	Metabolised by CYP2D6.
Nadolol	Non-selective	No	No	Hydrophilic	20 to 40%	Little	Largely excreted unchanged in the urine.
Nebivolol	Selective	No	No		12 to 96%	Extensive	Metabolised by CYP2D6.
Oxprenolol	Non-selective	No	Yes	Lipophilic	19 to 74%	25 to 80%	Extensively metabolised by the liver.
Pindolol	Non-selective	No	Yes	Moderately lipophilic	90 to 100%	Little	30 to 40% excreted unchanged in the urine, rest excreted by liver and kidney as inactive metabolites.
Propranolol	Non-selective	No	No	Lipophilic	30 to 70%	Up to 95%	Mainly metabolised by CYP2D6 with some contribution by CYP1A2.
Sotalol	Non-selective	No	No	Hydrophilic	75 to 90%	None	Largely excreted unchanged in the urine.
Timolol	Non-selective	No	No	Lipophilic	61%	About 50 to 70%	Mostly metabolised by the liver, with some involvement from CYP2D6. 20% excreted unchanged. Timolol and metabolites renally excreted.

*Intrinsic sympathomimetic activity (partial agonists)

Beta blockers + 5-Alpha reductase inhibitors

Finasteride and dutasteride do not appear to interact with beta blockers.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, **finasteride** 5 mg daily for 10 days caused no change in the pharmacokinetics or pharmacodynamics of a single 80-mg dose of **propranolol**.[1] Further, the manufacturers say that **finasteride** was used with beta blockers in clinical studies without any evidence of an interaction.[2,3] Similarly, **dutasteride** does not appear to interact with beta blockers.[4]

Beta blockers + Antacids or Kaolin-pectin

Some antacids and kaolin-pectin may cause a modest reduction in the absorption of atenolol, indenolol, propranolol, or sotalol, and possibly a slight increase in the absorption of metoprolol.

Clinical evidence

(a) Atenolol

In a study in 6 healthy subjects, **aluminium hydroxide** 5.6 g reduced the plasma levels of a single 100-mg dose of atenolol by 20%, which had no effect on the atenolol-induced reduction in exercising heart rate. Similarly, **aluminium hydroxide** had no significant effect on atenolol pharmacokinetics when both drugs were given together for 6 days.[1] Another study in 6 healthy subjects found that 30 mL of *Novalucol forte* (an **aluminium/magnesium-containing antacid**) reduced the peak plasma level and AUC of a single 100-mg dose of atenolol by 37% and 33%, respectively, which was considered to be of possible significance in some patients.[2]

In a study in 6 healthy subjects a single 500-mg dose of **calcium** (as the lactate, gluconate and carbonate) caused a 51% reduction in the peak plasma level of a single 100-mg dose of atenolol. **Calcium** also reduced the AUC of atenolol by 32%, and increased the elimination half-life from 6.2 to 11 hours. The effect of atenolol on heart rate was decreased by 12%. However, these changes were no longer statistically significant after 6 days of concurrent use, except for a 21% reduction in peak plasma atenolol levels, which would not be expected to be clinically relevant. In a further 6 hypertensive subjects, neither **calcium** 500 mg daily nor **aluminium hydroxide** 5.6 g daily had any influence on the blood pressure lowering effect of atenolol 100 mg daily, given for 4 weeks.[1]

(b) Indenolol

A study in *rats* found that when indenolol was given with either *Simeco* (**aluminium/magnesium hydroxide** with **simeticone**) or *Kaopectate* (**kaolin-pectin**), the $AUC_{0\text{-}6}$ was reduced by 15% and 30%, respectively.[3]

(c) Metoprolol

In 6 healthy subjects, 30 mL of *Novalucol forte* (an **aluminium/magnesium-containing antacid**) increased the peak plasma level and AUC of a single 100-mg dose of metoprolol by 25% and 11%, respectively.[2]

(d) Propranolol

In a study in 6 healthy subjects, **aluminium hydroxide gel** 30 mL did not affect either the plasma level of a single 40-mg dose of propranolol, or the reduction in exercise heart rate in response to propranolol.[4] In contrast, a study in 5 healthy subjects found that 30 mL of an **aluminium hydroxide gel** reduced the levels and AUC of a single 80-mg dose of propranolol by almost 60%.[5] *In vitro* and *animal* data suggest that **bismuth subsalicylate**, **kaolin-pectin** and **magnesium trisilicate** can also reduce the absorption of propranolol.[6,7]

(e) Sotalol

A study in 5 healthy subjects found that single doses of **aluminium hydroxide** suspension (*Neutragel*) or **calcium carbonate** suspension, given after an overnight fast, had negligible effects on the pharmacokinetics of a single 160-mg dose of sotalol.[8] However, a single dose of **magnesium hydroxide** slightly reduced the AUC of sotalol by 16%.[8] A further study in 6 healthy subjects found that when 20 mL of *Maalox* (**aluminium/magnesium hydroxide**) was given at the same time as 160 mg of sotalol, the maximum plasma level of the sotalol was reduced by 26% and its AUC was reduced by 21%. Changes in heart rates reflected these pharmacokinetic changes.[9] No interaction occurred when *Maalox* was given 2 hours after sotalol.[9]

Mechanism

Uncertain. The reduction in absorption could possibly be related to a delay in gastric emptying caused by the antacid, delayed dissolution due to an increase in gastric pH, or to the formation of a complex of the two drugs in the gut, which reduces absorption. However, one *in vitro* study indicated that sotalol was only subject to minor absorption or complexation interactions.[9] Another study found that 35 to 40% of sotalol was bound by magnesium hydroxide, but this may be reversible under physiological conditions and therefore unlikely to be relevant during long-term clinical use.[8]

Importance and management

Evidence for an interaction between antacids and beta blockers is generally limited, and largely confined to *animal* or single-dose studies, which may not reflect the situation with multiple dosing. Indeed, one study with atenolol and aluminium hydroxide found a modest pharmacokinetic interaction with single doses, but no interaction after 6 days of concurrent use. Some changes in beta blocker absorption may possibly occur but no study seems to have shown that there is a significant effect on the therapeutic effectiveness of the beta blockers with multiple dosing. However, it may be prudent to consider an interaction if the effects of beta blockers are reduced, especially during the initial stages of concurrent use. Separating the dosages by 2 hours was shown to avoid the interaction in one study with sotalol,[9] and this would seem a simple way of avoiding problems should they occur.

Beta blockers + Anticholinesterases

A small number of reports describe marked bradycardia and hypotension during the recovery period from anaesthesia and neuromuscular blockade, when patients taking beta blockers were given anticholinesterase drugs. However, normally no adverse reaction seems to occur. Note that oral and topical beta blockers given alone have caused myasthenic symptoms and myasthenia gravis in some patients.

Clinical evidence

(a) Anticholinesterase effects

Three patients developed myasthenic symptoms when given beta blockers (two taking **propranolol** and one taking **oxprenolol**). Two of them were effectively treated with **pyridostigmine**.[1] Another patient developed fulminant myasthenia gravis within 2 weeks of starting to take **acebutolol**.[2]

Similarly, in a patient with myasthenia gravis, the use of **timolol** eye drops was associated with a deterioration in muscle strength,[3] and in another patient, a serious deterioration in myasthenia.[4] These would appear to be drug-disease effects.

In a study in 10 myasthenic patients with mild to moderate symptoms, intravenous **propranolol** 100 micrograms/kg did not result in a worsening of neuromuscular transmission (assessed by muscle function tests and repetitive nerve stimulation), even though 8 of those with mild symptoms had reduced their **pyridostigmine** dose during the study to allow the effects of the additional drug to be more readily seen.[5]

(b) Bradycardia

1. Neostigmine. A study in 10 patients with severe hypertension due to renal ischaemia who were treated with **propranolol** 10 to 36 mg/kg daily (or equivalent doses of **oxprenolol** or **labetalol**) found that during surgery neostigmine consistently reduced heart rates to below 45 bpm despite atropinisation.[6] A patient taking **nadolol** 40 mg daily, recovering from surgery during which suxamethonium (succinylcholine) and pancuronium had been given, developed prolonged bradycardia of 32 to 36 bpm and hypotension (systolic blood pressure 60 to 70 mmHg) when neostigmine and atropine were given to reverse the neuromuscular blockade. Isoprenaline and phenylephrine infusions were required to maintain a systolic blood pressure of 90 mmHg, and were gradually reduced over 3 days. **Propranolol** was substituted for **nadolol**, and about 10 weeks later the patient underwent general anaesthesia again (this time without a neuromuscular blocker/neostigmine) and she recovered uneventfully.[7] Prolonged bradycardia and hypotension, requiring isoprenaline then adrenaline (epinephrine), were seen in an elderly woman taking **atenolol** 50 mg daily and nitrates when she was given neostigmine and atropine for the reversal of muscle relaxation at the end of general anaesthesia.[8] Another report similarly describes bradycardia in a patient taking **propranolol** when intravenous neostigmine was used to reverse pancuronium-induced blockade. This responded to atropine.[9]

2. Physostigmine. A patient taking **propranolol** 20 mg twice daily, recovering from surgery during which alcuronium had been used, received glycopyrronium and **neostigmine** without any change in heart rate. However, one hour later he developed severe bradycardia (a fall from 65 to 40 bpm) and hypotension (systolic blood pressure 70 mmHg) when given intravenous physostigmine 2 mg over 5 minutes, for extreme drowsiness attributed to the premedication. His symptoms responded to glycopyrronium.[10]

3. Pyridostigmine. A study in 8 hypertensive patients taking long-term **atenolol** or **propranolol** found no significant changes in heart rate and no serious adverse reactions when they were given low-dose oral pyridostigmine 30 mg three times daily for 2 days.[11]

Mechanism

It would appear that the bradycardic effects of the beta blockers and the acetylcholine-like effects of these anticholinesterase drugs can be additive. These were inadequately controlled by the use of atropine in some of the instances cited. The myasthenic symptoms may be due to beta blockers exerting a depressant effect on the neuromuscular junction.[2,3]

Importance and management

The information available indicates that marked adverse reactions between beta blockers and anticholinesterases after surgery are uncommon, but be aware of the possibility of an interaction if a patient becomes bradycardic or hypotensive shortly after surgery.

Limited information suggests that beta blockers given orally or topically could, in some cases, oppose the efficacy of anticholinesterases in the treatment of myasthenia gravis. However, one study suggests that not all patients are affected. Strictly speaking this is a drug-disease rather than a drug-drug interaction.

Beta blockers + Anticholinesterases; Centrally acting

The concurrent use of centrally-acting anticholinesterases and beta blockers may increase the risk of bradycardia.

Clinical evidence, mechanism, importance and management

An analysis of the French Pharmacovigilance Database for adverse drug reactions involving a centrally-acting anticholinesterase (**donepezil**, **galantamine** and **rivastigmine**), up to March 2006, found 83 potential drug interactions between anticholinesterases and beta blockers. Of these, 33 were thought to have caused adverse drug reactions, including syncope, bradycardia, arrhythmia or cardiac arrest. The concurrent use of a centrally-acting anticholinesterase drug and a drug with bradycardic effects resulted in 5 fatalities; however, it is unclear if any of these cases involved a beta blocker.[1]

It would appear that the effects of these centrally-acting anticholinesterases on heart rate can be additive with those of the beta blockers, sometimes resulting in a dramatic slowing of the heart. Be alert for bradycardia if a beta blocker is given with **donepezil**, **galantamine** or **rivastigmine**. The effects of **tacrine** do not appear to have been studied, but it would be expected to interact similarly.

Beta blockers + Aspirin or NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, although some studies have not found the increase to be clinically relevant. Similarly, multiple-dose aspirin, both in high and low dose, did not reduce the efficacy of antihypertensives including beta blockers in three studies. However, various small studies, have found some evidence of reduced beta blocker effects, either for hypertension or heart failure, in patients given NSAIDs including indometacin, piroxicam, ibuprofen and naproxen, or aspirin. Isolated case reports also describe hypertension in patients taking a beta blocker and an NSAID.

Celecoxib may decrease the metabolism of metoprolol, but in general the NSAIDs do not significantly affect the pharmacokinetics of the beta blockers.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,[1,2] the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.[1] Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,[1] the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,[2] the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.[1] The

mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on beta blockers are outlined in the subsections below.

(a) Aspirin and other salicylates

A small study in patients taking various antihypertensives (including beta blockers and diuretics) found that aspirin, in both low doses (650 mg daily) and high doses (3.9 g daily) for 3 or 4 weeks, did not cause clinically significant increases in blood pressure.[3] Similarly, a study in 11 patients taking a number of antihypertensives (which included a few patients taking **propranolol** or **pindolol**) found that aspirin 650 mg three times daily for 7 days did not affect the control of blood pressure.[4] In contrast, another study found that 5 g of aspirin given over 24 hours prevented the antihypertensive effects of a single 1-mg intravenous dose of **pindolol**, and a single 1- to 1.5-g dose of aspirin reduced the antihypertensive effect of a single 5-mg intravenous dose of **propranolol**.[5] Aspirin was reported not to affect the control of hypertension by **metipranolol**.[6] A retrospective study of patients with heart failure taking **carvedilol** found that aspirin did not significantly affect systolic blood pressure or heart rate but did observe that left ventricular ejection fraction improved less in those patients taking aspirin in addition to **carvedilol** The effect appeared to be dose-related.[7]

A single-dose study in 6 healthy subjects found that aspirin 500 mg did not affect the pharmacokinetics of **atenolol**.[8] Another study in 6 healthy subjects found that aspirin did not affect the pharmacokinetics of **metoprolol**, but the maximum plasma levels of aspirin were increased by **metoprolol**, although this was not considered to be clinically relevant.[9]

Sodium salicylate did not affect either the pharmacokinetics of **alprenolol** or its effects on heart rate and blood pressure during exercise in a single-dose study in healthy subjects.[10] **Imidazole salicylate** did not affect the blood pressure control of patients treated with **atenolol**.[11]

(b) Celecoxib

In a randomised, crossover study in 12 healthy subjects, celecoxib 200 mg twice daily for 7 days increased the AUC of a single 50-mg dose of **metoprolol** by 64%.[12]

(c) Diclofenac

A study in 16 patients taking **atenolol**, **metoprolol**, **propranolol** or **pindolol** and/or a diuretic found that diclofenac 50 mg three times daily had no effect on the control of blood pressure.[13]

(d) Flurbiprofen

A study in 10 patients with hypertension found that flurbiprofen 100 mg daily for 7 days did not affect the pharmacokinetics of single-doses of either **propranolol** 80 mg or **atenolol** 100 mg. However, the hypotensive effects of **propranolol** were reduced by the flurbiprofen, whereas those of **atenolol** were not affected.[14]

(e) Ibuprofen

In a randomised study in 6 hypertensive patients treated with thiazides and beta blockers, ibuprofen 400 mg every 8 hours caused significant increases in blood pressure (mean increases of about 5 to 7 mmHg)[15] The antihypertensive effect of **pindolol** was antagonised by ibuprofen in one patient.[16] However, in one randomised controlled study, ibuprofen 400 mg four times daily had no effect on the control of blood pressure in patients taking **propranolol**.[17]

(f) Indometacin

A study found that when indometacin 25 mg three times daily was given to hypertensive patients taking thiazides with or without beta blockers, their blood pressure increased by 8 to 10 mmHg.[3] The diastolic blood pressures of 7 hypertensive patients treated with **pindolol** 15 mg daily or **propranolol** 80 to 160 mg daily rose from 82 to 96 mmHg when they were given indometacin 100 mg daily over a 10-day period. Changes in systolic pressures were not statistically significant.[18]

In another study, indometacin 50 mg twice daily raised the blood pressure of patients taking **propranolol** 60 to 320 mg daily by 14/5 mmHg when lying and 16/9 mmHg when standing.[19] This interaction has also been seen in other studies in patients taking **atenolol**,[11,20,21] **labetalol**,[22] **metipranolol**,[6] **oxprenolol**,[23,24] and **propranolol**.[4,25] Two women with pre-eclampsia taking **propranolol** or **pindolol** became markedly hypertensive (rises in blood pressure from 135/85 to 240/140 mmHg, and from 130/70 to 230/130 mmHg, respectively) within 4 to 5 days of being given indometacin to inhibit premature contractions.[26]

(g) Naproxen

A study in hypertensive patients taking **timolol** and hydrochlorothiazide with amiloride found that naproxen 250 mg twice daily caused a 4 mmHg rise in diastolic blood pressure, but did not significantly increase systolic blood pressure.[27] Similarly, in another study, naproxen 500 mg twice daily caused an average 4 mmHg rise in systolic blood pressure in patients taking **atenolol**, but did not significantly increase diastolic blood pressure.[28] In contrast, another study found that naproxen caused no changes in hypertension controlled with **propranolol**,[29] and a study in patients taking antihypertensives [drugs not specified] found that naproxen did not cause clinically significant increases in blood pressure.[3] A case report describes one patient taking **propranolol** who had a marked rise in blood pressure when given naproxen.[30]

(h) Oxaprozin

A study in 32 hypertensive arthritic patients found that oxaprozin 1.2 g daily for 4 weeks did not affect the antihypertensive effects of **metoprolol** 100 mg twice daily, although at 2 weeks there was a significant increase in systolic blood pressure.[31]

(i) Parecoxib

In a randomised, crossover study, 15 healthy subjects were given a single 50-mg dose of **metoprolol** after taking valdecoxib (the main metabolite of parecoxib) 20 mg daily for 7 days. The AUC and maximum levels of **metoprolol**, and its effect of on heart rate were unchanged by the NSAID.[32]

(j) Piroxicam

A double-blind study found that about one-quarter of the patients given piroxicam 20 mg daily and **propranolol** 80 to 160 mg daily developed diastolic pressure rises of 10 mmHg or more when lying or standing.[33,34] Increases in both systolic and diastolic pressures (8.1/5.2 mmHg lying and 8.5/8.9 mmHg standing) were seen in another study in 3 patients.[35] In contrast, patients taking **propranolol** and piroxicam 20 mg daily had blood pressure rises of 5.8/2.4 mmHg when lying and 3.5/0.5 mmHg when standing, after 2 weeks, but these increases were not statistically significant.[36] Blood pressure showed a trend towards higher levels in another study in 20 patients given **timolol** and piroxicam 20 mg daily.[27]

A study in 6 healthy subjects given **atenolol** 100 mg daily and piroxicam 20 mg daily for 7 days found no pharmacokinetic interaction. An associated study in another 6 healthy subjects given **metoprolol** 100 mg twice daily and piroxicam 20 mg daily for 7 days found that **metoprolol** levels were increased by piroxicam, but not to a statistically significant extent.[37]

(k) Sulindac

Sulindac 200 mg twice daily had little or no effect on the control of hypertension in patients taking hydrochlorothiazide with amiloride and **atenolol**, **metoprolol**, **propranolol** or **pindolol**.[13] In another study, diastolic blood pressure was slightly and significantly lower when sulindac was given with **timolol**.[27] No statistically significant rises in blood pressure occurred in other studies in patients taking **propranolol**[29,33-35] or **atenolol**[21,28] or unspecified antihypertensives[3] given sulindac 200 mg twice daily. In contrast, another study claimed that patients given **propranolol** with sulindac 200 mg twice daily had blood pressure rises of 10.3/4.8 mmHg when standing and 2.4/7.1 mmHg when lying, after 2 weeks, but only the increase in standing systolic blood pressure statistically significant.[36] Similarly, a crossover study in 26 hypertensive patients taking **labetalol** found that sulindac 200 mg twice daily for 7 days raised the mean systolic blood pressure by 6 mmHg when sitting, and by 9 to 14 mmHg when standing, which was considered potentially clinically significant. Diastolic pressures were not affected.[22]

(l) Tenoxicam

In one study, the control of hypertension in 16 patients taking **atenolol** was not affected by tenoxicam 40 mg daily.[38]

Mechanism

Indometacin alone can raise blood pressure (13 hypertensive patients given indometacin 150 mg daily for 3 days had a mean systolic blood pressure rise from 118 mmHg to 131 mmHg).[39] One suggested reason is that indometacin inhibits the synthesis and release of two prostaglandins (PGA and PGE), which have a potent dilating effect on peripheral arterioles throughout the body. In their absence the blood pressure rises. Thus the hypotensive actions of the beta blockers are opposed by the hypertensive actions of indometacin. This mechanism has been questioned and it is possible that other physiological and pharmacological mechanisms have a

part to play.[3,40,41] One study found that although indometacin caused increases in blood pressure in treated hypertensive patients, other inhibitors of prostaglandin synthesis (aspirin, naproxen and sulindac) did not.[3] Further, all four drugs caused similar reductions in plasma renin activity and aldosterone concentration, which suggests that the effect of indometacin on blood pressure may not be dependent on such changes.[3]

Celecoxib inhibits the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.[12]

Importance and management

Overall, the evidence suggests that some patients taking beta blockers can have a rise in blood pressure when given an NSAID, but this may not always be clinically relevant. Some consider that the use of NSAIDs should be kept to a minimum in patients taking antihypertensives.[42] The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with high salt intake.[42] However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.[43] While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons (such as 'white-coat hypertension', poor adherence to treatment, or disease progression) may be more likely than any effect of concurrent NSAIDs.[43] There is insufficient data at present to clearly differentiate between NSAIDs, although there is some evidence that the effects of indometacin are greatest and those of sulindac least.

For the effects of NSAIDs on other antihypertensive drug classes see 'ACE inhibitors', (p.32), 'calcium-channel blockers', (p.1027) and 'thiazide diuretics', (p.1138).

A few multiple-dose studies have not found **aspirin** to alter the antihypertensive effect of beta blockers, even in high doses, but one single-dose high-dose study reported an interaction. Another study suggested that aspirin might attenuate the benefit of carvedilol in heart failure, but the evidence is currently too slim to warrant a change in practice.

Although **celecoxib** increased the levels of metoprolol, increases in plasma metoprolol levels of this size are unlikely to be clinically relevant in most patients. Those most at risk would be patients with heart failure, in whom the use of NSAIDs should generally be avoided.

Parecoxib (which is rapidly hydrolysed to valdecoxib) at low daily doses does not appear to interact with metoprolol. Nevertheless, the authors of the study suggest that the possibility of an interaction with higher doses cannot been excluded,[32] and the manufacturers of parecoxib suggest that caution is warranted.[44] However, the lack of interaction with low-dose parecoxib would seem to imply that higher doses would only have a moderate effect, if any, on metoprolol metabolism. Furthermore, metoprolol is generally considered to have a wide therapeutic index and therefore a very large rise in levels would be necessary for the interaction to become clinically relevant. The exception may be heart failure, where the beta blockers are considered to be narrow therapeutic index, but it should be noted that NSAIDs should generally be avoided in those with heart failure.

Beta blockers + Barbiturates

The plasma levels and the effects of beta blockers that are mainly metabolised by the liver (e.g. alprenolol, metoprolol, timolol) are reduced by the barbiturates. Alprenolol concentrations are halved by pentobarbital, but metoprolol is less affected.

Clinical evidence

(a) Pentobarbital

In a study in 6 hypertensive patients, pentobarbital 100 mg daily for 10 days at bedtime reduced the plasma levels of **alprenolol** 400 mg twice daily by 59%. On day 11, the mean pulse rate at rest had risen from 70 to 74 bpm and blood pressure had risen from 134/89 to 145/97 mmHg. The changes were seen within 4 to 5 days of starting the barbiturate, and decreased within 8 to 9 days of stopping it.[1] These results are similar to

those found in previous studies by the same research group using pentobarbital 100 mg daily in healthy subjects.[2,3] In one of these studies, pentobarbital reduced the plasma levels of a single 200-mg dose of **alprenolol** by 38%, 90 minutes after the **alprenolol** was given, and reduced its AUC by 43%. The elimination half-life of **alprenolol** was unchanged. There was also a 20% reduction in the effects of the beta blocker on heart rate during exercise.[3] In the other study, the AUC of oral **alprenolol** was reduced by about 80% by pentobarbital, but that of intravenous **alprenolol** was unaffected.[2]

Another study in 8 healthy subjects found that pentobarbital 100 mg daily for 10 days reduced the AUC of **metoprolol** 100 mg by 32% (range 2 to 46%).[4]

(b) Phenobarbital

In a study in 12 healthy subjects phenobarbital 100 mg daily for 7 days reduced the AUC of **timolol** by 24%, but this was not statistically significant.[5]

Mechanism

Barbiturates are potent liver enzyme inducers that can increase the metabolism and clearance of other drugs from the body. Beta blockers that are removed from the body principally by liver metabolism (e.g. alprenolol, metoprolol, timolol) can therefore possibly be cleared more quickly in the presence of a barbiturate.

Importance and management

The interaction between alprenolol and pentobarbital is well documented and likely to be of modest clinical importance when the beta blocker is being used to treat hypertension, and possibly angina. Monitor the effects of alprenolol and increase the dose as necessary. Where possible it may be preferable to replace the barbiturate with a non-interacting alternative, such as one of the 'benzodiazepines', (p.843), which only have minor effects on the beta blockers. Alternatively, consider using a different beta blocker. Those that are not hepatically metabolised (see 'Table 22.1', (p.995)) would not be expected to interact, but note that this does not appear to have been studied.

A reduced response is possible if any of the beta blockers that are extensively metabolised (see 'Table 22.1', (p.995)) are given with pentobarbital, but the effects on the AUC of metoprolol appear to be smaller than the effects on alprenolol. Detailed information about the clinical importance of this interaction is largely lacking, but seems likely to be minor. However, if a problem does occur consider the alternative measures suggested for alprenolol, above.

Evidence is largely lacking, but all barbiturates would be expected to interact similarly, although the extent of the interaction may vary. For example, the interaction between phenobarbital and timolol was not statistically significant, and a clinically relevant effect is unlikely.

Beta blockers + Bile-acid binding resins

Although both colestyramine and colestipol can moderately reduce the absorption of propranolol, this does not seem to reduce its effects. Colesevelam does not appear to affect the absorption of metoprolol.

Clinical evidence

(a) Colesevelam

A single-dose study in 33 healthy subjects found that colesevelam 4.5 g did not cause a clinically relevant alteration in the plasma levels of sustained-release **metoprolol** 100 mg.[1]

(b) Colestipol

When 6 healthy subjects took a single 120-mg dose of **propranolol** with a 10-g dose of colestipol the peak plasma **propranolol** levels were *raised* by 30%. However, if an additional 10 g dose of colestipol was taken 12 hours before the **propranolol** the peak plasma levels were decreased by 36% and the AUC was reduced by about 30%. No changes in blood pressure or pulse rates were seen.[2]

(c) Colestyramine

When 6 healthy subjects took a single 120-mg dose of **propranolol** with an 8-g dose of colestyramine the peak **propranolol** plasma levels were reduced by almost 25% and the AUC was reduced by 13%. An additional dose of colestyramine 12 hours before the **propranolol** reduced the AUC by 43%. However, no changes in blood pressure or pulse rate were seen.[2] Preliminary results of another study found that colestyramine (single unstated dose) caused no significant changes in the blood levels of **propranolol** in 5 patients with type II hyperlipidaemia taking **propranolol** 40 mg four times daily.[3]

Mechanism

Uncertain. It seems probable that both colestyramine and colestipol can, to some extent, bind to propranolol in the gut, thereby modestly reducing its absorption.

Importance and management

Information is limited. Even though both colestyramine and colestipol can modestly reduce the absorption of a single dose of propranolol, no changes in its effects were reported,[2] suggesting that the interaction is of minimal clinical importance. There is therefore no obvious reason for avoiding concurrent use. However, note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine, and 1 hour before or 4 hours after colestipol.

Beta blockers + Bupropion

A patient taking metoprolol developed bradycardia and hypotension when bupropion was also given.

Clinical evidence, mechanism, importance and management

A 50-year-old man taking **metoprolol** 75 mg twice daily and diltiazem 240 mg twice daily for hypertension developed fatigue 12 days after starting to take bupropion 150 mg twice daily. He was found to have a pulse rate of 43 bpm, a blood pressure of 102/65 mmHg, and signs of mild heart failure. He recovered within 24 hours of stopping all three drugs.[1] It was suggested that these effects had occurred as a result of raised **metoprolol** levels, which had occurred because bupropion inhibited the metabolism of **metoprolol** by the cytochrome P450 isoenzyme CYP2D6.

The manufacturers of bupropion have predicted this interaction and recommend that if **metoprolol** is added to treatment with bupropion, doses at the lower end of the range should be used. If bupropion is added to existing treatment, decreased dosages of **metoprolol** should be considered.[2,3] These precautions seem prudent, especially in patients with heart failure, where raised beta blocker levels seem most likely to cause an adverse effect.

It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see 'Table 22.1', (p.995), for a list).

Beta blockers + Calcium-channel blockers; Dihydropyridines

The use of beta blockers with felodipine, isradipine, lacidipine, nicardipine, nimodipine and nisoldipine normally appears to be useful and safe. However, severe hypotension and heart failure have occurred rarely when a beta blocker was given with nifedipine or nisoldipine. Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur on concurrent use, but they do not appear to be clinically important.

Clinical evidence

(a) Felodipine

A double-blind, crossover study in 8 healthy subjects found that over a 5-day period, **metoprolol** 100 mg twice daily did not affect the pharmacokinetics of felodipine 10 mg twice daily. However, the bioavailability and peak plasma levels of **metoprolol** were modestly increased by 31% and 38%, respectively.[1] Another study in 10 healthy subjects given felodipine 10 mg with either **metoprolol** 100 mg, **pindolol** 5 mg, **propranolol** 80 mg, or **timolol** 10 mg found no changes in heart rate, PR interval or blood pressure that might be considered to be harmful to patients with hypertension or angina. However, 7 of the 10 subjects reported some increase in adverse effects.[2]

(b) Isradipine

A preliminary report of a study in 24 healthy subjects found that **propranolol** 40 mg twice daily given with isradipine 5 mg twice daily caused some modest changes in the pharmacokinetics of both drugs (peak **propranolol** plasma levels increased by 17%, peak isradipine plasma levels reduced by 18%), but the AUCs were not significantly altered.[3] An earlier preliminary report by the same research group in 17 subjects found an increase in the **propranolol** AUC of 28%, a reduction in the isradipine AUC of 22%, and a 59% increase in the peak **propranolol** levels.[4]

(c) Lacidipine

Twelve patients with mild to moderate hypertension not satisfactorily controlled by **atenolol** alone were given lacidipine 4 mg daily with or without **atenolol** 100 mg daily for 14 days. There was no evidence of a significant change in drug levels, but there was a significant additive reduction in blood pressure during concurrent use, when compared with the reductions observed with either drug alone.[5]

Single-dose studies in 24 healthy subjects found that **propranolol** 160 mg reduced the peak plasma levels and AUC of lacidipine 4 mg by 38% and 42%, respectively, while the peak plasma levels and AUC of the **propranolol** were increased by 35% and 26%, respectively. There was a modest additive reduction of 4 to 6 mmHg in blood pressure, and the combination reduced the heart rate, but not to an extent greater than **propranolol** alone. No significant adverse effects were seen.[6] A further preliminary report of a study by the same authors, in which 12 hypertensive patients were given **propranolol** 160 mg twice daily and lacidipine 4 mg daily for 2 weeks, found a non-significant 30% increase in systemic availability of lacidipine, and no change in **propranolol** pharmacokinetics. In addition, no clinically significant alterations in ECG recordings, blood pressure, or pulse rate were seen.[7]

(d) Lercanidipine

The manufacturer notes that when lercanidipine was given with **metoprolol**, the bioavailability of lercanidipine was reduced by 50% while the bioavailability of **metoprolol** was unchanged. They suggest that any beta blocker may alter lercanidipine bioavailability.[8]

(e) Nicardipine

In a single-dose study in healthy subjects, nicardipine 30 mg did not affect the pharmacokinetics or pharmacodynamics of **atenolol** 100 mg.[9]

In another study, 14 healthy subjects were given nicardipine 50 mg every 12 hours and **metoprolol** 100 mg every 12 hours, both together and alone, for 11 doses. **Metoprolol** plasma levels were raised by 28% by the nicardipine in the 7 subjects who were of the extensive CYP2D6 metaboliser phenotype (that is, those with normal levels of this isoenzyme), but had no significant effect in the poor metabolisers (those lacking or deficient in CYP2D6). The extent of the beta-blockade was unchanged in all of them.[10]

Preliminary analysis of another study in healthy subjects found that the pharmacokinetics of both **propranolol** 80 mg twice daily and nicardipine 30 mg three times daily were unaffected when they were given together for 6 days.[11] However, two single-dose studies found that nicardipine 30 mg increased the AUC and peak plasma levels of **propranolol** 80 mg by 47% and 80%, respectively,[12] and raised the AUC and peak plasma levels of sustained-release **propranolol** 80 mg to a lesser extent (17% and 22%, respectively).[13] A related single-dose study found that in elderly healthy subjects nicardipine 30 mg increased the maximum plasma levels and AUC of **propranolol** 40 mg by about 100% and 80%, respectively. Nicardipine caused a further decrease in blood pressure, and attenuated the reduction in heart rate seen with **propranolol** alone.[14]

A study in 8 healthy subjects found that the increase in heart rate during exercise associated with a single 40-mg dose of nicardipine was reduced by one drop of **timolol** 0.5% put into each eye. Systolic blood pressure was also reduced during concurrent use, but nicardipine did not cause any further reduction in intraocular pressure than **timolol** alone.[15]

(f) Nifedipine

Nifedipine 10 mg three times daily did not alter the pharmacokinetics of **atenolol** 100 mg daily,[16,17] **betaxolol**,[18] **metoprolol** 100 mg twice daily[16,17] or **propranolol** 80 mg twice daily.[16] A single-dose study also found no pharmacokinetic interaction between nifedipine and **atenolol**.[19] However, a multiple-dose study found that nifedipine 10 mg three times daily increased the peak plasma level and AUC of **propranolol** 80 mg twice daily by 56% and 23%, respectively.[18] Another study found that the absorption of a single-dose of **propranolol** appeared to be faster, leading to higher initial concentrations, when it was given after nifedipine.[20]

Regardless of the pharmacokinetic changes, none of these studies in healthy subjects found any adverse haemodynamic effects as a result of giving nifedipine with any of these beta blockers.[16,18,19] Similarly, in studies in patients with normal left ventricular function there was no evidence of adverse haemodynamic effects when nifedipine (single-dose sublingual[21,22] or intravenously,[23] or daily dose orally[23]) was given with **atenolol**,[23] **celiprolol**[22] or **propranolol**.[21,24] However, there are a few earlier isolated case reports of hypotension and heart failure with the combination:

- Two patients with angina taking **alprenolol** or **propranolol** developed heart failure when they were given nifedipine 10 mg three times daily. The signs of heart failure disappeared when the nifedipine was withdrawn.[25]
- One out of 15 patients with hypertension and exertional angina progressively developed hypotension (90/60 mmHg) when given nifedipine 10 mg twice daily with **atenolol** 50 mg daily and a diuretic for one month.[26]
- A patient with angina taking **propranolol** 160 mg four times daily developed severe and prolonged hypotension (blood pressure initially not recordable, then 60 mmHg systolic) 18 days after nifedipine 10 mg three times daily was substituted for 'isosorbide', and this may have been a factor that led to fatal myocardial infarction.[27]
- Heart failure developed in a patient with angina taking **atenolol** (and various other drugs) when nifedipine 20 mg three times daily was given.[28]

A further report describes a patient who developed hypotension and severe bradycardia on two occasions after being given her usual antihypertensive medication of **labetalol** and extended-release nifedipine crushed and given via a nasogastric tube. Crushing the nifedipine tablet altered its release characteristics so that the total dose was released quickly resulting in profound hypotension. The **labetalol** produced additional hypotensive effects and prevented a compensatory increase in heart rate.[29]

(g) Nimodipine

In a preliminary report of a study in 12 healthy subjects, nimodipine 30 mg three times daily for 4 days had no significant effect on the changes in heart rate, blood pressure or cardiac output seen with either **propranolol** 40 mg or **atenolol** 25 mg three times daily. The pharmacokinetics of the beta blockers were also unaltered.[30]

(h) Nisoldipine

A single 20-mg dose of nisoldipine increased the steady-state AUC and peak plasma level of **propranolol** 160 mg daily by 35% and 55%, respectively. After concurrent use for 7 days, the AUC of **propranolol** was increased by 60% and the peak plasma level was increased by 55%. The combination enhanced blood pressure reduction to a small extent, but nisoldipine did not significantly reduce the effect of **propranolol** on heart rate.[31] Similarly, another study found that a single 20-mg dose of nisol-

dipine increased the AUC and peak plasma level of a single 40-mg dose of **propranolol** by 43% and 68%, respectively, and that the AUC and peak plasma level of nisoldipine increased by 30% and 57%, respectively. In this study, nisoldipine was reported to enhance beta-blockade.[32] However, the same research group later found that the steady-state pharmacokinetics of **propranolol** 80 mg twice daily and nisoldipine 10 mg twice daily were not affected by concurrent use for 7 days, but nisoldipine attenuated the decrease in forearm blood flow seen with propranolol.[33] The manufacturer of nisoldipine notes that severe hypotension can occur when it is given at the same time as beta blockers, and that, in isolated cases, signs of heart failure can also occur.[34]

Mechanism

Not understood. Where pharmacokinetic changes are seen, a possible reason is that the metabolism of the beta blockers is altered by changes in blood flow through the liver. The pharmacodynamic changes with nifedipine may be explained by the fact that nifedipine reduces the contractility of the heart muscle. This is counteracted by a sympathetic reflex increase in heart rate due to nifedipine-induced peripheral vasodilation, so that the ventricular output stays the same or is even improved. The presence of a beta blocker may oppose this to some extent by slowing the heart rate, which allows the negative inotropic effects of nifedipine to go unchecked.

The manufacturers of lercanidipine suggest that the reduction in lercanidipine bioavailability may be due to reduced hepatic blood flow caused by beta-adrenoceptor blockade.[8]

Importance and management

The concurrent use of beta blockers and the dihydropyridine calcium-channel blockers is common, and normally valuable. However, isolated cases of severe hypotension and heart failure have been seen in a few patients taking beta blockers and nifedipine or nisoldipine. It has been suggested that those likely to be most at risk are patients with impaired left ventricular function[35] (which is a caution for the use of nifedipine anyway) and/or those taking beta blockers in high dosage. Bear this in mind. It should also be noted that the topical use of beta blockers (such as timolol eye drops) may reduce heart rate and blood pressure. It may also be worth noting that all but one of the cases of an adverse reaction with a beta blocker and nifedipine occurred with 'short-acting' formulations, which are now considered unsuitable for long-term management of angina or hypertension, since they are associated with larger variations in blood pressure and heart rate. The remaining case was associated with the incorrect use of an extended-release nifedipine preparation.

Changes in the pharmacokinetics of the beta blockers and calcium-channel blockers may also occur, but these do not appear to be clinically important.

The manufacturer of lercanidipine suggests that, as a reduction in lercanidipine bioavailability may occur with any beta blocker, some adjustment of the lercanidipine dose may be needed.[8]

Beta blockers + Calcium-channel blockers; Diltiazem

The cardiac depressant effects of diltiazem and beta blockers are additive, and although concurrent use can be beneficial, close monitoring is recommended. A number of patients, (usually those with pre-existing ventricular failure or conduction abnormalities) have developed serious and potentially life-threatening bradycardia. Diltiazem increases the serum levels of propranolol and metoprolol, but not those of atenolol.

Clinical evidence

(a) Cardiac depressant effects

Ten patients were admitted to an intensive coronary care unit during one year with severe bradycardia (heart rates of 24 to 44 bpm) after taking diltiazem 90 to 360 mg daily with **propranolol** 30 to 120 mg daily, **atenolol** 50 to 100 mg daily, or **pindolol** 90 mg daily. All were relatively elderly and presented with lethargy, dizziness, syncope, chest pain, and in one case pulmonary oedema. The ECG abnormalities were localised in the sinus node, the primary rhythm disorders being junctional escape rhythms, sinus bradycardia and sinus pause. These resolved within 24 hours of withdrawing the drugs, although a temporary pacemaker was needed in 4 patients.[1]

In an analysis of drug use in cases listed in a post-mortem toxicology database in Finland for the period 2000 to 2006, drug combinations possessing potentially severe interactions were found in 267 cases (0.71% of cases). Combinations of beta blockers with verapamil or diltiazem accounted for 22 possible pharmacodynamic interactions. In one case, a 63-year-old man who died in a car accident was found to have slightly elevated levels of **bisoprolol** (0.13 mg/L) and therapeutic levels of diltiazem. It was speculated that the combination may have led to bradyar-

rhythmias or other adverse cardiac effects, which may have contributed to the fatality.[2]

Symptomatic and severe bradyarrhythmias of this kind have been described in case reports in 16 other patients taking diltiazem with **atenolol**,[3] **carteolol**,[4] **metoprolol**,[3,5,6] **nadolol**,[7] **pindolol**,[8] **propranolol**,[3,5,7,9] or **sotalol**.[4,8] AV block with unusual ECG changes (T-wave inversion and ST-segment depression) was found in a 16-year-old girl following an overdose of diltiazem and **propranolol**.[10] In a later prospective study of hospital admissions due to cardiovascular adverse drug reactions, bradycardia, hypotension, syncope and worsening heart failure were noted in 21 patients taking beta blockers with diltiazem. The beta blockers involved were **propranolol** (13 patients), **atenolol** (5), **metoprolol** (2) and **oxprenolol** (1).[11] Similarly severe sinus bradycardia occurred in 8 of 59 patients in three early clinical studies of the combination of diltiazem and **propranolol**.[12-14] One patient developed congestive heart failure.[14] In contrast, four other similar clinical studies did not report any adverse effects,[15-18] and in a single-dose study, one drop of **timolol** 0.5% eye drops did not cause an additional reduction in heart rate when it was given to healthy subjects with a 60-mg dose of diltiazem.[19]

(b) Pharmacokinetics

In healthy subjects, diltiazem increased the AUC of **propranolol** and **metoprolol** by 48% and 33%, respectively, and increased the maximum serum levels of these beta blockers by 45% and 71%, respectively. The pharmacokinetics of **atenolol** were not significantly affected by diltiazem.[20] Another study found that diltiazem caused a 24 to 27% reduction in **propranolol** clearance.[21]

Mechanism

The bradycardic effects of the beta blockers can be additive with the delay in conduction through the atrioventricular node caused by diltiazem.[8] This advantageously increases the antianginal effects in most patients, but in a few these effects may exacerbate existing cardiac abnormalities. Diltiazem apparently also inhibits the metabolism of propranolol and metoprolol, but the exact mechanism for this is not clear.[20]

Importance and management

The concurrent use of a beta blocker and diltiazem is unquestionably valuable and uneventful in many patients, but severe adverse effects can develop. This is well established. On the basis of 6 reports, the incidence of symptomatic bradyarrhythmia was estimated to be about 10 to 15%.[1] It can occur with different beta blockers, even with very low doses, and at any time from within a few hours of starting treatment to 2 years of concurrent use.[1] The main risk factors seem to be ventricular dysfunction, or sinoatrial or AV nodal conduction abnormalities,[1] which are usually contraindications to the use of diltiazem. Patients with normal ventricular function and no evidence of conduction abnormalities are usually not at risk. Concurrent use should be well monitored for evidence of adverse effects. Changes in the pharmacokinetics of the beta blockers may also occur, but these changes are probably not clinically important.

Beta blockers + Calcium-channel blockers; Verapamil

The cardiac depressant effects of verapamil and beta blockers are additive, and although concurrent use can be beneficial, serious cardiodepression (bradycardia, asystole, sinus arrest) sometimes occurs. It has been suggested that the combination should only be given to those who can initially be closely supervised. An adverse interaction can also occur with beta blockers given as eye drops.

Clinical evidence

(a) Pharmacodynamic interactions

In an analysis of drug use in cases listed in a post-mortem toxicology database in Finland, for the period 2000 to 2006, drug combinations possessing potentially severe interactions were found in 267 cases (0.71% of cases). Combinations of beta blockers with verapamil or diltiazem accounted for 22 possible pharmacodynamic interactions.[1]

1. Intravenous use. Ventricular asystole developed in a 70-year-old man and a 6-month-old baby when intravenous verapamil was given after the unsuccessful use of intravenous **practolol** to treat supraventricular tachycardia.[2] In a later study, the combination of intravenous verapamil and intravenous **practolol** produced a marked reduction in cardiac contractility, which was more evident when **practolol** was given first.[3]

2. Oral use. In one series, 34 out of 42 patients taking verapamil 360 mg daily with beta blockers (daily dose: **atenolol** 100 mg (34 patients), **atenolol** 50 mg (2), **propranolol** 160 mg (4), **pindolol** 20 mg (1), or **metoprolol** 100 mg (1)) experienced a reduction in anginal episodes over a mean period of 6.5 months while taking both drugs. However, 12 patients needed a reduced dosage or withdrawal of one or both drugs. One had non-specific symptoms (drugs withdrawn), 2 had bradyarrhythmias (drugs withdrawn) and 6 experienced dyspnoea (3 withdrawals and 3 dosage reductions), which were presumed to be secondary to left ventricular failure. Other complications were tiredness (2 patients) and postural hypotension (1 patient), which were dealt with by reducing the dosage.[4] In another study in 15 patients with angina who were taking **atenolol** with verapamil, 4 patients experienced profound lethargy, one had left ventricular failure and 4 had bradyarrhythmias.[5]

Other case reports and studies describe heart failure,[6,7] dyspnoea,[6,8,9] sinus arrest,[10,11] heart block,[10,12-14] hypotension,[6,7,9,11,14-17] and bradycardia[5,6,9,11,12,15-19] in patients taking verapamil with **alprenolol**,[10] **atenolol**,[7,10,11,13] **metoprolol**,[6,12,14,16] **propranolol**[8,9,15,17-19] or **pindolol**.[6] A number of reports noted that patients experiencing this interaction had reasonable left ventricular function.[6,11,13] Heart block and hypotension or cardiogenic shock has also been reported after verapamil was given with **atenolol**[20] or **propranolol**[21] in overdose.

3. Ocular use. In two cases, bradycardia occurred in patients taking verapamil and using **timolol** eye drops.[22,23] Another case has been reported, but this was complicated by the presence of 'flecainide', (p.1006).

(b) Pharmacokinetic interactions

1. Atenolol. In one study in a single patient, the pharmacokinetics of atenolol were not altered by verapamil.[24] A study in 15 patients found that the plasma levels of verapamil and atenolol varied greatly during individual and concurrent use but mean concentrations were not significantly

changed.[5] In another study, in 10 patients, the mean AUC of atenolol was not significantly increased by verapamil, but individual patients had atenolol AUC increases of up to 112%.[25]

2. Metoprolol. In a study in 10 patients, verapamil raised the metoprolol AUC by 33% and the peak plasma levels by 41%. The minimum pulse rate and systolic blood pressure (1 to 3 hours post dose) were also lower in those taking the combination than with metoprolol alone.[16] Similarly, in a single-dose study in 9 healthy subjects, the AUC and maximum plasma level of metoprolol were increased by 35% and 64%, respectively, and the AUC and half-life of verapamil were increased by 57% and 29%, respectively, when both drugs were given together.[26]

3. Propranolol. In healthy subjects, verapamil reduced the clearance of propranolol by 26 to 32% and increased its AUC by 46 to 58% after 6 days of concurrent use.[27] Similarly, in 5 patients, verapamil increased the peak plasma levels of propranolol by 94%, and increased its AUC by 66%.[19] Propranolol did not affect the pharmacokinetics of verapamil.[19] However, in another study in healthy subjects, no pharmacokinetic interaction was noted when propranolol and verapamil were taken together for 6 days.[28]

4. Talinolol. In a randomised, crossover study in 9 healthy subjects, a single 120-mg dose of *(R)*-verapamil reduced the bioavailability of a single 50-mg dose of talinolol by 25%.[29]

Mechanism

Both the beta blockers and verapamil have negative inotropic effects on the heart, which can be additive.[28] Given together they can cause marked bradycardia and may even depress the contraction of the ventricle completely. Verapamil can also raise the serum levels of beta blockers that are extensively metabolised in the liver (e.g. metoprolol, propranolol), probably by inhibiting their metabolism,[30] although the exact mechanism for this is unclear. It is thought that verapamil affects talinolol bioavailability by modulating intestinal P-glycoprotein.[29,31]

Importance and management

Well documented and well established interactions. Although concurrent use can be uneventful and successful, the reports cited here amply demonstrate that it may not always be safe. The difficulty is identifying the patients most at risk. In the UK, the BNF says that oral concurrent use should only be considered if myocardial function is well preserved, and that verapamil should not be injected in patients recently given beta blockers because of the risk of hypotension and asystole. They also note that, although 30 minutes has been suggested as a sufficient interval before giving a beta blocker when a verapamil injection has been given first, the safety of this has not been established.[32] The manufacturers of verapamil contraindicate its intravenous use in those receiving intravenous beta blockers.[33]

It has been advised that the initiation of treatment should be restricted to hospital practice, where the dose of each drug can be carefully titrated and the patient closely supervised, particularly during the first few days when adverse effects are most likely to develop.[4,5,19] Some have suggested that beta blockers that are extensively metabolised (e.g. metoprolol, propranolol) may possibly carry some additional risk because verapamil raises their serum levels.[24] However, others contend that, since the interaction occurs with atenolol (which is largely excreted unchanged in the urine), the pharmacodynamic effects are more important than any pharmacokinetic changes.[5,11,19] Note that the latter argument is probably valid, as changes of this size, or even more, in the AUC of beta blockers have proved not to be clinically important, even in those patients likely to be sensitive to the effects of the beta blockers, such as those with heart failure.

Beta blockers + Chloroquine or Hydroxychloroquine

Hydroxychloroquine and possibly chloroquine may increase the blood levels of metoprolol and probably other similarly metabolised beta blockers.

Clinical evidence, mechanism, importance and management

In a study in 7 healthy subjects, hydroxychloroquine 400 mg daily for 8 days increased the AUC and peak plasma levels of a single 100-mg dose of **metoprolol** by 65% and 72%, respectively.[1] The subjects in this study were of the extensive CYP2D6 metaboliser phenotype, meaning that they had normal levels of this isoenzyme. Hydroxychloroquine may inhibit the metabolism of **metoprolol** by the cytochrome P450 isoenzyme CYP2D6. The clinical significance of this interaction is unknown, but normally the beta blockers are considered to have a wide therapeutic range, and so raises in levels are generally well tolerated. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, but even in this patient group the rise in levels seems unlikely to be generally important. There appears to be no information about oth-

er beta blockers, but all those metabolised by CYP2D6 would be expected to be affected to some extent. See 'Table 22.1', (p.995), for a list.

In vitro study suggests that **chloroquine** may interact with **metoprolol** in the same way as hydroxychloroquine.[2] More study is needed to establish the clinical relevance of any interaction.

Beta blockers + Dextropropoxyphene (Propoxyphene)

A single-dose study has shown that the bioavailability of metoprolol is markedly increased by dextropropoxyphene and a case report is in line with these findings. The bioavailability of propranolol is also increased by dextropropoxyphene, but to a lesser extent.

Clinical evidence

A 48-year-old man taking **metoprolol** 100 mg daily developed dizziness and sweating 3 hours after taking dextropropoxyphene 200 mg and paracetamol (acetaminophen) 1.3 g. He was found to have a heart rate of 30 to 40 bpm and a blood pressure of 98/65 mmHg, which returned to normal over the following 8 hours. Assessment of blood samples showed that his normal **metoprolol** level was 89 nanograms/mL, but that this had risen to 160 nanograms/mL in the presence of dextropropoxyphene.[1]

Preliminary results of a study in healthy subjects suggest that after taking dextropropoxyphene (dose not stated) for a day the bioavailability of a single 100-mg oral dose of **metoprolol** was increased by almost 260% and the total body clearance was reduced by 18%. The bioavailability of a single 40-mg oral dose of **propranolol** was increased by about 70% by dextropropoxyphene.[2]

Mechanism

Dextropropoxyphene inhibits the metabolism of metoprolol and propranolol by the cytochrome P450 isoenzyme CYP2D6, which results in increased levels and therefore increased effects. Propranolol is probably affected to a lesser extent as it is also metabolised by CYP1A2.

Importance and management

Evidence is limited, but an interaction seems established. It seems likely that this interaction could occur with any of the beta blockers metabolised by CYP2D6 (see 'Table 22.1', (p.995)). Therefore it would be prudent to be alert for evidence of an increased response to the beta blocker but so far there seems to be very little evidence to suggest that concurrent use causes problems. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, and therefore some monitoring (e.g. shortness of breath, bradycardia, hypotension) may be prudent. No interaction would be expected with those beta blockers that are largely excreted unchanged in the urine (see 'Table 22.1', (p.995)).

Beta blockers + Diphenhydramine

Diphenhydramine moderately inhibits the metabolism of metoprolol.

Clinical evidence

In a placebo-controlled study in 16 healthy male subjects, a single 100-mg dose of **metoprolol** was given on day 3 of a 5-day course of diphenhydramine 50 mg three times daily. Diphenhydramine decreased the clearance of **metoprolol** by 46% and increased its AUC by 61% in the 10 subjects who were of the extensive CYP2D6 metaboliser phenotype (meaning those that had normal levels of this isoenzyme), but had no significant effect in the 6 poor metabolisers (that is, those lacking or deficient in CYP2D6). However, the **metoprolol** AUC in the extensive metabolisers taking diphenhydramine was still only about one-third of that in the poor metabolisers taking placebo, suggesting a limited effect. The effect of **metoprolol** on heart rate and systolic blood pressure during exercise was also increased by diphenhydramine in extensive metabolisers. However, as before, it was not as great as the effect of **metoprolol** alone in poor metabolisers.[1] The same group of researchers repeated this study in 20 healthy women and found broadly similar results.[2]

Mechanism

Diphenhydramine modestly inhibits the cytochrome P450 isoenzyme CYP2D6, which is responsible, in part, for the metabolism of metoprolol and some other beta blockers. CYP2D6 shows polymorphism, with some individuals lacking significant CYP2D6 activity (poor metabolisers), in whom diphenhydramine would have little or no effect. See 'Genetic factors', (p.4), for more information on genetic polymorphism.

Importance and management

Information appears to be limited to these studies. Increases in plasma metoprolol levels of this size are unlikely to be clinically relevant. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, but even in this patient group the rise in levels seems unlikely to be generally important. Indeed, despite the likely widespread use of extensively metabolised beta blockers (see 'Table 22.1', (p.995)) and diphenhydramine, no problems seem to have been reported.

Beta blockers + Dronedarone

Dronedarone increases the AUC of metoprolol in most patients. The increase in the negative inotropic effects are modest at the recommended therapeutic dose of dronedarone. Theoretically, additive bradycardia may occur if dronedarone is taken with a beta blocker.

Clinical evidence

In a study, 44 healthy subjects (39 extensive and 5 poor CYP2D6 metabolisers; that is, 39 subjects with normal levels of CYP2D6 and 5 subjects lacking or deficient in CYP2D6) were given **metoprolol** 200 mg daily for 13 days with dronedarone 800 mg, 1.2 g or 1.6 g daily from day 5. Dronedarone increased the AUC of **metoprolol** in a dose-dependent manner in the 39 subjects who were extensive metabolisers by 1.63-fold, 2.08-fold and 2.53-fold, respectively, without affecting **metoprolol** plasma levels. Concurrent use resulted in an additive dose-dependent negative inotropic effect.[1]

Mechanism

Dronedarone is structurally related to amiodarone, which is known to inhibit the cytochrome P450 isoenzyme CYP2D6, by which metoprolol is metabolised (see 'Amiodarone + Beta blockers', p.276). This study also shows that dronedarone inhibits CYP2D6, effectively making extensive metabolisers into poor metabolisers. For more information on metaboliser status, see 'Genetic factors', (p.4).

Importance and management

A pharmacokinetic interaction between dronedarone and metoprolol is established, but its clinical relevance is uncertain. The negative inotropic effect of metoprolol was almost doubled by the addition of dronedarone 1.6 g daily, but at the anticipated therapeutic dose of 800 mg the effects were modest. Other beta blockers that are metabolised by CYP2D6 (see

'Table 22.1', (p.995)) would be expected to interact similarly. Note that as dronedarone may cause bradycardia, and this would be expected to be additive with the effects of beta blockers, caution should be used with concurrent use.

Beta blockers + Fish oils

The hypotensive effect of propranolol may be enhanced by fish oil.

Clinical evidence, mechanism, importance and management

In a study, 36 patients with mild hypertension were given either **propranolol** 80 mg daily or fish oil 9 g daily (as capsules and equivalent to **eicosapentaenoic acid** 1.8 g and **docosahexaenoic acid** 1.1 g daily) for 36 weeks, followed by placebo for 4 weeks. A further group of 16 patients were given **propranolol** 80 mg daily for 12 weeks, **propranolol** plus fish oil 9 g daily for 12 weeks, **propranolol** plus fish oil placebo for 12 weeks, and finally **propranolol** placebo for 4 weeks. Fish oil alone decreased blood pressure to a similar extent to **propranolol**, and decreases in blood pressure with the combination were greater than with either **propranolol** or fish oil alone.[1]

A further similar study in 14 patients taking a beta blocker found that when they were also given 4 capsules of *Omacor* (equivalent to **eicosapentaenoic acid** 1.9 g and **docosahexaenoic acid** 1.5 g) daily for 6 weeks their blood pressure decreased by a further 3.3/1.9 mmHg.[2]

The mechanism is uncertain, but as fish oil seems to have a hypotensive effect of its own, it may enhance the hypotensive effect of any beta blocker. However, the effects are modest and so an adverse hypotensive response seems unlikely.

Beta blockers + Flecainide

The combined use of flecainide and beta blockers may have additive cardiac depressant effects. An isolated case of bradycardia and fatal AV block has been reported during the use of flecainide with sotalol, and bradycardia has been reported in a patient taking flecainide who was given timolol eye drops.

Clinical evidence, mechanism, importance and management

A study on cardiac function and drug clearance in 10 healthy subjects found that when **propranolol** 80 mg three times daily was given with flecainide 200 mg twice daily for 4 days the AUCs of both drugs were increased by 20 to 30%, and they had some additive negative inotropic effects.[1] A report describes a patient taking flecainide 100 mg twice daily who developed bradycardia and fatal atrioventricular conduction block 3 hours after taking a second dose of **sotalol** 40 mg.[2] Another report describes a patient with chronic atrial fibrillation that had been stable for 5 years during treatment with flecainide and verapamil. Within 3 days of starting **timolol** 0.1% eye drops twice daily, she developed bradycardia with a heart rate of 35 to 40 bpm. The eye drops were stopped and 16 hours after the last dose, her heart rate had increased to 90 to 100 bpm.[3] Careful monitoring has therefore been recommended if beta blockers are added to flecainide. Note that serious cardiac depression has been seen following the use of flecainide with other drugs that have negative inotropic effects such as 'verapamil', (p.294).

Beta blockers + Food

Food can increase, decrease or not affect the bioavailability of beta blockers.

Clinical evidence

Food increased the AUC of **propranolol** by 50 to 80%,[1-3] and increased the AUC of both **metoprolol**[1] and **labetalol**[4] by about 40%. In contrast, food did not affect the extent of absorption of a sustained-release formulation of **propranolol**,[2] and had very little effect on the absorption of **oxprenolol**[5,6] and **pindolol**.[7] In another study, food reduced the AUC of **atenolol** by about 20%.[8]

Mechanism

Food probably increases the bioavailability of propranolol, metoprolol and labetalol by changing the extent of their first pass metabolism through the liver.[2-4] It has been suggested that changes in propranolol disposition with a high protein meal may be partly due to a transient increase in hepatic blood flow[9-11] and rate of gastrointestinal absorption, which are subject to high intraindividual variation.[11] One study found that changes in hepatic blood flow, similar to those occurring with food consumption, had little effect on propranolol bioavailability.[12] A later study suggested that atenolol (and possibly other hydrophilic beta blockers, see 'Table 22.1', (p.995)) become tightly associated with bile acid micelles, preventing their absorption.[13]

Importance and management

None of the changes in beta blocker bioavailability associated with food have been shown to be of clinical importance, nor is it clear whether it matters if patients take these drugs in a regular pattern in relation to meals. Beta blocker serum levels vary widely between patients (a 20-fold difference in propranolol AUC has been noted),[1] and individualising the dose is therefore more of an issue than food intake.

Beta blockers + Grapefruit and other fruit juices

The bioavailability of celiprolol is markedly reduced by both grapefruit juice and orange juice, the bioavailability of atenolol is moderately reduced by orange juice, and the bioavailability of

talinolol is reduced by grapefruit juice. Acebutolol does not appear to interact with grapefruit juice to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Acebutolol

In a randomised, crossover study, 10 healthy subjects were given 200-mL of normal-strength grapefruit juice three times a day for 4 days (total of 11 drinks), with a single 400-mg dose of acebutolol on the morning of day 3. Grapefruit juice decreased the maximum plasma levels and AUC of acebutolol by a modest 19% and 6%, respectively. No significant changes in the heart rate or blood pressure were seen.[1]

(b) Atenolol

In a randomised, crossover study, 10 healthy subjects were given 200 mL of **orange juice** (from concentrate) three times daily with a single 50-mg dose of atenolol on the third day. **Orange juice** reduced the AUC and maximum plasma levels of atenolol by 40% and 49%, respectively, and also attenuated the atenolol-induced reduction in heart rate. However, the effect of atenolol on blood pressure was unchanged.[2] This suggests that orange juice could make atenolol less effective when it is used for rate control, but the clinical significance of this effect is unclear.

(c) Celiprolol

In a randomised, crossover study, 12 healthy subjects were given grapefruit juice 200 mL three times daily for 2 days. On the third day celiprolol 100 mg was given with the second of four 200 mL volumes of grapefruit juice, and on day 4 two further 200 mL volumes of grapefruit juice were given. The AUC and peak plasma levels of celiprolol were reduced by about 87% and 95%, respectively, and the half-life of celiprolol was slightly prolonged. However, grapefruit juice did not affect the changes in blood pressure or heart rate caused by celiprolol.[3] In a similar study in 10 healthy subjects, 200 mL of normal-strength **orange juice**, given two to four times daily for 4 days, with a single 100-mg dose of celiprolol on day 3. **Orange juice** reduced the AUC and peak plasma levels of celiprolol by 83% and 89%, respectively. The half-life of celiprolol was prolonged from 4.6 to 10.8 hours and the renal excretion of celiprolol was reduced by 77%. However, the effects of celiprolol on blood pressure or heart rate were not altered by the **orange juice**.[4]

The mechanism of this effect is not known, but suggestions include an effect on intraduodenal pH and the lipid solubility of celiprolol, or the formation of a complex between celiprolol and an ingredient of grapefruit or **orange juice** that interfered with celiprolol absorption. Alternatively, inhibition of uptake transporter proteins in the intestine may have reduced absorption.[3,4]

Although the clinical relevance of these effects has not been fully assessed, the studies suggest that the effects of celiprolol on blood pressure and heart rate are not affected. Nevertheless the marked reduction in celiprolol bioavailability in the presence of grapefruit or **orange juice** suggests this interaction may be of clinical significance in some patients.[3,4]

(d) Talinolol

Grapefruit juice 300 mL decreased the AUC of a single 50-mg dose of talinolol by 44%, decreased the maximum serum level by 42%, and increased the oral clearance by 62%. Similar results were seen after repeated administration of grapefruit juice over 6 days. However, the haemodynamic effects of talinolol were not altered.[5] Because P-glycoprotein levels did not appear to be affected by grapefruit juice, it was suggested that constituents in the juice might inhibit an uptake process other than P-glycoprotein. [Note that, in contrast, a study in *animals* found that the bioavailability of talinolol was increased by grapefruit juice.[6]] The decreases in talinolol levels are unlikely to be clinically relevant.

Beta blockers + H_2-receptor antagonists; Cimetidine

No clinically significant interaction appears to occur between the beta blockers and cimetidine, although the blood levels of some extensively metabolised beta blockers (e.g. metoprolol, propranolol) can be doubled. Isolated case reports describe bradycardia with atenolol, an irregular heart beat with metoprolol, and hypotension with labetalol, in patients also taking cimetidine.

Clinical evidence

(a) Acebutolol

A study *in animals* found that the pharmacokinetics of acebutolol were not affected by cimetidine, which suggests that a clinical interaction is unlikely.[1]

(b) Atenolol

A report briefly mentions a patient taking a beta blocker for angina who developed profound sinus bradycardia (36 bpm) and hypotension when cimetidine was also given.[2] The beta blocker was not specified, but it was identified as atenolol elsewhere.[3] Three well controlled studies in healthy subjects and patients found that cimetidine did not significantly alter the blood levels of atenolol, nor did it alter the effect of atenolol on heart rate.[4-9] Atenolol did not affect cimetidine pharmacokinetics.[6]

(c) Betaxolol

The plasma levels and pharmacokinetics of betaxolol were unaffected by cimetidine in one study.[10]

(d) Bisoprolol

A study in 6 healthy subjects found that the maximum plasma level, AUC and clearance of bisoprolol were not significantly affected by cimetidine,[11,12] although an analysis of the results by other authors suggested that cimetidine may cause a significant reduction in the renal clearance of bisoprolol.[13]

(e) Carvedilol

The plasma levels and pharmacokinetics of carvedilol were unaffected by cimetidine in one study.[14]

(f) Labetalol

The AUC and bioavailability of a single 200-mg oral dose of labetalol was increased by 66% and 56%, respectively, in 6 healthy subjects who took cimetidine 400 mg four times daily for 4 days.[15] One subject developed postural hypotension (70/40 mmHg), felt light-headed and almost fainted on standing.[15] Conversely, the AUC of intravenous labetalol was unaffected by cimetidine.[15]

(g) Metoprolol

A study in 6 healthy subjects given metoprolol 100 mg twice daily for a week found that cimetidine 1 g daily in divided doses increased the peak plasma levels of metoprolol by 70% and the AUC by 61%, but this did not increase the effect of metoprolol on the heart rate during exercise.[4-6] Metoprolol did not affect cimetidine pharmacokinetics.[6]

Three other studies confirmed that cimetidine increased metoprolol plasma levels after single or multiple doses, but none of the studies found that this interaction resulted in an increase in the effect of metoprolol on heart rate during exercise.[16-19] An isolated case describes one patient who complained of a "very irregular heart beat" while taking both drugs, which was much less marked when he took the two drugs separated by as much time as possible.[20] In contrast, two other studies found that cimetidine did not affect the plasma levels of a single 100-mg dose of metoprolol.[7,8]

(h) Nadolol

A review cites a study in which the plasma levels and pharmacokinetics of nadolol were not affected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were unchanged.[21]

(i) Nebivolol

In one study, cimetidine 400 mg twice daily increased the AUC and peak plasma levels of a single 5-mg dose of nebivolol by 48% and 23%, respectively, but did not alter the effect of nebivolol on blood pressure or heart rate.[22]

(j) Penbutolol

The plasma levels and pharmacokinetics of penbutolol[9,23] were not affected by cimetidine, and the effects of the beta blocker on heart rate and blood pressure were unchanged.[23]

(k) Pindolol

Cimetidine 1 g daily in divided doses increased the AUC and peak plasma levels of pindolol 10 mg twice daily by 30% and 33%, respectively, although these changes were not statistically significant.[9] In another study, cimetidine 400 mg twice daily increased the AUC of pindolol by about 40% and decreased its renal clearance by about 35%.[24]

(l) Propranolol

In a study, 12 healthy subjects were given cimetidine 300 mg four times daily for a week with propranolol 80 mg every 12 hours from day 3 onwards. The mean steady-state blood levels and the AUC of propranolol were raised by 47%, and the half-life was prolonged by 17%, but cimetidine did not alter the effect of propranolol on heart rate.[25] A number of other single-dose and steady-state studies confirm that cimetidine causes rises of 35 to 136% in the plasma levels, AUC and clearance of propranolol,[4-6,10,21,26-32] but this does not appear to increase the effect of the beta blocker on blood pressure,[21,27,29] or on heart rate, either at rest or during exercise.[4,21,27-29]

In contrast, one study found a further reduction in heart rate when cimetidine was given with propranolol.[33] In another study, the increase in the steady-state AUC of propranolol tended to be higher when cimetidine was given simultaneously with propranolol than when they were given separated by 10 hours (41% versus 26%), but the difference was not significant.[34] A letter describes one patient who had a three- to fourfold increase in the serum levels and AUC of a single 80-mg dose of propranolol after taking cimetidine 1 g daily for 6 weeks.[2]

In one study propranolol did not affect cimetidine pharmacokinetics.[6]

(m) Timolol

A double-blind study in 12 healthy subjects found that cimetidine 400 mg twice daily for 3 days did not modify the effect of a single drop of timolol 0.5%, put into each eye, on heart rate or intraocular pressure, to either a statistically or clinically relevant extent.[35]

Mechanism

The plasma levels of beta blockers extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP2D6 (e.g. metoprolol, nebivolol and propranolol) are increased because cimetidine reduces their metabolism by inhibiting the activity of the liver enzymes. However, this does not seem to be a complete explanation as cimetidine does not affect carvedilol, which is metabolised by CYP2D6, but does affect labetalol, which is not metabolised by CYP2D6.[15] Pindolol is partly excreted by an active renal tubular secretion mechanism, and cimetidine increases pindolol levels by inhibiting this mechanism.[24] Cimetidine may reduce the renal clearance of bisoprolol by a similar mechanism.[12] Therefore a renal mechanism may play a part. However, those beta blockers that are largely excreted unchanged in the urine (e.g. atenolol, nadolol) are not affected by cimetidine.[8,21]

Importance and management

These are well studied and established interactions, but despite the considerable rises in plasma levels that can occur when some beta blockers are given with cimetidine, the effects are not normally clinically important; cases describing clinically relevant effects (hypotension, bradycardia) appear rare. Normally the beta blockers are considered to have a wide therapeutic range, and so raises in levels are generally well tolerated. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, but even in this patient group the rise in levels seems unlikely to be generally important. However, it has been suggested that any patient with impaired liver function who are given cimetidine with beta blockers that are extensively metabolised in the liver (see 'Table 22.1', (p.995)) might possibly develop grossly elevated plasma levels, which could cause adverse effects. It would seem prudent to either monitor this type of patient (for effects such as hypotension, bradycardia, shortness of breath) or to use a non-interacting H_2-receptor antagonist, such as 'ranitidine', (p.1009).

Beta blockers + H2-receptor antagonists; Famotidine

Famotidine does not appear to interact with the beta blockers.

Clinical evidence, mechanism, importance and management

A survey of 15 patients taking beta blockers (**acebutolol**, **atenolol**, **betaxolol**, **nadolol**, **pindolol**, **propranolol** or **sotalol**) for 6 to 8 weeks found no evidence of changes in antihypertensive effects or bradycardia while they were taking famotidine 40 mg daily.[1] No interaction would be expected, and no special precautions would seem necessary if famotidine is taken with these or any other beta blocker.

Beta blockers + H_2-receptor antagonists; Nizatidine

An isolated report suggests that the reduction in heart rate caused by atenolol is increased by nizatidine.

Clinical evidence, mechanism, importance and management

After taking **atenolol** 100 mg daily for 7 days the mean resting heart rate of 12 healthy subjects fell from about 64 to 53 bpm three hours after dosing. A further fall of 6 bpm occurred when they were also given nizatidine 300 mg daily for 7 days. Nizatidine alone caused a fall in heart rate of about 8 bpm.[1]

However, up to the end of 2007, the manufacturers have had only 4 reports of bradycardia with nizatidine, by which time it had been used in more than 100 million patients, and the Adverse Drug Reactions On-line Information Tracking system (ADROIT) of the MHRA in the UK includes only one case of sinus bradycardia associated with nizatidine since its launch. Further, the manufacturers note there are no interaction reports of nizatidine with other drugs that have a bradycardic potential.[2] Therefore, a clinically significant interaction between beta blockers and nizatidine seems unlikely.

2. Flynn Pharma Ltd. Personal communication, February 2009.

Beta blockers + H_2-receptor antagonists; Ranitidine

Ranitidine does not alter either the steady-state plasma levels or the therapeutic effects of atenolol, nebivolol, propranolol or tertatolol. Some studies have shown moderate rises in metoprolol levels in those also given ranitidine.

Clinical evidence

In a study in 12 healthy subjects the plasma levels of **metoprolol** 100 mg twice daily were unaffected by ranitidine 300 mg daily for 7 days.[1] Two other studies also suggest that ranitidine did not significantly affect the plasma levels of **metoprolol**,[2-5] although these studies did find increases of up to 38% in the AUC of single intravenous or oral doses of **metoprolol**.[2-5] Another study found that ranitidine increased the AUC and plasma levels of **metoprolol** 100 mg twice daily by 55% and 34%, respectively.[6-8] All of these studies found that ranitidine did not alter the effect of **metoprolol** on heart rate during exercise.[1,2,5,6]

In a study in 5 healthy subjects, ranitidine 300 mg daily for 6 days did not affect the steady-state plasma levels of **propranolol** 160 mg daily nor did it alter the effect of **propranolol** on heart rate or blood pressure.[9] Similarly no changes in plasma **propranolol** levels were seen in other multiple-dose[10] or single-dose studies.[11-14]

In other studies, ranitidine 150 mg twice daily did not significantly alter the pharmacokinetic or pharmacodynamic effects of a single 5-mg dose of **nebivolol**,[15] a single 5-mg dose of **tertatolol**,[16] or **atenolol** 100 mg daily for 7 days.[6,8]

Mechanism

The rises in metoprolol serum levels caused by ranitidine in the two single-dose metoprolol studies are not understood, nor is it clear why one of four studies found an increase after multiple doses.

Importance and management

The possible effects of ranitidine on the plasma levels and effects of propranolol and metoprolol have been well studied. Although some studies have shown moderate rises in metoprolol levels, particularly after single-doses, the majority of the data from multiple-dose studies suggest that an interaction does not generally occur.

Less is known about atenolol, nebivolol and tertatolol, although no clinically relevant interactions have been seen. There is nothing to suggest that the concurrent use of ranitidine and any beta blocker should be avoided.

Beta blockers + Haloperidol

Carteolol may increase serum haloperidol levels. An isolated case report describes severe hypotension and cardiopulmonary arrest in a woman shortly after she was given haloperidol and propranolol. Plasma levels of haloperidol in three patients were not significantly changed by propranolol. The concurrent use of sotalol and haloperidol should generally be avoided because of the possible increased risk of QT prolongation.

Clinical evidence, mechanism, importance and management

(a) Carteolol

In a single-dose study in 8 healthy subjects, oral carteolol 10 mg increased the peak plasma level and AUC of haloperidol by about 25% and 40%, respectively and decreased its clearance by 33%, possibly by altering hepatic blood flow. The pharmacokinetics of carteolol were unaffected by haloperidol. Two patients experienced sleepiness with concurrent use, but this was mild and resolved within 24 hours.[1] These increases in haloperidol levels are modest, and therefore no particular precautions seem necessary if carteolol is also given.

(b) Propranolol

A middle-aged woman with schizophrenia and hypertension experienced three episodes of severe hypotension within 30 to 120 minutes of being given propranolol 40 to 80 mg and haloperidol 10 mg.[2] On two of the occasions she had a cardiopulmonary arrest. She fainted each time, became cyanotic, had no palpable pulses and had severe hypotension, but rapidly responded to cardiopulmonary resuscitation. She suffered no adverse consequences.[2] The reasons for the severe hypotension are not understood, although both drugs alone can cause hypotension.

A study found that the steady-state plasma levels of haloperidol 6 to 15 mg daily were not significantly changed in 3 patients by long-acting propranolol (given in incremental doses up to 480 mg daily).[3]

There seems to be only one case of an interaction between haloperidol and propranolol on record. Bearing in mind the widespread use of these drugs, this interaction would appear to be rare. There would seem to be little reason for avoiding concurrent use.

(c) Sotalol

Both haloperidol and sotalol can prolong the QT interval and should therefore not generally be used together, see ‘Drugs that prolong the QT interval + Other drugs that prolong the QT interval’, p.290.

Beta blockers + Hormonal contraceptives

The plasma levels of metoprolol are increased in women taking combined hormonal contraceptives, but the clinical importance of this is probably very small. Acebutolol, oxprenolol and propranolol pharmacokinetics are minimally affected by hormonal contraceptive use.

Clinical evidence

The peak plasma levels and the AUC of a single 100-mg dose of **metoprolol** were 36% and 70% higher, respectively, in 12 women taking low-dose combined oral contraceptives, when compared with a similar group not taking contraceptives. The elimination half-life of **metoprolol** was unaffected.[1] In a further study by the same research group, the AUC of **metoprolol** was 71% higher, the AUC of **oxprenolol** was 26% higher, the AUC of **propranolol** was 42% higher, and the AUC of **acebutolol** was marginally lower in women taking combined hormonal contraceptives, when compared with those not taking contraceptives. However only the **metoprolol** difference was statistically significant.[2] In another study in 8 women, the total clearance of a single 80-mg dose of **propranolol** was increased (although not significantly) by **ethinylestradiol** 50 micrograms daily, and an even smaller increase was seen when they were taking a combined hormonal contraceptive containing **ethinylestradiol** and **norethisterone**.[3]

Mechanism

The reason for the changes appears to be that ethinylestradiol alters the metabolism of these beta blockers. In the case of propranolol its conjugation and oxidation are increased by the ethinylestradiol.[3]

Importance and management

The increases in plasma levels of propranolol, oxprenolol and acebutolol are almost certainly too small to matter, but with metoprolol the changes are somewhat larger. Even so, changes of this size caused by the interactions of other drugs with beta blockers are not usually clinically relevant. No special precautions are generally necessary if any of these beta blockers are given to women taking combined oral contraceptives containing ethinylestradiol, (or those taking ethinylestradiol alone for other indications). Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, but even in this patient group the rise in levels seems unlikely to be generally important. There appears to be no information about other beta blockers, but all those metabolised by CYP2D6 would be expected to be affected to some extent. See 'Table 22.1', (p.995), for a list.

If beta blockers are being used to treat hypertension, it is of note that combined hormonal contraceptives may cause increases in blood pressure (but consider also 'Antihypertensives + Hormonal contraceptives or HRT', p.1050). Stopping combined hormonal contraceptives has been suggested as an effective antihypertensive intervention in women with hypertension.[4] Also be aware that some of the indications for beta blockers, including hypertension and migraine are cautions for, or preclude the use of, combined hormonal contraceptives.

Beta blockers + Hydralazine

The plasma levels of propranolol and other extensively metabolised beta blockers (such as metoprolol and oxprenolol) are increased by hydralazine, but no increase in adverse effects appears to have been reported.

Clinical evidence

In a study in 5 healthy subjects, single 25- and 50-mg doses of hydralazine increased the AUC of a single 40-mg dose of **propranolol** by 60% and 110%, respectively, and raised the peak plasma levels by 144 and 240%, respectively,[1] Similarly, in another single-dose study, hydralazine increased the AUC of **propranolol** by 62 to 77%.[2] However, a further single-dose study using sustained-release **propranolol** found that hydralazine had no effect on **propranolol** pharmacokinetics.[3]

In other studies hydralazine increased the AUC of sustained-release **oxprenolol** by 41% at steady-state;[4] whereas **oxprenolol** was found not to have a significant effect on the pharmacokinetics of hydralazine.[4]

Further studies have found that hydralazine increases the AUC of **metoprolol** by 30% after a single dose,[5] and by 38% at steady-state,[6] whereas hydralazine did not affect the AUC of **acebutolol** or **nadolol** in single-dose studies.[5]

Mechanism

Uncertain. Hydralazine appears to increase the bioavailability of those beta blockers that undergo high hepatic extraction and not those that are largely excreted unchanged in the urine. Hepatic extraction is discussed in more detail under 'Changes in first-pass metabolism', (p.4), and 'Table 22.1', (p.995), lists the metabolic routes of the commonly used systemic beta blockers. It has been suggested that hydralazine may alter hepatic blood flow or inhibit hepatic enzymes,[1,5,6] although other mechanisms may also be involved.[3,7,8]

Importance and management

Moderately well documented and established interactions, but the increased beta blocker plasma levels appear to cause no adverse clinical effect. Concurrent use is usually valuable in the treatment of hypertension, and it has been suggested that the addition of beta blockers may provide additional benefit in patients taking hydralazine and isosorbide dinitrate for heart failure.[9]

Beta blockers + Imatinib

The plasma levels of metoprolol are slightly increased by imatinib.

Clinical evidence

In a pharmacokinetic study in 20 Chinese patients, a single 100-mg dose of **metoprolol** was given alone and then on day 7 of a 9-day course of imatinib 400 mg twice daily. The AUC and maximum plasma levels of **metoprolol** were increased by about 20%, with an increase in AUC of 24% in 13 patients that were CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme) and by 17% in 7 patients that were said to be CYP2D6 intermediate metabolisers (those with lower levels of this isoenzyme). There were no clinically significant changes in laboratory parameters, vital signs or ECG recordings.[1]

Mechanism

The manufacturer notes that *in vitro*, imatinib inhibits the cytochrome P450 isoenzyme CYP2D6,[2] by which metoprolol is extensively metabolised. The study shows that clinically imatinib is only a weak CYP2D6 inhibitor.

Importance and management

The increase in metoprolol levels seen here is not clinically important, and no interaction would be expected. Nevertheless, the manufacturer of imatinib recommends that clinical monitoring should be considered in patients taking metoprolol when given imatinib, because they consider metoprolol to be a drug with a narrow therapeutic index.[2] However, metoprolol is only usually classified as such in patients with heart failure, and even then, increases of this magnitude are not considered clinically relevant. Therefore this advice seems over cautious. There appears to be no information about other beta blockers, but all those metabolised by CYP2D6 would be expected to be affected by imatinib to some extent. See 'Table 22.1', (p.995), for a list.

In addition, on the basis of this study, the manufacturer says that dose adjustments are not likely to be necessary when imatinib is given with any CYP2D6 substrates. However, they do recommend caution with those that have a narrow therapeutic index,[2] although this seems over cautious.

Beta blockers + Inotropes and Vasopressors

Effects on blood pressure and heart rate: the hypertensive effects of adrenaline (epinephrine) can be markedly increased in patients taking non-selective beta blockers such as propranolol. A severe and potentially life-threatening hypertensive reaction and/or marked bradycardia can develop. Cardioselective beta blockers such as atenolol and metoprolol interact minimally. Dobutamine would be expected to interact similarly, but some studies and case reports suggest that paradoxical effects may occur. The pressor effects of noradrenaline appear to be diminished by the beta blockers. An isolated report describes a fatal hypertensive reaction in a patient given propranolol and phenylephrine, but concurrent use normally seems to be uneventful.
Anaphylaxis: some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine).

Clinical evidence

A. Effects on blood pressure and heart rate

(a) Adrenaline (Epinephrine)

1. Non-selective beta blockers. An early study in 10 healthy subjects found that intravenous adrenaline (epinephrine) 5 micrograms/minute increased heart rates and caused minimal changes in blood pressure. However, after pretreatment with intravenous **propranolol** 10 mg, the same dose of adrenaline caused a *fall* in heart rate of 12 bpm and an increase in arterial pressure of 20/10 mmHg.[1] One case report describes 6 patients taking **propranolol** 20 to 80 mg daily, undergoing plastic surgery, who experienced marked hypertensive reactions (blood pressures in the range of 190/110 to 260/150 mmHg) and bradycardia when their eyelids and/or faces were infiltrated with 8 to 40 mL of local anaesthetic solutions of lidocaine containing 1:100 000 or 1:200 000 (10 or 5 micrograms/mL) of adrenaline. Cardiac arrest occurred in one patient.[2]
Similar marked increases in blood pressure, associated with marked bradycardia, have been described in other studies and case reports involving the use of adrenaline and **propranolol**.[3-11]
After pretreatment with a single 5-mg dose of **pindolol**, only small reductions in blood pressure (4 mmHg) and heart rate (about 5 bpm) were seen with the intra-oral injection of 3.6 mL of lidocaine 2% containing 1:80 000 adrenaline (45 micrograms of adrenaline) in healthy subjects.[12]
In 24 healthy subjects given either **nadolol**, atenolol or placebo for 1 week followed by an infusion of adrenaline, mean arterial pressure and calf vascular resistance rose markedly in the **nadolol**-treated group. Marked bradycardia also occurred in those given **nadolol** and adrenaline.[13]

2. Selective beta blockers. A study in which adrenaline (epinephrine) was given to patients taking **metoprolol**, found only a small rise in blood pressure.[4] This was confirmed in another study in which patients given identical infusions of adrenaline developed a hypertensive/bradycardic reaction while taking propranolol but not while taking **metoprolol**.[5] In 24 healthy subjects given either nadolol, **atenolol** or placebo for 1 week followed by an infusion of adrenaline, mean arterial pressure and calf vascular resistance was not affected in the **atenolol** group.[13]

3. Beta blockers with alpha-blocking activity. In 6 healthy subjects, giving adrenaline after intravenous **labetalol** 1 mg/kg, resulted in a 13 to 21 mmHg increase in mean arterial pressure and a 23 to 29 bpm reduction in heart rate, when compared with adrenaline alone.[14]

(b) Dobutamine

A 54-year-old man with severe heart failure was given **carvedilol** 3.125 to 6.25 mg twice daily. His symptoms worsened and he was admitted for treatment with intravenous dobutamine; the **carvedilol** was discontinued and other medications apart from furosemide were withheld short-term. Dobutamine was started at 1 microgram/kg per minute and gradually increased to 5 micrograms/kg per minute. However, with each 1 microgram/kg increment the systolic blood pressure *dropped* to about 70 mmHg for 5 to 10 minutes and then quickly returned to the baseline level of 80 to 84 mmHg. When the dose of dobutamine reached 5 micrograms/kg per minute, his systolic blood pressure dropped to 56 mmHg and the dobutamine was discontinued. The blood pressure returned to normal over the next 30 minutes. Two months later when the patient was no longer taking **carvedilol** he was again given intravenous dobutamine and his systolic blood pressure increased, as would be expected.[15]

(c) Isoprenaline (Isoproterenol)

In a study in patients with asthma, oral doses of the non-selective beta blockers **propranolol** 100 mg, **oxprenolol** 100 mg, **pindolol** 5 mg and **timolol** 10 mg blocked the bronchodilator response to inhaled isoprenaline 1.5 mg, but the selective beta blockers **metoprolol** 100 mg, **acebutolol** 300 mg and **atenolol** 100 mg did not interfere with bronchodilatation.[16]
In a placebo-controlled study in healthy subjects, isoprenaline 0.03 micrograms/kg per minute was infused over 5 minutes, 30 minutes before single oral doses of either **metoprolol** 40 mg or 80 mg or **propranolol** 40 mg were given. Isoprenaline 0.09 micrograms/kg per minute [for 5 minutes] was then given at intervals of 30 minutes starting 60 minutes after administration of the beta blocker. Isoprenaline increased heart rate by a mean of 32 bpm. Although the dose of isoprenaline was increased threefold after administration of the beta blockers, the effect of isoprenaline after **propranolol** was very small and consistently more reduced by **propranolol** than by **metoprolol**.[17] Another study in patients with hypertension found that the blood pressure and cardiac responses to isoprenaline were attenuated or inhibited by both intravenous **propranolol** and **pindolol**.[18] In a study in 6 healthy subjects, intravenous **labetalol** 1.5 mg/kg antagonised the increases in heart rate and diastolic pressure due to isoprenaline.[19] A further study in 12 healthy subjects found that a single 40-mg dose of **nadolol** attenuated isoprenaline-evoked venodilatation in the dorsal hand vein; **bisoprolol** 5 mg had no effect on the response to isoprenaline.[20]

(d) Noradrenaline (Norepinephrine)

A study in patients with hypertension found that the initial increase in heart rate due to noradrenaline was attenuated by intravenous **propranolol** 670 micrograms/kg and abolished by intravenous **pindolol** 35 micrograms/kg and the fall in systolic pressure was abolished by beta blockade. After the initial response, noradrenaline produced a fall in heart rate and rise in systolic pressure which was not affected by **propranolol** but virtually abolished by **pindolol**.[18] In another study in healthy subjects, the increase in blood pressure due to noradrenaline was antagonised by intravenous **labetalol** 1.5 mg/kg.[19] In studies in 12 healthy subjects, single doses of **bisoprolol** 5 mg or 10 mg were found to decrease the venoconstriction in the dorsal hand vein associated with infusion of noradrenaline; **nadolol** 40 mg had no effect on the response to noradrenaline.[21,22]

(e) Phenylephrine

A woman taking **propranolol** 40 mg four times daily for hypertension was given phenylephrine hydrochloride 10% solution, one drop in each eye, during an ophthalmic examination. About 45 minutes later she complained of a sudden and sharp bi-temporal pain and shortly afterwards became unconscious. She later died of an intracerebral haemorrhage due to the rupture of a berry aneurysm. She had received a similar dose of phenylephrine on a previous occasion in the absence of **propranolol** without any problems.[23]

However, no change in blood pressure was seen in a study in both normotensive subjects and patients taking **metoprolol** who were given 0.5 to 4-mg intranasal doses of phenylephrine every hour, to a total of 7.5 to 15 mg (4 to 30 times the usual dose).[24] Similarly, in a placebo-controlled study in 12 hypertensive patients, **propranolol** and **metoprolol** did not significantly alter the dose of intravenous phenylephrine required to cause a 25 mmHg increase in systolic blood pressure.[25] In a study in 12 healthy subjects, single doses of **bisoprolol** 5 mg or 10 mg were found to decrease the venoconstriction in the dorsal hand vein associated with infusion of phenylephrine.[21]

B. Anaphylaxis: resistance to treatment

A patient taking **propranolol** who suffered an anaphylactic reaction after receiving an allergy injection for desensitisation did not respond to adrenaline (epinephrine) and required intubation.[26] Anaphylactic shock, refractory to adrenaline, occurred in a penicillin-allergic patient taking **acebutolol** after she accidentally took amoxicillin.[27] Resistance to adrenaline treatment for anaphylaxis occurred in another patient using **timolol** eye drops.[28] It has also been proposed that the incidence and severity of anaphylactic reactions may be increased in those taking beta blockers,[29,30] one idea being that the adrenoceptors concerned with suppressing the release of the mediators of anaphylaxis may be blocked by either $beta_1$ or $beta_2$ antagonists.[29] However, one study failed to find any evidence to support an increased incidence of systemic reactions in patients taking beta blockers receiving allergen immunotherapy.[31] See also 'X-ray contrast media', (p.1021), and 'penicillins', (p.1014), for other anaphylactic reactions potentially exacerbated by beta blockers.

A beta-agonist bronchodilator, for example isoprenaline (isoproterenol) or salbutamol (albuterol) may be effective in patients taking beta blockers with anaphylaxis resistant to adrenaline,[29] and glucagon was effective in treating a severe anaphylactoid reaction in one patient taking a beta blocker.[30] Severe hypertension, sometimes with bradycardia, has been described following the use of adrenaline to treat allergic reactions, including presumed anaphylaxis, in patients taking **propranolol**.[6-8] These are discussed under *Effects on blood pressure and heart rate,* above.

Mechanism

Adrenaline (**epinephrine**) stimulates alpha- and beta-receptors of the cardiovascular system, the former results in vasoconstriction (mainly $alpha_1$) and the latter in both vasodilatation (mainly $beta_2$), and stimulation of the heart (mainly $beta_1$). The net result is usually a modest increase in heart rate and a small rise in blood pressure. However, if the beta-receptors are blocked by a non-selective beta blocker, such as propranolol or nadolol (see 'Table 22.1', (p.995) for a list), the unopposed alpha vasoconstriction causes a marked rise in blood pressure, followed by reflex bradycardia. Cardioselective beta blockers such as atenolol and metoprolol, which are more selective for $beta_1$ receptors, do not prevent the vasodilator action of adrenaline at $beta_2$ receptors to the same extent, and therefore the effect of any interaction is relatively small. Consequently, adrenaline has been used to assess the degree of beta blockade produced by propranolol and other beta blockers.[13,32]

Noradrenaline (**norepinephrine**) stimulates alpha receptors (although to a lesser extent than adrenaline) and $beta_1$ receptors but has minimal effects on $beta_2$ receptors. The precise mechanism for the effects of the beta blockers on the pressor effects of noradrenaline are unclear, but as beta blockers lower blood pressure and noradrenaline raises blood pressure a reduction in the response to noradrenaline is not unexpected.

Isoprenaline (**isoproterenol**) acts almost exclusively on beta-receptors and the increase in heart rate is due to stimulation of the heart ($beta_1$), increase in sympathetic nerve activity secondary to peripheral vasodilatation ($beta_2$), and direct effect on the heart ($beta_2$). Nadolol, pindolol and propranolol exert their effects by blockade at both $beta_1$ and $beta_2$ receptors while bisoprolol and metoprolol, which are selective for $beta_1$ receptors, exert less effect on the isoprenaline-induced effects on heart rate or venodilatation. Labetalol is also a non-selective beta blocker (and alpha blocker) and also antagonises the effects of isoprenaline.

Phenylephrine is largely an alpha stimulator, therefore beta blockers should have a minimal effect on its action.

Dobutamine is a $beta_1$, $beta_2$ and $alpha_1$ adrenergic agonist and carvedilol is a non-selective beta blocker, but at low doses it is primarily a selective $beta_1$ adrenergic antagonist and it is also an $alpha_1$ antagonist. It was proposed that the drop in blood pressure was caused by vasodilation due to vascular $beta_2$ receptor activation, which was not blocked by low doses of carvedilol.[15]

Importance and management

The interaction between propranolol and **adrenaline** (**epinephrine**) is established. It may be serious and potentially life-threatening, depending on the dosage of adrenaline used. Marked and serious blood pressure rises and severe bradycardia have occurred in patients given 300 micrograms of adrenaline (0.3 mL of 1:1000) subcutaneously[6-8] or 40 to 400 micrograms by infiltration of the skin and eyelids during plastic surgery.[2] Adrenaline 15 micrograms given intravenously can cause an almost 40% fall in heart rate.[9] Patients taking non-selective beta blockers such as propranolol (see 'Table 22.1', (p.995) for a list) should only be given adrenaline in very reduced dosages because of the marked bradycardia and hypertension that can occur. Acute hypertensive episodes have been controlled with chlorpromazine or phentolamine (both of which are alpha blockers). Hydralazine,[2,10] nifedipine[7] and aminophylline[10] have also been used. Reflex bradycardia may be managed with atropine and the pre-emptive use of glycopyrrolate has also been suggested.[10] A less marked effect is likely with the cardioselective beta blockers,[4] such as atenolol and metoprolol (see 'Table 22.1', (p.995) for a list). Local anaesthetics used in dental surgery usually contain very low concentrations of adrenaline (e.g. 5 to 20 micrograms/mL, i.e. 1:200 000 to 1:50 000) and only small volumes are usually given, so that an undesirable interaction is unlikely.

Similar effects to those seen with adrenaline (hypotension and reflex bradycardia) are also theoretically possible if **dobutamine**, which also causes alpha- and beta-receptor stimulation, is given with a beta blocker (see adrenaline under *Mechanism*, above), but the case report describing *hypotension* suggests that the effects may not always be predictable.

In general, the beta blockers appear to attenuate the rise in blood pressure caused by **noradrenaline** (**norepinephrine**); beta blockers are often omitted in patients requiring inotropic support with noradrenaline for this reason. Some sources suggest that noradrenaline will interact with beta blockers in the same way as adrenaline, but there does not seem to be any evidence supporting this prediction. Furthermore, it should be noted that the beta effects of noradrenaline are not the same as those of adrenaline (see *Mechanism*, above).

No interaction between **phenylephrine** and the beta blockers would be expected, and apart from the single unexplained case cited above, the literature appears to support this. Concurrent use normally appears to be clinically unimportant, particularly bearing in mind the widespread use of beta blockers and the ready availability of phenylephrine in the form of non-prescription cough-and-cold remedies and nasal decongestants.

Similarly, an interaction resulting in hypertension and reflex bradycardia would not be expected if **isoprenaline** (**isoproterenol**) is given with a beta blocker, and the studies support this theory. However, the studies do suggest that the bronchodilator effects of isoprenaline may be antagonised by non-selective beta blockers.

Beta blockers + Itraconazole

Itraconazole markedly increases the bioavailability of celiprolol and only slightly affects the pharmacokinetics of atenolol, without affecting heart rate or blood pressure.

Clinical evidence, mechanism, importance and management

(a) Atenolol

In a study in 10 healthy subjects itraconazole 200 mg twice daily for 5 doses had only minor effects on the pharmacokinetics of a single 50-mg dose of atenolol and no effects on heart rate or blood pressure were seen.[1]

(b) Celiprolol

In a study in 12 healthy subjects, itraconazole 200 mg twice daily for 5 doses increased the AUC of a single 100-mg dose of celiprolol by 80%, without increasing its half-life. However, itraconazole did not increase the effect of celiprolol on heart rate or blood pressure.[2]

It was suggested that itraconazole probably increases the absorption of celiprolol by inhibiting P-glycoprotein in the intestinal wall.[2] Although the increase in plasma levels was marked, it was suggested that it is unlikely to be clinically relevant because celiprolol has a wide therapeutic range.[2]

Beta blockers + Macrolides

The serum levels of talinolol and possibly nadolol are increased by erythromycin, and telithromycin may increase the bioavailability of metoprolol. A study suggests that telithromycin does not adversely affect sotalol-induced QT prolongation, whereas the combined use of sotalol and intravenous erythromycin should generally be avoided because of the possible additive effects on QT interval prolongation.

Clinical evidence, mechanism, importance and management

(a) Metoprolol

The peak plasma level and AUC of metoprolol are reported to be increased by about 38% by **telithromycin**, but the elimination half-life is not affected. The manufacturer of **telithromycin** considers the increased exposure to metoprolol may be of clinical importance in patients with heart failure, and that in such patients, caution is suggested.[1] However, other interactions suggest that the levels of metoprolol may need to be almost doubled before this interaction becomes clinically relevant, even in patients with heart failure.

(b) Nadolol

A study, in which 7 healthy subjects were given a single 80-mg dose of nadolol after **erythromycin** 500 mg plus neomycin 500 mg every 6 hours for 2 days, suggested an increase in the rate of beta blocker absorption (reduced time to maximum plasma level, but no effect on AUC). A decrease in the elimination half-life was also seen.[2] More study is needed to determine the clinical significance of these findings, but any effect seems likely to be small.

(c) Sotalol

Sotalol prolongs the QT interval and should generally not be given with other drugs that do the same, such as intravenous **erythromycin**, because of the increased risk of torsade de pointes arrhythmia (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290). **Telithromycin** does not appear to be associated with QT prolongation and a study in 24 healthy women found that a single 800-mg dose of **telithromycin** had no adverse effect on the QT-prolongation induced by a 160-mg dose of sotalol. **Telithromycin** slightly reduced the AUC and maximum serum levels of sotalol, which was attributed to a decrease in its absorption,[3] but this is expected to be of little clinical significance.

(d) Talinolol

A single-dose study in 8 healthy subjects found that the AUC and serum levels of talinolol 50 mg were increased by 51% and 26%, respectively, by **erythromycin** 2 g. It was suggested that the increased bioavailability of talinolol was due to increased intestinal absorption caused by the inhibition of P-glycoprotein by **erythromycin**.[4]

The clinical relevance of these effects is unclear, but until more is known it may be prudent to monitor the outcome of concurrent use to ensure the beta blocker effects are not excessive.

Beta blockers + Metoclopramide

A patient with scleroderma suffered a fatal cardiac arrest after receiving intravenous labetalol and intravenous metoclopramide postoperatively. Metoclopramide increased the rate of absorption of a conventional formulation of propranolol, but did not affect a sustained-release preparation.

Clinical evidence, mechanism, importance and management

(a) Labetalol

A 38-year-old patient with scleroderma, hypertension (for which she was taking lisinopril) and gangrene of her left index finger underwent minor hand surgery. While in postoperative care her blood pressure rose to 153/120 mmHg and she was given intravenous labetalol 10 mg. About 15 minutes later she experienced nausea and vomiting, and so she was given intravenous metoclopramide 10 mg. About 5 minutes later her heart rate decreased to 38 bpm and she became unresponsive with no palpable

pulse: an ECG showed junctional bradycardia. She was initially resuscitated but died about 13 hours later after a further episode of bradycardia, despite full supportive treatment. It was noted that the bradycardia did not respond well to atropine, and there was persistent hypotension, despite escalating vasopressor use.

Scleroderma and lisinopril may have contributed to the failure to resuscitate the patient; however, bradycardia or heart block and hypotension may occur with intravenous metoclopramide. In this patient the use of labetalol may have exacerbated the effects of metoclopramide by causing reductions in ventricular contractility due to its beta-adrenergic effects and limiting vasoconstrictive compensatory mechanisms due to alpha-adrenergic effects.[1] However, it has subsequently been suggested that this reaction may have been due to local anaesthetic toxicity rather than a drug interaction,[2] although this was disputed by the original authors.[3]

A study in 11 untreated hypertensive patients found that intravenous metoclopramide (7.5 micrograms/kg per minute for 30 minutes) caused a slight decrease in the responsiveness to labetalol 400 to 600 mg daily. However, as metoclopramide only attenuated the systolic blood pressure response to labetalol by 3 mmHg this effect seems unlikely to be clinically significant in most patients.[4]

(b) Propranolol

In a study in 12 healthy subjects metoclopramide syrup 20 mg, given 30 minutes before sustained-release propranolol 160 mg, had no effect on the pharmacokinetics of propranolol.[5] In contrast, an earlier brief report found that the rate of absorption of a conventional formulation of propranolol 80 mg was increased by intravenous metoclopramide 10 mg in 4 healthy subjects. In the first 2 hours after dosing, propranolol levels were increased by 1.3 to 2.5-fold.[6] However, these changes are unlikely to be clinically relevant.

Beta blockers + Morphine

Morphine may moderately raise the serum levels of esmolol in some patients. The fatal doses of morphine and propranolol are markedly reduced by concurrent use in *animals*, but the clinical relevance of this in man is uncertain.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy men a 3-mg injection of morphine sulfate increased the steady-state levels of a 300 microgram/kg per minute infusion of **esmolol**, given over 4 hours. However, the increases were only statistically significant in 2 of the subjects (increase of 46%), and were considered to be of no clinical importance. The pharmacokinetics of morphine were unchanged.[1]

Studies in *animals* have shown that the median fatal dose of **propranolol** was reduced two- to sevenfold by morphine in *mice*[2] and the median lethal dose of morphine was reduced fifteen- to sixteenfold by **propranolol** in *rats*.[3] The same interaction has also been seen in *dogs*.[3] There do not appear to be any published reports of synergistic toxicity involving morphine and **propranolol**, so the clinical relevance of this is uncertain.

Beta blockers + Penicillins

Plasma atenolol levels are halved by 1-g doses of ampicillin, but no important interaction occurs if atenolol is given with ampicillin 250 mg every 6 hours. One brief report suggests that anaphylactic reactions to penicillins may be more severe in patients taking beta blockers.

Clinical evidence

In a single-dose study in 6 healthy subjects, **ampicillin** 1 g reduced the AUC of **atenolol** 100 mg by 40%, and decreased its bioavailability from 60% to 36%.[1] Similarly, when **atenolol** 100 mg was given with **ampicillin** 1 g daily for 6 days, the mean steady-state plasma atenolol level was reduced by 52% (from 199 to 95 nanograms/mL), and the AUC was reduced by 52%. The blood pressure lowering effect of **atenolol** at rest was not affected, but after exercise a small rise in systolic pressure of up to 17 mmHg occurred, whereas diastolic pressure was unchanged. The effects of **atenolol** on reducing heart rate during exercise were diminished from 24% to 11% at 12 hours.[1]

A further single-dose study found that when **atenolol** 50 mg was given with oral **ampicillin** 1 g the AUC of **atenolol** was reduced by 52%, whereas when **ampicillin** 250 mg four times daily was given for 24 hours, the AUC was only reduced by 18%.[2]

A brief report describes 2 patients, one taking **nadolol** and one taking **propranolol**, who developed fatal anaphylactic shock after taking **phenoxymethylpenicillin**. The authors suggested that, as fatal reactions to penicillins are rare, the reaction had been exacerbated by the presence of a non-selective beta blocker.[3] For a report of anaphylaxis associated with **amoxicillin**, refractory to adrenaline treatment, in a patient taking **acebutolol**, see 'Beta blockers + Inotropes and Vasopressors', p.1011.

Mechanism

Uncertain. Ampicillin, in large doses, apparently affects the absorption of atenolol.

Importance and management

Information about interactions between penicillins and beta blockers is limited, but the absorption interaction between 1 g dose of ampicillin and atenolol appears to be established. The clinical importance awaits full evaluation but the modest effects on blood pressure and heart rate[1] suggest that it is of limited importance. Information about other beta blockers and penicillins is lacking. Information on potentiation of anaphylaxis is too limited to make comment, but note that some evidence suggests that anaphylactic shock in patients taking beta blockers may be resistant to treatment with adrenaline (epinephrine), see 'Beta blockers + Inotropes and Vasopressors', p.1011.

Beta blockers + Phenothiazines

The concurrent use of chlorpromazine with propranolol can result in a marked rise in the plasma levels of both drugs. A similar interaction appears to occur between thioridazine and pindolol. Propranolol markedly increases plasma thioridazine levels. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive: a handful of case reports suggest that this could occasionally be serious. The concurrent use of sotalol and phenothiazines that prolong the QT interval should generally be avoided.

Clinical evidence

(a) Chlorpromazine

In 4 healthy subjects and one hypertensive patient the mean steady-state levels of **propranolol** 80 mg every 8 hours were raised by 70% (from 41.5 nanograms/mL to 70.2 nanograms/mL) when they were given chlorpromazine 50 mg every 8 hours.[1] The increase was considerable in some subjects but barely detectable in others. A sixth subject taking **propranolol** promptly fainted when getting out of bed after the first dose of chlorpromazine. He was found to have a pulse rate of 35 to 40 bpm and a

blood pressure of 70/0 mmHg. He rapidly recovered, achieving a pulse rate of 85 bpm and a blood pressure of 120/70 mmHg when given atropine 3 mg. However, it is unclear whether the adverse effect was due to chlorpromazine alone, or to an interaction with **propranolol**.[1]

Propranolol (mean daily dose 8.1 mg/kg) increased the serum chlorpromazine levels of 7 schizophrenics by about 100 to 500%, and raised the plasma levels of the active metabolites of chlorpromazine by about 50 to 100%.[2] The same or similar work by the same authors is described elsewhere.[3] One of the patients was withdrawn from the study because he suffered a cardiovascular collapse while taking both drugs.[3] It has been suggested that the value of **propranolol** in the treatment of schizophrenia probably results from the rise in serum chlorpromazine levels.[3]

A report briefly mentions a diabetic girl who had an episode of minor hypotension with chlorpromazine that appeared to have been exacerbated by **sotalol**.[4] A schizophrenic patient taking chlorpromazine and **tiotixene** experienced delirium, grand mal seizures and skin photosensitivity, attributed to a rise in the serum levels of the antipsychotic drugs caused by increasing doses of **propranolol** (up to a total of 1.2 g daily).[5]

(b) Thioridazine

Serum **pindolol** levels were 2.5-fold higher in 7 patients taking thioridazine than in 17 patients taking haloperidol, phenytoin, and/or phenobarbital.[6] Furthermore, **pindolol** 40 mg daily increased serum thioridazine levels by about 50% in 8 patients.[6]

Two patients, who were stable taking thioridazine 600 or 800 mg daily, had three- and fivefold rises in plasma levels, respectively, when given **propranolol**, in increasing doses up to a total of 800 mg daily, over 26 to 40 days. No signs or symptoms of thioridazine toxicity were seen even though plasma levels had risen into the toxic range.[7] Similarly, in another study thioridazine levels rose by about 55 to 370% in 5 patients taking **propranolol** 320 to 520 mg daily.[8]

Mechanism

Pharmacokinetic evidence[1] and *animal* studies[9] suggest that propranolol and chlorpromazine mutually inhibit the liver metabolism of the other drug so that both accumulate within the body. The mechanism of the interaction between propranolol and thioridazine is probably similar. Thioridazine is an inhibitor of cytochrome P450 isoenzyme CYP2D6 and may inhibit the metabolism of propranolol and metoprolol, which are substrates for this isoenzyme. Both beta blockers and phenothiazines can cause hypotension, and these effects could be additive.

Importance and management

The interaction between propranolol and chlorpromazine appears to be established although information is limited. Concurrent use should be well monitored and the dosages reduced if necessary. The same precautions apply with propranolol and thioridazine.[7] The manufacturer of **metoprolol** advises caution with the concurrent use of thioridazine.[10] Normally the beta blockers are considered to have a wide therapeutic range, and so increases in levels are generally well tolerated. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, and therefore, until the magnitude of any interaction is known, some monitoring (e.g. for shortness of breath, bradycardia, hypotension) may be prudent.

There seems to be no information about any interaction between other beta blockers and phenothiazines, but if the mechanism of interaction suggested above is true, it seems possible that other beta blockers that are mainly cleared from the body by liver metabolism might interact similarly with chlorpromazine, whereas those mainly cleared unchanged in the urine are less likely to have a pharmacokinetic interaction, although additive hypotensive effects would still be expected. See 'Table 22.1', (p.995), for information on the metabolism of the commonly used systemic beta blockers.

Note that **sotalol** and some phenothiazines, including chlorpromazine and thioridazine prolong the QT interval (see 'Table 9.2', (p.290) for a more extensive list). Combined use should therefore generally be avoided, because of the increased risk of torsade de pointes. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Beta blockers + Phenylpropanolamine

A small rise in blood pressure may occur in patients taking beta blockers who take single doses of phenylpropanolamine, but there only appears to be one case report (in a patient taking oxprenolol with methyldopa and phenylpropanolamine) that describes an adverse effect from this interaction. Propranolol attenuates the blood pressure rise seen with phenylpropanolamine.

Clinical evidence, mechanism, importance and management

(a) Effect on beta blockers

A study in 13 patients taking various antihypertensives, including 5 taking unnamed beta blockers, found that a single dose of *Dimetapp Extentabs* (phenylpropanolamine 75 mg with brompheniramine 12 mg) caused a blood pressure rise of 1.7/0.9 mmHg over a 4-hour period, which was not statistically or clinically significant.[1] Another study in 7 stabilised hypertensive patients taking beta blockers (**atenolol** 5 patients, **metoprolol** 1, **propranolol** 1) found that a single 25-mg dose of rapid-release phenylpropanolamine (*Super Odrinex*) increased the mean peak blood pressures by about 8/5 mmHg over a 6-hour period.[2] These rises in blood pressure after single doses are small and relatively short-lived, and probably of little clinical importance. A later multiple dose study in the same subjects (only 5 of whom completed the study), taking the same beta blockers, found that on day 1 phenylpropanolamine increased diastolic blood pressure by 9 to 16 mmHg, and on day 7 by up to 14 mmHg. The day 1 and day 7 results were not statistically different, which suggests that the increase in blood pressure is not enhanced by multiple dosing.[3] Note that a marked rise in blood pressure was seen in one patient taking methyldopa and oxprenolol when phenylpropanolamine was also given, see 'Methyldopa + Nasal decongestants', p.1070.

(b) Effect on phenylpropanolamine

In a placebo-controlled study in 6 healthy subjects, **propranolol** given either orally as a pretreatment or intravenously after phenylpropanolamine, was found to antagonise the rise in blood pressure induced by the phenylpropanolamine. Oral phenylpropanolamine 75 mg alone increased blood pressure from 116/63 to 148/83 mmHg; pretreatment with oral **propranolol** 80 mg every 6 hours reduced the baseline blood pressure to 107/62 mmHg and the increase with phenylpropanolamine was lower, reaching only 119/72 mmHg. Intravenous **propranolol** 0.3 mg/kg given after the phenylpropanolamine decreased blood pressure from 144/87 to 121/84 mmHg.[4]

Beta blockers + Pilocarpine

The concurrent use of pilocarpine and beta blockers is said to be associated with a risk of conduction disorders.

Clinical evidence, mechanism, importance and management

The manufacturer of *oral* pilocarpine notes that it should be given with caution to patients taking beta blockers because of the possibility of con-

duction disorders.[1] Although palpitations are said to be common with the use of oral pilocarpine there appears to be no published reports to suggest that the concurrent use of a beta blocker presents an additional risk.

Adverse effects from pilocarpine *eye drops* appear rare but cases of cardiac decompensation have been reported, although these followed the use of excessive doses of pilocarpine before surgery.[2]

Beta blockers + Policosanol

Policosanol appears to increase the blood pressure-lowering effects of beta blockers.

Clinical evidence

In a randomised study in patients aged 60 to 80 years taking beta blockers, the addition of policosanol 5 mg tablets daily (titrated to a dose of 2 to 4 tablets) found that the average blood pressure was reduced from about 141/83 mmHg to 131/81 mmHg after one year, and to 126/79 mmHg after 3 years. The efficacy of policosanol was not reduced and adverse effects were actually slightly lower in the policosanol group.[1]

Mechanism

Policosanol is thought to reduce vascular resistance.

Importance and management

Policosanol increased the blood pressure-lowering effects of beta blockers and the clinical study suggests that the effect is gradual and beneficial. Furthermore, adverse effects related to hypotension were not reported. It therefore appears that, as with other conventional antihypertensives, policosanol may increase the effects of the beta blockers and so some caution is warranted, but no adverse effects such as first-dose hypotension would be expected.

Beta blockers + Potassium-depleting drugs

The use of potassium-depleting diuretics can precipitate the development of potentially life-threatening torsade de pointes arrhythmias in patients taking sotalol, unless potassium levels are maintained. This would also be expected with other potassium-depleting drugs such as corticosteroids, possibly some laxatives, and intravenous amphotericin.
Chlortalidone and hydrochlorothiazide may reduce the bioavailability of celiprolol, but the evidence for this is sparse.

Clinical evidence

(a) Pharmacokinetic effects

A study in 12 healthy subjects found that when **sotalol** 160 mg was given with **hydrochlorothiazide** 25 mg the pharmacokinetics of both drugs were unchanged.[1]

The manufacturers of **celiprolol** suggest that **chlortalidone** and **hydrochlorothiazide** reduce its bioavailability.[2] This appears to be based on an *in vitro* study,[3] which found that **chlortalidone** and **hydrochlorothiazide** blocked the active transport of **celiprolol** across the intestinal epithelium. The authors of this study also cite a single-dose study that found that **chlortalidone** decreased the bioavailability of **celiprolol**, but details are not given.

(b) QT-prolongation

A 4-year study in cardiac clinics in South Africa identified 13 patients who developed syncope and a prolonged QT interval while taking **sotalol** 80 to 480 mg daily. Twelve patients were taking a combined preparation (*Sotazide*) containing **sotalol** 160 mg and **hydrochlorothiazide** 25 mg. Eleven patients were being treated for hypertension, one for ventricular asystoles, and one for both. Polymorphous ventricular tachycardia was seen in 12 of the patients, and torsade de pointes were seen in 10 of these 12. Arrhythmias occurred within 72 hours of starting **sotalol** in 6 patients, and at varying intervals from 10 days to 3 years in the other 6 patients. Definite hypokalaemia (defined by the study as serum potassium of less than 3.5 mmol/L) was detected in 8 of the 13 patients. Four of the patients were also taking other drugs known to prolong the QT interval, namely disopyramide and tricyclic antidepressants. The problems resolved in all of the cases within 12 hours of stopping the **sotalol** and giving potassium supplements when indicated.[4] A further case of torsade de pointes has also been reported in a patient who developed hypokalaemia while taking **sotalol** and **hydrochlorothiazide**.[5]

Mechanism

Potassium-depleting drugs may cause hypokalaemia, which increases the potential for torsade de pointes arrhythmia with any drug that prolongs the QT interval, including sotalol.

Importance and management

The interaction between potassium-depleting diuretics such as hydrochlorothiazide and sotalol that results in QT prolongation is established, clinically important and potentially life threatening.

Torsade de pointes may occur in patients taking sotalol alone and who appear to have no predisposing factors.[6] One study found that there is an increased risk of proarrhythmia as the dose of sotalol is increased, with an abrupt change occurring at doses greater than 320 mg daily.[7] According to the manufacturer, the incidence of severe proarrhythmias, including torsade de pointes, in clinical study patients taking sotalol was less than 2% for doses up to 320 mg daily, but more than doubled at higher doses.[8] However, torsade de pointes can occur even with small doses of sotalol if potassium depletion is present or allowed to develop.[8,9] It is clearly very important therefore to ensure that potassium levels are maintained if potassium-depleting drugs are given with sotalol. A list of potassium-depleting diuretics is given in 'Table 26.1', (p.1121). Other drugs that may cause potassium depletion include **corticosteroids** and intravenous **amphotericin**. It has also been suggested that stimulant **laxatives**, may cause potassium depletion, but note that this generally tends to occur with abuse, or long-term use.

The interactions of chlortalidone and hydrochlorothiazide with celiprolol are poorly documented and their clinical significance is unclear, although it would be expected to be limited.

Beta blockers + Propafenone

Plasma metoprolol and propranolol levels can be markedly raised (two to fivefold) by propafenone. This has led to toxicity in some cases.

Clinical evidence

(a) Metoprolol

Four patients with ventricular arrhythmias taking metoprolol 150 to 200 mg daily had a two to fivefold rise in their steady-state metoprolol plasma levels when they were given propafenone 150 mg three times daily. One of them developed distressing nightmares, and another had acute

left ventricular failure with pulmonary oedema and haemoptysis, which resolved when the metoprolol dosage was reduced or stopped. In four other patients taking metoprolol 50 mg three times daily and propafenone 150 mg three times daily, it was found that stopping metoprolol did not affect propafenone plasma levels.[1] Single-dose studies in healthy subjects found a twofold decrease in the clearance of metoprolol and a further 20% reduction in exercise-induced tachycardia at 90 minutes when propafenone was also given.[1]

A patient developed neurotoxicity (including vivid nightmares, fatigue, headache) when given metoprolol 100 mg daily in divided doses, which worsened while it was being withdrawn and replaced by propafenone 300 mg daily. The symptoms disappeared when both drugs were stopped.[2]

(b) Propranolol

In a study in 12 healthy subjects propafenone 225 mg every 8 hours more than doubled the steady-state plasma levels of propranolol 50 mg every 8 hours. However, the beta-blocking effects were only modestly increased and the propafenone pharmacokinetics remained unchanged.[3]

Mechanism

It is suggested that propafenone reduces the metabolism of metoprolol and propranolol by the liver, thereby reducing their clearance and raising serum levels.[1,3]

Importance and management

Information is limited but the interaction would seem to be established. Concurrent use need not be avoided but anticipate the need to reduce the dosage of metoprolol and propranolol. Monitor closely because some patients may experience adverse effects. If the suggested mechanism of interaction is correct it is possible (but not confirmed) that other beta blockers that undergo liver metabolism will interact similarly but not those largely excreted unchanged in the urine. See 'Table 22.1', (p.995) for the metabolism of some commonly used beta blockers. Also note that propafenone and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression.

Beta blockers + Protease inhibitors

Ritonavir (including ritonavir used in low dose as a pharmacokinetic enhancer) may increase plasma levels of metoprolol and propranolol. Tipranavir (with ritonavir) is predicted to increase metoprolol levels.

Clinical evidence, mechanism, importance and management

(a) Metoprolol

Metoprolol is metabolised by the cytochrome P450 isoenzyme CYP2D6, and because of this the manufacturer advises caution when it is given with a potent inhibitor of CYP2D6, such as **ritonavir**, as this may result in raised metoprolol plasma levels.[1] Some CYP2D6 inhibitors can raise metoprolol levels to the point where the beta blocker loses its selectivity, and this is of importance in patients being treated with metoprolol for heart failure. If both drugs are given, it may be prudent to monitor for symptoms such as shortness of breath, hypotension and bradycardia, and reduce the dose of metoprolol or withdraw the beta blocker as appropriate. However, the manufacturers of **tipranavir** note that **tipranavir** with **ritonavir** may raise metoprolol levels, and contraindicate the combination when metoprolol is used for heart failure.[2]

(b) Propranolol

As propranolol is metabolised by CYP2D6 the US manufacturers[3] suggest that inhibitors of this isoenzyme may inhibit propranolol metabolism. Some CYP2D6 inhibitors have been seen to interact (such as 'quinidine', (p.1017)), but the pharmacokinetic effects are modest in many cases, probably because propranolol is also metabolised by CYP1A2. However, **ritonavir** also inhibits CYP1A2, and therefore a larger rise in propranolol levels than that seen with other CYP2D6 inhibitors could occur. It would therefore seem prudent to monitor for decreases in blood pressure and heart rate if **ritonavir** is given with propranolol.

Beta blockers + Proton pump inhibitors

Omeprazole does not affect the pharmacokinetics of metoprolol or propranolol, and lansoprazole does not affect the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, **omeprazole** 20 mg daily for 8 days had no effect on the steady-state plasma levels of **propranolol** 80 mg twice daily, and no effect on resting and exercising heart rates or blood pressure.[1] Another study found that **omeprazole** 40 mg daily for 8 days had no effect on the steady-state plasma levels of **metoprolol** 100 mg daily.[2]

A double-blind crossover study in 18 healthy subjects found that **lansoprazole** 60 mg daily for 7 days did not significantly affect the pharmacokinetics of a single 80-mg dose of **propranolol**.[3]

Metoprolol and **propranolol** are mainly metabolised by cytochrome P450 isoenzyme CYP2D6 and so would not be expected to interact with **lansoprazole** and **omeprazole**, which are inhibitors of and substrates for CYP2C19. No dosage adjustments would therefore seem necessary if these proton pump inhibitors are given with **propranolol** or **metoprolol**.

Beta blockers + Quinidine

An isolated report describes a patient taking quinidine who developed marked bradycardia when using timolol eye drops. Other case reports describe orthostatic hypotension when quinidine was given with atenolol, propranolol or unnamed beta blockers. Quinidine can raise plasma metoprolol, propranolol, and timolol levels.

Both sotalol and quinidine can prolong the QT interval, which may increase the risk of torsade de pointes arrhythmia if they are used together.

Clinical evidence

(a) Atenolol

Orthostatic hypotension occurred in a 56-year-old woman taking isosorbide dinitrate, diltiazem and quinidine sulfate 300 mg four times daily, 3 days after she started taking atenolol 50 mg daily. This resolved within 2 days of stopping the atenolol. Before starting the quinidine, she had previously taken atenolol and the other drugs without problems.[1]

(b) Metoprolol

A metabolic study in 5 healthy subjects who had normal levels of CYP2D6 (extensive metabolisers) found that a single 50-mg dose of quinidine markedly inhibited the metabolism of a single 100-mg dose of metoprolol, which effectively made the subjects poor metabolisers (i.e. those that are deficient or lacking CYP2D6). The plasma levels of metoprolol were approximately tripled. Quinidine had no effect on metoprolol pharmacokinetics in 5 poor metabolisers.[2] Similar results have been found when quinidine 50 mg daily was given with metoprolol 100 mg twice daily for 7 days,[3] and when a 20-mg dose of metoprolol was given intravenously following either a single 50-mg dose of quinidine or quinidine slow-release tablets 250 mg twice daily for 3 days.[4] The effect on heart-rate reduction was small given the increase in metoprolol levels.[3]

(c) Propranolol

A single-dose pharmacokinetic study found that quinidine 200 mg doubled the AUC and the peak plasma levels of a 20-mg dose of propranolol. Maximum heart rates during exercise were suppressed by 45% more than propranolol alone.[5] Other studies have also found that quinidine increases the AUC of propranolol two- to threefold,[6,7] and this has resulted in increased beta-blockade.[7]

In 7 patients, propranolol 40 to 400 mg daily increased the peak plasma levels of a single 200-mg dose of quinidine by more than 50% and decreased its clearance by almost 40%, when compared with 8 control patients not taking propranolol. However, the quinidine elimination half-life was unchanged.[8] In contrast, two other studies did not find any interaction between propranolol and quinidine.[9,10]

A man taking propranolol 40 mg four times daily developed orthostatic hypotension, with symptoms of dizziness and faintness on standing, when he took quinidine 200 mg four times daily. This resolved when quinidine was withdrawn.[11] The same authors subsequently briefly reported another two cases of orthostatic hypotension when quinidine was given with **unnamed beta blockers**.[12]

(d) Sotalol

Although one study reports the safe concurrent use of sotalol and quinidine,[13] both drugs can prolong the QT interval, which may increase the risk of torsade de pointes arrhythmia if they are used together. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for a general review of QT-prolongation and drug interactions.

(e) Timolol

An elderly man taking quinidine sulfate 500 mg three times daily for premature atrial beats was hospitalised with dizziness 12 weeks after starting to use timolol 0.5% eye drops for open-angle glaucoma. He was found to have a sinus bradycardia of 36 bpm. The symptoms abated when the drugs were withdrawn and normal sinus rhythm returned after 24 hours. The same symptoms developed within 30 hours of re-starting both drugs, but disappeared when the quinidine was withdrawn.[14]

In a later study in healthy subjects, a single 50-mg oral dose of quinidine was given 30 minutes before 2 drops of timolol 0.5% ophthalmic solution, put into each *nostril*. In 13 patients with normal levels of CYP2D6 (extensive metabolisers), quinidine caused a further decrease in heart rate and increase in plasma timolol levels, when compared with timolol alone. Giving quinidine with timolol in these extensive metabolisers gave results similar to giving timolol alone in 5 poor metabolisers of CYP2D6 (i.e. those that are deficient or lacking CYP2D6).[15] In another study, quinidine augmented the plasma levels and cardiac effects of intravenous timolol.[16]

Mechanism

Quinidine appears to increase metoprolol, propranolol and timolol plasma levels by inhibiting the cytochrome P450 isoenzyme CYP2D6, thereby reducing their clearance.[2,7,15] As CYP2D6 shows polymorphism, these interactions would be most apparent in patients with normal CYP2D6 activity (extensive metabolisers), effectively making them poor metabolisers. See 'Genetic factors', (p.4), for further information on genetic polymorphism.

Importance and management

The pharmacokinetic interaction between quinidine and metoprolol, propranolol and timolol would seem to be established, but it is of uncertain clinical importance. Normally the beta blockers are considered to have a wide therapeutic range, and so raises in levels are generally well tolerated. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, and therefore some monitoring in this patient group (e.g. for shortness of breath, bradycardia, hypotension) may be prudent. There appears to be no information about other beta blockers, but all those metabolised by CYP2D6 would be expected to be affected to some extent. See 'Table 22.1', (p.995), for a list.

Only one isolated case of possible excessive beta-blockade has been reported (with quinidine and timolol eye drops). Concurrent use need not be avoided (and may be beneficial in the treatment of atrial fibrillation), but some care is warranted as both quinidine and the beta blockers have negative inotropic effects, which could be additive and result in unwanted cardiodepression. The general relevance of the isolated reports of orthostatic hypotension with atenolol or propranolol and quinidine is uncertain.

Both quinidine and sotalol prolong the QT interval. The general consensus is that the combination of two drugs that prolong the QT interval should usually be avoided, or only used with great caution. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for more information about the concurrent use of QT prolonging drugs.

Beta blockers + Quinolones

Ciprofloxacin reduces the clearance of metoprolol. The concurrent use of sotalol and quinolones that prolong the QT interval should generally be avoided.

Clinical evidence, mechanism, importance and management

(a) Ciprofloxacin

Preliminary evidence from 7 healthy subjects given a single 100-mg dose of **metoprolol** suggested that pretreatment with 5 doses of ciprofloxacin 500 mg, given every 12 hours, increased the AUC of *(+)*-metoprolol by 54% and reduced its clearance by 39%. The AUC of *(–)*-metoprolol was increased by 29% and its clearance reduced by 12%.[1] It has been suggested that this interaction may occur because ciprofloxacin inhibits the activity of the cytochrome P450 isoenzymes concerned with the metabolism and clearance of **metoprolol**. However, this is questionable as **metoprolol** is metabolised, predominantly, by the cytochrome P450 isoenzyme CYP2D6 while ciprofloxacin inhibits CYP1A2. Changes of this size, or even more, in the AUC of beta blockers are not usually considered to be clinically relevant because the beta blockers have a wide therapeutic margin. Patients with heart failure are usually more at risk, because drugs such as metoprolol lose their selectivity at higher levels, but even in this patient group the rise in levels seems unlikely to be generally important.

(b) Quinolones that prolong the QT interval

In an analysis of cases of torsade de pointes associated with fluoroquinolones on the FDA Adverse Events Reporting System database, two cases of torsade de pointes were noted in patients taking a fluoroquinolone with **sotalol** (there were 37 cases identified, and 19 occurred in patients also taking other drugs known to prolong the QT interval).[2] **Sotalol** has class III antiarrhythmic effects and prolongs the QT interval, and this could be additive with the effects of quinolones that prolong the QT interval (e.g. **gatifloxacin**, **moxifloxacin**, **sparfloxacin**, see 'Table 9.2', (p.290)).The concurrent use of **sotalol** and these quinolones should generally be avoided (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

Beta blockers + Rifampicin (Rifampin)

Rifampicin increases the clearance of bisoprolol, carvedilol, celiprolol, metoprolol, tertatolol and talinolol, and reduces their plasma levels. The extent to which this reduces the effects of these beta blockers is uncertain, but it is probably small. Similar effects have been seen when atenolol is given with rifampicin, but a case report suggests that occasionally the effects may be of clinical relevance. The effects of rifampicin on propranolol appear more pronounced, but evidence regarding the clinical relevance of this appears to be lacking.

Clinical evidence

(a) Atenolol

A case report describes a man taking atenolol for angina whose exercise threshold before developing angina symptoms appreciably worsened when he was given rifampicin. Rifampicin was stopped, and after a week **rifabutin** was started. **Rifabutin** did not cause any change in his baseline exercise tolerance.[1] In a randomised, placebo-controlled, crossover study, 9 healthy subjects were given rifampicin 600 mg daily for 5 days, with a single 100-mg dose of atenolol on day 6. Although some pharmacokinetic changes were seen they were variable between subjects and in most cases slight. Heart rate and blood pressure were on average slightly higher in the presence of rifampicin (3.5 bpm and 4.3/3.9 mmHg, respectively), suggesting a modest reduction in the effects of atenolol, which was expected to be of only minor clinical relevance.[2]

(b) Bisoprolol

The AUC of bisoprolol 10 mg daily was reduced by 34% in healthy subjects given rifampicin 600 mg daily.[3]

(c) Carvedilol

Rifampicin 600 mg daily for 12 days caused a 60% decrease in the maximum serum levels and the AUC of carvedilol.[4]

(d) Celiprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 200-mg dose of celiprolol by 55%.[5]

(e) Metoprolol

In a study in healthy subjects, rifampicin 600 mg daily reduced the AUC of a single 100-mg dose of metoprolol by 33%.[6]

(f) Propranolol

In a study in 6 healthy subjects, rifampicin 600 mg daily for 3 weeks increased the oral clearance of propranolol almost threefold. Increasing the rifampicin dosage to 900 or 1200 mg daily did not further increase the clearance. Four weeks after withdrawing the rifampicin the blood levels of propranolol had returned to normal.[7] In a similar study the oral clearance of propranolol was increased by about fourfold by rifampicin 600 mg daily for 3 weeks in both poor and extensive metabolisers of propranolol.[8]

(g) Talinolol

In a study in 8 healthy subjects, rifampicin 600 mg daily decreased the AUC of a single-dose of talinolol 30 mg intravenously or 100 mg orally by 21% and 35%, respectively.[9]

(h) Tertatolol

Rifampicin 600 mg daily for a week increased the clearance of tertatolol almost threefold and reduced the half-life from 9 hours to 3.4 hours. A slight reduction in the effects of tertatolol on blood pressure was seen and heart rates were raised from 68 to 74 bpm.[10]

Mechanism

Rifampicin is a potent liver-enzyme inducer that increases the metabolism and clearance of extensively metabolised beta blockers such as propranolol and metoprolol. Rifampicin may also interact by mechanisms other than enzyme induction. Rifampicin increases duodenal P-glycoprotein expression, so increased clearance of talinolol (which is not hepatically metabolised) may be due to induction of P-glycoprotein, which increases the excretion of talinolol.[9] The effects on atenolol, which is not extensively metabolised, are also possibly due to induction of P-glycoprotein,[2] although this needs confirmation.

Importance and management

The interactions between rifampicin and the beta blockers are established. Their clinical importance is uncertain but probably small.[10] Nevertheless, they cannot be completely dismissed as the case report with atenolol shows. Consider increasing the dosage of the beta blocker if there is any evidence that the therapeutic response is inadequate. Any beta blockers that undergoes extensive liver metabolism would be expected to be affected by the enzyme-inducing effects of rifampicin (see 'Table 22.1', (p.995)). Those beta blockers mainly lost unchanged in the urine would not be expected to be affected, but it appears that an interaction may occur with beta blockers that are substrates for P-glycoprotein, such as talinolol.

Beta blockers + SSRIs

Fluoxetine can increase serum pindolol and carvedilol levels. Isolated reports describe lethargy and bradycardia in patients taking metoprolol with fluoxetine, and propranolol with fluoxetine or fluvoxamine. Paroxetine may increase levels of metoprolol resulting in increased beta-blocking effects, and this has led to AV block in one case. Citalopram and escitalopram may also increase metoprolol levels. Sertraline does not alter the beta-blocking effects of atenolol, and fluvoxamine does not alter the pharmacokinetics of atenolol, although slight bradycardia and hypotension were reported.

Clinical evidence

(a) Citalopram

The UK manufacturers of citalopram say that no pharmacodynamic interactions have been noted in clinical studies in which citalopram was given with beta blockers.[1] However, the US manufacturers say that although the concurrent use of **metoprolol** and citalopram has no clinically significant effect on heart rate and blood pressure, the plasma levels of **metoprolol** are increased twofold, which may decrease its cardioselectivity.[2]

(b) Escitalopram

The manufacturers say that escitalopram causes a 50% increase in the plasma levels of **metoprolol** and an 82% increase in its AUC. They note that, although the concurrent use of **metoprolol** and escitalopram has no clinically significant effect on heart rate and blood pressure, this increase in plasma levels may decrease the cardioselectivity of **metoprolol**.[3]

(c) Fluoxetine

Metoprolol 100 mg daily improved the angina of a man who had undergone a coronary artery bypass 4 years earlier. A month later he was given fluoxetine 20 mg daily for depression. Within 2 days he complained of profound lethargy, and his resting heart rate was found to have fallen from 64 to 36 bpm. The fluoxetine was withdrawn, and within 5 days his heart

rate returned to 64 bpm. The **metoprolol** was replaced by **sotalol** 80 mg twice daily and fluoxetine reintroduced without problems.[4]

A patient taking **propranolol** 40 mg twice daily developed bradycardia of 30 bpm, heart block and syncope 2 weeks after starting fluoxetine 20 mg daily. This patient possibly also had some pre-existing conduction disease contributing to the effect.[5]

When 9 healthy subjects were given **pindolol** 5 mg every 6 hours with fluoxetine (20 mg daily for 3 days and then 60 mg daily for another 7 days), the **pindolol** AUC rose by about 75% and its clearance fell by about 45%, when compared with a single 5-mg dose of **pindolol**. Only mild to moderate alterations in pulse rate and blood pressure were seen.[6] Some studies including a high proportion of patients with first-episode depression have suggested that the antidepressant response to fluoxetine is accelerated by **pindolol**[7] while other studies in patients with predominantly chronic or recurrent depression did not find an enhanced response.[8] A crossover study in 10 patients with heart failure, taking **carvedilol** 25 to 50 mg twice daily, found that the addition of fluoxetine 20 mg daily for 28 days increased the AUC of ***(R)*-carvedilol** by 77%, and decreased the clearance of both enantiomers by 44 to 56%. However, these pharmacokinetic changes were of little clinical significance, and there were no changes in blood pressure, heart rate, and heart rate variability.[9]

(d) Fluvoxamine

A 79-year-old man who had taken **propranolol** for prophylaxis of migraine for several years developed fatigue and lightheadedness within a few days of starting fluvoxamine. He was admitted to hospital with syncope and bradycardia of 38 bpm but recovered after both drugs were discontinued.[10] Fluvoxamine 100 mg daily raised the plasma levels of **propranolol** 160 mg daily fivefold in healthy subjects, but the bradycardic effects were only slightly increased (by 3 bpm). The diastolic pressure following exercise was only slightly reduced but the general hypotensive effects remained unaltered.[11] Fluvoxamine did not change the plasma levels of **atenolol** 100 mg daily, but the heart-slowing effects were slightly increased and the hypotensive effects were slightly decreased.[11]

(e) Paroxetine

A patient taking paroxetine 20 mg daily developed presyncope and complete AV block 15 days after starting **metoprolol** 50 mg daily. Both drugs were stopped and the AV block resolved over 5 days. **Metoprolol** was then reinstated for 5 days without any sign of bradyarrhythmia. Two weeks after replacing **metoprolol** with amlodipine and aspirin, paroxetine was reintroduced at 10 mg daily and gradually increased to 20 mg daily without any signs of bradyarrhythmia.[12] A study in 8 healthy subjects found that paroxetine 20 mg daily for 6 days increased the AUCs of ***(R)*-** and ***(S)*-metoprolol** by eightfold and fivefold, respectively, after a single 100-mg dose of **metoprolol**. The maximum plasma concentration and elimination half-life were increased about twofold. The beta-blocking effects of **metoprolol** were more sustained and the reduction in exercise systolic pressure was more pronounced when paroxetine was also taken, when compared with **metoprolol** alone.[13]

(f) Sertraline

In a single-dose study in 10 healthy subjects, the beta-blocking effects of **atenolol** 50 mg were unchanged by sertraline 100 mg given 5 hours before the **atenolol**.[14,15]

Mechanism

Fluoxetine and paroxetine inhibit the cytochrome P450 isoenzyme CYP2D6 thus inhibiting the metabolism of some beta blockers (e.g. propranolol, metoprolol, carvedilol) so that they accumulate, the result being that their effects, such as bradycardia, may be increased.[4] Citalopram and escitalopram may also inhibit CYP2D6. *In vitro* studies with human liver microsomes found that fluoxetine and paroxetine are potent inhibitors of metoprolol metabolism whereas fluvoxamine, sertraline and citalopram have less of an effect.[16] However, fluvoxamine also potently inhibits the metabolism of propranolol by CYP1A2.[10,17] Beta blockers that are not extensively metabolised, such as atenolol and sotalol, would not be expected to be affected.

Pindolol may augment the antidepressant effect of fluoxetine by its antagonistic effects at 5-HT_{1A} receptors.[7,8,18]

Importance and management

Pharmacokinetic interactions have been found between fluoxetine, fluvoxamine or paroxetine and some beta blockers, but despite marked pharmacokinetic changes, the clinical effects are not generally significant. However, be aware that there are a few isolated reports of AV block with metoprolol and paroxetine and severe bradycardia with beta blockers and fluoxetine, or fluvoxamine. If problems arise, the interaction can apparently be avoided by giving a beta blocker (such as atenolol), which is not extensively metabolised. Alternatively, sertraline and citalopram seem to be less likely than the other SSRIs to interact with extensively metabolised beta blockers.[16] However, because metoprolol is considered to have a narrow therapeutic index in the treatment of heart failure, the UK manufacturers of escitalopram say that caution and possible dosage adjustments are warranted on concurrent use.[19] Similarly the manufacturers of paroxetine suggest that concurrent use should be avoided if metoprolol is being used for heart failure.[20] Remember that fluoxetine and particularly its metabolite have long half-lives so that this interaction may possibly still occur for some days after the fluoxetine has been stopped.

There appears to be no information about other beta blockers, but all those metabolised by CYP2D6 would be expected to be affected by paroxetine and fluoxetine to some extent. See 'Table 22.1', (p.995), for a list. Note that one of the manufacturers of **timolol**[21] predict this interaction with all SSRIs; however, most are less potent inhibitors of CYP2D6 than fluoxetine and paroxetine and therefore less likely to interact to a clinically relevant extent.

The combination of pindolol with fluoxetine may be advantageous in the treatment of depression in some patients.[7,8]

Beta blockers + Sulfinpyrazone

The antihypertensive effects of oxprenolol can be reduced or abolished by sulfinpyrazone. The pharmacokinetics of metoprolol are not affected by sulfinpyrazone.

Clinical evidence

Oxprenolol 80 mg twice daily was given to 10 hypertensive subjects for 15 days, which reduced their mean supine blood pressure from 161/101 mmHg to 149/96 mmHg, and their heart rate from 72 bpm to 66 bpm. When they were additionally given sulfinpyrazone 400 mg twice

daily for 15 days, their mean blood pressure rose to about the former level. The reduction in mean heart rate remained unaffected. Sulfinpyrazone attenuated the reduction in cardiac workload seen with **oxprenolol** alone by about half.[1]

A study in 9 healthy subjects found that sulfinpyrazone 400 mg twice daily did not affect the pharmacokinetics of **metoprolol** 100 mg twice daily. No adverse effects were noted in healthy subjects during concurrent use.[2]

Mechanism

Not understood. One idea is that the sulfinpyrazone inhibits the production of vasodilatory (antihypertensive) prostaglandins by the kidney. This would oppose the actions of the oxprenolol. However, if this was the case, an interaction with metoprolol would also be expected, but this does not seem to be the case.

Importance and management

Information seems to be limited. If sulfinpyrazone is given to patients taking oxprenolol for hypertension, the effects should be monitored. It seems possible that this interaction could be accommodated by raising the dosage of the oxprenolol but this needs confirmation. The effect of this interaction on cardiac workload appears to be less important, but it would still be prudent to monitor concurrent use if oxprenolol is used for angina. Metoprolol may be a suitable alternative to oxprenolol as it does not appear to interact with sulfinpyrazone. There appears to be no information regarding other beta blockers.

Beta blockers + Tobacco or Nicotine ± Caffeine

Tobacco smoking can reduce the beneficial effects of beta blockers on heart rate and blood pressure. Some increase in the dosage of the beta blocker may be necessary. Drinking coffee may have a similar but smaller effect, probably due to the caffeine content. Nicotine attenuates the effects of tobacco withdrawal, and this effect may be enhanced by some beta blockers.

Clinical evidence

(a) Caffeine

In a placebo-controlled study in 12 healthy subjects, taking **propranolol** 240 mg or **metoprolol** 300 mg, two 150-mL cups of caffeine-containing coffee (made from 24 g of coffee) increased the mean blood pressure by 7%/22% with **propranolol** and 7%/19% with **metoprolol**. The increase with placebo was similar, at 4%/16% mmHg. The beta blockers and placebo were given in divided doses over 15 hours before the test.[1]

(b) Nicotine

A placebo-controlled, single-dose study in smokers given **carvedilol** 25 or 50 mg 140 minutes before a 4-mg nicotine lozenge found that **carvedilol** attenuated nicotine-induced increases in heart rate and blood pressure and also attenuated the self-reported 'bad effects' of nicotine but did not affect tobacco withdrawal symptoms.[2] Another similar study in 9 smokers found that a single 200-mg dose of **labetalol** attenuated the effects of a 15-mg/kg intravenous injection of nicotine on heart rate, whereas a single 100-mg dose of **labetalol** had no effect. Both doses of **labetalol** had no effect on the increase in blood pressure caused by nicotine. **Labetalol** 200 mg in conjunction with nicotine caused a greater attenuation in the symptoms of tobacco withdrawal than **labetalol** 100 mg.[3]

(c) Tobacco smoking

A placebo-controlled study in 10 smokers with angina pectoris, taking **propranolol** 240 mg daily or **atenolol** 100 mg daily, found that smoking reduced their plasma **propranolol** levels by 25%, when compared with a non-smoking phase. Plasma **atenolol** levels were not significantly altered. Both of the beta blockers reduced heart rate at rest and during exercise, but the reductions were less when subjects smoked (effects attenuated by 8 to 14%).[4]

Other studies found that serum **propranolol** levels in smokers were about half those in non-smokers.[5,6]

In another study, smoking caused an increase in blood pressure and heart rate in patients with angina and these effects were still evident, to a reduced extent, during **propranolol** treatment. In addition smoking abolished the beneficial effects of **propranolol** on ST-segment depression.[7]

(d) Tobacco smoking and caffeine

Eight patients with mild hypertension taking **propranolol** 80 mg twice daily, **oxprenolol** 80 mg twice daily or **atenolol** 100 mg daily over a 6-week period had their blood pressure monitored after smoking 2 tipped cigarettes and drinking coffee, containing 200 mg of caffeine. Their mean blood pressure rises over the following 2 hours were 8.5/8 mmHg in those taking **propranolol**, 12.1/9.1 mmHg in those taking **oxprenolol** and 5.2/4.4 mmHg in those taking **atenolol**.[8]

Mechanism

Smoking tobacco increases heart rate, blood pressure and the severity of myocardial ischaemia, probably as a direct effect of the nicotine and due to the reduced oxygen-carrying capacity of the blood.[4,7] These actions oppose and may even totally abolish the beneficial actions of the beta blockers. In addition, smoking stimulates the liver enzymes concerned with the metabolism of some beta blockers (e.g. propranolol) so that their serum levels are reduced. In contrast, the use of a beta blocker appears to enhance the beneficial effects of nicotine on tobacco withdrawal symptoms.

Caffeine causes the release of catecholamines, such as adrenaline, into the blood, which could account for the increases in heart rate and blood pressure that were seen in one study.[8] The blood pressure rise may be exaggerated in the presence of non-selective beta blockers, which block vasodilatation leaving the alpha (vasoconstrictor) effects of adrenaline unopposed. This will also oppose the actions of the beta blockers.

Importance and management

Evidence for an interaction between tobacco smoking and/or coffee intake and beta blockers is generally sparse. Smoking tobacco and (to a very much lesser extent) drinking coffee may oppose the effects of the beta blockers in the treatment of angina or hypertension, but the extent of any effect appears relatively modest. However, patients should be encouraged to stop smoking because, quite apart from its other toxic effects, it aggravates myocardial ischaemia, increases heart rate and can impair blood pressure control. If patients continue to smoke, it may be necessary to raise the dosages of the beta blockers. The effects of the caffeine are quite small and there seems to be no strong reason to forbid the intake of beverages containing caffeine (e.g. tea, coffee, cola), but the excessive consumption of large amounts may not be a good idea, particularly in those who also smoke.

Evidence for an interaction between nicotine replacement therapy and beta blockers is also sparse; however, the concurrent use of nicotine and a beta blocker may actually be beneficial in minimising the effects of tobacco withdrawal. This requires further study.

Beta blockers + X-ray contrast media

There is some evidence to suggest that use of a beta blocker is a risk factor for anaphylactoid reactions to X-ray contrast media. Severe hypotension has been seen in two patients taking beta blockers who were given sodium meglumine amidotrizoate and in a further patient taking atenolol who was given iohexol.

Clinical evidence

A case-control study of anaphylactoid reactions to X-ray contrast media found that the risk of bronchospasm during intravenous contrast media procedures was associated with beta blocker use and also with asthma, while the risk of major and life-threatening anaphylactoid reactions were associated with cardiovascular disorders. The use of a beta blocker also increased the risk of hospitalisation in those patients who had a severe anaphylactoid reaction.[1]

Two patients, one taking **nadolol** and the other **propranolol**, developed severe hypotensive reactions when given **sodium meglumine amidotrizoate** as a contrast agent for X-ray urography. Both patients developed slowly progressive erythema on the face and arms followed by tachycardia and a weak pulse. Each was successfully treated with subcutaneous adrenaline (epinephrine) and hydrocortisone.[2]

Another patient who had developed a transient rash during cardiac catheterisation 6 years earlier, and who was subsequently given **atenolol**, developed generalised urticaria and severe hypotension immediately after an injection of **iohexol** for coronary angiography. The hypotension was refractory to aggressive standard treatment with adrenaline, atropine, and dopamine and the patient remained in shock (BP 60/34 mmHg). Noradrenaline (norepinephrine) infusion produced a modest improvement (BP 80/40 mmHg), but significant improvement in blood pressure occurred only after intravenous injections of glucagon 1 mg.[3]

See also, *Anaphylaxis* under 'Beta blockers + Inotropes and Vasopressors', p.1011.

Mechanism

Iodinated contrast media are associated with hypersensitivity reactions due to the release of histamine. It is suggested that beta blockers compromise the ability of the body to cope with the effects of histamine release.[2]

Importance and management

Limited documentation. Withdrawal of the beta blocker 2 to 3 days before use of contrast media has been suggested,[2] but because of the potential for beta blocker withdrawal syndromes this must be considered on an individual risk/benefit basis.[1] Pretreatment with an antihistamine such as diphenhydramine and a corticosteroid such as prednisone may reduce the risk of reactions.[3-5] Ephedrine and cimetidine have also been tried, but their use is controversial.[5] Use of low osmolality, non-ionic contrast media may reduce the risk of adverse reactions, including anaphylaxis.[1,5,6] However, even mild reactions to contrast media may sensitise the patient and a serious anaphylactoid reaction may occur on further exposure, despite pretreatment and the use of low osmolality contrast media.[3] Pre-testing with a small amount of the contrast media has been shown to be a poor predictor of a reaction.[5]

When anaphylactic reactions do occur in patients taking beta blockers, it may be preferable to use a beta-agonist bronchodilator such as isoprenaline, rather than adrenaline (epinephrine).[2] Glucagon, which has inotropic and chronotropic actions that are only minimally antagonised by beta blockers, may also be effective in reversing anaphylactoid shock in patients taking beta blockers.[3]

Beta blockers; Atenolol + Allopurinol

In a study in 6 healthy subjects, allopurinol 300 mg daily for 6 days did not affect the steady-state pharmacokinetics of atenolol 100 mg daily.[1] No special precautions would therefore appear to be necessary on concurrent use.

1. Schäfer-Korting M, Kirch W, Axthelm T, Köhler H, Mutschler E. Atenolol interaction with aspirin, allopurinol, and ampicillin. *Clin Pharmacol Ther* (1983) 33, 283–8.

Beta blockers; Metoprolol + Acetylcholine

An isolated case describes bronchospasm, which developed when a patient taking metoprolol was given intra-ocular acetylcholine.

Clinical evidence, mechanism, importance and management

An elderly patient with a history of hypertension, obstructive pulmonary disease and stable angina, taking several drugs including metoprolol, experienced severe bronchospasm and pulmonary oedema immediately following the intra-ocular injection of acetylcholine chloride during cataract surgery. Her blood pressure rapidly increased, and she became tachycardic. She had also received phenylephrine eye drops before surgery. The patient may have been more sensitive to the pulmonary effects of acetylcholine, such as bronchospasm, because of pre-existing disease and the presence of metoprolol.[1] It was suggested that phenylephrine may also have been involved, but cases of an interaction between phenylephrine and beta blockers are rare, see 'Beta blockers + Inotropes and Vasopressors', p.1011.

The general clinical relevance of this single case is uncertain but it seems likely to be small.

1. Rasch D, Holt J, Wilson M, Smith RB. Bronchospasm following intraocular injection of acetylcholine in a patient taking metoprolol. *Anesthesiology* (1983) 59, 583–5.

Beta blockers; Metoprolol + Sevelamer

In a study in 31 healthy subjects the concurrent use of a single 2.418-g dose of sevelamer did not alter the AUC of a single 100-mg dose of metoprolol.[1] No particular precautions therefore seem necessary on concurrent use.

1. Burke SK, Amin NS, Incerti C, Plone MA, Lee JW. Sevelamer hydrochloride (Renagel®), a phosphate-binding polymer, does not alter the pharmacokinetics of two commonly used antihypertensives in healthy volunteers. *J Clin Pharmacol* (2001) 41, 199–205.

Beta blockers; Nebivolol + Spironolactone

The concurrent use of spironolactone and nebivolol does not appear to affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A randomised study in 36 healthy subjects given nebivolol 10 mg daily with spironolactone 25 mg daily found no clinically significant changes in the pharmacokinetics of spironolactone and its metabolites canrenone and 7α-thiomethyl spirolactone. Further, spironolactone is reported not to affect the pharmacokinetics of nebivolol.[1] No particular precautions therefore seem necessary on concurrent use, although note that both drugs can lower blood pressure, and this should be borne in mind if they are both given.

1. Morton TL, Tu HC, Lui S, Chervenick SW, Rackley RJ, Huang MY. Lack of pharmacokinetic interaction between nebivolol and spironolactone. *Clin Pharmacol Ther* (2005) 77, P46.

Beta blockers; Propranolol + Ascorbic acid (Vitamin C)

Ascorbic acid reduces the bioavailability of propranolol but the extent of the reduction is too small to be of clinical significance.

Clinical evidence, mechanism, importance and management

A study in 5 healthy subjects given a single 80-mg dose of propranolol found that a single 2-g dose of ascorbic acid reduced the maximum plasma levels of propranolol by 28%, reduced the AUC by 37% and reduced the recovery of propranolol metabolites in the urine by 66%. The reduction in

heart rate in response to propranolol was also very slightly diminished. The reason for this interaction appears to be that ascorbic acid reduces both the absorption and the metabolic conjugation of propranolol.[1] However, none of the changes seen would appear to be of clinical relevance.

1. Gonzalez JP, Valdivieso A, Calvo R, Rodríguez-Sasiaín JM, Jimenez R, Aguirre C, du Souich P. Influence of vitamin C on the absorption and first pass metabolism of propranolol. *Eur J Clin Pharmacol* (1995) 48, 295–7.

Beta blockers; Propranolol + Dextromoramide

An isolated report describes two patients who developed marked bradycardia and severe hypotension when they were given propranolol and dextromoramide following the induction of anaesthesia.

Clinical evidence, mechanism, importance and management

Two women about to undergo a partial thyroidectomy were given propranolol 30 mg and dextromoramide 1.25 or 4 mg by injection during the pre-operative period, after which anaesthesia was induced with a barbiturate. Each woman developed marked bradycardia and severe hypotension, which responded rapidly to intravenous atropine.[1] The authors of the report attributed this effect to the use of dextromoramide and propranolol; however, the reasons for this response are not established (e.g. the induction of anaesthesia may have played a part) and therefore the general significance of this interaction (if such it is) is unclear.

1. Cabanne F, Wilkening M, Caillard B, Foissac JC, Aupecle P. Interférences médicamenteuses induites par l'association propranolol-dextromoramide. *Anesth Analg Reanim* (1973) 30, 369–75.

Beta blockers; Propranolol + Miscellaneous

The manufacturers predict that propranolol levels will be raised by inhibitors and substrates of CYP1A2 (such as ciprofloxacin) and inhibitors and substrates of CYP2C19 (such as fluconazole and tolbutamide).

Clinical evidence, mechanism, importance and management

(a) CYP1A2 substrates or inhibitors

As propranolol is partly metabolised by CYP1A2 the US manufacturer[1] predicts that its levels may be raised by substrates or inhibitors of this isoenzyme.

However, data for 'imipramine', (p.1500), 'isoniazid', (p.348), and 'theophylline', (p.1433), (substrates of CYP1A2) suggest that in fact propranolol raises the levels of these drugs.

Inhibitors of CYP1A2 raise propranolol levels (as seen with 'fluvoxamine', (p.1019)) and therefore an interaction with **ciprofloxacin** (as predicted by the manufacturer) seems possible. However, note that propranolol levels fluctuate greatly between individuals, and propranolol is not exclusively metabolised by CYP1A2, and so any interaction seems likely to produce only moderate clinical effects.

(b) CYP2C19 substrates or inhibitors

The US manufacturer[1] suggests that raised propranolol levels may occur with **fluconazole** or **tolbutamide**, which are an inhibitor and a substrate of CYP2C19, respectively. However, CYP2C19 only plays a small part in propranolol metabolism. Further, the manufacturer also notes that omeprazole and lansoprazole (both inhibitors and substrates for CYP2C19) do not interact with propranolol (see 'Beta blockers + Proton pump inhibitors', p.1017), and so a clinically significant interaction involving CYP2C19 seems unlikely.

1. Inderal LA (Propranolol hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, November 2007.

Beta blockers; Propranolol + Misoprostol

Misoprostol does not significantly alter the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, misoprostol 400 micrograms twice daily raised the AUC of propranolol 80 mg twice daily by about 20 to 40%, and this remained raised 7 days after misoprostol was discontinued.[1] However, as these findings were unexpected, the authors conducted a randomised, crossover, placebo-controlled study and ensured that propranolol was at steady state before assessing the effect of misoprostol. No significant effects on the pharmacokinetics of propranolol were found.[2] No dosage adjustment of propranolol would therefore seem necessary if misoprostol is given.

2. Bennett PN, Fenn GC, Notarianni LJ, Lee CE. Misoprostol does not alter the pharmacokinetics of propranolol. *Postgrad Med J* (1991) 67, 455–7.

Beta blockers; Propranolol + Nefazodone

Nefazodone does not significantly affect the pharmacokinetics of propranolol.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects found that nefazodone 200 mg every 12 hours reduced the AUC of propranolol 40 mg every 12 hours by 14% and decreased its maximum plasma levels by 29%, but no clinically significant changes in the response to propranolol or relevant adverse effects were seen. The pharmacokinetics of nefazodone were also largely unchanged.[1] No special precautions would therefore seem to be necessary if both drugs are given.

1. Salazar DE, Marathe PH, Fulmor IE, Lee JS, Raymond RH, Uderman HD. Pharmacokinetic and pharmacodynamic evaluation during coadministration of nefazodone and propranolol in healthy men. *J Clin Pharmacol* (1995) 35, 1109–18.

Beta blockers; Propranolol + Sucrose polyesters

One study suggests that sucrose polyesters (e.g. *Olestra*) do not interact with propranolol.

Clinical evidence, mechanism, importance and management

Eight healthy subjects were given sucrose polyester 18 g and a single unstated dose of propranolol. Sucrose polyester had no effect on the pharmacokinetics of propranolol.[1] Sucrose polyesters, are non-absorbable, non-calorific fat replacements. It has been concluded that sucrose polyesters are unlikely to reduce the absorption of oral drugs in general.[2]

2. Goldman P. Olestra: assessing its potential to interact with drugs in the gastrointestinal tract. *Clin Pharmacol Ther* (1997) 61, 613–18.

Beta blockers; Sotalol + Paracetamol (Acetaminophen)

One isolated report suggests that paracetamol may enhance the effects of sotalol on heart rate.

Clinical evidence, mechanism, importance and management

A brief report describes 9 patients with hypertension who were given a single 240-mg dose of sotalol daily for 2 weeks. Sotalol alone reduced the heart rate by 10 bpm by day 10; however, 5 of the patients also given paracetamol 2 g daily in three divided doses on days 8 to 10 (for headache), and in these patients there was an average reduction in heart rate of

18 bpm.[1] This appears to be an old and isolated report and therefore the clinical relevance of any interaction seems likely to be small.

1. Tongia SK. Paracetamol augments the sotalol-induced bradycardia in man. *Indian J Physiol Pharmacol* (1982) 26, 97–8.

Beta blockers; Sotalol + Terfenadine

Episodes of torsade de pointes arrhythmia developed in a woman taking sotalol when terfenadine was added.

Clinical evidence, mechanism, importance and management

A 71-year-old woman with a history of atrial fibrillation was successfully treated with sotalol 80 mg twice daily. She started to take terfenadine 60 mg twice daily, and 8 days later developed repeated self-limiting episodes of torsade de pointes arrhythmia. On one occasion she required resuscitation. Both drugs were stopped and no further episodes of arrhythmia occurred 72 hours after temporary pacing was discontinued.[1]

It seems likely that what happened resulted from the additive effects of both drugs on the QT interval, which can lead to the development of torsade de pointes. This case confirms a previous mention of the possibility of this interaction.[2]

Although this seems to be the first report of this interaction, it is consistent with the known pharmacology of both drugs. Torsade de pointes is potentially life threatening, so the concurrent use of these two drugs should generally be avoided. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for a further discussion on the concurrent use of drugs that prolong the QT interval.

2. Woosley RL, Chen Y, Freiman JP, Gillis RA. Mechanism of the cardiotoxic actions of terfenadine. *JAMA* (1993) 269, 1532–6.

Beta blockers; Talinolol + Carbamazepine

Carbamazepine may modestly reduce the absorption of talinolol.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that the concurrent use of **carbamazepine** 600 mg daily and **talinolol** 100 mg daily for 18 days decreased the AUC of **talinolol** by about 15%. These changes were thought to be due to changes in the intestinal transport of **talinolol**, caused by **carbamazepine**-induced changes in the expression of the drug transporter protein MRP2. However, AUC changes of this magnitude are not of clinical relevance, and therefore no dosage alterations would be expected to be needed on concurrent use.[1]

1. Giessmann T, May K, Modess C, Wegner D, Hecker U, Zschiesche M, Dazert P, Grube M, Schroeder E, Warzok R, Cascorbi I, Kroemer HK, Siegmund W. Carbamazepine regulates intestinal P-glycoprotein and multidrug resistance protein MRP2 and influences disposition of talinolol in humans. *Clin Pharmacol Ther* (2004) 76, 192–200.

Beta blockers; Talinolol + St John's wort (*Hypericum perforatum*)

St John's wort modestly decreases the plasma levels of talinolol.

Clinical evidence

In a randomised study, a single oral dose of talinolol 50 mg was given to 9 healthy subjects after 12-days of St John's wort (Jarsin, Lichtwer Pharma) 900 mg daily. St John's wort was found to reduce the AUC and oral bioavailability of talinolol by about 31% and 25%, respectively. The non-renal clearance of a single dose of talinolol 30 mg given as a 30 minute infusion was increased by about 26%. Other pharmacokinetic parameters of both oral and intravenous talinolol were not significantly affected.[1]

Mechanism

Talinolol is a known substrate for P-glycoprotein. This study found that the levels of intestinal P-glycoprotein in the duodenal biopsy samples of 9 subjects were raised by St John's wort, leading to a reduction in the absorption of talinolol.

Importance and management

Information appears to be limited to this study but it is in line with the known effects of St John's wort on substrates of P-glycoprotein, such as digoxin (consider also 'Digoxin + St John's wort (*Hypericum perforatum*)', p.1115). The modest decrease in talinolol levels suggests that, in most patients, this interaction is unlikely to be clinically significant. Nevertheless, consider this interaction if blood pressure is difficult to control.

1. Schwarz UI, Hanso H, Oertel R, Miehlke S, Kuhlisch E, Glaeser H, Hitzl M, Dresser GK, Kim RB, Kirch W. Induction of intestinal P-glycoprotein by St John's wort reduces the oral bioavailability of talinolol. *Clin Pharmacol Ther* (2007) 81, 669–78.

Beta blockers; Talinolol + Sulfasalazine

Sulfasalazine markedly reduces the absorption of talinolol.

Clinical evidence

In a study in 8 healthy subjects the AUC of talinolol 50 mg was reduced by 91% by sulfasalazine 4 g. The maximum serum levels were also markedly reduced, from 112 nanograms/mL to 23 nanograms/mL in 3 subjects, and to undetectable levels in the other 5 subjects.[1]

Mechanism

Not known. It is suggested that talinolol is adsorbed onto the sulfasalazine, thereby preventing its absorption.[1]

Importance and management

Information is limited to this study, but it would appear to be an established and probably clinically important interaction. The efficacy of the talinolol would be expected to be markedly reduced, but this does not appear to have been studied. If the mechanism suggested by the authors is true, their advice to separate the dosages by 2 to 3 hours should minimise this interaction.[1] Nevertheless, it would still be prudent to monitor the outcome of concurrent use (e.g. blood pressure). More study is needed to confirm the clinical effects of the interaction, how effective separating the doses is, and whether other beta blockers behave similarly.

1. Terhaag B, Palm U, Sahre H, Richter K, Oertel R. Interaction of talinolol and sulfasalazine in the human gastrointestinal tract. *Eur J Clin Pharmacol* (1992) 42, 461–2.

Beta blockers; Talinolol + Surfactant excipients

The surfactant excipient d-α-Tocopheryl polyethylene glycol 1000 succinate (TPGS) increases the bioavailability of talinolol, whereas another surfactant poloxamer 188 has no effect.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects given talinolol 50 mg via nasogastric tube, either alone, with **d-α-tocopheryl polyethylene glycol 1000 succinate** (**TPGS**; 0.04%), or with **poloxamer 188** (0.8%), found that **TPGS** increased the peak plasma level and AUC of talinolol by 100% and 39%, respectively, probably by inhibition of intestinal P-glycoprotein. **Poloxamer 188** did not significantly affect the pharmacokinetics of talinolol.[1] No relevant changes in heart rate or blood pressure were noted with either surfactant, and the increase in talinolol levels caused by **TPGS** was only modest. Therefore a clinically relevant interaction seems unlikely.

1. Bogman K, Zysset Y, Degen L, Hopfgartner G, Gutmann H, Alsenz J, Drewe J. P–glycoprotein and surfactants: effect on intestinal talinolol absorption. *Clin Pharmacol Ther* (2005) 77, 24–32.

23

Calcium-channel blockers

This section is primarily concerned with those interactions where the activity of the calcium-channel blockers is changed by the presence of another drug. Where the calcium-channel blocker is the affecting drug, the relevant monograph is usually categorised under the heading of the affected drug.

Calcium-channel blockers in current clinical usage affect the slow L-type channel. They are usually classified by their chemical structure, which determines their selectivity for vascular smooth muscle over myocardium, and hence their potential to slow the heart rate (negative inotropic activity) see 'Table 23.1', (below). Interactions due to additive inotropic effects will therefore apply only to the benzothiazepine (diltiazem) and phenylalkylamine-type (verapamil) calcium-channel blockers, and usually not to the dihydropyridine-type (e.g. nifedipine) calcium-channel blockers. All three types of calcium-channel blocker will have additive hypotensive effects with other drugs with blood-pressure lowering activity.

Calcium-channel blockers also undergo interactions due to altered metabolism. Both verapamil and diltiazem are principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and also inhibit this enzyme (see 'Table 1.4', (p.6)). They are therefore affected by drugs that induce or inhibit CYP3A4, and also themselves interact with drugs metabolised by CYP3A4.

Many of the dihydropyridine-type calcium-channel blockers are also metabolised by CYP3A4, and are affected by inducers or inhibitors of this isoenzyme to varying degrees. However, they do not generally inhibit CYP3A4, or other isoenzymes to a clinically relevant extent. The exception is perhaps nicardipine, which may cause a clinically relevant inhibition of CYP3A4.

Mibefradil is a calcium-channel blocker that acts on the fast T-type calcium channel. It was withdrawn soon after it was launched because of identification of an increasing number of serious drug interactions caused by its inhibitory effects on CYP3A4 and CYP2D6. It was thought that the practical problems of implementing all the warnings relating to these interactions were too difficult and risky.

Table 23.1 Classification of calcium-channel blockers that act on slow L-type channels

Class	*Rate limiting?*	*Effect on AV or SA node*	*Examples*
Dihydropyridine	No	Little or none	Amlodipine, Barnidipine, Benidipine, Felodipine, Isradipine, Lacidipine, Lercanidipine, Manidipine, Nicardipine, Nifedipine, Nilvadipine, Nimodipine,† Nisoldipine, Nitrendipine
Benzothiazepine	Yes	Depression (negative inotropic activity)	Diltiazem
Phenylalkylamine	Yes	Depression (negative inotropic activity)	Gallopamil, Verapamil

†Nimodipine crosses the blood-brain barrier and therefore affects cerebral blood vessels, and is used for cerebral ischaemia.

Calcium-channel blockers + Aliskiren

Verapamil is predicted to raise aliskiren levels. The concurrent use of aliskiren and amlodipine does not result in any clinically significant pharmacokinetic changes. The use of aliskiren with calcium-channel blockers is expected to result in additive blood pressure lowering effects.

Clinical evidence, mechanism, importance and management

(a) Amlodipine

In a study, 18 healthy subjects were given amlodipine 10 mg daily and aliskiren 300 mg daily, either alone, or together for 2 weeks. Amlodipine increased the AUC of aliskiren by 29%, but there was no significant change in the maximum plasma level of aliskiren, although the time to maximum plasma concentration increased from 1 to 3 hours. The pharmacokinetics of amlodipine were not affected by aliskiren.[1] The UK manufacturers note that, in patients who did not adequately respond to amlodipine 5 mg, the addition of aliskiren 150 mg resulted in a lowering of the blood pressure similar to that achieved by giving amlodipine 10 mg.[2]

A change in the AUC of aliskiren of 29% would not be expected to be clinically relevant, and therefore the dose of aliskiren does not need to be adjusted in amlodipine is also given. However, as expected, the concurrent use of amlodipine with aliskiren results in additive effects on blood pressure: other calcium-channel blockers seem likely to interact in the same way.

(b) Verapamil

Aliskiren is a substrate of the transporter protein, P-glycoprotein. Potent inhibitors of P-glycoprotein have increased the exposure to aliskiren by up to fivefold. The UK manufacturers therefore contraindicate the use of any potent P-glycoprotein inhibitors, and specifically name verapamil.[2]

Calcium-channel blockers + Antihistamines

An isolated report describes increased adverse effects in two patients when terfenadine was given with nifedipine or verapamil. The manufacturers of lercanidipine advise caution with the concurrent use of astemizole and terfenadine. Verapamil markedly increased the AUC of a single dose of fexofenadine in one study, but another study found a much more modest effect. However, even a marked increase may not be clinically important. Diltiazem does not appear to affect the pharmacokinetics of fexofenadine. In one study no pharmacodynamic interaction occurred between diltiazem and mizolastine, and mizolastine did not alter diltiazem pharmacokinetics. Nifedipine is predicted to increase the levels of mizolastine.

Clinical evidence, mechanism, importance and management

(a) Fexofenadine

In a study in 12 healthy subjects **verapamil** 240 mg daily for 6 days increased the AUC of a single 120-mg dose of fexofenadine 2.5-fold and increased its maximum level 2.9-fold. There was marked interindividual variation in these effects.[1] Another study showed a smaller 30% increase in maximum level of fexofenadine when a single 60-mg dose was given to subjects who had taken **verapamil** 240 mg daily for 10 days. However, after 38 days of **verapamil**, the maximum level and clearance of fexofenadine was not significantly changed.[2] Fexofenadine is not metabolised by cytochrome P450, and it was suggested that **verapamil** may have increased fexofenadine bioavailability by inhibiting P-glycoprotein or OATPs, which are drug transporters.[1]

In another study, pretreatment with slow-release **diltiazem** did not affect the pharmacokinetics of fexofenadine.[3]

Note that fexofenadine has a relatively wide therapeutic range and marked increases in fexofenadine levels with 'erythromycin', (p.671) and 'ketoconazole', (p.665) did not increase adverse effects and were not associated with any prolongation of the QT interval. This suggests that a clinically relevant interaction between **verapamil** and fexofenadine is not expected, but some caution may be warranted until further experience is gained.

(b) Mizolastine

A double-blind, crossover study in 12 healthy subjects taking **diltiazem** 60 mg three times daily found that the concurrent use of mizolastine 10 mg daily for 5 days did not alter ECGs or blood pressures. No significant increases in adverse effects were seen and the pharmacokinetics of **diltiazem** remained unchanged. However, mizolastine pharmacokinetics were not assessed.[4] Some manufacturers of **nifedipine**[5] and mizolastine[6] suggest that concurrent use may raise mizolastine levels by inhibition of the cytochrome P450 isoenzyme CYP3A4, and caution is therefore advised,[6] presumably because mizolastine has a weak potential to prolong the QT interval. If caution is required with **nifedipine**, then this should be extended to both **diltiazem** and **verapamil**, since these are both moderate inhibitors of CYP3A4. Further study is needed. However, note that nifedipine is not usually known to interact by inhibiting CYP3A4.

(c) Terfenadine and Astemizole

An isolated report describes severe angina in a patient taking **nifedipine** 10 mg three times daily when she took terfenadine 60 mg for seasonal allergy. A second patient taking **verapamil** 80 mg three times daily also experienced adverse effects (including severe headache and confusion) after taking a single 60-mg dose of terfenadine.[7] **Verapamil**, **diltiazem**, and to a lesser extent **nicardipine** are inhibitors of CYP3A4, but there appear to be no other reports of interactions with terfenadine or astemizole (both substrates of CYP3A4). Of all the calcium-channel blockers, only the UK manufacturer of **lercanidipine** advises caution during the concurrent use of terfenadine and astemizole;[8] however, lercanidipine does not appear to inhibit CYP3A4, and therefore an interaction, at least by this mechanism, seems unlikely.

Calcium-channel blockers + Aprepitant

The concurrent use of aprepitant and diltiazem increases the levels of both drugs. Fosaprepitant moderately raises diltiazem levels. It seems likely that verapamil will interact with both drugs in the same way as diltiazem.

Clinical evidence

The US manufacturer notes that the use of aprepitant 230 mg daily with **diltiazem** 120 mg three times daily for 5 days increased the AUC of aprepitant twofold and increased the AUC of **diltiazem** by 70% in patients with hypertension. Nevertheless, aprepitant did not alter the effects of **diltiazem** on heart rate or blood pressure.[1] The UK manufacture of fosaprepitant notes that when subjects with mild to moderate hypertension were given a 100-mg infusion of fosaprepitant with **diltiazem** 120 mg three times daily, the AUC of **diltiazem** was increased by 40%, and the AUC of **fosaprepitant** was increased by 50%. A small but clinically meaningful decrease in blood pressure occurred, but the heart rate and PR interval were not affected to a clinically relevant extent.[2]

Mechanism

Both aprepitant, its prodrug fosaprepitant, and diltiazem are substrates and inhibitors of the cytochrome P450 isoenzyme CYP3A4. Concurrent use therefore inhibits the metabolism of the other drug. The effects on fosaprepitant may be smaller because it is given intravenously.

Importance and management

Evidence appears to be limited to these two, apparently unpublished studies by the manufacturers, but the findings are in line with the known effects of the drugs. The manufacturer of aprepitant[1] recommends caution if moderate inhibitors of CYP3A4 are also given, and this would be expected to include diltiazem. Although the effects of diltiazem were not increased in the study with aprepitant, the smaller rise that occurred with fosaprepitant did have some clinically relevant effects on blood pressure, and it may therefore be prudent to be aware of a potential decrease in blood pressure if either of these antiemetics is given to a patient taking diltiazem.

It may be prudent to consider giving the lower dose of aprepitant, where possible, as a twofold increase in its levels is likely to be clinically significant. Be alert for adverse effects such as hiccups, fatigue, constipation, and headache. Furthermore, the CYP3A4 inhibitory effects are dose-dependent and using a smaller dose may minimise the effects on diltiazem. The rise in fosaprepitant levels is not expected to be clinically significant.

Evidence about other calcium-channel blockers is lacking, but note that **verapamil** is also a moderate CYP3A4 inhibitor, and therefore would be expected to interact similarly.

Calcium-channel blockers + Aspirin or NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, although some studies have not found the increase to be clinically relevant. Some small pharmacokinetic interactions may occur, but they do not appear to be clinically relevant.

Some small studies suggest that low-dose aspirin does not alter the antihypertensive effect of felodipine, isradipine, nifedipine or nitrendipine, and long-term aspirin did not alter the cardiovascular benefits of nitrendipine.

Two reports describe abnormal bruising and prolonged bleeding times in two patients and one healthy subject taking verapamil with aspirin. There are conflicting reports as to whether or not gastrointestinal bleeding is increased by giving NSAIDs with calcium-channel blockers.

One report suggests that calcium-channel blockers, particularly nifedipine, may increase the risk of acute renal failure associated with NSAIDs.

Table 23.2 Summary of epidemiological studies and meta-analyses of the effect of NSAIDs on blood pressure in patients taking antihypertensive drugs

Study type	*Patients*	*Antihypertensives*	*NSAIDs*	*Findings*	*Refs*
Case-control (2005)	184 cases 762 controls (UK primary care)	Not stated. Median of two different drugs	Ibuprofen (78 cases) Diclofenac (60) Other (25)	BP control in treated hypertensives was not affected by use of NSAIDs. No evidence that either systolic BP or diastolic BP differed according to type of NSAID.	1
Retrospective analysis (2004)	8538 patients with rheumatic disease and hypertension	Not stated	NSAID (1164 patients) Celecoxib (654) Rofecoxib (417)	NSAID or celecoxib use was not associated with difficulty in controlling blood pressure, but rofecoxib use was (odds ratio 1.38).	2
Meta-analysis (1994)	50 randomised controlled studies in 771 patients or healthy subjects	Beta blockers (15) Vasodilators (18) Diuretics (12)	Indometacin (33 studies) Sulindac (7) Ibuprofen (5) Piroxicam (4) Flurbiprofen (4)	NSAIDs elevated mean supine BP by 5 mmHg. NSAIDs antagonised all antihypertensives, but only the effect on beta blockers was statistically significant (6.2 mmHg). Among the NSAIDs, only the effect of piroxicam was statistically significant, with piroxicam, indometacin and ibuprofen causing the greatest increase, and sulindac and flurbiprofen the least.	3
Case-control (1993)	133 cases 133 controls	Hydrochlorothiazide, furosemide, methyldopa, propranolol	Ibuprofen (30% of cases) Indometacin (22%) Naproxen (18%) Sulindac (13%)	Systolic BP was about 5 mmHg higher (not statistically significant) in those taking NSAIDs, but diastolic BP did not differ. Findings the same if indometacin users removed.	4
Cross-sectional cohort (1993)	2800 elderly patients (12% taking both an NSAID and antihypertensives)	Not stated	Not stated	NSAID use was associated with a 29% increased risk of hypertension in those taking antihypertensives, but not in those not taking antihypertensives.	5
Meta-analysis (1993)	54 studies with 108 NSAID treatment arms in 1213 hypertensive patients	Not stated	Indometacin (600 patients) Naproxen (72) Piroxicam (51) Ibuprofen (55) Sulindac (277)	Increase in mean arterial pressure with indometacin 3.6 mmHg, naproxen 3.7 mmHg, piroxicam 0.5 mmHg, decrease in mean arterial pressure with ibuprofen 0.8 mmHg, sulindac 0.16 mmHg. The difference between indometacin and sulindac was statistically significant.	6

Clinical evidence

A. Antagonism of antihypertensive effects

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking antihypertensives, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both COX-2 inhibitors and non-selective NSAIDs. In two meta-analyses,[1,2] the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.[2] Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,[1] the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,[2] the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by antihypertensive in one analysis.[1] The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for diuretics. However, the differences between the groups were not significant.

The findings of individual clinical and pharmacological studies that have studied the effects of aspirin or specific NSAIDs on specific calcium-channel blockers are outlined in the subsections below.

(a) Aspirin

1. Felodipine. In the Hypertension Optimal Treatment (HOT) study, 18 790 treated hypertensive patients, about 82% of whom were taking a calcium-channel blocker, usually felodipine alone or in combination, were also given either aspirin 75 mg daily or placebo for an average of 3.8 years. It was found that long-term, low-dose aspirin does not interfere with the blood pressure lowering effects of the antihypertensive drugs studied.[3]

2. Isradipine. A study in 20 patients with essential hypertension, who had been taking isradipine 2.5 mg daily for 8 weeks found that the addition of aspirin 100 mg daily for a further 8 weeks did not affect the antihypertensive efficacy of the calcium-channel blocker.[4]

3. Nifedipine. In a small study in 18 patients, low-dose aspirin 100 mg daily for 2 weeks did not alter the blood pressure lowering effect of nifedipine 30 to 60 mg daily, given as a modified-release preparation.[5]

4. Nitrendipine. A study in 19 patients with essential hypertension, who had taken nitrendipine 10 mg daily for 8 weeks found that the addition of aspirin 100 mg daily for a further 8 weeks did not affect the antihypertensive efficacy of the calcium-channel blocker.[4] A post-hoc analysis of the Syst-Eur study of nitrendipine-based antihypertensive treatment found no difference in cardiovascular outcome between 861 patients who were also taking long-term aspirin (700 patients) and/or other NSAIDs (161 patients) and 2882 patients who had never taken aspirin or NSAIDs. Patients in this study were randomised to receive nitrendipine, which could be combined or replaced by enalapril, hydrochlorothiazide, or both.[6]

5. Unnamed calcium-channel blockers. In a randomised study, the use of low-dose aspirin 100 mg daily for 3 months did not alter blood pressure control in patients taking calcium-channel blockers or ACE inhibitors, when compared with placebo.[7]

(b) Diclofenac

A study in elderly women with hypertension found that diclofenac 25 mg three times daily for one week had no effect on the control of their blood pressure with **nifedipine**.[8] In 18 healthy subjects, the AUC of **isradipine** 5 mg twice daily for a week was not affected by a single 50-mg dose of diclofenac, but the maximum plasma levels were raised by a modest 20%. Platelet aggregation was unaffected and the pharmacokinetics of the diclofenac were unchanged.[9] Hypertensive subjects taking slow-release **verapamil** 240 mg daily had a 26% reduction in the AUC of **verapamil** when they took diclofenac 75 mg twice daily.[10]

(c) Ibuprofen

A study in 12 patients with mild or moderate essential hypertension controlled with **amlodipine** 10 mg daily, found that ibuprofen 400 mg three times daily for 3 days increased the mean blood pressure by 7.8/3.9 mmHg.[11] However, 53 hypertensive patients had no changes in their blood pressure control with **verapamil** 240 or 480 mg daily when they also took ibuprofen 400 mg three times daily for 3 weeks.[12]

(d) Indometacin

In a study in 10 patients with mild to moderate essential hypertension indometacin 100 mg daily for a week did not significantly affect the hypotensive effects of **nifedipine** 20 mg twice daily.[13] In contrast, in another study, indometacin 100 mg in divided doses over 24 hours was found to raise the mean arterial pressure by 17 to 20 mmHg in 5 out of 8 hypertensive patients taking **nifedipine** 15 to 40 mg daily.[14]

Five other studies, two in healthy subjects[15,16] and 3 in patients with hypertension[17-19] found that indometacin did not alter the blood pressure lowering effects of **amlodipine**,[19] **felodipine**,[15,17] **nicardipine**[16] or **verapamil**.[18] Similarly, in 24 healthy elderly subjects, the haemodynamic effects of **nimodipine** 30 mg three times daily were not affected to a clinically relevant extent by indometacin 25 mg twice daily in, although the AUC of **nimodipine** and its maximum plasma levels were slightly increased.[20] However, in 15 patients taking **nitrendipine** 5 to 20 mg twice daily, indometacin 25 mg three times daily raised systolic and diastolic blood pressure by a mean of 4 mmHg.[21]

(e) Naproxen

A placebo-controlled study in 100 patients taking **nicardipine** 30 mg three times daily found that naproxen 375 mg twice daily caused no clinically relevant changes in the control of their blood pressure.[22] In another study, 55 hypertensive patients had no changes in their blood pressure control with **verapamil** 240 to 480 mg daily when they were given naproxen 250 mg twice daily for 3 weeks.[12] Similarly, naproxen 375 mg twice daily had no effect on the pharmacokinetics of **verapamil** in hypertensive subjects.[10]

(f) Piroxicam

A study in hypertensive patients given up to 440 mg of **verapamil** daily found that piroxicam 20 mg daily for 4 weeks did not significantly alter the antihypertensive effects of **verapamil**.[23]

(g) Sulindac

A study in elderly women with hypertension found that sulindac 100 mg three times daily for one week had no effect on the control of their blood pressure with **nifedipine**.[8]

A study in hypertensive patients given up to 440 mg of **verapamil** daily found that sulindac 200 mg twice daily for 4 weeks did not significantly alter the antihypertensive effects of **verapamil**.[23]

B. Antiplatelet effects and gastrointestinal bleeding

Abnormal bruising and prolonged bleeding times occurred in a woman taking **verapamil** 80 mg three times daily when she took **aspirin** 650 mg several times a week for headaches. The bruising ceased when the **verapamil** was stopped. Her normal bleeding time of 1 minute rose to 4.5 minutes while she was taking **verapamil**, and to 9 minutes while she was taking **verapamil** and **aspirin**. A healthy subject taking the same doses of **verapamil** and **aspirin** noticed the appearance of new petechiae and her bleeding time rose from 4.5 minutes to more than 15 minutes in the presence of both drugs.[24] An 85-year-old man taking enteric-coated **aspirin** 325 mg daily developed widespread and serious ecchymoses of his arms and legs and a retroperitoneal bleed about 3 weeks after starting to take **verapamil** 240 mg daily.[25]

A prospective cohort study[26] in 1636 elderly hypertensive patients, and a case-control study,[27] found that calcium-channel blockers were associated with an increased risk of gastrointestinal bleeding, when compared with beta blockers. In one of the studies, **verapamil** was associated with the highest rate of bleeding, followed by **diltiazem** and **nifedipine**.[26] However, two other studies indicated that gastrointestinal bleeding was not increased by calcium-channel blockers.[28,29] Furthermore, a post-hoc analysis of the Syst-Eur data found that there was no interaction between chronic NSAID intake (81% **aspirin**) and antihypertensive use (based on **nitrendipine**) in terms of the incidence of gastrointestinal bleeding. In fact, the results suggested that chronic NSAID use tended to be associated with a *lower* incidence of bleeding in patients taking **nitrendipine**-based therapy than those receiving placebo.[6]

C. Effects on renal function

A case-control study using the UK General Practice Research Database found that current NSAID use increased the risk of acute renal failure (relative risk 3.2 compared with non-NSAID use) and this risk was further increased by the concurrent use of a calcium-channel blocker (relative risk 7.8); **nifedipine** appeared to be most likely to interact.[30]

Mechanism

A. Antagonism of antihypertensive effects

There is some evidence that NSAIDs may increase blood pressure in patients taking antihypertensives. Possible explanations for this include inhibition of vasodilator and natriuretic prostaglandins in the kidney and/or a decrease in vascular or endothelial prostaglandin synthesis, resulting in salt retention and vasoconstriction.[31] In contrast, low-dose aspirin appears not to affect the blood pressure lowering effects of calcium-channel blocker-based antihypertensive therapy.[3]

B. Antiplatelet effects and gastrointestinal bleeding

The prolonged bleeding times noted with verapamil[24] may occur as a result of inhibition of platelet aggregation, because calcium-channel blockers interfere with the movement of calcium ions through cell membranes, which can affect platelet function. This appears to be additive with the effects of other antiplatelet drugs. It was suggested that vasodilation produced by calcium-channel blockers in conjunction with inhibition of platelet aggregation may increase the risk of bleeding, or at least prevent the normal vasoconstrictive response to bleeding,[26] although a protective effect of beta blockers rather than an adverse effect of calcium-channel blockers may also be the reason.[28]

C. Effects on renal function

It has been suggested that the increased adverse renal effects seen when NSAIDs are given with nifedipine may be due to nifedipine-induced potential afterload reduction (renal hypoperfusion) secondary to an excess decrease in blood pressure, particularly among the elderly. However, the use of cardiac medications might also be markers of underlying conditions such as cardiovascular disease, low circulating plasma volume and/or already compromised renal function.[30]

Importance and management

Although several studies exist, the evidence for an interaction between the calcium-channel blockers and NSAIDs or aspirin is still somewhat inconclusive. Some consider that the use of NSAIDs should be kept to a minimum in patients taking antihypertensives. The effects may be greater in the elderly and in those with relatively high blood pressure, as well as in those with a high salt intake.[32] However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.[33] While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs (e.g. poor compliance or 'white-coat' hypertension).[33] There is insufficient data at present to clearly differentiate between NSAIDs. However, there is some limited evidence to suggest that the interaction of NSAIDs with calcium-channel blockers is less than that with ACE inhibitors.[5,17,19] For the effects of NSAIDs on other antihypertensive drugs, see 'ACE inhibitors', (p.32), 'beta blockers', (p.997) and 'thiazide diuretics', (p.1138).

The risk of renal failure with NSAIDs appears to be increased in patients taking calcium-channel blockers, particularly nifedipine, but it is not clear whether this is due to the drugs or the disease state. A low circulating plasma volume can increase the risk of adverse renal effects and so caution has been suggested in the elderly, especially in patients with hypertension and/or heart failure.[30]

Clinically significant interactions between NSAIDs and calcium-channel blockers that result in bleeding appear to be rare.

Calcium-channel blockers + Azoles

Itraconazole can markedly raise the serum levels of felodipine, which increases its adverse effects, in particular ankle and leg oedema. A few case reports suggest that isradipine and nifedipine can interact similarly with itraconazole, and that fluconazole can also interact with nifedipine. Ketoconazole can markedly raise the plasma levels of lercanidipine and nisoldipine. Caution is warranted with calcium-channel blockers when azole antifungals, particularly itraconazole and ketoconazole, are used.

Clinical evidence

(a) Felodipine

In a placebo-controlled study in 9 healthy subjects, **itraconazole** 200 mg daily for 4 days, increased the AUC of a single 5-mg dose of felodipine sixfold, and its maximum plasma levels were increased eightfold. The effects of the felodipine on blood pressure and heart rate were also increased.[1]

A 52-year-old woman, who had been taking felodipine 10 mg daily for hypertension for a year, without problems, developed ankle and leg swell-

ing within 7 days of starting **itraconazole** 100 mg daily for tinea pedis. The oedema disappeared within 2 to 4 days of stopping the **itraconazole**.[2] Virtually the same reaction occurred in another woman taking both drugs. Later tests found that her AUC_{0-6} of a single 5-mg dose of felodipine was increased at least fourfold (possibly up to tenfold) while taking **itraconazole**, and ankle swelling was noted.[2]

(b) Isradipine

Ankle swelling was noted in a patient taking isradipine 5 mg daily when **itraconazole** 200 mg twice daily was also taken.[2]

(c) Lercanidipine

The manufacturer of lercanidipine notes that an interaction study found that **ketoconazole** increased the AUC of *S*-lercanidipine and its peak plasma levels 15-fold and eightfold, respectively.[3]

(d) Nifedipine

A report describes massive pitting oedema in the legs and ankles of a patient taking nifedipine when **itraconazole** 100 mg twice daily was also taken.[4] Another patient similarly had ankle oedema and markedly raised serum nifedipine levels (trough levels raised almost fivefold) while taking **itraconazole**.[5] A patient with malignant phaeochromocytoma, whose persistent hypertension was controlled with nifedipine, had a rise in blood pressure when **fluconazole** 200 mg daily was *stopped*. His blood pressure fell again when the **fluconazole** was restarted. A later study found that his maximum nifedipine plasma levels and AUC_{0-5} were raised about threefold by **fluconazole**.[6]

(e) Nisoldipine

A study in 7 healthy subjects found that **ketoconazole** 200 mg daily for 5 days increased the AUC and peak plasma levels of a single 5-mg dose of nisoldipine 24-fold and 11-fold, respectively. The levels of nisoldipine metabolite were similarly increased.[7]

Mechanism

Ankle swelling due to precapillary vasodilatation is a relatively common adverse effect of the dihydropyridine calcium-channel blockers, and this effect appears to be dose-related. Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A subfamily of isoenzymes, which are inhibited by itraconazole, ketoconazole and to a lesser extent by fluconazole. Therefore in the presence of these antifungals the levels of the calcium-channel blockers are raised and their adverse effects increased.

Importance and management

The interaction between felodipine and itraconazole would appear to be established and clinically important. It also seems that isradipine, lercanidipine, nifedipine and nisoldipine can interact similarly with itraconazole, ketoconazole, and possibly fluconazole. It is likely that all calcium-channel blockers will behave in the same way, although probably to a greater or lesser extent. Note that fluconazole is only likely to interact in doses of greater than 200 mg daily (see under 'azole antifungals', (p.233)).

Other azoles such as **posaconazole**, which is a potent inhibitor of CYP3A4, and **voriconazole** would be expected to interact similarly. Note that, at the maximum doses **miconazole** oral gel is sufficiently absorbed to potentially have systemic effects, and may therefore also interact. If any of these azoles is given to a patient on established treatment with a calcium-channel blocker be alert for the need to lower the dosage of the calcium-channel blocker. It would seem prudent to monitor for adverse effects, such as hypotension, headache, flushing, and oedema. However, note that the UK manufacturer of lercanidipine[3] specifically contraindicates the concurrent use of itraconazole or ketoconazole.

Calcium-channel blockers + Bile-acid binding resins

Colesevelam slightly reduces the bioavailability of verapamil, and colestipol slightly reduces the bioavailability of diltiazem.

Clinical evidence, mechanism, importance and management

(a) Colesevelam

A study in 31 healthy subjects found that a single 4.5-g dose of colesevelam reduced the peak plasma levels and AUC of a single 240-mg dose of **verapamil** by about 33% and about 15%, respectively. These changes were not considered to be clinically significant.[1]

(b) Colestipol

A study in 12 healthy subjects found that colestipol reduced the AUC and peak plasma levels of a single 120-mg dose of sustained-release **diltiazem** by 22% and 36%, respectively, and those of a single 120-mg dose of immediate-release **diltiazem** by 27% and 33%, respectively. In a further study sustained-release **diltiazem** 120 mg was given alone, 1 hour before or 4 hours after multiple doses of colestipol. The AUC of **diltiazem** was decreased by 17% when it was taken 1 hour before colestipol and by 22% when taken 4 hours after colestipol. This suggests that the effects of colestipol on **diltiazem** bioavailability are not reduced by separating their administration. However, these small reductions in the AUC of **diltiazem** are unlikely to result in a reduction in its efficacy. Nevertheless, the authors advise caution if these drugs are used concurrently.[2]

Calcium-channel blockers + Calcium-channel blockers

Plasma levels of both nifedipine and diltiazem are increased by concurrent use and blood pressure is reduced accordingly. Verapamil is predicted to interact similarly with nifedipine. Amlodipine levels are raised by diltiazem (and therefore possibly verapamil). There are isolated reports of intestinal occlusion attributed to the concurrent use of nifedipine and diltiazem. Note that if nimodipine is used with another calcium-channel blocker, the hypotensive effect may be increased and careful monitoring is recommended.

Clinical evidence

Pretreatment of 6 healthy subjects with **diltiazem** 30 or 90 mg three times daily for 3 days was found to increase the AUC of a single 20-mg dose of **nifedipine** two- and threefold, respectively.[1] Similar and related results are reported elsewhere.[2,3] In another study it was found that **nifedipine** 10 mg three times daily for 3 days increased the maximum plasma levels of a single 60-mg dose of **diltiazem** by 54% and increased its AUC by 49%.[4]

One of the manufacturers of **amlodipine** briefly mentions that, in elderly patients, **diltiazem** increases the levels of **amlodipine** by 50%, and this is accompanied by an increase in its effects.[5]

A patient taking **nifedipine** 20 mg twice daily developed abdominal distension and vomiting, 2 days after starting to take **diltiazem** 100 mg twice daily. Both calcium-channel blockers were stopped and abdominal X-ray suggested paralytic ileus, which resolved, but then recurred when both drugs were restarted.[6] Another report describes a patient taking diltiazem, who developed complete or partial intestinal occlusion on three occasions, each time when **nifedipine** was added.[7]

Mechanism

The increase in nifedipine and diltiazem levels is thought to occur as a result of a reduction in the metabolism of both drugs in the liver.[4] It has been suggested that an increased relaxant effect on smooth muscle resulted in

intestinal occlusion,[7] and this may related to increased the increased nifedipine levels.[6]

Importance and management

Established interactions but of uncertain clinical importance. Some manufacturers of nifedipine advise caution when it is used with diltiazem because of possible increases in nifedipine levels.[8,9] They say a reduction in the dose of nifedipine should be considered.[9] **Verapamil** is likely to interact similarly with nifedipine,[9] as it has similar effects to diltiazem on hepatic metabolism. Some caution may also be prudent if diltiazem or, in theory, verapamil are given with amlodipine. Consider increasing blood pressure monitoring.

Information about the use of combinations of other calcium-channel blockers appears to be lacking. However, the manufacturers of **nimodipine**[10,11] warn that the blood pressure lowering effect of other calcium-channel blockers could be enhanced by the addition of nimodipine: the UK manufacturer[10] advises careful monitoring of the patient.

Note that the clinical use of two calcium-channel blockers is rarely justified and consideration should be given to stopping one or other of the drugs, as appropriate.

Calcium-channel blockers + Calcium compounds

An isolated report describes antagonism of the antiarrhythmic effects of oral verapamil due to the use of oral calcium. Note that intravenous calcium compounds are sometimes given before intravenous verapamil, where the hypotensive effects of verapamil would be detrimental, and calcium has been used to reverse the effects of calcium-channel blocker overdose.

Clinical evidence, mechanism, importance and management

An elderly woman with atrial fibrillation, successfully treated for over a year with **verapamil**, developed atrial fibrillation within a week of starting to take an oral calcium compound 1.2 g with calciferol (vitamin D) 3000 units daily for diffuse osteoporosis. Her serum calcium levels had risen from 2.45 to 2.7 mmol/L. Normal sinus rhythm was restored by giving 500 mL of sodium chloride 0.9% and repeated doses of furosemide 20 mg and **verapamil** 5 mg by intravenous injection.[1]

Verapamil acts by inhibiting the passage of calcium ions into cardiac muscle cells and it would appear that in this case the increased concentration of calcium ions outside the cells opposed the effects of the **verapamil**.

The general importance of this isolated case is uncertain, but bear it in mind in the event of an unexpected reduction in **verapamil** effects.

Note that intravenous calcium compounds are sometimes given before intravenous verapamil in the treatment of ventricular arrhythmias to prevent verapamil-induced hypotension in situations where this could be detrimental. This is said not to affect the antiarrhythmic efficacy.[2] Calcium, usually in the form of intravenous calcium gluconate, is used as an antidote in cases of overdose of calcium-channel blockers.

There therefore seems no reason to avoid the use of calcium in patients taking calcium-channel blockers, but, if the effects of the calcium-channel blocker are diminished, it may be prudent to consider monitoring serum calcium levels.

Calcium-channel blockers + Clonidine

Two hypertensive patients taking verapamil developed complete heart block after they also started to take clonidine. The hypotensive effects of nifedipine and clonidine were additive in hypertensive patients. Transdermal clonidine has been successfully used with nifedipine or diltiazem in small studies.

Clinical evidence

(a) Diltiazem

In a clinical study, transdermal clonidine decreased blood pressure in 58 of 60 patients with hypertension inadequately controlled by sustained-release diltiazem 90 mg twice daily. The addition of clonidine did not cause a significant decrease in heart rate.[1]

(b) Nifedipine

In a study in 12 patients, sustained-release clonidine 250 micrograms daily for 2 weeks increased the hypotensive effects of nifedipine 20 mg twice daily by about 5 mmHg (mean blood pressure reduction). Clonidine did not alter the slight heart rate increase seen with nifedipine.[2] In a clinical study, in 39 patients with hypertension inadequately controlled by nifedipine GITS (gastrointestinal therapeutic system) 30 to 60 mg daily, transdermal clonidine successfully decreased blood pressure in all 35 patients who completed a titration phase and then an 8-week maintenance phase.[3]

(c) Verapamil

A 54-year-old woman with refractory hypertension (blood pressure 240/140 mmHg) and hyperaldosteronism, was given verapamil 160 mg three times daily and spironolactone 100 mg daily for 10 days, and had a reduction in her blood pressure to 180/100 mmHg. Clonidine 150 micrograms twice daily was then added, and after the second dose she became confused and her blood pressure was found to have fallen to 90/70 mmHg, with a heart rate of 50 bpm. She had developed complete AV block, which resolved when all the drugs were stopped. A 65-year-old woman with persistent hypertension did not have a satisfactory reduction in blood pressure with extended-release verapamil 240 mg daily (blood pressure 165/100 mmHg). Clonidine 150 micrograms twice daily was then added, and the next day a routine ECG showed that she had a nodal rhythm of 80 bpm, which developed into complete AV block. Her blood pressure had fallen to 130/80 mmHg.[4]

Mechanism

Not fully understood. Verapamil very occasionally causes AV node disturbances, but both of these patients had normal sinus rhythm before the clonidine was added. Clonidine alone has been associated with AV node dysfunction in hypertensive patients. It would seem, therefore, that these effects were additive in these two patients.[4]

Importance and management

Information about the interaction between verapamil and clonidine seems to be limited to the one report.[4] Its authors say that a review of the literature from 1966 to 1992 revealed no reports of any adverse interactions between these drugs. Nonetheless, they suggest that it would now be prudent to give these two drugs together with caution and good monitoring in any patient, even in those without sinus or AV node dysfunction.

There was no adverse effect on heart rate in one study in patients taking diltiazem and using transdermal clonidine and the additive blood pressure lowering effect seen with nifedipine is what would be expected with the use of clonidine and any calcium-channel blocker. One US manufacturer of clonidine warns about the potential for additive effects such as bradycardia and AV block if calcium-channel blockers are also given;[5] however, this seems most likely to be a problem with diltiazem or verapamil,

rather than the dihydropyridine-type calcium-channel blockers (see 'Table 23.1', (p.1025)).

Calcium-channel blockers + Dantrolene

An isolated report describes acute hyperkalaemia and cardiovascular collapse when intravenous dantrolene was given to a patient taking verapamil. Another case describes severe hyperkalaemia in a patient taking diltiazem when intravenous dantrolene was given. *Animal* studies have found similar effects with the combination of dantrolene and verapamil or diltiazem. Nifedipine and amlodipine do not appear to interact.

Clinical evidence, mechanism, importance and management

(a) Diltiazem

A case report describes a 42-year-old patient who developed severe hyperkalaemia after being given an intravenous infusion of dantrolene sodium 200 mg, before the induction of anaesthesia for coronary artery bypass grafting. Preoperatively, the patient was taking metoprolol twice daily and diltiazem 30 mg every 6 hours.[1] One *animal* study also suggests that diltiazem may sometimes interact with dantrolene to produce hyperkalaemia and cardiovascular collapse.[2] Note that, in the UK the use of diltiazem with dantrolene infusion is generally contraindicated because the combination of a calcium-channel blocker and dantrolene is said to be potentially dangerous.

(b) Verapamil

A case report describes a 60-year-old man with insulin-dependent diabetes undergoing a right hemicolectomy. Due to inoperable coronary artery disease, which was causing angina pain, he was taking verapamil 80 mg three times daily. On the morning of surgery he was given verapamil 80 mg with his pre-operative sedation and then, 2 hours later at the start of surgery, he was given intravenous dantrolene 220 mg over 30 minutes, because he was known to have previously had malignant hypertension. After surgery, when he was in intensive care, it was found that his potassium had risen from 4.6 mmol/L before surgery to 6.1 mmol/L at the end of surgery (about 90 minutes after the dantrolene infusion). He was given 10 units of insulin, but an hour later his potassium was 7.1 mmol/L. He was given more insulin, but then developed metabolic acidosis and some cardiac depression, which resolved when he was given bicarbonate and hetastarch 5%. He received three further doses of dantrolene without incident.[3]

The authors of the report attributed the effects seen to an interaction between verapamil and dantrolene. They note that hyperkalaemia has been seen following dantrolene infusions, but the case they cite in support of this suggestion actually describes hyperkalaemia in response to *suxamethonium*. Furthermore, the UK and US manufacturers of dantrolene do not include hyperkalaemia as an adverse effect.[4,5] Nevertheless, the overall picture is that hyperkalaemia, of whatever cause, can apparently increase the myocardial depression caused by verapamil.[6,7] This case seems to be the only report of an interaction between verapamil, and several factors do not make this a clear-cut case of an interaction. However, hyperkalaemia and cardiovascular collapse have been seen in *pigs* and *dogs* given dantrolene and verapamil,[8-10] and so an interaction cannot be completely ruled out. The manufacturers of dantrolene recommend that the combination of intravenous dantrolene sodium and calcium-channel blockers, such as verapamil, is not used during the management of malignant hyperthermia crisis,[4,5] and one manufacturer of verapamil contraindicates intravenous dantrolene.[11]

(c) Miscellaneous

Studies suggest that **amlodipine**[6] and **nifedipine**[2] do not interact with dantrolene and they may therefore be safer alternatives to diltiazem or verapamil. In the case above with verapamil[3] the patient later underwent further surgery while taking **nifedipine**, without any significant adverse effect (although the potassium was moderately raised at 5.4 mmol/L).

Calcium-channel blockers + Diuretics

No pharmacokinetic interaction appears to occur between hydrochlorothiazide and diltiazem or isradipine. Similarly, spironolactone does not alter the pharmacokinetics of felodipine. Combinations of diuretics and calcium-channel blockers are used clinically for their additive antihypertensive effects.

Clinical evidence, mechanism, importance and management

A study in 21 healthy subjects given **diltiazem** 60 mg four times daily (for 21 doses) and **hydrochlorothiazide** 25 mg twice daily (for 11 doses), either alone or in combination, found that at steady-state there was no clinically significant pharmacokinetic interaction between the two drugs.[1] **Diltiazem** and **verapamil** increase the levels of **eplerenone**, and dosage adjustments are recommended, see 'Potassium-sparing diuretics; Eplerenone + CYP3A4 inhibitors', p.1135.

The pharmacokinetics of **isradipine** and **hydrochlorothiazide** are not affected by concurrent use,[2,3] and **spironolactone** 50 mg was found not to affect either the pharmacokinetics or the clinical effects of **felodipine**.[4]

Amlodipine was found to be effective (13/11 mmHg fall in blood pressure) with an acceptable safety profile when added to **hydrochlorothiazide** in patients with inadequately controlled hypertension.[5] The manufacturers say that **amlodipine** has been safely given with **thiazides** and no dosage adjustment of **amlodipine** is required.[6,7]

Additive antihypertensive effects are expected when diuretics such as **hydrochlorothiazide** are used in combination with calcium-channel blockers, and such combinations are used clinically.

Calcium-channel blockers + Food

Some modified-release preparations of felodipine, nifedipine, and nisoldipine show markedly increased levels when given with food, particularly high-fat food. The bioavailability of lercanidipine is markedly increased and the absorption of manidipine is improved by food. Food modestly decreases the rate and extent of absorption of nimodipine capsules and food also modestly decreases the peak level of nicardipine. Food does not appear to

have a clinically significant effect on the absorption of amlodipine, diltiazem, isradipine, or verapamil.

Clinical evidence

(a) Amlodipine

There was no difference in rate or extent of absorption of amlodipine capsules between the fed and fasted state in a study in healthy subjects.[1] Similarly, another study in healthy subjects found that a high-fat meal had no effect on the bioavailability of amlodipine.[2]

(b) Diltiazem

The rate and extent of absorption of both a slow-release and a conventional tablet of diltiazem were unaffected by food in healthy subjects.[3] Similarly, in a study in healthy subjects, the pharmacokinetic parameters of another sustained-release formulation of diltiazem (*Mono-Tildiem LP*) showed only minor changes when given with food.[4]

(c) Felodipine

The manufacturer of one prolonged-release tablet of felodipine (*Vascalpha*) notes that taking it with a high-fat meal markedly increased the maximum level (2- to 2.5-fold) without altering the extent of absorption.[5]

(d) Isradipine

Compared with the fasted state, the pharmacokinetic parameters of isradipine differed by less than 20% when modified-release and standard-release formulations of isradipine were given with a light meal.[6]

(e) Lercanidipine

The manufacturer notes that the oral bioavailability of lercanidipine is increased fourfold when it is taken up to 2 hours after a high-fat meal.[7]

(f) Manidipine

In a study in 12 healthy subjects, the bioavailability of single 20-mg dose of manidipine was increased by 42% when given after a standard breakfast rather than in the fasting state. Peak plasma levels were increased by about 25% by food (not statistically significant), and the rate of absorption was unaffected.[8]

(g) Nicardipine

Nicardipine peak plasma levels are reduced by 30% when given with a high-fat meal.[9] When a sustained-release preparation of nicardipine (*Cardene SR*) was given with a high-fat breakfast, the mean maximum plasma concentration was 45% lower, the AUC was 25% lower and trough levels were 75% higher, compared with the fasting state.[10]

(h) Nifedipine

Some single-dose studies suggested that food might delay the absorption of nifedipine[11] and reduce its peak levels,[12,13] but a multiple dose study found that food did not have an important effect on the steady-state levels of nifedipine in a 'biphasic' formulation.[14] A further single-dose study in healthy subjects found that the bioavailability of two modified-release preparations of nifedipine (*Adalat OROS* or *Nifedicron*) were not significantly different when they were given in the fasting state, although the maximum plasma levels were 31 micrograms/L and 53 micrograms/L, respectively. The bioavailability and maximum plasma level (38 micrograms/L) of *Adalat OROS* were similar when given after a high-fat or in the fasting state. However, the maximum plasma level of *Nifedicron* increased 2.4-fold to 128 micrograms/L after a high-fat breakfast. Although the bioavailability of *Nifedicron* was only modestly increased by food, the increase in plasma levels indicates a loss of modified-release characteristics and suggests that the effect of food on nifedipine may depend on the product formulation.[15] Similar results were found in another study.[16] The manufacturer of another modified-release preparation of nifedipine (*Adalat CC*) also notes that administration immediately after a high-fat meal increased the peak plasma level by 60% without altering the AUC.[17]

(i) Nimodipine

The US manufacturer notes that taking nimodipine capsules after a standard breakfast reduced the AUC by 38% and the peak level by 68%, when compared with the fasted state in healthy subjects.[18]

(j) Nisoldipine

The manufacturer of an extended-release nisoldipine preparation (*Sular*) notes that food with a high fat content markedly increases the maximum plasma level (by up to 300%), but decreases total exposure by 25%. They note that this appears to be specific to the controlled-release preparation, as food had a lesser effect on the immediate-release tablet.[19]

(k) Verapamil

The absorption of verapamil from a multiparticulate sustained-release preparation was not affected when it was given with food.[20]

Mechanism

The increase in bioavailability of manidipine in the presence of food may be because it is lipophilic and solubilised by food and bile secretions.[8] Other lipophilic dihydropyridine calcium-channel blockers include lercanidipine,[21] felodipine and nisoldipine.[8] Food may alter the release characteristics of modified-release preparations of drugs, increasing the rate of absorption of the drug, and thereby potentially increasing effects.

Importance and management

Some modified-release preparations of felodipine, nifedipine and nisoldipine have shown markedly increased peak levels when given with meals, particularly if they are high in fat content. Because of this increase, the manufacturers of *Vascalpha* (felodipine),[5] *Adalat CC* (nifedipine)[17] and *Sular* (nisoldipine)[19] recommend that they are taken on an empty stomach[5,17] or with a light meal,[5] avoiding high-fat meals.[5,19] Note that these precautions do not apply to all preparations of these calcium-channel blockers (e.g. *Plendil* (felodipine) can be taken irrespective of meals), so the manufacturer's literature needs to be consulted.

Food markedly increases the bioavailability of lercanidipine, and it should therefore be taken at least 15 minutes before meals.[7] However, food modestly increases the extent of absorption of manidipine, and it has been recommended that manidipine should be given with food.[8]

In contrast, food modestly decreases the absorption of nimodipine *capsules*, and the US manufacturer says they should preferably be taken not less than one hour before, or 2 hours after, meals.[18] Food also modestly decreases the peak level of nicardipine, and the manufacturers of the sustained release preparation suggest that taking *Cardene SR* with a meal reduces the fluctuation in plasma levels.[10,22]

Food had no clinically significant effect on the absorption of amlodipine, diltiazem, isradipine, or verapamil from the preparations studied (see *Clinical evidence*, above).

Calcium-channel blockers + Grapefruit juice

Grapefruit juice very markedly increases the bioavailability of felodipine, manidipine and nisoldipine and alters their haemodynamic effects. The bioavailability of nicardipine, nifedipine, nimodipine, nitrendipine or verapamil are also increased, but the haemodynamic effects appear to be less, whereas the bioavailability of amlodipine and diltiazem are only minimally affected. An isolated report describes peripheral oedema and weight gain in a black man taking nifedipine when also drinking grapefruit juice, and case reports suggest that amlodipine may occasionally interact with grapefruit juice.

Clinical evidence

(a) Grapefruit juice

There are several studies on the effects of grapefruit juice on calcium-channel blockers. These are summarised in 'Table 23.3', (p.1035). In addition, an isolated report describes a 54-year-old black African man taking **nifedipine** retard 60 mg daily, lisinopril 5 mg daily and aspirin 75 mg who presented with peripheral oedema, weight gain, and apparently improved blood pressure control of a period of about 6 months. Over this time he had been drinking about 400 mL of freshly squeezed grapefruit juice every morning as part of a diet regimen. He was advised to stop drinking grapefruit juice, and 2 weeks later the oedema had disappeared, he had lost 2 kg in weight, and his blood pressure was slightly higher (140/85 mmHg) than when he presented (130/80 mmHg).[1] Other cases have been reported with amlodipine. In 2002 the Adverse Drug Reactions Advisory Committee (ADRAC) in Australia reported that they had received three case reports describing an interaction between amlodipine and grapefruit juice. No details were given.[2]

(b) Whole grapefruit

Some studies have found that grapefruit pulp (equivalent to one fruit), grapefruit segments (including seed but devoid of vascular layer), or grapefruit segment-free extract (extract of peel and pith) may increase the AUCs of **nifedipine**, **nisoldipine** and **felodipine** by 30%, 30%, and threefold, respectively.[3,4]

Mechanism

Complex. It has been suggested that the increases in bioavailability are due to components of the fruit juice particularly furanocoumarins including bergamottin (also found in Seville (or bitter) oranges and lime juice) and 6',7'-dihydroxybergamottin;[5-10] other components including flavonoids such as naringin[11-13] (but not quercetin[14]) or sesquiterpenoids[15] might also be involved, but appear to have a more minor role. These components inhibit the activity of the cytochrome P450 isoenzymes CYP3A subfamily in the intestinal wall so that the first-pass metabolism of these calcium-channel blockers is reduced, thereby increasing their bioavailability and therefore their effects. Grapefruit juice has little effect on hepatic CYP3A4 and this is borne out by the fact that it interacts with oral but not intravenous preparations. Therefore, the sensitivity of the interaction with grapefruit juice may be related to the oral bioavailability of the calcium-channel blocker.[16,17] Thus, amlodipine and diltiazem with high bioavailability are least affected, nifedipine is intermediate; and felodipine[16] and nisoldipine,[17] which have lower bioavailability, are most sensitive to the activity of grapefruit juice. The exception is verapamil, which has low bioavailability and appears to be only modestly affected by grapefruit juice, but this is possibly because cytochrome P450 isoenzymes other than CYP3A4 are involved in its metabolism.[16] The plasma protein binding[17] or lipophilicity[18] of the calcium-channel blocker may also contribute to the strength of the interaction, as drugs with a higher plasma protein binding ratio such as manidipine[17] or highly lipophilic drugs such as **lercanidipine**[18] are predicted to interact with grapefruit juice to a greater extent than nifedipine.

The authors of the case report,[1] suggested that black Africans may be more susceptible to any interaction, as they already have reduced systemic clearance of nifedipine, when compared with Caucasians. However, the magnitude of the interaction shows wide variation among individuals, which is presumably related to CYP3A4 levels in the intestinal epithelium, and therefore it might be anticipated that the higher the CYP3A4 levels, the greater the interaction.

Furanocoumarins and possibly other components of grapefruit juice may also increase the levels of calcium-channel blockers by inhibition of intestinal P-glycoprotein efflux transport.[5,6,16]

Importance and management

These are established interactions and several manufacturers of felodipine[19-21] suggest that it should not be taken with grapefruit juice. Similar advice is given for most other calcium-channel blockers. However, the UK manufacturer of lercanidipine[22] contraindicates its use with grapefruit juice and one manufacturer of verapamil[23] also contraindicate grapefruit juice, although other manufacturers suggest that this interaction appears to be of little clinical relevance[24] in the majority of patients. It is noteworthy that only one probable case report of the interaction appears to have been published.

Generally speaking, the studies suggest that the concurrent use of grapefruit juice and most calcium channel-blockers other than felodipine, and possibly manidipine or nisoldipine, need not be avoided. However, it would be worth checking the diet of any patient who complains of increased or excessive adverse effects with any calcium-channel blocker (e.g. hypotension, headache, flushing, oedema). Any problems can be solved either by avoiding grapefruit juice, or, where possible, by swapping the calcium-channel blocker for one less likely to interact (although note that cases have been reported with amlodipine, which is generally considered as unlikely to interact). Note that some studies suggest that the effects of grapefruit juice can persist for several days, and this should be taken into account when adjusting treatment.

It has also been suggested that **whole grapefruit** or products made from **grapefruit peel** such as marmalade should also be avoided in patients taking felodipine.[4]

Table 23.3 Summary of pharmacokinetic studies involving calcium-channel blockers and grapefruit juice*

Calcium-channel blocker	*Pharmacokinetic effects*	*Pharmacodynamic effects*	*Refs*
Amlodipine	AUC increased by 7 to 16%, which would not be expected to be clinically significant.	No clinically relevant changes in healthy subjects.	1-3
Diltiazem	AUC increased by10 to 20%, which would not be expected to be clinically significant.	No clinically relevant changes in healthy subjects.	4, 5
Felodipine	AUC increased 2- to 3-fold in healthy subjects. Marked and variable increases in felodipine bioavailability. Effects of grapefruit juice may continue for at least 24 hours after intake. Extended-release tablets less affected; AUC increased by 60 to 100%. IV felodipine not affected.	Decreased blood pressure and increased heart rate seen. Adverse effects (headache; facial flushing; lightheadedness) also increased.	6-17
Manidipine	AUC increased 2.3- to 3-fold.	Adverse effects (headache; flushing; palpitations) more frequent.	18
Nicardipine	AUC increased by 40 to 80%. IV nicardipine not affected.	No clinically relevant effects in healthy subjects, apart from an increase in heart rate.	19
Nifedipine	AUC increased by 10 to 100%. Effects of GFJ may last at least 3 days after intake. IV nifedipine not affected.	One patient experienced a drop in blood pressure.	6, 20-25
Nimodipine	AUC increased by 50%. Effects of grapefruit juice may last at least 4 days after intake.	Heart rate increased in healthy subjects.	26
Nisoldipine	AUC increased 2- to 4-fold. Effects of GFJ may last 3 days after intake.	Some studies suggest blood pressure decreased and heart rate slightly increased in healthy subjects, whereas others suggest no clinically relevant effects occur.	27, 28
Nitrendipine	AUC increased 2.3-fold.	No clinically relevant changes in healthy subjects.	29
Verapamil	No clinically relevant effects with a single drink of grapefruit juice, but AUC increased by 30 to 50% with multiple doses. Pharmacokinetic effect showed considerable intersubject variation.	Effects generally not clinically significant in healthy subjects, but the PR interval was prolonged in 2 subjects; this was considered to be of borderline significance (increases to above 350 milliseconds in 2 subjects, usual maximal PR intervals of 200 to 260 milliseconds).	30-32

*The usual volume of grapefruit juice used in the studies was 200 to 250 mL

Calcium-channel blockers + H_2-receptor antagonists

The plasma levels of diltiazem, felodipine, isradipine, lacidipine, nifedipine, nimodipine, nisoldipine, and nitrendipine are increased by cimetidine. High doses of cimetidine may increase the bioavailability of lercanidipine. The manufacturers of nicardipine advise caution with cimetidine, although studies suggest no clinically important interactions occur. Cimetidine does not interact with amlodipine, and it is uncertain whether cimetidine interacts significantly with verapamil. Ranitidine appears to interact only minimally with calcium-channel blockers, if at all. There is no pharmacokinetic interaction between famotidine and nifedipine.

Clinical evidence

(a) Amlodipine

A crossover study in 12 healthy subjects found that **cimetidine** 400 mg twice daily for 14 days had no effect on the pharmacokinetics of amlodipine 10 mg.[1]

(b) Diltiazem

In a single-dose study, **cimetidine** increased the AUC of diltiazem by 25 to 50% and increased its serum levels by 40%.[2] In a study in 6 healthy subjects, **cimetidine** 300 mg before meals and at bedtime for a week increased the AUC of a single 60-mg oral dose of diltiazem by 50% and increased its peak plasma levels by 57%. In the same study, **ranitidine** 150 mg twice daily for a week had no significant effect on the AUC of diltiazem.[3] No adverse interaction was seen in 22 patients given calcium-channel blockers, including diltiazem, with oral **famotidine** for 6 to 8 weeks.[4]

(c) Felodipine

In a study in 12 subjects, **cimetidine** 1 g daily increased the AUC of felodipine 10 mg by 56%, and raised its peak serum level by 54%. There was a short lasting effect on heart rate but the clinical effects were minimal.[5]

(d) Isradipine

The manufacturer of isradipine[6] notes that **cimetidine** increases the bioavailability of isradipine by about 50%.

(e) Lacidipine

In a study in healthy subjects a single 800-mg dose of **cimetidine** increased the maximum plasma level of a single 4-mg dose of lacidipine by 59% and increased its AUC by 74%. Pulse rate and blood pressure were unaffected.[7]

(f) Lercanidipine

The manufacturers of lercanidipine state that **cimetidine** 800 mg daily causes no significant alteration in the plasma levels of lercanidipine;[8,9] the AUC and maximum plasma concentration were increased by a mean of 11%,[9] which would not be expected to be clinically relevant. However, they suggest that the bioavailability of lercanidipine and its hypotensive effects may be increased by higher doses of **cimetidine**.[8,9]

(g) Nicardipine

In a study in 12 healthy subjects, intravenous **cimetidine** 300 mg every 6 hours for 48 hours did not alter the pharmacokinetics or pharmacodynamics of a 12-hour intravenous infusion of nicardipine 24 mg.[10] In a review of patients prescribed H_2-receptor antagonists, no adverse interaction was seen in 22 patients given calcium-channel blockers, including nicardipine, with **famotidine** for 6 to 8 weeks.[4]

(h) Nifedipine

In a pharmacokinetic study, **cimetidine** 1 g daily for a week increased the AUC of nifedipine 40 mg daily by about 60% and increased the maximum plasma levels by about 90%. **Ranitidine** 150 mg twice daily for a week caused an insignificant rise of about 25% in maximum nifedipine plasma levels and AUC.[11] Seven hypertensive patients had a fall in mean blood pressure from 127 mmHg to 109 mmHg after taking nifedipine 40 mg daily for 4 weeks, and a further fall to 95 mmHg after they also took **cimetidine** 1 g daily for 3 weeks. When they took **ranitidine** 300 mg instead of **cimetidine**, blood pressure was not significantly affected.[11,12] Other studies clearly confirm that **cimetidine** causes a very significant rise in plasma nifedipine levels and an increase in its effects, whereas **ranitidine** interacts only minimally.[13-19] Overall, cimetidine appears to increase the AUC of nifedipine by about 1.5- to 2-fold and the maximum plasma concentration by about 1.6- to 2-fold.[20]

A study found no pharmacokinetic interaction between nifedipine and **famotidine**, but **famotidine** reversed the effects of nifedipine on systolic time intervals and significantly reduced the stroke volume and cardiac output.[21,22] In a review of patients prescribed H_2-receptor antagonists, no adverse interaction was seen in 22 patients given calcium-channel blockers, including nifedipine, with **famotidine** for 6 to 8 weeks.[4]

(i) Nimodipine

In a study in 8 healthy subjects, **cimetidine** 1 g daily for 7 days increased the bioavailability of nimodipine 30 mg three times daily by 75%, but the haemodynamic effects were unchanged. **Ranitidine** did not interact.[23]

(j) Nisoldipine

A study in 8 healthy subjects found that taking **cimetidine** 1 g in divided doses on the day before the study and then three 200 mg doses every 4 hours on the study day, increased the bioavailability of a single 10-mg dose of nisoldipine by about 50%, but the haemodynamic effects of the nisoldipine were unaltered.[24] The manufacturer reports that **cimetidine** 400 mg twice daily increases the AUC and maximum plasma concentration of nisoldipine by 30 to 45%, whereas **ranitidine** does not interact.[25]

(k) Nitrendipine

In a study, 9 healthy subjects were given **cimetidine** 800 mg before a single 20-mg dose of nitrendipine, and **cimetidine** 400 mg in divided doses after the nitrendipine. **Cimetidine** increased the bioavailability of nitrendipine by 154% but its haemodynamic effects were unchanged.[26] Another study found that the AUC of oral nitrendipine 20 mg daily for 1 week was increased by about 50% by ranitidine and its clearance was decreased, but there were no changes in the haemodynamic measurements (systolic time intervals, impedance cardiography).[27,28] A further study found that **ranitidine** increases the AUC of nitrendipine by 89%, but no adverse effects were noted as a result of this increase.[29]

(l) Verapamil

A study in 8 healthy subjects found that **cimetidine** 300 mg every 6 hours for 8 days did not affect the pharmacokinetics of a single 10-mg intravenous dose of verapamil, but the bioavailability of a 120-mg oral dose of verapamil was increased from 26% to 49%. There was, however, no significant change in oral clearance and the changes in the PR interval caused by the verapamil were unaltered in the presence of **cimetidine**.[30]

Another study found that **cimetidine** 300 mg four times daily for 5 days reduced the clearance of a single intravenous dose of verapamil by 21% and increased its elimination half-life by 50%.[31] A further study found that **cimetidine** 400 mg twice daily for a week increased the bioavailability of verapamil from 35% to 42% and its apparent oral clearance was reduced by almost 30%.[32] Yet another study found that **cimetidine** increased the bioavailability of both enantiomers of verapamil and increased the effect of verapamil on atrioventricular conduction.[33] In contrast, other studies have found that the pharmacokinetics[34,35] and pharmacodynamics[34] of verapamil were unaffected by **cimetidine**.

Mechanism

It is believed that cimetidine increases the bioavailability of nifedipine and other interacting calcium-channel blockers by inhibiting their oxidative metabolism by the liver. It has been proposed that ranitidine may increase the bioavailability of nifedipine by lowering gastric acidity.[15]

Importance and management

The interaction of cimetidine with nifedipine is established. Concurrent use need not be avoided but the increase in the calcium-channel blocker effects should be taken into account and blood pressure monitored. If necessary, a dosage reduction should be considered; a reduction of 40 to 50% has been suggested.[36,37] Cimetidine also increases the bioavailability of diltiazem, felodipine, isradipine, lacidipine, nimodipine and nitrendipine, although the haemodynamic changes usually appear minimal. Nevertheless, the dose of these calcium-channel blockers may possibly need to be reduced; it has been suggested that the dosage of diltiazem should be reduced by 30 to 50%,[36,37] and the dosage of isradipine should be reduced by 50%.[6]

The interaction between verapamil and cimetidine is not well established, but, until more is known, it may be prudent to monitor concurrent use for verapamil adverse effects. It has been suggested that the verapamil dose may need to be reduced by 50%.[37] Similarly, high doses of cimetidine may increase the hypotensive effects of lercanidipine and caution is advised.[8,9] One study indicated no interaction between nicardipine and cimetidine, but the manufacturers note that cimetidine increases nicardipine plasma levels and careful monitoring is recommended.[38,39] Amlodipine and cimetidine do not interact and one study suggests that cimetidine does not alter the clinical effects of nisoldipine.

Ranitidine does not interact significantly with diltiazem, nifedipine, nimodipine or nisoldipine, and famotidine does not interact with nifedipine. Ranitidine may therefore be a suitable non-interacting alternative to cimetidine with these and probably other calcium-channel blockers. Note that the nitrendipine AUC was increased by 50% and 89% by ranitidine, although this was not considered clinically relevant.

Calcium-channel blockers + Hormonal contraceptives

A 21-day course of combined hormonal contraceptives appeared to have little effect on the AUC of nifedipine, but the AUC of its metabolite was reduced. Diltiazem may slightly raise estradiol levels.

Clinical evidence

(a) Combined hormonal contraceptives

A study in 23 healthy women investigated the influence of oral contraceptives on the pharmacokinetics of a single 10-mg dose of **nifedipine**. The intake of oral contraceptives containing **dienogest** 2 mg with **ethinylestradiol** 30 micrograms or **levonorgestrel** 125 micrograms with **ethinylestradiol** 30 micrograms for 21 days did not influence the AUC of **nifedipine**, but the $AUC_{0–24}$ of its main metabolite, dehydronifedipine, was reduced by about 25%.

(b) Estradiol

A study in 5 healthy postmenopausal women given **diltiazem** 30 mg twice daily for 4 days with a single 2-mg oral dose of estradiol on day 2, found that there was a slight but non-significant increase in the maximum levels of estrone.[1]

Mechanism

The reduction in dehydronifedipine levels suggests that the formation rate of the metabolite was reduced, probably because the contraceptive reduced the metabolism of nifedipine to dehydronifedipine by the cytochrome P450 isoenzyme CYP3A4.[2]

Diltiazem is a moderate inhibitor of the cytochrome P450 isoenzyme CYP3A4 and would be expected to decrease the metabolism of estradiol.

Importance and management

The effects of combined hormonal contraceptives on nifedipine appear minimal, but a multiple-dose study would be needed to confirm the expected lack of a clinically relevant interaction. The current data suggests that the efficacy of nifedipine would not be expected to be reduced by a pharmacokinetic mechanism; however, for further comments on the effect of hormonal contraceptives on blood pressure, see 'Antihypertensives + Hormonal contraceptives or HRT', p.1050.

The increase in oestrogen levels caused by diltiazem is small and unlikely to cause any clinically significant adverse effects. However, the dose of diltiazem given in the study was much lower than commonly prescribed doses, the number of patients involved in the study was small, and therefore these results may not accurately reflect the effect of concurrent use..The available data is insufficient to warrant any change in practice, but more study is needed to confirm the absence of a clinically relevant interaction.

Calcium-channel blockers + Imatinib

A man taking nifedipine developed a gallstone after starting imatinib. Imatinib is predicted to increase levels of dihydropyridine-type calcium-channel blockers.

Clinical evidence, mechanism, importance and management

A patient taking **nifedipine** developed nausea, vomiting and abdominal pain 8 weeks after starting to take imatinib 400 mg [daily]. Ultrasound showed a thickened gallbladder wall, dilatation of the principal bile ducts and a gallstone. He had not previously had any gall bladder disease. Imatinib was stopped until the abdominal pain was resolved and then restarted at half the initial dose.[1]

Imatinib is known to be an inhibitor of cytochrome P450 isoenzyme CYP3A4, by which nifedipine is metabolised. It was suggested that imatinib may have inhibited the metabolism of **nifedipine**, leading to an increase in its effects on lipids, leading to an increase in biliary secretion and gallstone development.[1] However, gallstones would not usually be considered a sign of raised nifedipine levels.

The reason for the case report of gallstones is unclear. The manufacturers suggest that the levels of the **dihydropyridine-type calcium-channel blockers** may be increased by imatinib.[2,3] This seems reasonable, as imatinib raises the levels of the CYP3A4 substrate simvastatin, see 'Statins + Imatinib', p.1337. It would therefore seem prudent to monitor the concurrent use of these calcium-channel blockers and imatinib for an increase in calcium-channel blocker adverse effects, such as hypotension, headache, flushing, and oedema.

Calcium-channel blockers + Macrolides

Erythromycin markedly increases the bioavailability of felodipine. Isolated reports describe increased felodipine or verapamil effects and toxicity in patients also given erythromycin. There are also a few reports of verapamil or nifedipine toxicity with clarithromycin, and two with verapamil and erythromycin (prolonged QT interval) or telithromycin. A retrospective analysis revealed 3 cases of sudden cardiac death in patients taking erythromycin with diltiazem or verapamil, which represented about a fivefold increase in risk. No increased risk was seen with nifedipine and erythromycin.

Clinical evidence

(a) Diltiazem

A patient who had marked hypotension and bradycardia when **erythromycin** was added to verapamil and propranolol (see *Verapamil*, below) had previously taken **erythromycin** with diltiazem and a beta blocker without any reported adverse effects.[1]

In a retrospective cohort study, there was one sudden cardiac death in 106 person-years among patients taking diltiazem with **erythromycin**. When combined with the two deaths with concurrent verapamil and **erythromycin**, this represented about a fivefold increase in risk of sudden death when compared with those who were not taking CYP3A4 inhibitors (defined as ketoconazole, itraconazole, fluconazole, diltiazem, verapamil or troleandomycin) or **erythromycin**.[2]

(b) Felodipine

In a pharmacokinetic study, 12 healthy subjects were given felodipine 10 mg before and after taking **erythromycin** 250 mg four times daily for a day.[3] The felodipine AUC was increased almost threefold by the **erythromycin**, the maximum plasma levels were more than doubled and the half-life prolonged from 6.9 to 11.1 hours.[3]

A hypertensive woman taking felodipine 10 mg daily developed tachycardia, flushing and massive ankle oedema within 2 to 3 days of starting to take **erythromycin** 250 mg twice daily. Her blood pressure had fallen from 120/90 to 110/70 mmHg. She fully recovered within a few days of stopping the **erythromycin**.[4]

(c) Nifedipine

1. Clarithromycin. A 77-year-old man with slight renal impairment, taking sustained-release nifedipine 60 mg twice daily, captopril, and doxazosin, had persistent systolic hypertension (170 to 180 mmHg). Two days after starting to take clarithromycin 500 mg twice daily for breathing difficulty and cough, his blood pressure was 140/70 mmHg at a routine appointment, and the doxazosin dose was halved and valsartan substituted for captopril. Later that day, he was admitted with hypotension (80/40 mmHg) and bradycardia (40 bpm). Clarithromycin was replaced with erythromycin and the antihypertensives stopped. After 3 days his

blood pressure was stabilised with nifedipine 60 mg daily and furosemide, and the clarithromycin was restarted. Septic shock was ruled out as a cause of the hypotension.[5]

2. Erythromycin. In a retrospective cohort study, there were no sudden deaths from cardiac causes in 114 person-years of the use of oral erythromycin with calcium-channel blockers that do not inhibit CYP3A4 to a clinically relevant extent (mostly nifedipine).[2] This was in contrast to the increased risk of sudden death with erythromycin and diltiazem (see above) or verapamil (see below).

(d) Verapamil

1. Clarithromycin. A 53-year-old woman on haemodialysis 3 times a week, and a range of medicines including digoxin, was given clarithromycin 250 mg and verapamil 120 mg both twice daily because of an acute exacerbation of chronic obstructive pulmonary disease and a recurrence of atrial fibrillation. After 24 hours she experienced dizziness and episodes of fainting. A day later her supine blood pressure was 89/39 mmHg and her pulse rate 50 bpm. Verapamil was stopped and she recovered within 2 days, after which verapamil was re-started at a dose of 40 mg before each dialysis session. The authors suggest that, although an interaction between digoxin and verapamil cannot be ruled out, the digoxin levels were very low before verapamil was started, and they therefore believe that the effects seen cannot entirely have been due to raised digoxin levels.[6] Another report[1] describes a 77-year-old woman with hypertension, taking propranolol and verapamil, who developed marked bradycardia (37 to 50 bpm), within 4 days of starting a course of clarithromycin 500 mg twice daily. The problem was solved by temporarily reducing the dose of verapamil from 80 mg twice daily to 40 mg twice daily and halving the dose of propranolol until the clarithromycin course had been finished. Essentially the same thing happened 2 years later when erythromycin was added (see below).

2. Erythromycin. A 79-year-old woman taking verapamil 240 mg twice daily and ramipril was admitted to hospital with extreme fatigue and dizziness one week after starting a course of erythromycin 2 g daily for a respiratory tract infection. Her blood pressure was 80/60 mmHg and her respiratory rate was 18 breaths per minute. ECG showed complete AV block, escape rhythm of 50 bpm, pattern of left bundle-branch block and QTc interval prolongation (583 milliseconds compared with 436 milliseconds 20 days before admission). Verapamil and erythromycin were stopped and intravenous fluids, dopamine and calcium were given. Her blood pressure increased to 110/70 mmHg and after 4 days the QTc interval prolongation had resolved and her heart rate was 76 bpm.[7] Another patient taking verapamil and propranolol developed marked bradycardia and hypotension 2 days after starting to take erythromycin 333 mg three times daily.[1]

In a retrospective cohort study, there were two sudden cardiac deaths in 78 person-years among patients taking verapamil with erythromycin. When combined with the one death with current diltiazem and erythromycin, this represented about a fivefold increase in risk of sudden death when compared with those who used were not taking CYP3A4 inhibitors (defined as ketoconazole, itraconazole, fluconazole, diltiazem, verapamil or troleandomycin) or erythromycin.[2]

3. Telithromycin. A 76-year-old woman taking verapamil 180 mg daily experienced shortness of breath and weakness 2 days after starting telithromycin 800 mg daily for a sinus infection. She was found to have marked hypotension (systolic BP 50 to 60 mmHg) and bradycardia (30 bpm). She required a transvenous pacemaker for 3 days and pressor drugs.[8]

Mechanism

Calcium-channel blockers are metabolised in the gut wall and liver by the cytochrome P450 CYP3A subfamily of isoenzymes, which are inhibited by erythromycin, clarithromycin, and telithromycin, so that in their presence a normal oral dose becomes in effect an overdose with its attendant adverse effects.[1,3,4,8] Verapamil, erythromycin[7] and possibly clarithromycin are also P-glycoprotein inhibitors, which may contribute to the pharmacokinetic interaction by reducing the elimination of the calcium-channel blocker,[6] or by increasing macrolide absorption.[7]

Erythromycin has been associated with prolongation of the QT interval; an effect that is likely to be increased by drugs that increase erythromycin levels such as diltiazem and verapamil.[2]

Importance and management

Information seems to be limited but the interaction would appear to be established and clinically important, although its incidence is probably low. Anticipate the need to reduce the felodipine or verapamil dosage if erythromycin or clarithromycin, or possibly also telithromycin, is added. Nifedipine may also interact. Other reports suggests that the cardiac toxicity of erythromycin may be increased by verapamil,[2,7] and diltiazem,[2] and the authors of one of these reports consider that erythromycin should not be used with CYP3A4 inhibitors (that is diltiazem and verapamil).[2] There seem to be no reports of interactions between any of the other calcium-channel blockers and macrolides. However, because of the theoretical possibility of an interaction, many of the manufacturers of calcium-channel blockers warn of the possibility of increased plasma levels with macrolides such as erythromycin, clarithromycin, or telithromycin, and suggesting monitoring the outcome of concurrent use (e.g. for hypotension, headache, flushing, and oedema), reducing the calcium-channel blocker dose where necessary. However, the UK manufacturer of **lercanidipine** contraindicates the concurrent use of erythromycin.[9] Note that some macrolides such as **azithromycin** appear to have little or no effect on the CYP3A subfamily and so would be less likely to interact.

Calcium-channel blockers + Magnesium compounds

Pregnant women have developed bilateral hand contractures or muscular weakness and then paralysis, after receiving magnesium sulfate either alone or with nifedipine. Profound hypotension occurred in two women when nifedipine was added to magnesium sulfate and methyldopa. However, a retrospective study did not find these effects.

Clinical evidence

(a) Hypotension

Two women with pre-eclampsia, unsuccessfully treated with methyldopa and magnesium sulfate, experienced severe hypotension when a single 10-mg oral dose of **nifedipine** was added.[1] In contrast, a study in 10 women with severe pre-eclampsia receiving magnesium sulfate found that oral **nifedipine** 10 mg followed by 20 mg every 20 minutes, caused a steady decrease in mean arterial pressure and severe hypotension was not observed.[2] Moreover, in a retrospective study, the incidence of hypotension in 162 women given **nifedipine** and magnesium sulfate was lower than in 183 receiving magnesium sulfate and no antihypertensive (41.4% versus 53%).[3] For further details of this study, see (b) below.

(b) Neuromuscular blockade and hypocalcaemia

A report describes symptomatic hypocalcaemia (serum calcium levels 1.35 mmol/L) in a woman at 33 weeks gestation after she received magnesium sulfate and **nifedipine**.[4] However, this report also describes this effect in a patient taking magnesium sulfate alone. Both women experienced bilateral hand contractures and were successfully treated with calcium gluconate.[4]

A pregnant woman at 32 weeks gestation was effectively treated for premature uterine contractions with **nifedipine**, 60 mg orally over 3 hours, and later 20 mg every 8 hours. When contractions began again 12 hours later she was given magnesium sulfate 500 mg intravenously. She devel-

oped jerky movements of the extremities, complained of difficulty in swallowing, paradoxical respirations and an inability to lift her head from the pillow. The magnesium was stopped and the muscle weakness disappeared over the next 25 minutes.[5]

A woman at 28 weeks gestation with mild pre-eclampsia was given an infusion of magnesium sulfate 2 g/hour. Her plasma magnesium levels were found to be 2.75 mmol/L. No untoward reactions developed when she took a 20-mg dose of **nifedipine**, but 30 minutes after taking a second dose [by implication 3 to 4 hours later] she complained of flushing and sweating and had difficulty in lifting her head and limbs. Shortly afterwards almost complete muscular paralysis developed. The magnesium sulfate was stopped and a dramatic improvement followed within 15 minutes of a 1-g intravenous injection of calcium gluconate.[6]

In contrast, a retrospective analysis found no increased risk of serious magnesium-related maternal adverse effects in 162 women with pre-eclampsia who were also given **nifedipine** compared with 32 women receiving another antihypertensive or 183 who received no antihypertensive. The women receiving **nifedipine** had more severe pre-eclampsia and a longer magnesium sulfate infusion. However, the incidence of neuromuscular weakness was about 53% in these women, compared with 53% in those receiving another antihypertensive and 45% in those receiving no antihypertensive. These differences were not statistically significant. Moreover, the incidence of maternal hypotension was lower in those receiving **nifedipine** than in those receiving no antihypertensive (see (a) above).[3]

Mechanism

The probable reason for neuromuscular effects is that both drugs can seriously reduce the amount of calcium ions needed for normal muscular contraction. Nifedipine inhibits the inflow of extracellular calcium across cell membranes. Magnesium probably acts in the same way, and also reduces intracellular calcium by activating adenyl cyclase and increasing cyclic adenosine monophosphate (cAMP). In addition magnesium stimulates calcium-dependent ATPase, which promotes calcium uptake by the sarcoplasmic reticulum. The result is muscular paralysis, which is reversed by giving large amounts of calcium. Magnesium sulfate is also known to have neuromuscular blocking activity. Both drugs can also cause hypotension, which could be additive.

Importance and management

Direct information about the neuromuscular effects and hypotensive effects of the combination of nifedipine and magnesium seems to be limited. Although a few cases of possible additive effects have been reported, one large retrospective study did not find an increase in risk of neuromuscular effects or of hypotension with combined use. Nevertheless, one manufacturer of nifedipine advises particular caution when it is used in combination with intravenous magnesium sulfate in pregnant women, and recommends careful monitoring of blood pressure.[7] The same interaction would be expected to occur with other calcium-channel blockers, but this does not appear to have been studied.

Calcium-channel blockers + Melatonin

Melatonin may have some modest effects on blood pressure in patients taking nifedipine.

Clinical evidence

Forty-seven subjects with mild to moderate hypertension well-controlled with **nifedipine** GITS 30 mg or 60 mg daily for the past 3 months were given melatonin immediate-release capsules 5 mg each evening for 4 weeks. At the end of the 4 weeks, there was a modest increase in mean 24-hour systolic and diastolic blood pressure of 6.5 mmHg and 4.9 mmHg, respectively, and an increase in heart rate of 3.9 bpm. However, there was no difference in single-time point 'clinic' blood pressure (136/85 mmHg versus 138/87 mmHg) and heart rate. While taking melatonin, there was a greater incidence of drowsiness, during the morning, and weakness. One subject dropped out of the study complaining of marked weakness.[1]

Mechanism

Unknown. Melatonin has been reported to possess blood pressure-lowering properties when used alone and was expected to have additive effects with nifedipine.[1]

Importance and management

The chronic use of melatonin appears to modestly impair the hypotensive effects of nifedipine and increase the blood pressure and heart rates of patients. However, this was only detected on 24-hour blood pressure monitoring, and was not apparent with single-measures of blood pressure at the clinic. Therefore, given that the overall change was small, the clinical relevance of the effect is probably minor. Nevertheless, it is not clear just why this change occurred, and until more is known, it may be prudent to consider the use of melatonin if blood pressure is hard to control in any patient taking a calcium-channel blocker.

Calcium-channel blockers + Nitrates

As may be expected, enhanced hypotensive effects can occur when calcium-channel blockers are given with nitrates. Some manufacturers of amlodipine,[1,2] diltiazem,[3] nifedipine[4] and verapamil[5] suggest that the concurrent use of long-acting nitrates and/or sublingual glyceryl trinitrate may be safely undertaken. However, one manufacturer of diltiazem suggests caution in those also taking nitrates, as increased hypotensive effects and faintness, due to additive vasodilating effects, may occur. They recommend that the dosage of any concurrent nitrate should be increased gradually.[6]

Calcium-channel blockers + NNRTIs

Efavirenz decreases the bioavailability of diltiazem, whereas diltiazem has no clinically significant effect on efavirenz pharmacokinetics. Potentially, other calcium-channel blockers might be expected to interact similarly with efavirenz. Delavirdine is predicted to inhibit the metabolism of the calcium-channel blockers.

Clinical evidence, mechanism, importance and management

(a) Delavirdine

The manufacturer of delavirdine warns that it may inhibit the metabolism of calcium-channel blockers (they name **amlodipine**, **diltiazem**, **felodipine**, **isradipine**, **nifedipine**, **nicardipine**, **nimodipine**, **nisoldipine** and **verapamil**), resulting in increased concentrations of the calcium-channel blocker. Caution is warranted and clinical monitoring of patients is recommended.[1] It would seem prudent to monitor blood pressure closely if delavirdine is given to a patient taking a calcium-channel blocker, decreasing the dose of the calcium-channel blocker if necessary. If a calcium-channel blocker is to be started in a patient taking efavirenz it would seem prudent to start with the lowest possible dose and titrate carefully,

according to response. Note that this interaction probably occurs because delavirdine is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which the calcium-channel blockers are metabolised. Therefore if dose titration of the calcium-channel blocker proves difficult it may be prudent, where possible, to try an alternative class of drugs. Note that ACE inhibitors, angiotensin II receptor antagonists and beta blockers are not known to be affected by CYP3A4.

(b) Efavirenz

In a study in healthy subjects, efavirenz 600 mg daily decreased the steady-state AUC and maximum plasma level of **diltiazem** by 69% and 60%, respectively. Levels of diltiazem metabolites were also reduced. The pharmacokinetics of efavirenz were not altered to a clinically relevant extent.[2,3] The manufacturer of efavirenz suggests that the dose of **diltiazem** may need to be adjusted [increased], depending on clinical response.[2,3]

No data are available on the potential interaction of efavirenz with other calcium-channel blockers. However, efavirenz is known to induce CYP3A4, the main route of metabolism of many of the calcium-channel blockers, and therefore efavirenz may be expected to reduce their levels. The manufacturers suggest that any dose adjustments should be guided by clinical response (e.g. blood pressure).[2,3] Note that ACE inhibitors, angiotensin II receptor antagonists and beta blockers are not known to be affected by CYP3A4, and therefore they may provide a suitable alternative in some patients..

Calcium-channel blockers + Phenobarbital

Phenobarbital greatly reduces the levels and/or increases the clearance of felodipine (one case), nifedipine, nimodipine, and verapamil. Primidone is expected to interact similarly. Other calcium-channel blockers are expected to be similarly affected by both phenobarbital and primidone.

Clinical evidence

(a) Felodipine

Felodipine levels were studied in 10 patients with epilepsy. After taking felodipine 10 mg daily for 4 days the peak levels of felodipine were found to be 1.6 nanomol/L which was much lower than that in 12 control subjects not taking antiepileptic drugs (level 8.9 nanomol/L). Of the 10 patients, one was taking phenobarbital.[1]

(b) Nifedipine

In a pharmacokinetic study in 15 healthy subjects the clearance of a single 20-mg dose of nifedipine was increased almost threefold after they took phenobarbital 100 mg daily for 2 weeks. The nifedipine AUC was reduced by about 60%.[2]

(c) Nimodipine

A study in 8 epileptic patients receiving long-term antiepileptic treatment (including 4 who were taking phenobarbital and 2 who were taking phenobarbital with carbamazepine) found that the AUC of a single 60-mg oral dose of nimodipine was reduced by about 85%, when compared with a group of healthy subjects.[3]

(d) Verapamil

A study in 7 healthy subjects found that phenobarbital 100 mg daily for 3 weeks increased the clearance of verapamil 80 mg every 6 hours fourfold and reduced the bioavailability fivefold.[4]

Mechanism

Phenobarbital is an enzyme inducer that can increase the metabolism of calcium-channel blockers by the cytochrome P450 isoenzyme CYP3A4 in the liver. This results in lower plasma levels of the calcium-channel blocker.

Importance and management

Phenobarbital markedly reduces nifedipine, nimodipine and verapamil levels, and probably has a similar effect on felodipine levels. A considerable increase in the dosage of these calcium-channel blockers will probably be needed in patients taking phenobarbital. The UK manufacturers of nimodipine and **isradipine** contraindicate[5] or recommend avoidance of concurrent use,[6] and the US manufacturer of felodipine suggests that, since a clinically significant interaction may be anticipated, an alternative antihypertensive should be considered in patients receiving phenobarbital long-term.[7] Note that ACE inhibitors and angiotensin II receptor antagonists are not known to be affected by CYP3A4, and therefore may provide a suitable alternative to a calcium-channel blocker in some patients.

As **primidone** is metabolised to phenobarbital, it seems likely that it may interact similarly. There is no direct information of interactions with other calcium-channel blockers, but as they are metabolised, to a greater of lesser extent, in the same way they would generally be expected to interact similarly with both phenobarbital and primidone.

Calcium-channel blockers + Phenothiazines

The hypotensive adverse effects of the phenothiazines are expected to be additive with the known blood pressure lowering effects of the calcium-channel blockers.

Clinical evidence, mechanism, importance and management

An isolated report describes a patient taking chlorpromazine, who was given **nifedipine** the day before surgery, and then developed marked hypotension during surgery, which was eventually controlled with noradrenaline (norepinephrine).[1] It was suggested that the hypotension was due to an interaction between **nifedipine** and chlorpromazine. Although in general the hypotensive adverse effects of phenothiazines would be expected to be additive with the blood pressure lowering effects of the calcium-channel blockers there are many other factors that mean that the hypotensive effects seen in the case cannot be directly attributed to an interaction. For example, the dose of nifedipine given was not stated, the patient was additionally taking cimetidine, which can increase the bioavailability of nifedipine, see 'Calcium-channel blockers + H_2-receptor antagonists', p.1036, and, furthermore, the concurrent use of antihypertensives and general anaesthetics can also result in enhanced hypotension, for example, see 'Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists', p.102. Nevertheless, because of the known effects of both groups of drugs, some caution seems prudent on their concurrent use. Warn patients to take time in getting up to minimise orthostatic hypotension.

1. Stuart-Taylor ME, Crosse MM. A plea for noradrenaline. *Anaesthesia* (1989) 44, 916–17.

Calcium-channel blockers + Protease inhibitors

A patient taking nifedipine experienced hypotension, oedema and acute renal failure when lopinavir/ritonavir also given. Symptomatic orthostasis occurred in another patient taking nifedipine with nelfinavir and then ritonavir and indinavir. A further patient had similar symptoms when nelfinavir was given with felodipine. Atazanavir markedly increased diltiazem bioavailability with an increase in cardiac effects in a study in healthy subjects. Similarly, ritonavir/indinavir caused a modest to marked increase in diltiazem and amlodipine levels. Based on this evidence, protease inhibitors, especially ritonavir are predicted to raise the levels of all calcium-channel blockers.

Clinical evidence

(a) Amlodipine

In a study in 18 healthy subjects, **indinavir** 800 mg twice daily and **ritonavir** 100 mg twice daily given with amlodipine 5 mg daily for 7 days, increased the median AUC of amlodipine by 90%. Amlodipine had no effect on the steady-state AUCs of the protease inhibitors.[1] For mention of a patient who tolerated amlodipine and **lopinavir** with **ritonavir** after serious adverse effects had occurred with nifedipine and these protease inhibitors, see below.

(b) Diltiazem

1. Atazanavir. A study in healthy subjects found that atazanavir 400 mg daily given with diltiazem 180 mg daily resulted in a two- to threefold increase in the bioavailability of diltiazem and its metabolite desacetyldiltiazem. The pharmacokinetics of atazanavir were not affected by diltiazem. There was an increase in the maximum PR interval with combined use compared to that found with atazanavir alone.[2,3]

2. Indinavir with Ritonavir. In a study in 13 healthy subjects indinavir 800 mg twice daily and ritonavir 100 mg twice daily, given with diltiazem 120 mg daily for 7 days, modestly increased the median AUC of diltiazem by 27%, which was not statistically significant. However, two of the subjects had a fourfold increase in the AUC of diltiazem, and the desacetyl-diltiazem AUC was doubled. Diltiazem had no effect on the steady-state AUCs of the protease inhibitors.[1]

(c) Felodipine

A woman taking metoprolol 50 mg daily and felodipine 5 mg daily for hypertension developed bilateral leg oedema, orthostatic hypotension, and other symptoms including dizziness and fatigue, 3 days after starting HAART following a needle-stick injury. The antiretrovirals included zidovudine, lamivudine, and **nelfinavir** 2 g daily. Antihypertensive treatment was stopped and the adverse effects abated within 3 days. The patient was then successfully switched to a diuretic-based regimen without recurrence of oedema.[4]

(d) Nifedipine

A 51-year-old HIV-positive man with coronary artery disease, hypertension and osteoarthritis, and taking atenolol, also started taking extended-release nifedipine 60 mg daily. When his blood pressure control improved he was given zidovudine 300 mg, lamivudine 150 mg, and **nelfinavir** 1.25 g all twice daily. Within 3 days of starting the antiretrovirals he experienced dizziness, weakness and hypotension and developed complete heart block with a junctional escape rhythm. His ECG returned to normal within 24 hours of stopping the antiretrovirals, but he developed orthostatic symptoms within 2 days of restarting **nelfinavir**. He later tolerated a regimen consisting of stavudine, didanosine and efavirenz without any episodes of dizziness, hypotension or bradycardia. However, when he was given zidovudine, abacavir, **ritonavir**, and **indinavir**, he experienced hypotension, decreased heart rate, weakness and fatigue. His symptoms were controlled by modifying his antihypertensives, including discontinuation of atenolol and reduction of the dose of nifedipine to 30 mg daily.[5]

Another case report describes a patient taking antihypertensive drugs including nifedipine 30 mg twice daily, who developed malaise, severe hypotension, oliguria and progressive generalised oedema on the second day of taking **lopinavir** with **ritonavir**. He had previously developed hypotension and progressive renal failure when receiving nifedipine and HAART (including **lopinavir** with **ritonavir**). All antihypertensive and antiretroviral drugs were discontinued and the patient improved, but the same symptoms recurred after the nifedipine and then **lopinavir** and **ritonavir** were reintroduced. All drugs were stopped, then HAART (including **lopinavir** with **ritonavir**) was reintroduced again and **amlodipine** 15 mg daily was substituted for nifedipine. This regimen was well tolerated.[6]

Mechanism

Protease inhibitors, particularly ritonavir (see 'Antivirals', (p.913)), are potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which the calcium-channel blockers are extensively metabolised. It appears that some protease inhibitors can cause a clinically relevant increase in calcium-channel blocker levels. Verapamil, diltiazem and possibly nicardipine can also inhibit CYP3A4, and might therefore theoretically reduce the metabolism of the protease inhibitors. However, the effect might depend on which is the more potent inhibitor, since, in the studies above, diltiazem did not affect atazanavir, indinavir or ritonavir levels.

Importance and management

Although information is limited, the pharmacokinetic interactions between some protease inhibitors and calcium-channel blockers are predictable, and potentially serious. To date, clinically relevant increases in calcium-channel blocker levels or effects have been shown for amlodipine with indinavir and ritonavir (in combination), diltiazem with atazanavir and lopinavir with ritonavir, felodipine with nelfinavir, nifedipine with nelfinavir, indinavir with ritonavir and lopinavir with ritonavir (in combination). Caution would be required with any of these combinations, anticipating the need to use lower doses of the calcium-channel blocker.

All protease inhibitors can inhibit CYP3A4 to a greater or lesser extent. Many are given with ritonavir as a pharmacokinetic enhancer, and this lower dose is also expected to interact.[7,8] Further, all calcium-channel blockers are metabolised, to a greater or lesser extent, by CYP3A4. Consequently, any combination of calcium-channel blocker and protease inhibitor has the potential to interact, although the severity of the interaction is likely to vary between individual pairs of drugs. Therefore it would be prudent to monitor patients for calcium-channel blocker adverse effects (e.g. hypotension, headache, flushing, and oedema), and consider reducing the dose of the calcium-channel blocker as necessary. Particular caution may be warranted with **verapamil** because adverse cardiac effects (conduction disorders) are more commonly associated with this particular calcium-channel blocker.

Note that the UK manufacturer of **lercanidipine**[9] contraindicates the concurrent use of ritonavir or other strong inhibitors of CYP3A4, which would be expected to include most, if not all protease inhibitors. The manufacturers of **atazanavir** specifically recommend that, if diltiazem is also given, its initial dose should be reduced by 50% with subsequent dose titration and ECG monitoring.[2,3]

It has been suggested that other antihypertensive drugs such as ACE inhibitors and diuretics, which are primarily eliminated renally, could be considered as alternatives to calcium-channel blockers:[10] this seems prudent advice.

Calcium-channel blockers + Quinupristin/Dalfopristin

Quinupristin/dalfopristin modestly increased the AUC of nifedipine. Other calcium-channel blockers are predicted to be similarly affected.

Clinical evidence, mechanism, importance and management

The manufacturer notes that the AUC of repeated-dose **nifedipine** was increased by 40% by quinupristin/dalfopristin, and the maximum level was increased by 20%.[1] This is probably because quinupristin/dalfopristin inhibits the metabolism of **nifedipine** by the cytochrome P450 isoenzyme CYP3A4.[2] Although the clinical relevance of these increases have not been assessed, an increase in the AUC of nifedipine of 40% is fairly modest. The manufacturers of **nifedipine** advise blood pressure monitoring and, if necessary, a reduction of the **nifedipine** dosage during concurrent use.[1,3] It is predicted that other calcium-channel blockers[2] will also have their levels raised by quinupristin/dalfopristin, and this seem likely, as all calcium-channel blockers are metabolised, at least in part, by CYP3A4; however, the extent of the interaction is likely to vary between drugs. It may therefore be prudent to be alert for an increase in their effects (e.g. a

drop in blood pressure, headache, flushing, peripheral oedema) and reduce the dose if problems occur.

Calcium-channel blockers + Rifampicin (Rifampin)

Rifampicin markedly reduces the plasma levels of diltiazem, nifedipine, nilvadipine, verapamil and possibly reduces those of barnidipine, isradipine, lercanidipine, manidipine, nicardipine, nimodipine, and nisoldipine. Rifapentine and rifabutin would also be expected to reduce the levels of the calcium-channel blockers.

Clinical evidence

(a) Barnidipine and Manidipine

A brief report states that elderly patients with hypertension well-controlled with calcium-channel blockers including barnidipine or manidipine had blood pressure rises when rifampicin was added. Increased dosages or additional antihypertensives were needed to control the blood pressures, and reduced doses were required when the rifampicin was withdrawn.[1]

(b) Diltiazem

A study in 12 subjects found that the peak plasma level following a single 120-mg oral dose of diltiazem alone was 186 nanograms/mL, but after taking rifampicin 600 mg daily for 8 days maximum plasma diltiazem levels were less than 8 nanograms/mL.[2] One patient with angina controlled with diltiazem 120 mg daily began to feel chest pain at rest one month after starting rifampicin and isoniazid.[3]

(c) Nifedipine

A woman with hypertension well controlled with nifedipine 40 mg twice daily, had a blood pressure rise from under 160/90 mmHg to 200/110 mmHg within 2 weeks of starting to take antitubercular treatment, which included rifampicin 450 mg daily. When the rifampicin was stopped and then restarted, the blood pressure fell and then rose again. The peak nifedipine plasma levels and the AUC fell by about 60% in the presence of rifampicin.[4] Another patient had anginal attacks refractory to nifedipine while taking rifampicin, but which were controlled by nifedipine when the rifampicin was stopped. Restarting rifampicin reduced nifedipine levels (peak plasma levels and AUCs roughly halved) and increased the number of anginal attacks.[3] Yet another patient taking nifedipine had a loss of blood pressure control when given rifampicin.[5]

Six healthy subjects were given nifedipine 20 micrograms/kg intravenously and nifedipine 20 mg orally on separate days before and after taking rifampicin 600 mg daily for 7 days. The pharmacokinetics of intravenous nifedipine were not significantly changed by the rifampicin, but the oral clearance increased from 1.5 L/minute to 20.9 L/minute and the bioavailability fell from about 41% to 5%.[6] A pharmacokinetic study in 6 healthy subjects found that when a single 10-mg oral dose of nifedipine was taken 8 hours after a single 1.2-g dose of rifampicin, the bioavailability of nifedipine was reduced to 36%, its half-life was more than halved, and its clearance increased threefold.[7]

(d) Nilvadipine

A study in 5 healthy normotensive subjects found that rifampicin 450 mg daily for 6 days reduced the peak plasma level and AUC of a single 4-mg dose of nilvadipine by about 20-fold and 30-fold, respectively. The hypotensive effect and reflex tachycardia associated with nilvadipine alone in these subjects was also abolished by rifampicin.[8]

(e) Nisoldipine

There is some evidence to suggest that nisoldipine is ineffective in reducing blood pressure in the presence of rifampicin.[1,4]

(f) Verapamil

The observation that a patient whose raised blood pressure was not reduced by verapamil while receiving antitubercular drugs, prompted a study in 4 other patients.[9] No verapamil could be detected in the plasma of 3 patients who took a single 40-mg dose of verapamil with rifampicin 450 to 600 mg daily, isoniazid 5 mg/kg daily, and ethambutol 15 mg/kg daily. A maximum verapamil level of 20 nanograms/mL was found in the fourth patient. Six other subjects not taking antitubercular drugs had a mean maximum verapamil plasma concentration of 35 nanograms/mL.[9] Similar results have been reported by the same authors in another study.[10]

Supraventricular tachycardia was inadequately controlled in a patient taking rifampicin 600 mg daily and isoniazid 300 mg daily, despite a verapamil dose of 480 mg every 6 hours. Substitution of the rifampicin by ethambutol resulted in a fourfold rise in serum verapamil levels.[11] A later study in 6 healthy subjects found that after taking rifampicin 600 mg daily for 2 weeks the oral bioavailability of verapamil was reduced from 26% to 2%, and the effects of verapamil on the ECG were abolished.[12] Yet another study in elderly patients similarly found that rifampicin 600 mg daily markedly increased the clearance of verapamil 120 mg twice daily. The effects of verapamil on AV conduction were almost abolished.[13]

Mechanism

Rifampicin reduces the effectiveness of nifedipine and verapamil to a greater extent after oral than after intravenous use. The evidence suggests that rifampicin increases the cytochrome P450 isoenzyme CYP3A4-mediated metabolism of calcium-channel blockers in the gastrointestinal wall,[6,13,14] thereby reducing their oral bioavailability. **Rifabutin** and **rifapentine** are also inducers of CYP3A4, although to a lesser extent than rifampicin, and would therefore also be expected to reduce the levels of the calcium-channel blockers.

Importance and management

The interactions between diltiazem, nifedipine, or verapamil, and rifampicin are established and of clinical importance. There is some evidence that barnidipine, manidipine, nilvadipine, and nisoldipine interact with rifampicin and the manufacturers of a number of other calcium-channel blockers (e.g. **lercanidipine**[15] and **nicardipine**[16]) warn of similar interactions. Monitor the effects closely if rifampicin is given with any calcium-channel blocker, being alert for the need to make a marked increase in their dosage. However, note that some manufacturers of nifedipine,[17] and **nimodipine**[18] contraindicate their use with rifampicin and some manufacturers of diltiazem[19] and **isradipine**[20] suggest avoiding concurrent use. **Rifabutin** and **rifapentine** would also be expected to reduce levels of calcium-channel blockers, although perhaps to a lesser extent than rifampicin. However, there does not appear to be any data to prove this. Note that, with some of the reduction in levels seen, it seems unlikely that blood pressure control will be possible with calcium-channel blockers in patients taking rifampicin. Therefore other drugs such as beta blockers or ACE inhibitors may be required, where appropriate. However, note that these classes of drugs are not entirely free of interactions with rifampicin, although the effects seem less marked than with some of the calcium-channel blockers. See also 'Beta blockers + Rifampicin (Rifampin)', p.1019, and 'ACE inhibitors + Rifampicin (Rifampin)', p.37.

Calcium-channel blockers + SSRIs

Two patients taking verapamil and two taking nifedipine developed increased adverse effects (oedema, headaches, nausea, flushing, orthostatic hypotension) when they also took fluoxetine. Fluoxetine appears to increase nimodipine levels, whereas nimodipine may decrease fluoxetine levels. Fluoxetine does not appear to alter lercanidipine pharmacokinetics.

Clinical evidence

(a) Lercanidipine

The manufacturer notes that a study in elderly subjects found that **fluoxetine** had no clinically relevant effects on the pharmacokinetics of lercanidipine. No other details were given.[1]

(b) Nifedipine

A patient taking nifedipine 60 mg daily developed nausea and flushing after also starting to take **fluoxetine** 20 mg every other day. The adverse effects gradually disappeared over the next 2 to 3 weeks when the nifedipine dosage was halved.[2] An 80-year-old woman taking nifedipine developed tachycardia, hypotension and profound weakness 10 days after starting to take **fluoxetine** 20 mg daily. On admission to hospital 8 days later she was unable to stand, her standing blood pressure was 90/50 mmHg and her heart rate was 120 bpm. She fully recovered within a week of stopping the fluoxetine.[3]

(c) Nimodipine

The manufacturer notes that, in elderly patients, nimodipine 30 mg twice daily given with **fluoxetine** 20 mg daily resulted in an increase in plasma levels of nimodipine, a reduction in plasma levels of fluoxetine, and a trend towards increased levels of the metabolite norfluoxetine,[4] but no specific values were given.

(d) Verapamil

A woman taking verapamil 240 mg daily developed oedema of the feet and ankles, and neck vein distension within 6 weeks of starting to take **fluoxetine** 20 mg every other day. The oedema resolved within 2 to 3 weeks of reducing the verapamil dosage to 120 mg daily.[2] Another patient taking verapamil 240 mg daily for the prophylaxis of migraine developed morning headaches (believed by the patient not to be migraine) about one week after his **fluoxetine** dosage was increased from 20 to 40 mg daily. The headaches stopped when the verapamil dosage was reduced and then stopped.[2]

Mechanism

The calcium-channel blockers are metabolised by the cytochrome P450 isoenzyme CYP3A4, which can be inhibited by fluoxetine. This results in a marked reduction in the metabolism and clearance of the calcium-channel blockers. The reactions reported appear to be the exaggeration of the adverse effects of these calcium-channel blockers, possibly due to an increase in their levels.

Importance and management

Although a pharmacokinetic interaction might be predicted, information on an important clinical interaction appears to be limited to these reports. This suggests that adverse interactions occur only rarely. Bear the possibility of a pharmacokinetic interaction in mind if a patient shows an exaggerated response to a calcium-channel blocker after starting fluoxetine, being alert for the need to reduce the drug dosages (note that reducing the fluoxetine dose resolved the interaction in some of the cases described above). The clinical significance of the interaction between nimodipine and fluoxetine is not known,[4] and without knowing the extent of the interaction making clinical recommendations is difficult; however, until more is known it may be prudent to monitor for an increase in adverse effects with nimodipine, such as hypotension, and a reduction in the response to fluoxetine when both drugs are given.

Information about other calcium-channel blockers with fluoxetine, or other SSRIs, appears to be lacking.

Calcium-channel blockers + St John's wort (*Hypericum perforatum*)

St John's wort significantly reduces the bioavailability of nifedipine and verapamil. Other calcium-channel blockers would be expected to interact similarly.

Clinical evidence

(a) Nifedipine

In a study in 10 healthy subjects, St John's wort 900 mg daily for 14 days decreased the maximum levels and AUC of a single 10-mg oral dose of nifedipine by about 38% and 45%, respectively. The maximum levels and AUC of the active metabolite of nifedipine, dehydronifedipine, were raised by about 45% and 26%, respectively. The St John's wort preparation used was standardised to contain hypericin 0.3% and hyperforin 5%.[1]

(b) Verapamil

In a study in 8 healthy subjects, verapamil 24 mg was given as a jejunal perfusion over 100 minutes both before and after they took St John's wort tablets *(Movina;* containing 3 to 6% hyperforin) 300 mg three times daily for 14 days. St John's wort did not affect jejunal permeability or the absorption of either *R*- or *S*-verapamil. The AUCs of *R*- and *S*-verapamil were decreased by 78% and 80%, respectively, and the peak plasma levels were decreased by 76% and 78%, respectively. The terminal half-life was not changed significantly. The AUC for *R*-verapamil was sixfold higher than that of *S*-verapamil, and St John's wort did not change this ratio.[2]

Mechanism

It appears that St John's wort decreased the bioavailability of both nifedipine and verapamil by inducing their metabolism by the cytochrome P450 isoenzyme CYP3A4 in the gut. An effect on P-glycoprotein-mediated transport is not likely, as intestinal permeability was not significantly altered.[2]

Importance and management

The general importance of this interaction is unclear, as neither study reported on the clinical outcome of these reductions in calcium-channel blocker levels. Patients taking St John's wort with nifedipine or verapamil should have their blood pressure and heart rate monitored to ensure they are still effective, and the dose should be adjusted if needed. There appears to be no information about other calcium-channel blockers, but as they are all metabolised by CYP3A4, to a greater or lesser extent, it would seem prudent to monitor concurrent use carefully. If an interaction occurs it may be prudent to use an alternative class of drugs (ACE inhibitors, angiotensin II receptor antagonists and beta blockers are not known to be affected by CYP3A4), or advise against the use of St John's wort.

Calcium-channel blockers + Valproate

Nimodipine and possibly nifedipine levels are raised by valproate.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 8 patients with epilepsy who had been taking valproate alone for at least 4 months were given a single 60-mg dose of **nimodipine**. The AUC of **nimodipine** was about 50% higher, when compared with that found in a control group not taking valproate.[1] The **nimodipine** dosage may need to be reduced if it is given with valproate.

One manufacturer of **nifedipine** suggests that there is a theoretical possibility that levels of **nifedipine** may be increased in the presence of valproate,[2] and advises that blood pressure should be monitored and, if necessary, a reduction in the dose of **nifedipine** should be considered.[2] Note that they suggest that this may occur because valproate inhibits the cytochrome P450 isoenzyme CYP3A4, by which **nifedipine** is metabolised; however, clinically relevant examples of valproate interacting by this mechanism are largely lacking.

Calcium-channel blockers + X-ray contrast media

The hypotensive effects of an intravenous bolus of an ionic X-ray contrast medium can be increased by the presence of calcium-channel blockers. No interaction or only a small interaction appears to occur with non-ionic contrast media.

Clinical evidence, mechanism, importance and management

It is well recognised that ionic x-ray contrast media used for ventriculography reduce the systemic blood pressure due to peripheral vasodilation. They also have a direct depressant effect on the heart muscle. A comparative study of the haemodynamic response of 65 patients found that the hypotensive effect of a bolus dose of an ionic agent (0.5 mL/kg of **meglumine amidotrizoate** and **sodium amidotrizoate** with edetate sodium or disodium) was increased by the concurrent use of **nifedipine** or **diltiazem**. Haemodynamic effects occurred earlier (3.1 seconds compared with 12.9 seconds), were more profound (a fall in systolic pressure of 48.4 mmHg compared with 36.9 mmHg) and more prolonged (62 seconds compared with 36 seconds).[1] A similar interaction was seen in *dogs* given **verapamil**.[2] No interaction or only a minimal interaction was seen in the patients and *dogs* when non-ionic contrast media (**iopamidol** or **iohexol**) were used instead.[1,2] The clinical relevance of these findings is uncertain. Note that calcium-channel blockers have been tried to prevent the nephrotoxicity of contrast media.

Calcium-channel blockers; Amlodipine + Chloroquine

A case report attributes an acute hypotensive episode to the use of amlodipine with chloroquine.

Clinical evidence, mechanism, importance and management

A case report describes a 48-year-old hypertensive man, who had been taking amlodipine 5 mg daily for 3 months with optimal blood pressure control. Because he had self-diagnosed malaria, he took chloroquine base 600 mg: two hours later he fainted and had a systolic blood pressure of 80 mmHg, and an unrecordable diastolic blood pressure. He was given supportive fluids and recovered over the following 2 hours. The severe adverse reaction was attributed to acute synergistic hypotensive, venodilator and cardiac effects of the two drugs.[1] However, any interaction remains unproven, as there was no re-challenge, and it seems reasonable that the faint may simply have been as a result of the fever from which he was suffering. Furthermore, the authors note that concurrent use of these two drugs would be expected to be quite frequent, and this appears to be the only case reported. No special precautions are therefore considered warranted based on this isolated case report.

1. Ajayi AAL, Adigun AQ. Syncope following oral chloroquine administration in a hypertensive patient controlled on amlodipine. *Br J Clin Pharmacol* (2002) 53, 404–5.

Calcium-channel blockers; Nifedipine + Co-trimoxazole

Adverse effects (leg cramps, facial flushing) have been reported in one patient taking nifedipine when co-trimoxazole was also taken. One study found that co-trimoxazole had no effect on the pharmacokinetics and hypotensive action of a single dose of nifedipine.

Clinical evidence, mechanism, importance and management

The observation of a patient taking nifedipine who developed leg cramps and facial flushing (possibly as a result of raised plasma nifedipine levels) when given co-trimoxazole, prompted further study of this possible interaction in 9 healthy subjects. After taking co-trimoxazole 960 mg twice daily for 3 days the pharmacokinetics and hypotensive effects of a single 20-mg dose of nifedipine were found to be unchanged.[1] No special precautions would therefore normally seem to be necessary on concurrent use.

1. Edwards C, Monkman S, Cholerton S, Rawlins MD, Idle JR, Ferner RE. Lack of effect of co-trimoxazole on the pharmacokinetics and pharmacodynamics of nifedipine. *Br J Clin Pharmacol* (1990) 30, 889–91.

Calcium-channel blockers; Nifedipine + Ginkgo (*Ginkgo biloba*)

Ginkgo may increase the levels and some of the effects of nifedipine.

Clinical evidence

In the preliminary report of a clinical study, 22 healthy subjects were given ginkgo 120 mg daily for 18 days before a single 10-mg oral dose of nifedipine. Ginkgo increased the levels of nifedipine by about 50%.[1]

In another study, a single 240-mg dose of ginkgo extract did not significantly affect the pharmacokinetics of a single 10-mg oral dose of nifedipine when they were given at the same time to 8 healthy subjects. However, the maximum level tended to increase (30% increase), and two subjects experienced a doubling of nifedipine maximum serum levels. In addition, the incidence and severity of headaches, hot flushes and dizziness tended to be higher with the combination when compared with nifedipine alone. Subjects also experienced increased heart rate with the combination although the decrease in blood pressure was unaffected.[2] The ginkgo extract used in this study contained 24% flavonoids and 6% terpene lactones.

Mechanism

Ginkgo may inhibit the cytochrome P450 isoenzyme CYP3A4, which would reduce the metabolism of nifedipine, a CYP3A4 substrate, and increase its levels. Note that simultaneous administration of single doses is probably insufficient to completely evaluate CYP3A4 inhibition. Note also that clinically relevant CYP3A4 inhibition has not been seen with ginkgo and the conventional CYP3A4 probe substrates such as midazolam.

Importance and management

Limited clinical data suggest that ginkgo may raise the levels of nifedipine and increase its effects. Until more is known, some caution might be warranted when they are used together. Monitor for signs of nifedipine

adverse effects such as headaches, hot flushes, dizziness and palpitations. If they become apparent, advise the patient to stop taking ginkgo.

Calcium-channel blockers; Nifedipine + Terbinafine

A study in 12 healthy subjects found that terbinafine 250 mg did not alter the pharmacokinetics of nifedipine 30 mg (as *Procardia XL*).[1]

1. Cramer JA, Robbins B, Barbeito R, Bedman TC, Dreisbach A, Meligeni JA. Lamisil®: interaction study with a sustained release nifedipine formulation. *Pharm Res* (1996) 13 (9 Suppl), S436.

Calcium-channel blockers; Nifedipine + Vancomycin

An isolated case report suggests that the hypotensive effects of the rapid infusion of vancomycin may occur more readily in those who are already vasodilated with nifedipine, but it seems likely that the effects seen were solely due to the vancomycin.

Clinical evidence, mechanism, importance and management

A man with severe systemic sclerosis was hospitalised for Raynaud's phenomenon and dental extraction. After he started taking nifedipine 40 mg daily, he was given intravenous vancomycin 1 g in 200 mL of dextrose 5% over 30 minutes. After 20 minutes he experienced a severe headache and was found to have a marked macular erythema on the upper trunk, head, neck and arms. His blood pressure fell to 100/60 mmHg and his pulse rate was 90 bpm. He recovered spontaneously.[1] The authors of the report acknowledge the possibility of 'red-man syndrome' caused by the vancomycin, and suggest that it may occur more readily in those already vasodilated with nifedipine. However, given that this is an isolated report, and the vancomycin was given over 3 times faster than the recommended rate, it seems likely that this is purely an adverse effect of vancomycin.

Calcium-channel blockers; Nitrendipine + Bile acids

Chenodeoxycholic acid and ursodeoxycholic acid reduce the AUC of nitrendipine.

Clinical evidence, mechanism, importance and management

In a single-dose study, 6 healthy subjects were given nitrendipine 10 mg with or without either **chenodeoxycholic acid** 200 mg or 600 mg, or **ursodeoxycholic acid** 50 mg. **Chenodeoxycholic acid** 200 mg decreased the peak plasma level and AUC of nitrendipine by about 20%, whereas **chenodeoxycholic acid** 600 mg had a greater effect, reducing the peak plasma level and AUC of nitrendipine by 54% and 68%, respectively. **Ursodeoxycholic acid** reduced the peak plasma level and AUC of nitrendipine by 54% and 75%, respectively. The reduction in the AUC of nitrendipine was possibly due to the effects of the bile acids on tablet disintegration or more probably on drug solubilisation.[1] The clinical importance of the interaction is not known, but the extent of the reduction in the AUC of nitrendipine suggests that its effects may be diminished. It may therefore be prudent to consider monitoring the outcome of concurrent use, increasing the dose of nitrendipine as necessary.

1. Sasaki M, Maeda A, Sakamoto K-I, Fujimura A. Effect of bile acids on absorption of nitrendipine in healthy subjects. *Br J Clin Pharmacol* (2001) 52, 699–701.

Calcium-channel blockers; Verapamil + Ceftriaxone and Clindamycin

An isolated report describes the development of complete heart block in a man taking verapamil, which was attributed to the use of intravenous ceftriaxone and clindamycin. However, the validity of this interaction has been questioned.

Clinical evidence, mechanism, importance and management

A 59-year-old man who had been taking sustained-release verapamil 240 mg twice daily for 2 years and phenytoin 300 mg daily for several years, developed complete heart block an hour after being given intravenous ceftriaxone 1 g and clindamycin 900 mg for bilateral pneumonia. He needed cardiopulmonary resuscitation and the insertion of a temporary pacemaker, but spontaneously recovered normal sinus rhythm after 16 hours, and subsequently made a full recovery. The reasons for this serious reaction are not known, but the authors of the report postulate that these two antibacterials precipitated acute verapamil toxicity, possibly by displacing it from its plasma protein binding sites. Although both antibacterials are highly protein-bound (93% or more),[1] they are acidic and do not bind to the same sites as the verapamil (a base), so that this mechanism of interaction seems very unlikely. This seems to be the first and only report of this reaction, and the suggestion by the authors that it was due to a drug interaction has been seriously questioned.[2] There seems to be no other evidence that either of these antibacterials interact with verapamil, either given orally or intravenously. The current evidence is insufficient to suggest that extra caution is warranted if these drugs are given concurrently.

2. Horn JR, Hansten PD. Comment: pitfalls in reporting drug interactions. *Ann Pharmacother* (1993) 27, 1545–6.

Calcium-channel blockers; Verapamil + Sulfinpyrazone

The clearance of verapamil is markedly increased by sulfinpyrazone.

Clinical evidence, mechanism, importance and management

A study in 8 healthy subjects found that sulfinpyrazone 800 mg daily for a week, increased the clearance of a single oral dose of verapamil by about threefold, possibly due to an increase in its liver metabolism.[1] The clinical importance of this effect is uncertain, but be alert for reduced verapamil effects. It seems probable that the dosage of verapamil may need to be increased, or an alternative drug considered.

24

Cardiovascular drugs, miscellaneous

The drugs dealt with in this section include the centrally acting drugs (e.g. clonidine, methyldopa), inotropes and vasopressors (e.g. adrenaline, phenylephrine), adrenergic neurone blockers (e.g. guanethidine), some vasodilator antihypertensives (e.g. hydralazine, diazoxide), nitrates (e.g. glyceryl trinitrate), potassium channel activators (e.g. nicorandil), peripheral vasodilators (e.g. pentoxifylline), calcium sensitisers (e.g. levosimendan), endothelin receptor antagonists (e.g. ambrisentan, bosentan and sitaxentan), direct renin inhibitors (e.g. aliskiren) and other drugs used in the management of angina (e.g. ivabradine and ranolazine).

(a) Miscellaneous antihypertensives

The combination of two antihypertensive drugs often results in an increased antihypertensive action. Likewise the combination of drugs that may have hypotension as an adverse effect, can lead to an unexpected increase in hypotension. Examples of this type of interaction are discussed in the monograph 'Antihypertensives + Other drugs that affect blood pressure', p.1051. Some drugs are known to antagonise the effect of antihypertensives, and these are also generally discussed in this monograph.

(b) Sympathomimetics

Many of the inotropes and vasopressors have actions on the sympathetic nervous system. Noradrenaline (norepinephrine) is the principal neurotransmitter involved in the final link between nerve endings of the sympathetic nervous system and the adrenergic receptors of the organs or tissues innervated. The effects of stimulating this system can be reproduced or mimicked by exogenous noradrenaline and by a number of other drugs that also stimulate these receptors. The drugs that behave in this way are described as 'sympathomimetics' and act either directly, like noradrenaline, on the adrenergic receptors, or indirectly by releasing stored noradrenaline from the nerve endings. Some drugs do both. This is very simply illustrated in 'Figure 24.1', (below).

The adrenergic receptors of the sympathetic system are not identical but can be subdivided into two main types, namely alpha and beta receptors, which can then be further subdivided. The sympathomimetics are categorised in 'Table 24.1', (p.1048), and a brief summary of the principal effects of stimulation of these receptors is listed below:

- Alpha$_1$ (vasoconstriction, increased blood pressure and sometimes reflex bradycardia; contraction of smooth muscle; mydriasis in the eye)
- Alpha$_2$ (role in feedback inhibition of neurotransmitter release; inhibition of insulin release)
- Beta$_1$ (increased rate and force of contraction or the heart)
- Beta$_2$ (vasodilatation and bronchodilation; uterine relaxation and decreased gastrointestinal motility; release of insulin)

A third distinct group of receptors, which occur primarily within the CNS and may be affected by some sympathomimetics, are the dopamine receptors.

It is therefore possible to broadly categorise the sympathomimetics into groups according to their activity.

Given these wide ranging actions on a number of different receptors the group 'sympathomimetics' is clearly a very diverse collection of drugs with a wide range of uses. One should not, therefore, extrapolate the interactions seen with one drug to any other without fully taking into account their differences. For this reason, where possible, this term has been avoided and drugs have been grouped by therapeutic use. This section is generally concerned with the interactions of sympathomimetics that have predominately cardiovascular actions (mainly through stimulation of alpha$_1$ and/or beta$_1$ receptors). Those used as decongestants (through stimulation of alpha receptors with or without beta activity) are mainly discussed in 'Miscellaneous', (p.1546), but some of these drugs are also given intravenously for their pressor actions, in which case their interactions are discussed here. Interactions involving beta agonists, such as salbutamol, which selectively stimulate the beta$_2$ receptors in bronchi causing bronchodilation, are mainly covered in 'Respiratory drugs', (p.1413) and interactions involving dopaminergics, such as levodopa, are dealt with in 'Antiparkinsonian and related drugs', (p.784).

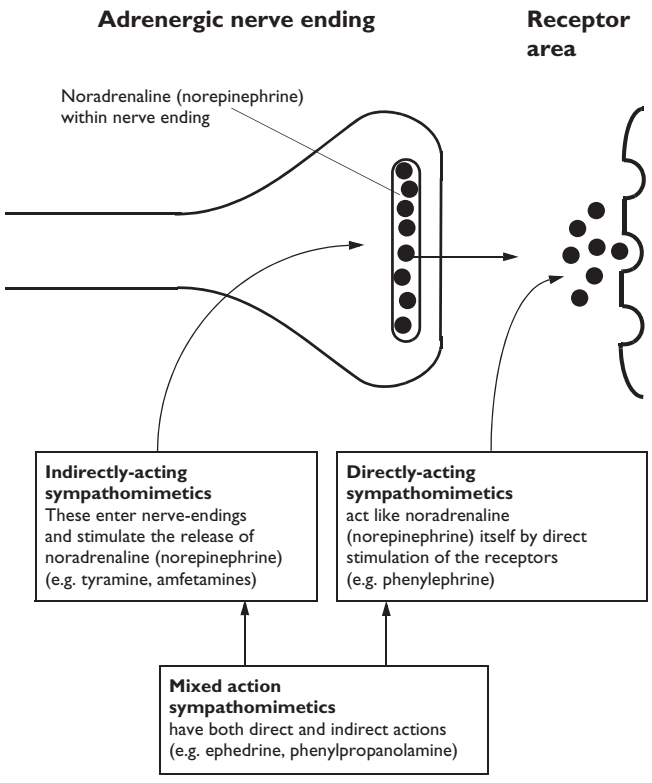

Fig. 24.1 A very simple illustration of the modes of action of indirectly-acting, directly-acting and mixed action sympathomimetics at adrenergic neurones.

Table 24.1 A categorisation of some sympathomimetic drugs

Drug	*Receptors stimulated*
Direct stimulators of alpha and beta receptors	
Adrenaline (Epinephrine)	Beta more marked than alpha
Mainly direct stimulators of alpha receptors	
Phenylephrine	Predominantly alpha
Metaraminol	Predominantly alpha
Methoxamine	Predominantly alpha
Noradrenaline (Norepinephrine)	Predominantly alpha
Mainly direct stimulators of beta-1 receptors	
Dobutamine	Predominantly beta-1, some beta-2 and alpha
Dopamine	Predominantly beta-1, some alpha
Direct stimulators of beta-1 and beta-2 receptors (beta-agonist bronchodilators)	
Bambuterol	Predominantly beta-2
Fenoterol	Predominantly beta-2
Formoterol	Predominantly beta-2
Isoetharine	Predominantly beta-2
Isoprenaline (Isoproterenol)	Beta-1 and beta-2
Orciprenaline	Predominantly beta-2
Pirbuterol	Predominantly beta-2
Reproterol	Predominantly beta-2
Rimiterol	Predominantly beta-2
Ritodrine	Predominantly beta-2
Salbutamol (Albuterol)	Predominantly beta-2
Salmeterol	Predominantly beta-2
Terbutaline	Predominantly beta-2
Tulobuterol	Predominantly beta-2
Direct and indirect stimulators of alpha and beta receptors	
Ephedrine	Alpha and beta
Etefedrine	Alpha and beta
Phenylpropanolamine	Alpha and beta
Pseudoephedrine	Alpha and beta
Mainly indirect stimulators of alpha and beta receptors	
Amfetamine (Amphetamine)	Alpha and beta – also central stimulant
Mephentermine	Alpha and beta – also central stimulant
Methylphenidate	Alpha and beta – also central stimulant
Tyramine	Alpha and beta

Aliskiren + Miscellaneous

A number of studies found that there were no clinically significant pharmacokinetic interactions between aliskiren and allopurinol, atenolol, cimetidine, digoxin, fenofibrate, irbesartan, isosorbide mononitrate, lovastatin, ramipril or valsartan. There was no pharmacokinetic interaction between aliskiren and celecoxib, but the concurrent use of aliskiren with NSAIDs in patients with renal impairment such as the elderly, may result in further deterioration in renal function and even renal failure.

Clinical evidence, mechanism, importance and management

(a) Allopurinol

In a study in 20 healthy subjects given aliskiren 300 mg daily, allopurinol 300 mg daily for 5 days did not affect the AUC or peak plasma levels of aliskiren, although there was wide variability in plasma levels.[1]

(b) Angiotensin II receptor antagonists

A study in 18 healthy subjects given aliskiren 300 mg daily for 11 days with **valsartan** 320 mg daily for the last 4 days found that the AUC of aliskiren was reduced by 26% and the AUC of **valsartan** was decreased by 14%.[2] The US manufacturer states that multiple dosing with **irbesartan** reduces the peak levels of aliskiren by up to 50%.[3] However, in a study in healthy subjects and patients with renal impairment, **irbesartan** 300 mg daily for 7 days had no effect on the pharmacokinetics of steady-state aliskiren 300 mg daily and concurrent use was well tolerated.[4]

(c) Cimetidine

In a study in 22 healthy subjects given aliskiren 300 mg daily for 7 days, followed by aliskiren with cimetidine 800 mg daily for a further 5 days, cimetidine increased the peak plasma levels and AUC of aliskiren by 25% and 20%, respectively.[1] Another study in 12 healthy subjects given cimetidine 800 mg daily for 5 days, the AUC, peak plasma level and half-life of a single 150-mg dose of aliskiren given on day 3 were increased by 17%, 19%, and 15%, respectively.[5] These modest pharmacokinetic changes would not be expected to be clinically relevant.

(d) Digoxin

In a study, 19 healthy subjects were given aliskiren 300 mg daily for 7 days, then after a washout period, digoxin 250 micrograms daily for 9 days, with aliskiren 300 mg daily added for a further 7 days. Digoxin had no significant effect on the pharmacokinetics of aliskiren. The AUC of digoxin was reduced by 15%, but peak digoxin levels were unaffected by aliskiren.[6] This modest change in digoxin levels would not be expected to be clinically relevant.

(e) Food

The AUC and peak plasma levels of aliskiren are reduced by about 70% and 85%, respectively when it is taken with a high-fat meal.[3,7] The UK manufacturer recommends taking aliskiren with a light meal, preferably at the same time each day.[7] Due to lack of data, a possible interaction between aliskiren and **grapefruit juice** cannot be excluded. Therefore, the UK manufacturer advises that grapefruit juice should not be taken with aliskiren.[7]

(f) Isosorbide mononitrate

In a study, 18 healthy subjects were given isosorbide mononitrate alone for 3 days, then after a washout period, aliskiren 300 mg daily for 7 days, then aliskiren was given with isosorbide mononitrate 40 mg daily for a further 3 days. There was no clinically significant pharmacokinetic interaction but dizziness and low blood pressure were more frequent during concurrent use than with either drug alone.[8] It may be prudent to be alert for these effects if both drugs are given, and adjust the doses accordingly.

(g) NSAIDs

In a study, aliskiren 300 mg daily was given to 22 healthy subjects for 7 days alone, and then with **celecoxib** 200 mg twice daily for a further 4.5 days. **Celecoxib** caused a slight (14%) reduction in the aliskiren AUC and there was wide variability in peak plasma levels. Dizziness was more frequently reported during concurrent use than with either drug alone.[1] In a single-dose study, **celecoxib** 200 mg caused a slight increase (about 9%) in the AUC of aliskiren and increased peak plasma levels by 36%.[5] Although there is not a significant pharmacokinetic interaction between aliskiren and celecoxib, NSAIDs may reduce the antihypertensive effect of aliskiren through their action on the renin-angiotensin system. Furthermore, in dehydrated or elderly patients with some renal impairment, the concurrent aliskiren and NSAIDs may result in further deterioration of renal function and possible renal failure. The UK manufacturer recommends caution, especially in the elderly.[7]

(h) Other drugs

Single-dose studies found no pharmacokinetic interactions between aliskiren 150 mg and either **lovastatin** 40 mg or **atenolol** 100 mg.[5] In a study in 21 healthy subjects, there was no pharmacokinetic interaction between aliskiren 300 mg daily and **fenofibrate** 200 mg daily.[9]

Peak plasma levels of aliskiren were increased by about 30% and the AUC was increased by about 15% when it was given with **ramipril** in an initial dose of 2.5 mg titrated to 10 mg daily. The AUC of **ramipril** was increased by 22% during the use of aliskiren.[2] These pharmacokinetic changes would not be expected to be clinically relevant, although additive blood pressure lowering effects may occur.

Aliskiren + P-glycoprotein inducers and inhibitors

Atorvastatin, ciclosporin and ketoconazole increase aliskiren levels, probably by inhibiting P-glycoprotein. Other P-glycoprotein inhibitors are predicted to interact similarly, and P-glycoprotein inducers (e.g. rifampicin) are predicted to lower aliskiren levels.

Clinical evidence

(a) Atorvastatin

In a study, 20 healthy subjects were given aliskiren 300 mg daily for 11 days, with atorvastatin 80 mg daily for the last 4 days. Atorvastatin increased the AUC and peak plasma levels of aliskiren by 47% and 50%, respectively, and reduced its clearance by 34%. Peak levels of atorvastatin were reduced by 23% during the concurrent use of aliskiren, but there were no clinically significant effects on the AUC of atorvastatin and its metabolites.[1]

(b) Ciclosporin

A study in healthy subjects found that ciclosporin, in doses of 200 mg or 600 mg, increased the peak levels and AUC of a single 75-mg dose of aliskiren by about 2.5-fold and 5-fold, respectively. It was suggested that these increases may be higher with larger doses of aliskiren.[2,3]

(c) Ketoconazole

In a study, 20 healthy subjects were given aliskiren 300 mg daily for 11 days, with the concurrent use of ketoconazole 200 mg twice daily for the last 4 days. Ketoconazole increased the AUC, peak plasma levels and minimum plasma levels of aliskiren by 76%, 81% and 64%, respectively. The clearance of aliskiren was reduced by 43%.[1] Ketoconazole is therefore predicted to effectively double the dose of aliskiren, and doses of this order (up to 600 mg of aliskiren daily) have been found to be well-tolerat-

ed.[2] A daily dose of ketoconazole 400 mg is predicted to increase blood levels further.[3]

Mechanism

P-glycoprotein is reported to be the major efflux system involved in the intestinal absorption and biliary excretion of aliskiren. The potential for interactions mediated by P-glycoprotein probably depends on the degree of inhibition of the transporter. Therefore moderate and potent inhibitors of P-glycoprotein such as ketoconazole and ciclosporin cause significant increases in aliskiren levels.

Importance and management

Evidence for an interaction between aliskiren and atorvastatin, ciclosporin or ketoconazole is limited, but in line with the way these drugs are known to interact. Moderate and potent inhibitors of P-glycoprotein cause significant increases in the plasma levels of aliskiren and it is suggested that they may have greater effects on tissue levels. The manufacturers of aliskiren therefore contraindicate its use with potent inhibitors of P-glycoprotein such as ciclosporin and **quinidine**.[2,3]

The UK manufacturer advises caution if aliskiren is given with ketoconazole or other moderate inhibitors of P-glycoprotein. They specifically name **amiodarone**, **clarithromycin**, **erythromycin**, **itraconazole**, and **telithromycin**.[2] The effect of atorvastatin is more modest, but until more is known, some caution is probably advisable if it is given with aliskiren. If any of these drugs are given with aliskiren it may be prudent to be alert for aliskiren adverse effects such as diarrhoea, dyspepsia and hypotension. Adjust the aliskiren dose as necessary.

The effect of aliskiren on atorvastatin is not expected to be clinically relevant. Studies with P-glycoprotein *inducers* do not appear to have been undertaken, but based on the known effects of the P-glycoprotein inhibitors, it is logical to expect that they may decrease aliskiren levels. The UK manufacturers specifically name **rifampicin** and **St John's wort**.[2] It may therefore be prudent to monitor concurrent use for aliskiren efficacy.

Antihypertensives + Hormonal contraceptives or HRT

Oral combined hormonal contraceptives are associated with increased blood pressure and may antagonise the efficacy of antihypertensive drugs. However, the effects are far greater with the high-dose contraceptives that were used historically, and the risks appear to be smaller with the newer low-dose contraceptives. The risks with progestogen-only contraceptives seem to be negligible.
Drospirenone HRT appears to further decrease blood pressure when given with enalapril or hydrochlorothiazide.

Clinical evidence, mechanism, importance and management

(a) Hormonal contraceptives

Early after the introduction of the oral **combined hormonal contraceptives** it was realised that they can cause increases in blood pressure and clinical hypertension.[1,2] One study[3] from the 1970s, in 83 women, found that the average rise in blood pressure was 9.2/5 mmHg, and that it was about twice as likely to occur as in those not taking a contraceptive. Another study from the 1980s found that women taking an oral combined hormonal contraceptive containing **levonorgestrel** 250 micrograms and **ethinylestradiol** 50 micrograms had higher blood pressures (systolic and diastolic blood pressures were 3.6 to 5 mmHg and 1.9 to 2.7 mmHg higher, respectively) than a similar group of women using non-hormonal contraception.[4] Additionally, cases were noted where antihypertensives (at that time, commonly **guanethidine** and/or **methyldopa**) were not that effective in women with hypertension taking oral **combined hormonal contraceptives**.[2,5] Although modern oral **combined hormonal contraceptives** are lower dose, they are still associated with a small increased risk of elevated blood pressure.[6,7] A UK study found that oral **combined hormonal contraceptives** were associated with a 2.6/1.8 mmHg rise in blood pressure, whereas oral **progestogen-only contraceptives** did not affect blood pressure.[6] A review of four studies also found no significant association between high blood pressure and the use of oral **progestogen-only hormonal contraceptives** during follow-up periods of 2 to 3 years.[8] A study in women who had been using depot **medroxyprogesterone** for 10 years, found that it did not raise blood pressure.[9]

This is only a very brief review of this subject, but the risks of hypertension with **combined hormonal contraceptives** appear to be modest. Nevertheless, it is generally advised that **combined hormonal contraceptives** are not used in women with hypertension, and they should be avoided in women with other risk factors for cardiovascular disease. Where considered appropriate, oral **combined hormonal contraceptives** may be used in women with treated hypertension, if blood pressure control is good. However, **progestogen-only contraceptives** are usually the preferred hormonal method of contraception in women with hypertension.[10] Although **drospirenone** HRT has been shown to lower blood pressure (see *Drospirenone HRT*, below), there appear to be no data on blood pressure in women taking the drospirenone-containing **combined hormonal contraceptives**.

(b) Menopausal HRT

In general, use of menopausal HRT has been found to have little effect on blood pressure in hypertensive women.[11]

Drospirenone HRT. In a study in 24 postmenopausal women with hypertension taking **enalapril** 10 mg twice daily, the use of **enalapril** with drospirenone 3 mg with **estradiol** 1 mg (12 women) produced a significant *decrease* in blood pressure of 9/5 mmHg after 14 days of treatment, when compared with the placebo group (12 patients).[12] In another study, 34 hypertensive postmenopausal women taking **hydrochlorothiazide** 25 mg daily were given either drospirenone 3 mg with **estradiol** 1 mg or placebo. Mean systolic and diastolic blood pressures were *reduced* significantly (by 7.2 mmHg and 4.5 mmHg, respectively) when compared with the placebo group, and drospirenone with **estradiol** also counteracted the **hydrochlorothiazide**-induced potassium loss. Drospirenone with **estradiol** did not affect the pharmacokinetics of **hydrochlorothiazide**.[13]
Note that drospirenone is an analogue of spironolactone, and shares its aldosterone antagonist effects, thereby lowering blood pressure and having some potassium-sparing effects.
Bear in mind the possibility that drospirenone HRT might further decrease blood pressure in women taking antihypertensives. However, hypertension has also been reported as an adverse effect.[14,15] It would be prudent to monitor blood pressure on starting concurrent use.
Note also that drospirenone has some potassium-sparing effects, which attenuated the effect of **hydrochlorothiazide** in the study cited, and might be additive with the effect of ACE inhibitors and angiotensin II receptor antagonists, see 'Drospirenone-containing contraceptives or HRT + Potassium-sparing drugs', p.1197.

Antihypertensives + Other drugs that affect blood pressure

The blood pressure lowering effect of the antihypertensives can be enhanced by other antihypertensives, as would be expected. Although first-dose hypotension (dizziness, lightheadedness, fainting) can occur with some combinations, the additive effects are usually clinically useful. Perhaps of more concern is the use of antihypertensives with drugs that lower blood pressure as an adverse effect, where the effects may not be anticipated. Some drugs antagonise the blood pressure-lowering effects of the antihypertensives and should therefore be used with caution.

Clinical evidence, mechanism, importance and management

(a) Antihypertensive drugs

Enhanced hypotensive effects should be expected when using two antihypertensives together and it is widely acknowledged that most people require more than one antihypertensive to control blood pressure.[1,2] In the US, more than two-thirds of patients receive two or more antihypertensives in order to reach the desired target blood pressure. Not only does this improve blood pressure control, but adverse effects can also be reduced as lower doses of each drug can be used.[3]

Therefore many antihypertensive combinations produce additive hypotensive effects that are exploited clinically. Calcium-channel blockers and diuretics (see 'Calcium-channel blockers + Diuretics', p.1032) are often used together for additional blood pressure lowering in patients with hypertension. However, the side effects of the drug combinations may also be additive, and although there are only a few reports describing these additive interactions, they are highly probable, and caution is advised when using two antihypertensives together. The most common symptoms seen in hypotensive patients are dizziness, fatigue, headache, nausea, confusion, general weakness, lightheadedness, faintness and possible loss of consciousness.

Investigation of whether the effects of two antihypertensives is additive, greater than additive or less than additive is difficult to assess.[2] However, in some cases combining two or more antihypertensives has led to severe, first-dose hypotension, see 'Alpha blockers + ACE inhibitors or Angiotensin II receptor antagonists', p.93. Further, life-threatening bradycardia, asystole and sinus arrest can occur when antihypertensives that cause cardiodepression are given together (see 'Beta blockers + Calcium-channel blockers; Diltiazem', p.1002).

In contrast, a sharp and serious rise in blood pressure (rebound hypertension) can occur following the sudden withdrawal of clonidine, and this can be exacerbated in the presence of a beta blocker (see 'Clonidine and related drugs + Beta blockers', p.1053). In some cases fatalities have occurred. 'Table 24.2', (p.1052) lists antihypertensive combinations that have been implicated in adverse events.

(b) Drugs with significant hypotensive adverse effects

Caution must also be used when combining two or more drugs that, although not primarily indicated for hypertension, may have blood pressure lowering adverse effects. In fact, it is these drugs, rather than drugs commonly given for their blood pressure lowering effects that may cause more of a problem, as the effects are less likely to be deliberately sought. These drugs are listed in 'Table 24.3', (p.1052) with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

(c) Drugs that antagonise hypotensive effects

When using antihypertensive drugs it is important to consider the implications of using drugs that antagonise their effects. The NSAIDs are the prime example of this. In the US, NSAIDs and steroids are reported to be the most common classes of drugs that raise blood pressure. Calcineurin inhibitors (ciclosporin and tacrolimus) and epoetins are reported to raise blood pressure in most patients.[4] Similarly, **danazol** is reported oppose the action of antihypertensives, possibly by increasing fluid retention.[5] Drugs that are thought to antagonise the effects of antihypertensives are listed in 'Table 24.4', (p.1052), with cross-references to the individual monographs that discuss the reports of adverse effects from these combinations.

Antihypertensives + Phenylpropanolamine

A single dose of a sustained-release preparation of phenylpropanolamine and brompheniramine was found to cause a minor and clinically insignificant rise in the blood pressures of patients taking various antihypertensives.

Clinical evidence, mechanism, importance and management

A randomised, double-blind, crossover study in 13 patients with hypertension controlled with unnamed **diuretics** (7), **ACE inhibitors** (6), **beta blockers** (5), **calcium-channel blockers** (1) and a **centrally acting alpha-agonist** (1) found that a single dose of *Dimetapp Extentabs* (phenylpropanolamine 75 mg with brompheniramine 12 mg) caused only a minor rise in blood pressure of 1.7/0.9 mmHg over 4 hours.[1] This sustained-release preparation in this dose has therefore no clinically important effect on blood pressure, but (as the authors point out), these results do not necessarily apply to different doses and immediate-release preparations. A marked rise in blood pressure was seen in one patient taking **methyldopa** and **oxprenolol** when given phenylpropanolamine, see 'Methyldopa + Nasal decongestants', p.1070. Consider also 'Beta blockers + Phenylpropanolamine', p.1015.

Clonidine + Antipsychotics

The hypotensive adverse effects of the phenothiazines, and possibly haloperidol may be additive with the antihypertensive effects of clonidine. Patients may feel faint and dizzy if they stand up quickly.

Clinical evidence

One report describes a patient who experienced dizziness and hypotension (systolic blood pressure 76 mmHg) about an hour after being given **chlorpromazine** 100 mg, clonidine 100 micrograms and furosemide 40 mg. Another patient also experienced hypotension 2 hours after being given clonidine 100 micrograms and a 1-mg intramuscular dose of **haloperidol**.[1]

There is also an isolated and unexplained case of a patient with psychosis taking **fluphenazine decanoate** who began to exhibit delirium, agitation, disorientation, short-term memory loss, confusion and clouded consciousness within 10 days of starting to take clonidine 200 micrograms daily. These symptoms disappeared when the clonidine was stopped and returned when it was re-started. Previous use of **haloperidol** with clonidine had been uneventful.[2]

Mechanism

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. However, note that in contrast to the case report above, *animal* studies have shown that chlorpromazine *reduces* the antihypertensive effect of clonidine.[3]

Importance and management

The increased hypotension and orthostasis that can occur if phenothiazines are used with antihypertensive drugs such as clonidine is established. Note that, of the phenothiazines, **levomepromazine** is particularly associated with postural hypotension. One report suggests that haloperidol may interact similarly. Monitor, particularly during the initial stages of concurrent use, and warn patients that if they feel faint and dizzy they should lie down, and that they should remain lying down until symptoms abate completely. Dose adjustment may be necessary.

Table 24.2 Antihypertensive + Antihypertensive drug interactions

Drugs	*Additive antihypertensive interactions*
ACE inhibitors	ACE inhibitors + Beta blockers ACE inhibitors + Calcium-channel blockers ACE inhibitors + Clonidine ACE inhibitors + Diuretics; Loop, Thiazide and related Alpha blockers + ACE inhibitors or Angiotensin II receptor antagonists

Table 24.3 Antihypertensive drug interactions involving drugs with significant hypotensive properties or adverse effects

Drugs	*Additive antihypertensive interactions*
Alcohol	Alcohol + Antihypertensives
Anaesthetics	Anaesthetics, general + ACE inhibitors or Angiotensin II receptor antagonists Anaesthetics, general + Beta blockers Anaesthetics, general + MAOIs and related drugs Anaesthetics, local + Antihypertensives
Antipsychotics	ACE inhibitors + Antipsychotics Beta blockers + Haloperidol Clonidine + Antipsychotics Clozapine + Antihypertensives Guanethidine + Antipsychotics Methyldopa + Haloperidol
Dopamine agonists (e.g. apomorphine, bromocriptine etc.)	Apomorphine + Miscellaneous Bromocriptine and other dopamine agonists + ACE inhibitors
Levodopa	Guanethidine + Levodopa Levodopa + Methyldopa
Moxisylyte	Moxisylyte + Miscellaneous
Phosphodiesterase type-5 inhibitors	Phosphodiesterase type-5 inhibitors + Alpha blockers Phosphodiesterase type-5 inhibitors + Antihypertensives Phosphodiesterase type-5 inhibitors + Nitrates
Procarbazine	Procarbazine + Miscellaneous
Tizanidine	Tizanidine + Antihypertensives
Other drugs suggested to cause hypotension but where no reports of adverse interaction found	Aldesleukin Alprostadil MAOIs

Table 24.4 Antihypertensive drugs and drugs antagonising their effect

Drugs	*Antagonising antihypertensive interactions*
Amfetamines	Guanethidine + Amfetamines and related drugs
High-dose aspirin	ACE inhibitors + Aspirin
Carbenoxolone	Carbenoxolone + Antihypertensives
Hormonal contraceptives	Antihypertensives + Hormonal contraceptives or HRT
Epoetin	ACE inhibitors and Angiotensin II receptor antagonists + Epoetins
NSAIDs	ACE inhibitors + NSAIDs Alpha blockers + Aspirin or NSAIDs Angiotensin II receptor antagonists + Aspirin or NSAIDs Beta blockers + Aspirin or NSAIDs Calcium-channel blockers + Aspirin or NSAIDs Guanethidine + NSAIDs Hydralazine + NSAIDs Thiazide diuretics + NSAIDs
Phenylpropanolamine	Antihypertensives + Phenylpropanolamine Beta blockers + Phenylpropanolamine
Other drugs suggested to antagonise the effects of antihypertensives	Corticosteroids

The manufacturers of clonidine note that a reduced antihypertensive effect may occur with antipsychotics with alpha-blocking properties (e.g. chlorpromazine),.[4] but the only evidence for this appears to come from *animal* data. However, it has been suggested that the tricyclics may interact by a similar mechanism, see 'Clonidine and related drugs + Tricyclic and related antidepressants', p.1054.

Clonidine and related drugs + Beta blockers

The use of clonidine with beta blockers can be therapeutically valuable, but a sharp and serious rise in blood pressure (rebound hypertension) can follow the sudden withdrawal of clonidine, which may be worsened by the presence of a beta blocker. Moxonidine is predicted to interact similarly. Isolated cases of marked bradycardia and hypotension have been seen in patients given clonidine with esmolol. There are also two reports describing paradoxical hypertension when clonidine was given with a beta blocker.

Clinical evidence

(a) Antagonism of the hypotensive effects

In a study in 10 patients, the concurrent use of **sotalol** 160 mg daily and clonidine 450 micrograms daily caused a marked rise in blood pressure in 6 of the 10 patients, compared with either clonidine alone (3 patients) or **sotalol** alone (3 patients). Of the 4 patients who did not have a marked rise in blood pressure, 2 patients had blood pressures that were lower than with either drug alone, and 2 patients had no appreciable change in blood pressure.[1] Two cases of hypertension involving clonidine with **propranolol** have also been described,[2] and in some studies the concurrent use of clonidine and **nadolol**[3] or **propranolol**[4] has been no more effective than either drug alone.

(b) Bradycardia and hypotension

A man anaesthetised with thiopental and diamorphine, with oxygen, nitrous oxide, enflurane and atracurium, was given clonidine 50 micrograms to control hypertension. After 15 minutes he became tachycardic with a heart rate of up to 170 bpm. **Esmolol** 75 mg was given by slow infusion, whereupon his heart rate fell to 20 bpm. He responded to atropine 1.2 mg, adrenaline (epinephrine) 1 mg and calcium chloride 10 mL with a stable heart rate of 110 bpm.[5] In a clinical study, 32 patients were given **esmolol** during surgery: one patient developed marked hypotension and bradycardia, which responded to ephedrine 10 mg. It was noted that this patient had been receiving clonidine.[6] A subset of 5 patients involved in a study investigating the use of clonidine with **propranolol** and minoxidil had a reduction in blood pressure when clonidine (200 to 400 micrograms daily) was added. After the discontinuation of **propranolol**, blood pressure returned to that seen before clonidine was added, indicating that **propranolol** and clonidine have additive hypotensive actions.[7] Similarly, **atenolol** and clonidine have been found to have additive hypotensive effects.[3,4]

(c) Peripheral vascular disorders

The manufacturer of clonidine notes that the concurrent use of a beta blocker may possibly potentiate peripheral vascular disorders.[8] This is based on the known pharmacology of the drugs,[9] and no specific cases appear to have been reported.

(d) Rebound hypertension

A woman with a blood pressure of 180/140 mmHg was taking clonidine and **timolol**. When the clonidine was stopped in error, she developed a violent throbbing headache and became progressively confused, ataxic and semicomatose, and had a grand mal convulsion. Her blood pressure was found to have risen to over 300/185 mmHg.[10]

A number of other reports describe similar cases of hypertensive rebound (a sudden and serious rise in blood pressure) within 24 to 72 hours of stopping the clonidine, apparently worsened by the presence of **propranolol**.[11-15] The symptoms resemble those of phaeochromocytoma, and include tremor, apprehension, flushing, nausea, vomiting, severe headache, and a serious rise in blood pressure. One patient died from a cerebellar haemorrhage.[14]

Mechanism

The normal additive hypotensive effects of these drugs result from their actions at different but complementary sites in the cardiovascular system. Just why antagonism sometimes occurs is unexplained. The hypertensive rebound following clonidine withdrawal is thought to be due to an increase in the levels of circulating catecholamines. With the beta (vasodilator) effects blocked by a beta blocker, the alpha (vasoconstrictor) effects of the catecholamines are unopposed and the hypertension is further exaggerated.

Importance and management

The interaction whereby the beta blockers seriously worsen the rebound hypertension following clonidine withdrawal is well established. This adverse effect can be controlled by stopping the beta blocker several days before starting a gradual withdrawal of clonidine.[16] A successful alternative is to replace the clonidine and the beta blocker with labetalol,[17] which is both an alpha and a beta blocker: The blood catecholamine levels still rise markedly (20-fold) and the patient may experience tremor, nausea, apprehension and palpitations, but no serious blood pressure rise or headaches appear to occur.[17] The dose of labetalol will need to be titrated to effect, with regular checks on the blood pressure over 2 to 3 days. If a hypertensive episode develops, it can be managed with an alpha-blocking drug such as phentolamine.[11] Diazoxide is also said to be effective.[10,14] Reintroduction of oral or intravenous clonidine should also stabilise the situation. It is clearly important to emphasise to patients taking clonidine and beta blockers that they should not stop taking these drugs without seeking medical advice.

Clonidine and atenolol (a cardio-selective beta blocker) have additive hypotensive effects and smaller doses of clonidine can be given, which decreases its troublesome adverse effects (sedation and dry mouth). In contrast, limited evidence suggests that if clonidine is given with propranolol or nadolol (non-selective beta blockers) the blood pressure reductions were the same as with either drug alone, although this has not been confirmed in other studies. The weight of evidence suggests that paradoxical hypertension is rare.[1,2]

There appears to be no evidence regarding this interaction with **moxonidine**, which is related to clonidine. Moxonidine is reported to have less affinity for central alpha-receptors than clonidine and therefore would be expected to present less of a risk. Furthermore, no such rebound hypertension has been seen when moxonidine is withdrawn. However, to be on the safe side the manufacturers advise that any beta blocker should be stopped first, followed by the moxonidine a few days later.[18,19]

Clonidine + Bupropion

In a study in 8 healthy subjects, bupropion 100 mg three times daily for 9 days did not reduce the hypotensive effect of a single 300-microgram dose of oral clonidine.[1]

1. Cubeddu LX, Cloutier G, Gross K, Grippo R, Tanner L, Lerea L, Shakarjian M, Knowlton G, Harden TK, Arendshorst W and Rogers JF. Bupropion does not antagonize cardiovascular actions of clonidine in normal subjects and spontaneously hypertensive rats. *Clin Pharmacol Ther* (1984) 35, 576–84.

Clonidine and related drugs + CNS depressants

Increased sedation may occur if alcohol or other CNS depressants are taken with clonidine, moxonidine, guanfacine or guanabenz.

Clinical evidence, mechanism, importance and management

Sedation is a common adverse effect of clonidine and other central alpha-adrenoceptor agonists such as **moxonidine**, **guanfacine** and **guanabenz**, particularly during the initial stages of treatment.[1-4] However, the effects of this in the presence of other CNS depressants does not appear to have been widely studied.

In one study with **moxonidine**, the cognitive function of 24 healthy subjects was not impaired by moxonidine 400 micrograms daily, but the presence of moxonidine was found to increase the cognitive impairment caused by **lorazepam** 1 mg daily.[1] For this reason the manufacturer warns that the sedative effects of the benzodiazepines may possibly be enhanced by moxonidine,[2] and this also seems possible with the related drugs **clonidine**, **guanfacine** and **guanabenz**. Patients starting treatment with these drugs should be warned that their tolerance to **alcohol** and other CNS depressant drugs may be diminished. Patients who are affected should not drive or operate machinery.

Clonidine + Hormonal contraceptives

The sedative effects of intravenous clonidine were increased in one study by an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

A study[1] in a group of 10 women found that the sedative effects of a single 1.3-microgram/kg dose of intravenous clonidine were increased by an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 or 250 micrograms). The clinical importance of this is uncertain. Consider also 'Antihypertensives + Hormonal contraceptives or HRT', p.1050.

Clonidine + Naloxone

Naloxone does not appear to alter the blood pressure lowering effects of clonidine, or its effects on heart rate.

Clinical evidence, mechanism, importance and management

A study in *animals* suggesting naloxone blocked the antihypertensive effects of clonidine prompted a placebo-controlled study in 6 patients with hypertension. Each patient received a single oral dose of clonidine 300 micrograms during an infusion of either naloxone 6 micrograms/kg per hour or placebo for 8 hours. Supine and standing blood pressure and heart rate were monitored. Naloxone was not found to affect the hypotensive or bradycardic effect of clonidine.[1]

1. Rogers JF, Cubeddu LX. Naloxone does not antagonize the antihypertensive effect of clonidine in essential hypertension. *Clin Pharmacol Ther* (1983) 34, 68–73.

Clonidine + Prazosin

There is some evidence to suggest that prazosin can reduce the antihypertensive effects of clonidine, whereas some other evidence suggests that this does not occur.

Clinical evidence, mechanism, importance and management

In 18 patients with essential hypertension, the hypotensive effect of a 150-microgram intravenous dose of clonidine was reduced by 47% by prazosin (mean dose 11 mg three times daily for 4 days).[1] A later crossover study by the same research group in 17 patients with essential hypertension (mean blood pressures 170/103 mmHg) found that clonidine 300 micrograms daily for 4 days reduced the mean blood pressure by 38/18 mmHg and prazosin 6 mg daily for 3 days reduced the mean blood pressure by 10/4 mmHg. However, when prazosin and clonidine were given together the mean blood pressure was only reduced to a similar extent as prazosin alone (12/6 mmHg).[2] Similarly, some earlier studies had suggested that the concurrent use of clonidine and prazosin produced only a modest,[3] or no additive antihypertensive effect.[4] Conversely, other studies using the combination have not reported a reduced antihypertensive effect.[5,6] In the presence of prazosin the rebound hypertension following clonidine withdrawal was said to be moderate (a rise from 145/85 mmHg to 169/104 mmHg).[6]

Clonidine is an $alpha_2$ agonist, whereas prazosin is an $alpha_1$ blocker. Consequently, it has been postulated that the drugs may be partially antagonistic when given together, and the authors of the first study cite a number of *animal* studies to support this.[1] Although not conclusive, it seems possible that concurrent use may not always be favourable. Therefore it would seem prudent to monitor the effects of concurrent use on blood pressure.

Clonidine + Rifampicin (Rifampin)

Rifampicin does not interact with clonidine.

Clinical evidence, mechanism, importance and management

In 6 subjects taking clonidine 200 micrograms twice daily the use of rifampicin 600 mg twice daily for 7 days did not affect the elimination kinetics of clonidine, or its effects on pulse rate or blood pressure.[1] No special precautions would seem necessary on concurrent use.

1. Affrime MB, Lowenthal DT, Rufo M. Failure of rifampin to induce the metabolism of clonidine in normal volunteers. *Drug Intell Clin Pharm* (1981) 15, 964–6.

Clonidine and related drugs + Tricyclic and related antidepressants

The tricyclic antidepressants reduce or abolish the antihypertensive effects of clonidine and a case report describes a hypertensive crisis as a result of this interaction. Moxonidine is expected to interact similarly. The tetracyclics, maprotiline and mianserin do

not appear to alter the antihypertensive effects of clonidine, although a case report describes a hypertensive crisis in a patient taking the related drug mirtazapine with clonidine.

Clinical evidence

(a) Tetracyclic and related antidepressants

In a study in 8 healthy subjects, **maprotiline** 100 mg in four divided doses over 22 hours did not alter the effect of a single 300-microgram dose of clonidine on blood pressure or heart rate.[1] **Mianserin** 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 5 patients receiving clonidine.[2,3] Similarly, in healthy subjects, **mianserin** pretreatment did not significantly alter the hypotensive action of a single 300-microgram dose of clonidine.[2,4] In contrast, an isolated report describes hypertensive urgency in a man with end-stage renal disease taking clonidine, metoprolol and losartan when **mirtazapine** (a **mianserin** analogue) was added for depression.[5]

(b) Trazodone

A 12-year-old boy taking clonidine 100 micrograms three times daily and dexamfetamine 15 mg twice daily was given trazodone 50 mg at bedtime. After a few weeks his trazodone dose was increased to 100 mg at bedtime. Within 45 minutes of taking his first increased dose he had a hypotensive episode with bradycardia and sedation. The trazodone dose was reduced back to 50 mg, but the drug was discontinued 2 weeks later because of low blood pressure.[6]

(c) Tricyclic antidepressants

Desipramine 75 mg daily for 2 weeks caused the lying and standing blood pressures of 4 out of 5 hypertensive patients taking clonidine 600 to 1800 micrograms daily (with chlortalidone or hydrochlorothiazide) to rise by 22/15 mmHg and 12/10 mmHg respectively.[7] This interaction has been seen in other patients taking **clomipramine**, **desipramine** and **imipramine**.[8-11] In one study, the antihypertensive effects of a single intravenous dose of clonidine were reduced by about 50% in 6 patients given **desipramine** for 3 weeks.[12] Similarly, in 8 healthy subjects, the blood pressure lowering effect of a single 300-microgram dose of clonidine was reduced by 40 to 50% when it was given on day 9 of treatment with **imipramine** 25 mg three times daily.[13] An elderly woman taking clonidine 200 micrograms daily developed severe frontal headache, dizziness, chest and neck pain and tachycardia of 120 bpm with hypertension (230/124 to 130 mmHg) on the second day of taking **imipramine** 50 mg for incontinence.[14]

A case report describes a 73-year-old woman, who developed rebound hypertension and tachycardia on the withdrawal of clonidine. This may have been made worse by the presence of **amitriptyline**.[15]

A man with severe pain, well controlled with **amitriptyline**, sodium valproate and intrathecal boluses of diamorphine, experienced severe pain within 5 minutes of an intrathecal test dose of clonidine 75 micrograms. It was considered that an interaction between the tricyclic and the clonidine may have been responsible.[16]

Mechanism

Not understood. One idea is that the tricyclics desensitise or block central alpha$_2$-receptors.[17] This would explain the interaction with mirtazapine (a mianserin analogue), which also has alpha-blocking properties.[5] However, mianserin (also an alpha blocker) did not interact.[2] Another idea is that tricyclics block noradrenaline uptake. However, maprotiline, which also blocks noradrenaline uptake, did not interact.[1] Trazodone, which also has alpha-blocking properties was predicted to inhibit the effect of clonidine based on a study in *animals* where it antagonised the hypotensive effect of clonidine when given centrally (note this effect was not seen when it was given intravenously).[18] The case of hypotension described could be explained by the hypotensive effect of trazodone alone, but may have been compounded by the hypotensive effect of clonidine.

Importance and management

The interaction between clonidine and the tricyclics is established and clinically important. The incidence is uncertain but an interaction is not seen in all patients.[7] Avoid concurrent use unless the effects can be monitored. Increasing the dose of clonidine may possibly be effective. The clonidine dose was apparently successfully titrated in 10 out of 11 hypertensive patients already taking amitriptyline or imipramine.[19] Only clomipramine, desipramine and imipramine have been implicated so far, but other tricyclics would be expected to behave similarly (amitriptyline, **nortriptyline** and **protriptyline** have been shown to interact in *animals*[20]). The tetracyclic antidepressants maprotiline and mianserin do not generally appear to interact with clonidine. The isolated case of hypotension with trazodone and the isolated case of severe pain with amitriptyline and clonidine are of unknown general importance.

There appears to be no evidence regarding an interaction between **moxonidine** and the tricyclics. The manufacturer of moxonidine advises avoiding tricyclic antidepressants, because of the lack of clinical experience of concurrent use.[21] Presumably, this is because moxonidine is related to clonidine. It may therefore be prudent to follow the same precautions described for clonidine.

Diazoxide + Hydralazine

Severe hypotension, in some cases fatal, has followed the use of high doses of intravenous diazoxide, given before or after hydralazine.

Clinical evidence

A previously normotensive 25-year-old woman had a blood pressure of 250/150 mmHg during the 34th week of pregnancy, which did not respond to intravenous magnesium sulfate 4 g. Her blood pressure fell transiently to 170/120 mmHg when she was given hydralazine 15 mg intravenously. One hour later intravenous diazoxide 5 mg/kg resulted in a blood pressure fall to 60/0 mmHg. Despite large doses of noradrenaline (norepinephrine), the hypotension persisted and the woman died.[1]

Other cases of severe hypotension in patients given high doses of intravenous diazoxide and intravenous or oral hydralazine are described in this[1] and other studies and reports.[2-4] In some instances the patients had also received other antihypertensives such as methyldopa[1] or reserpine.[1,4] At least three of the cases had a fatal outcome.[4]

Mechanism

Not fully understood. The (vasodilatory) hypotensive effects of the two drugs are additive and it would seem that in some instances the normal compensatory responses of the cardiovascular system to maintain an ade-

quate blood pressure reach their limit. This can occur with intravenous diazoxide alone.[2]

Importance and management

The concurrent use of intravenous diazoxide and hydralazine should be undertaken extremely cautiously with thorough monitoring. Note that the doses of diazoxide used in the above reports were frequently higher than those currently recommended for hypertensive crises.[5] In addition, there are now many more options available for the treatment of very severe hypertension, and the BNF in the UK considers intravenous diazoxide to be one of the less suitable choices.[5] Moreover, diazoxide was frequently associated with clinically important hypotension when used in pregnancy, and is not considered a good choice in this situation.[6]

Diazoxide + Other drugs with hyperglycaemic activity

The risk of hyperglycaemia is increased if diazoxide is given with other drugs with hyperglycaemic activity (e.g. the thiazides, chlorpromazine, corticosteroids, combined hormonal contraceptives).

Clinical evidence, mechanism, importance and management

An isolated report[1] describes a child receiving long-term treatment for hypoglycaemia with diazoxide 8 mg/kg daily in divided doses and **bendroflumethiazide** 1.25 mg daily, who developed a diabetic pre-coma and severe hyperglycaemia after taking a single 30-mg dose of **chlorpromazine**. The reason for this reaction is not understood but one idea is that all three drugs had additive hyperglycaemic effects. Enhanced hyperglycaemia has been seen in other patients given diazoxide with **trichlormethiazide**.[2] Caution is clearly needed to ensure that the hyperglycaemic effects do not become excessive. The manufacturers of diazoxide also mention that the risk of hyperglycaemia may be increased by **corticosteroids** or oestrogen-progestogen combinations (e.g. **combined hormonal contraceptives**).[3]

Endothelin receptor antagonists + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole increases bosentan levels by twofold: fluconazole is predicted to have a greater effect. Ketoconazole modestly increases ambrisentan levels. Fluconazole and ketoconazole do not interact with sitaxentan.

Clinical evidence, mechanism, importance and management

(a) Ambrisentan

A study in 16 healthy subjects found that **ketoconazole** 400 mg daily for 4 days increased the AUC and maximum concentration of a single 10-mg dose of ambrisentan by 35% and 20%, respectively. These modest increases are not expected to be clinically relevant, therefore no ambrisentan dose adjustment is required if **ketoconazole** is also given.[1] It seems unlikely that other azoles will interact with ambrisentan, but this does not appear to have been studied.

(b) Bosentan

In a randomised crossover study, 10 healthy subjects were given bosentan 62.5 mg twice daily for 11 doses, either alone, or with **ketoconazole** 200 mg daily. The maximum plasma level of bosentan was increased 2.1-fold, and the AUC was increased 2.3-fold (range 1.4- to 4-fold) by **ketoconazole**. This interaction probably occurs because bosentan is metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor.[2]

Other potent CYP3A4 inhibitors (e.g. **itraconazole**) are expected to interact similarly to **ketoconazole**.[3] However, because **fluconazole** (a moderate inhibitor of CYP3A4) also inhibits CYP2C9, another enzyme involved in the metabolism of bosentan, it is anticipated that it could cause even larger increases in bosentan levels.

The clinical significance of raised the bosentan levels is unclear. Bosentan has been tolerated in single-doses of up to 2.4 g in healthy subjects, although elevations in liver transaminases have been seen during long-term, high-dose treatment.[2] Even so, the manufacturers do not recommend the combination of **fluconazole** with bosentan because of the risk of liver toxicity.[3] Similarly using **ketoconazole** or **itraconazole** in combination with a CYP2C9 inhibitor (the manufacturers name **voriconazole**) and bosentan is also not recommended.[3] Other drugs that inhibit CYP2C9 are listed in 'Table 1.3', (p.6).

Until more is known, it may be prudent to carefully monitor liver function when the combination is used. The manufacturers suggest that no adjustment of the bosentan dose is likely to be required when it is used with **ketoconazole**.[3]

(c) Sitaxentan

The concurrent use of **fluconazole** and sitaxentan did not affect the pharmacokinetics of either drug. Similarly, the concurrent use of **ketoconazole** and sitaxentan did not affect the pharmacokinetics of either drug.[4] No dose adjustment therefore seems necessary on concurrent use.

4. Thelin (Sitaxentan sodium). Encysive (UK) Ltd. UK Summary of product characteristics, April 2009.

Endothelin receptor antagonists + Miscellaneous

The pharmacokinetics of bosentan were not significantly altered when it was taken with losartan or nimodipine. Sitaxentan does not affect nifedipine pharmacokinetics. Omeprazole does not alter the pharmacokinetics of ambrisentan, and sitaxentan does not alter the pharmacokinetics of omeprazole.

Clinical evidence, mechanism, importance and management

(a) Losartan

A study in healthy subjects found that the pharmacokinetics of **bosentan** 125 mg twice daily were unaffected by the concurrent use of losartan 100 mg once daily for 9 doses.[1]

(b) CYP2C19 substrates

1. Ambrisentan. Ambrisentan is metabolised, in part, by the cytochrome P450 isoenzyme CYP2C19, and therefore caution is advised if potent CYP2C19 inhibitors are also given, presumably because of the possibility that ambrisentan levels may be raised. However, the US manufacturer notes that concurrent use with **omeprazole** (a CYP2C19 substrate and inhibitor) does not have clinically significant effects on ambrisentan pharmacokinetics,[2] and therefore a clinically relevant interaction seems unlikely.

2. Sitaxentan. The manufacturers of sitaxentan note that it is an inhibitor of the cytochrome P450 isoenzyme CYP2C19, and it may therefore decrease the levels of other drugs metabolised by this isoenzyme.[3] However, in one

study, **omeprazole** (a CYP2C19 substrate and inhibitor) was found to increase the AUC of sitaxentan by 30%, which is not considered to be clinically significant.[3]

(c) Nifedipine

Sitaxentan does not alter the clearance of nifedipine (given as three 10 mg doses).[3,4] The manufacturer states that, because the dose of nifedipine was small, a significant effect with larger doses cannot be ruled out.[3] However, note that **sitaxentan** did not affect the pharmacokinetics of other CYP3A4 substrates such as sildenafil (see 'Phosphodiesterase type-5 inhibitors + Endothelin receptor antagonists', p.1535) to a clinically significant extent, and so an interaction at any nifedipine dose seems unlikely.

(d) Nimodipine

In a study of 6 patients with subarachnoid haemorrhage, the pharmacokinetics of a single 500-mg intravenous dose of **bosentan** were not affected by the concurrent use of nimodipine (dose not specified).[5]

Endothelin receptor antagonists + Rifampicin (Rifampin)

Rifampicin may cause transient increases in trough levels of bosentan, but at steady-state plasma levels of bosentan are decreased. Rifampicin may affect the pharmacokinetics of ambrisentan.

Clinical evidence, mechanism, importance and management

(a) Ambrisentan

The drug interactions of ambrisentan have not been studied in detail *in vivo*, and are largely based on *in vitro* predictions. Ambrisentan is a substrate of a number of drug transporters. Therefore the US manufacturer advises caution in patients also taking drugs that affect transporter proteins, such as **rifampicin**, which is known to induce multiple hepatic enzymes and P-glycoprotein.[1] Until more is known, monitor the outcome of concurrent use closely.

(b) Bosentan

In a crossover study in 9 healthy subjects, bosentan 125 mg twice daily was given for 6 and a half days, either alone or with rifampicin 600 mg daily (which was given with the evening dose of bosentan for 6 days). Rifampicin decreased the AUC and peak plasma levels of bosentan by 58% and 53%, respectively. Trough levels of bosentan were increased up to 15-fold on day 2 of concurrent use, but fell with subsequent treatment and by day 4 were lower than those with bosentan alone. The initial increase in bosentan levels was possibly due to the inhibition, by rifampicin, of the hepatic uptake of bosentan by organic ion-transporting polypeptides (OATP1B1 and OATP1B3).[2,3] The decrease in bosentan levels at steady-state were probably due to its increased metabolism in the presence of rifampicin, due to induction of the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. The continued decrease in bosentan levels to below those of bosentan alone may be explained by autoinduction of its own metabolism.[2] The UK manufacturer warns that the risk of liver dysfunction with bosentan may be increased when it is given with inhibitors of the bile salt export pump such as rifampicin, and therefore suggest that concurrent use is not recommended.[4]

4. Tracleer (Bosentan monohydrate). Actelion Pharmaceuticals UK Ltd. UK Summary of product characteristics, July 2009.

Endothelin receptor antagonists; Bosentan + Food

In a study in 16 healthy subjects the pharmacokinetics of bosentan were not significantly changed by the presence of food. Bosentan may therefore be given without regard to meal times.[1]

1. Dingemanse J, Bodin F, Weidekamm E, Kutz K, van Giersbergen P. Influence of food intake and formulation on the pharmacokinetics and metabolism of bosentan, a dual endothelin receptor antagonist. *J Clin Pharmacol* (2002) 42, 283–9.

Glyceryl trinitrate (Nitroglycerin) + Antimuscarinics

Dry mouth associated with the use of antimuscarinic drugs may reduce the dissolution and thus, the effectiveness of sublingual glyceryl trinitrate tablets.

Clinical evidence, mechanism, importance and management

There is a report of a patient taking **imipramine** who found that the effects of glyceryl trinitrate sublingual tablets for the relief of angina were delayed. The patient had a dry mouth associated with the antimuscarinic adverse effects of **imipramine** and the problem was resolved when imipramine was discontinued.[1] Another brief report notes that the dissolution of glyceryl trinitrate sublingual tablets following **atropine** may take over 5 minutes.[2] Drugs with antimuscarinic effects, such as the **tricyclic antidepressants** and **disopyramide**, depress salivation and many patients complain of having a dry mouth. In a study in patients with angina of effort, both the sublingual and oral spray formulations were equally effective if the oral mucosa was moist (7 patients), but the oral spray was found to be better than sublingual tablets in patients with dry mouth (10 patients).[3] Sublingual glyceryl trinitrate tablets will dissolve less readily under the tongue in patients with dry mouth, thereby reducing glyceryl trinitrate absorption and effects. 'Table 18.1', (p.784), and 'Table 18.2', (p.786) list drugs that have antimuscarinic effects. A possible alternative is to use a glyceryl trinitrate spray in patients who suffer from dry mouth.

Glyceryl trinitrate (Nitroglycerin) + Aspirin

Some limited evidence suggests that analgesic doses of aspirin can increase the levels of glyceryl trinitrate given sublingually, possibly resulting in an increase in its adverse effects such as hypotension and headache. Paradoxically, long-term aspirin use appears to reduce the effects of intravenous glyceryl trinitrate used for vasodilatation in patients following coronary artery bypass surgery.

Clinical evidence

(a) Intravenous effects reduced

A study in patients following coronary artery bypass surgery found that those who had been taking aspirin 150 or 300 mg daily (33 patients) for at least 3 months, needed more glyceryl trinitrate to control blood pressure during the recovery period than those who had not taken aspirin (33 patients). To achieve the blood pressure criteria required, the aspirin-group needed an 8.2 micrograms/minute infusion of glyceryl trinitrate. The dose remained relatively high at 3.3 micrograms/minute even after 8 hours, whereas the non-aspirin group needed only 5.5 micrograms/minute, which was reduced to 1.9 micrograms/minute after 8 hours.[1]

(b) Sublingual effects increased

When aspirin 1 g was given to 7 healthy subjects followed one hour later by 800 micrograms of glyceryl trinitrate sublingual spray, the mean plasma glyceryl trinitrate levels 30 minutes after administration were

increased by 54% (from 0.24 to 0.37 nanograms/mL). The haemodynamic effects of the glyceryl trinitrate (including heart rate and reduced diastolic blood pressure) were enhanced. Some changes were seen when aspirin 500 mg was given every 2 days (described as an anti-aggregant dose) but the effects were not statistically significant.[2,3]

(c) Sublingual effects unchanged

A study in 40 healthy subjects who were given 650 mg aspirin or placebo, followed after one to 2 hours by sublingual glyceryl trinitrate 432 micrograms found no significant alterations in the peak haemodynamic response or in the area under the time-pressure and time-pulse curves. There was a transient pressor response, which occurred one minute after glyceryl trinitrate was given: this was blunted by aspirin. Taken alone, this change was significant, but when the overall pattern of changes during the 30 minute study was considered, the differences were not significant.[4]

Mechanism

Not understood. Prostaglandin-synthetase inhibitors such as aspirin can, to some extent, suppress the vasodilator effects of glyceryl trinitrate by blocking prostaglandin release. However, it seems that a much greater pharmacodynamic interaction also occurs, in which aspirin reduces the flow of blood through the liver, so that the metabolism of the glyceryl trinitrate is reduced, thus increasing its levels, and therefore its effects.

Importance and management

A confusing and unexplained situation. It seems possible that patients taking sublingual glyceryl trinitrate may experience an exaggeration of its adverse effects such as hypotension and headaches if they are taking analgesic doses of aspirin. Also be aware that long-term aspirin use may reduce the vasodilatory effects of intravenous glyceryl trinitrate. The antiplatelet effects of aspirin and glyceryl trinitrate appear to be additive.[5]

Glyceryl trinitrate (Nitroglycerin) + Nifedipine

The effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine in two studies. Nifedipine and intravenous glyceryl trinitrate had additive vasodilator effects in one study, but the preliminary results of another study found that nifedipine may increase glyceryl trinitrate requirements.

Clinical evidence, mechanism, importance and management

(a) Sublingual glyceryl trinitrate

In 9 patients with stable chronic angina, there was no significant haemodynamic interaction between sublingual glyceryl trinitrate and a single 20-mg dose of nifedipine, or nifedipine 20 mg three times daily for 5 days.[1] In another study in healthy subjects, the venodilatory effect of sublingual glyceryl trinitrate was not altered by pretreatment with nifedipine 10 mg.[2] No special precautions are required during concurrent use.

(b) Intravenous glyceryl trinitrate

In 7 patients with severe congestive heart failure, a single 10-mg dose of oral nifedipine increased stroke volume, with a peak effect at 30 minutes. The addition of intravenous glyceryl trinitrate at 2 hours further increased stroke volume and increased the cardiac index.[3] Therefore the addition of glyceryl trinitrate enhanced the vasodilator action of nifedipine. Conversely, in the preliminary findings of a comparative study of 3 groups of patients undergoing coronary bypass graft surgery, those taking nifedipine 20 mg twice daily needed initial doses of intravenous glyceryl trinitrate (to reduce cardiac workload, maintain graft patency and control blood pressure) that were about 40% higher than those in the other two groups; one taking nifedipine 10 mg twice daily for hypertension, and the other a control group of normotensive patients. Moreover, these higher doses had little effect on the initial mean systolic blood pressure of half of the group taking nifedipine 20 mg twice daily, and they needed an additional infusion of nitroprusside.[4] It was suggested that as glyceryl trinitrate is converted to nitric oxide to elicit its vasodilator effect, it is possible that the nifedipine inhibits the enzymic production of the nitrous oxide. This appears to be the only study to suggest a negative interaction, and the clinical relevance of its findings is unclear. Note that this study was non-randomised, and there may have been other important differences between the patients in each group that would account for the effects seen.

Guanethidine + Amfetamines and related drugs

The antihypertensive effects of guanethidine can be reduced or abolished by drugs including dexamfetamine, ephedrine, metamfetamine and methylphenidate. The blood pressure may even rise higher than before treatment with the antihypertensive.

Clinical evidence

When 16 hypertensive patients taking guanethidine 25 to 35 mg daily were given single-doses of **dexamfetamine** 10 mg orally, **ephedrine** 90 mg orally, **metamfetamine** 30 mg intramuscularly or **methylphenidate** 20 mg orally, the hypotensive effects of the guanethidine were completely abolished, and in some instances the blood pressures rose higher than before treatment with the guanethidine.[1] Another report describes the same interaction between guanethidine and **dexamfetamine**.[2]

Mechanism

These drugs are all indirectly-acting sympathomimetic amines, which not only prevent guanethidine-like drugs from entering the adrenergic neurones of the sympathetic nervous system, but also displace the antihypertensive drug already there.[3] As a result the blood pressure lowering effects are lost. In addition these amines release noradrenaline (norepinephrine) from the neurones, which raises the blood pressure. Thus the antihypertensive effects are not only opposed, but the pressure may even be raised higher than before treatment.[3-8]

Importance and management

Well documented, well established, and clinically important interactions. Other drugs, such as **phenylpropanolamine**, which is also an indirectly-acting sympathomimetic, are likely to interact similarly. Patients taking guanethidine should avoid indirectly-acting sympathomimetics, see 'Table 24.1', (p.1048), for a list. Warn them against the temptation to use proprietary non-prescription nasal decongestants containing any of these amines to relieve the nasal stuffiness commonly associated with the use of guanethidine and related drugs. The same precautions apply to the sympathomimetics used as appetite suppressants (although note that the use of these drugs for this indication is not generally recommended). However, one brief report stated that **diethylpropion** has been used with guanethidine without any adverse events.[9] Note that the antihypertensive use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes.

Guanethidine increases the hypertensive effects of the *directly*-acting sympathomimetics used as inotropes and vasopressors, see 'Inotropes and Vasopressors + Guanethidine', p.1064.

Guanethidine + Antipsychotics

Large doses of chlorpromazine may reduce or even abolish the antihypertensive effects of guanethidine, although in some patients the inherent hypotensive effects of the chlorpromazine may possibly predominate. Case reports suggest that haloperidol and tiotixene may interact similarly. Molindone is reported not to interact with guanethidine, and a single-dose of prochlorperazine did not interact with guanethidine.

Clinical evidence

Two severely hypertensive patients, with stable blood pressure while taking guanethidine 80 mg daily, were given **chlorpromazine** 200 to 300 mg daily. The diastolic blood pressure of one patient rose over 10 days from 94 mmHg to 112 mmHg and continued to rise to 116 mmHg, even when the **chlorpromazine** was withdrawn. Similarly, the diastolic pressure of the other patient rose from 105 mmHg to 127 mmHg, and then to 150 mmHg, even after the **chlorpromazine** had been withdrawn.[1] Other reports also describe marked rises in blood pressure in patients taking guanethidine with **chlorpromazine** 100 to 400 mg daily.[2-4]

Three hypertensive patients taking guanethidine 60 to 150 mg daily had an increase in their blood pressure when **haloperidol** 6 to 9 mg daily was added. The blood pressure rose from 132/95 mmHg to 149/99 mmHg in the first patient; from 125/84 mmHg to 148/100 mmHg in the second patient; and from 138/91 mmHg to 154/100 mmHg in the third patient. **Tiotixene** 60 mg daily was later given to one of the patients and the blood pressure rose from 126/87 mmHg to 156/110 mmHg.[2] These results have been reported elsewhere.[3,4]

However, a single 25-mg dose of **prochlorperazine** did not significantly antagonise the effect of guanethidine 15 to 20 mg daily in 5 patients.[5] In another study in 7 patients taking guanethidine 50 to 95 mg daily, the addition of **molindone** 30 to 120 mg daily had no effect on blood pressure.[6]

Mechanism

Chlorpromazine prevents the entry of guanethidine into the adrenergic neurones of the sympathetic nervous system resulting in a loss of its blood pressure-lowering effects. The other interacting antipsychotics probably have similar effects. This is essentially the same mechanism of interaction as that seen with the tricyclic antidepressants (consider also 'Guanethidine + Tricyclic and related antidepressants', p.1060).

Importance and management

Direct information is limited but the interaction between guanethidine and chlorpromazine is established and can be clinically important. It may take several days to develop. Not all patients may react to the same extent.[2,7] Monitor concurrent use and raise the guanethidine dose if necessary. It is uncertain how much chlorpromazine is needed before a significant effect occurs, but the smallest dose of chlorpromazine used in the studies was 100 mg with 90 mg guanethidine, which raised the blood pressure by 40/23 mmHg.[2] The inherent hypotensive effects of the chlorpromazine may possibly reduce the effects of this interaction. Other antipsychotics (particularly the phenothiazines) might be expected to interact similarly and this has been seen with tiotixene and haloperidol. The effects should be monitored. However, molindone is reported not to interact, and a single-dose of prochlorperazine did not interact. Note that the antihypertensive use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes.

Guanethidine + Levodopa

Levodopa appeared to enhance the antihypertensive effects of guanethidine in two patients.

Clinical evidence, mechanism, importance and management

A brief report describes a patient taking guanethidine and a diuretic who, when given levodopa (dose not stated), required a reduction in his daily dose of guanethidine, from 60 to 20 mg. Another patient similarly treated was able to discontinue the diuretic.[1] The suggested reason is that the hypotensive adverse effects of the levodopa are additive with the effects of the guanethidine. Direct information seems to be limited to this report but it would be wise to confirm that excessive hypotension does not develop if levodopa is added to treatment with guanethidine. Note that the antihypertensive use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes, but note that any antihypertensive may interact in this way, see 'Antihypertensives + Other drugs that affect blood pressure', p.1051.

Guanethidine + MAOIs

The antihypertensive effects of guanethidine can be reduced by nialamide, and probably therefore by other non-selective MAOIs.

Clinical evidence, mechanism, importance and management

Four out of 5 hypertensive patients taking guanethidine 25 to 35 mg daily had a rise in blood pressure from 140/85 mmHg to 165/100 mmHg six hours after being given a single 50-mg dose of **nialamide**.[1] The reason for this effect is not understood but one idea is that the MAOIs possibly oppose the guanethidine-induced loss of noradrenaline from sympathetic neurones. In *animal* studies, effective antagonism of guanethidine was shown by those MAOIs that also possess sympathomimetic effects (**phenelzine** and **tranylcypromine**), but not by **iproniazid** or **nialamide**,[2] and the antagonism was weaker than that seen with some other sympathomimetics.[3]

Direct clinical information seems to be limited to the single dose study,[1] but it would be prudent to monitor the effects if any non-selective MAOI is given to patients taking any guanethidine-like drug. The manufacturers of guanethidine actually contraindicate the use of MAOIs because of the possibility of the release of large quantities of catecholamines and the risk of hypertensive crisis. They recommend that at least 14 days should elapse between stopping an MAOI and starting guanethidine.[4] Note that the antihypertensive use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes.

Guanethidine + NSAIDs

Phenylbutazone and kebuzone reduce the antihypertensive effects of guanethidine.

Clinical evidence, mechanism, importance and management

When 20 patients taking guanethidine 75 mg daily were given **phenylbutazone** or **kebuzone** 750 mg daily the mean systolic blood pressure rose by 20 mmHg (from 169 mmHg to 189 mmHg).[1] This rise represents about

a 35% reduction in the antihypertensive effect of guanethidine. The mechanism of this interaction is uncertain but it is probably due to salt and water retention caused by these pyrazolone compounds. Direct evidence seems to be limited to this report. Patients taking guanethidine should be monitored if **phenylbutazone** or **kebuzone** is given concurrently. There does not appear to be any information on guanethidine and other NSAIDs, but indometacin, in particular, is well known to reduce the efficacy of other classes of antihypertensives, see for example 'ACE inhibitors + NSAIDs', p.32. Some caution may therefore be warranted with other NSAIDs.

Guanethidine + Tricyclic and related antidepressants

The antihypertensive effects of guanethidine are reduced or abolished by amitriptyline, desipramine, imipramine, nortriptyline and protriptyline. Doxepin in doses of 300 mg or more daily interacts similarly, but in smaller doses appears not to do so, although one case is reported with doxepin 100 mg daily. A few case reports suggest that maprotiline and mianserin do not interact with guanethidine.

Clinical evidence

(a) Tricyclic antidepressants

Five hypertensive patients taking guanethidine sulfate 50 to 150 mg daily had a mean arterial blood pressure rise of 27 mmHg when they were also given **desipramine** 50 or 75 mg daily or **protriptyline** 20 mg daily for one to 9 days. The full antihypertensive effects of the guanethidine were not re-established until 5 days after the antidepressants were withdrawn.[1]

The same interaction has been described in other reports, with guanethidine and **desipramine**,[2,3] **imipramine**,[4] **amitriptyline**,[5-7] **protriptyline**[3] or **nortriptyline**.[8] The interaction may take several days to develop fully and can last an average of 5 days after discontinuation of the tricyclic.[2] Some studies, and clinical experience suggests that **doxepin** does not begin to interact until doses of about 200 to 250 mg daily are used, then at 300 mg or more daily it interacts to the same extent as other tricyclics.[9-13] However, in one case excessive hypertension occurred in a man taking guanethidine and **doxepin** 100 mg daily.[14]

(b) Tetracyclic antidepressants

Maprotiline 25 mg three times daily caused no appreciable change in blood pressure in 2 patients taking guanethidine.[7] Similarly, in a study in 2 patients, **mianserin** 20 mg three times daily for 2 days did not alter the antihypertensive efficacy of guanethidine.[15]

Mechanism

The guanethidine-like drugs exert their hypotensive actions by entering the adrenergic nerve endings associated with blood vessels using the noradrenaline uptake mechanism. The tricyclics successfully compete for the same mechanism so that the antihypertensives are unable to reach their site of action, and as a result, the blood pressure rises once again.[16] The differences in the rate of development, duration and extent of the interactions reflect the pharmacokinetic differences between the various tricyclics, as well as individual differences between patients.

Importance and management

A very well documented and well established interaction of clinical importance. Not every combination of guanethidine and tricyclic antidepressant has been studied but all are expected to interact similarly, to a greater or lesser extent. Concurrent use should be avoided unless the effects are very closely monitored and the interaction balanced by raising the dose of the antihypertensive. Note that the antihypertensive use of guanethidine and related adrenergic neurone blockers has largely been superseded by other antihypertensive drug classes.

Guanfacine + Phenobarbital or Phenytoin

In two patients, the concurrent use of phenobarbital or phenytoin increased the metabolism of guanfacine.

Clinical evidence, mechanism, importance and management

When a hypertensive patient with chronic renal failure who was taking guanfacine 4 mg daily, was given phenobarbital 10 mg daily the antihypertensive effects of guanfacine were noted to be reduced and its dose was progressively raised over about 18 months to 12 mg daily. Phenobarbital was eventually stopped. Single measurements of the pharmacokinetics of guanfacine, both when the patient was taking phenobarbital, and 2 months after cessation of phenobarbital, found that the half-life of guanfacine increased fourfold when the phenobarbital was stopped.[1] The manufacturer also reports a similar case with phenytoin and guanfacine.[2] Phenobarbital and phenytoin probably induce the metabolism of guanfacine. Patients taking these drugs are likely to need more frequent doses of guanfacine. Primidone is metabolised to **phenobarbital**, and **fosphenytoin** is a prodrug of phenytoin. These drugs may therefore be expected to interact similarly.

2. Guanfacine hydrochloride. Watson Laboratories, Inc. US Prescribing information, October 2007.

Guanfacine + Tricyclic antidepressants

A single case report describes a reduced antihypertensive response to guanfacine in a patient given amitriptyline and later imipramine. The sedative effects of guanfacine and tricyclics are predicted to be additive.

Clinical evidence

A 38-year-old woman with stable hypertension, taking guanfacine 2 mg daily, had a rise in her mean blood pressure from 138/89 mmHg to 150/100 mmHg while taking **amitriptyline** 75 mg daily for 14 days. The patient's blood pressure fell again when the **amitriptyline** was stopped. A month later her blood pressure rose to 142/98 mmHg after she had taken **imipramine** 50 mg daily for 2 days, and fell again when it was stopped.[1]

Mechanism

Uncertain. A possible reason is that, like clonidine (another alpha-2 agonist), the uptake of guanfacine into neurones within the brain is blocked by tricyclic antidepressants, thereby reducing its effects.

Importance and management

Direct information is limited to this report, but it is supported by *animal* studies[2] and consistent with the way another alpha-2 agonist interacts with tricyclic antidepressants (see 'Clonidine and related drugs + Tricyclic and

related antidepressants', p.1054). Be alert for this interaction in any patient given guanfacine and any tricyclic antidepressant. **Guanabenz** is another alpha-2 agonist that might interact similarly, but as yet there is no direct clinical evidence that it does so. Note that the sedative effects of guanfacine or guanabenz and tricyclics would be predicted to be additive.

Hydralazine + Adrenaline (Epinephrine)

The manufacturers note that patients taking hydralazine who develop hypotension while undergoing surgery should *not* be treated with adrenaline (epinephrine).[1] This is because hydralazine frequently causes tachycardia,[2] and adrenaline would enhance this.[1]

1. Apresoline (Hydralazine hydrochloride). Amdipharm. UK Summary of product characteristics, November 2007.
2. Lin M-S, McNay JL, Shepherd AMM, Musgrave GE, Keeton TK. Increased plasma norepinephrine accompanies persistent tachycardia after hydralazine. *Hypertension* (1983) 5, 257–63.

Hydralazine + Food

The effect of food on hydralazine absorption is uncertain: food increased the AUC of hydralazine in two studies, had no effect in one study, and decreased it in three others. In other studies, a bolus dose of enteral feed decreased the AUC of hydralazine, but an enteral feed infusion had no effect.

Clinical evidence, mechanism, importance and management

Food *enhanced* the bioavailability of a single 50-mg dose of hydralazine in healthy subjects by two- to threefold in one study.[1] Similar findings were reported by the same research group with conventional hydralazine tablets, but not slow-release tablets.[2] In contrast, others found that food had no effect on the AUC of hydralazine in healthy subjects.[3] Furthermore, other studies have found that food decreases the AUC of hydralazine by 46% when it is given as oral solution,[4] by 44% after conventional tablets,[5] and by 29% (not statistically significant) after a slow-release preparation.[5] A reduction in the antihypertensive effect of hydralazine was noted in the first of these studies,[4] but no significant alteration in antihypertensive effect was seen in the second.[5] Similarly, another study reported a decrease in the AUC of hydralazine of 55% when it was given with a meal, and 62% when it was given with a bolus dose of **enteral feed**, but no significant change when it was given during an **enteral feed infusion**.[6]

The widely different findings of these studies may be related to the problems in analysing hydralazine and its metabolites, all of which are unstable. All these studies were single-dose, and no studies have adequately assessed the possible clinical importance of any pharmacokinetic changes in long-term clinical use. Note that the bioavailability of hydralazine varies widely between individuals depending on their acetylator status. No recommendations can be made as to whether or not hydralazine should be taken at a set time in relation to meals.

Hydralazine + NSAIDs

Oral indometacin abolished the hypotensive effects of intravenous hydralazine in one study, but no effect was found in another. In patients with pulmonary hypertension, intravenous indometacin reduced the effects of intravenous hydralazine, and in patients with hypertension, intravenous diclofenac reduced the effects of intravenous dihydralazine.

Clinical evidence, mechanism, importance and management

In 9 healthy subjects, oral **indometacin** 50 mg every 6 hours for four doses abolished the hypotensive response to intravenous hydralazine 150 micrograms/kg, and the subjects only responded when given another dose of hydralazine 30 minutes later.[1] A study in 7 patients with pulmonary hypertension given **indometacin** 50 mg and hydralazine 350 micrograms/kg, both intravenously, either alone, or concurrently, also found that the effects of hydralazine (reduction in systemic arterial pressure, heart rate, cardiac index) were reduced by **indometacin**.[2] In contrast, another study in 9 healthy subjects[3] found that oral **indometacin** 25 mg four times daily for 2.5 days did not affect the hypotensive response to a single 200-microgram/kg intravenous dose of hydralazine.

Thus it is not clear if **indometacin** interacts with intravenous hydralazine, and it is uncertain if an interaction occurs when hydralazine is given orally.

On the other hand, a single-dose study in 4 hypertensive subjects found that the actions of intravenous **dihydralazine** (effects on blood pressure, urinary excretion, heart rate and sodium clearance) were reduced by intravenous **diclofenac**.[4]

NSAIDs can cause increases in blood pressure due to their effects on sodium and water retention. Various NSAIDs have been reported to reduce the efficacy of other antihypertensive drug classes, for example see 'ACE inhibitors + NSAIDs', p.32. It would therefore be prudent to monitor concurrent use of hydralazine and any NSAID.

Inotropes and Vasopressors + Amfetamines

The manufacturers of amfetamine and dexamfetamine state that amfetamines enhance the adrenergic effects of noradrenaline (norepinephrine).[1,2] This may result in increased vasoconstriction, and could enhance the pressor effects of noradrenaline (norepinephrine). Other inotropes and vasopressors with adrenergic actions may be similarly affected, but this does not appear to be specifically mentioned. Consider 'Table 24.1', (p.1048), for a list of these drugs.

2. Dexedrine (Dextroamphetamine sulfate). GlaxoSmithKline. US Prescribing information, July 2008.

Inotropes and Vasopressors + Antimuscarinics

The hypertensive and other serious adverse effects of intravenous phenylephrine and phenylephrine absorbed from *eye drops* can be markedly increased by intravenous or intramuscular atropine.

Clinical evidence

A brief report describes 7 cases of pseudo-phaeochromocytoma, with severe rises in blood pressure and tachycardia, which occurred in young adults and children when they underwent eye operations and were given phenylephrine 10% eye drops and atropine. Only two of them had any pre-existing cardiovascular illness (moderate hypertension). All were under general anaesthesia with propofol, phenoperidine and vecuronium, and premedicated with intramuscular **atropine**, and some were later given more intravenous **atropine** to control the bradycardia that occurred as a result of stretching the oculomotor muscles. The total atropine doses were less than 10 micrograms/kg in adults and 20 micrograms/kg in children. At least 0.4 mL of phenylephrine 10% was used. In three cases left ven-

tricular failure and pulmonary oedema occurred, which needed monitoring in intensive care.[1] The authors say that no further cardiovascular adverse events were observed during similar procedures when steps were taken to reduce the amount of phenylephrine used and absorbed (see *Importance and Management*, below). Before this case report was made, a number of cases of cardiovascular adverse effects (severe hypertension, cardiac arrhythmias, myocardial infarction) had been reported for phenylephrine eye drops (usually 10%), or subconjunctival injection, and many of these patients had also received antimuscarinics (**atropine**, **cyclopentolate**, **homatropine**, **hyoscine**, **tropicamide**),[2-6] although the contribution, if any, of these antimuscarinics to the adverse effects is unknown.

In a study, 6 healthy subjects were given an intravenous phenylephrine infusion at incremental rates before and after being given three intravenous doses of **atropine**, 20, 10, and 10 micrograms/kg at 90, 120 and 150 minutes, respectively. It was found that phenylephrine 420 nanograms/kg per minute raised the diastolic and systolic blood pressures by 4 mmHg before using atropine, and 17 mmHg after atropine was given. For safety reasons the increases in blood pressure were limited to 30 mmHg above the baseline.[7]

Mechanism

Phenylephrine causes vasoconstriction, which can raise the blood pressure. Normally this would be limited by a baroreflex mediated by the vagus nerve, but if this cholinergic mechanism is blocked by atropine or other antimuscarinics, the rise in blood pressure is largely uncontrolled. Severe hypertension may occur, and other adverse cardiac events such as acute cardiac failure may follow.

Importance and management

A surprisingly large amount of phenylephrine can be absorbed from eye drops, and the potential cardiovascular adverse effects of this are well documented. The reports cited here suggest that these risks are clearly increased by the systemic use of atropine. The authors of one of the reports[1] found that the systemic absorption of phenylephrine can be reduced by using lower concentrations of phenylephrine, swabbing to minimise the amount that drains into the nasolachrymal duct to the nasal mucosa where rapid absorption occurs, and reducing the drop size by using a thin-walled cannula. Others have demonstrated that a cannula reduced the dose of phenylephrine given by two-thirds without loss of efficacy.[8] Other suggestions for reducing systemic absorption of phenylephrine are punctal plugging, nasolachrymal duct compression, and lid closure after instillation of the eye drop.[8] Note that phenylephrine eye drops are contraindicated in those with cardiovascular disease.[9] Note also that topical phenylephrine is commonly used with a topical antimuscarinic to enhance mydriasis.

Inotropes and Vasopressors + Calcium compounds

Calcium chloride infusions reduce the cardiotonic effects of adrenaline (epinephrine) and dobutamine, but not those of amrinone.

Clinical evidence, mechanism, importance and management

In a double-blind, randomised, crossover study in 12 patients following coronary artery bypass grafting, calcium chloride (10 mg/kg bolus followed by a 2 mg/kg per hour infusion) was found to attenuate the effects of **adrenaline** (**epinephrine**) 10 and 30 nanograms/kg per minute, given for 8 minutes each. **Adrenaline** alone produced a significant increase in the cardiac index, but following the calcium infusion **adrenaline** had no significant effect and the maximal **adrenaline**-induced increase in cardiac index was reduced by 70%. **Adrenaline** 30 nanograms/kg per minute alone increased mean arterial blood pressure from 87 mmHg to 95 mmHg; calcium chloride also raised blood pressure from 85 mmHg to 93 mmHg. After calcium was given, **adrenaline** had no further significant effect on blood pressure.[1]

Some of these workers also studied the mode of action of **dobutamine** in 22 patients recovering from coronary artery bypass surgery.[2] It was found that an infusion of calcium chloride (1 mg/kg per minute initially, then 0.25 mg/kg per minute) attenuated the increase in cardiac output produced by an infusion of **dobutamine** 2.5 to 5 micrograms/kg per minute by 30%. In a group of 24 similar patients the cardiotonic actions of **amrinone** (a phosphodiesterase inhibitor) were unaffected by the calcium infusion.[2]

Just how the calcium alters the effects of **adrenaline** and **dobutamine** is not known, but as they are both beta-receptor agonists a reasonable suggestion is that calcium interferes with the signal transduction through the beta-adrenergic receptor complex. The clinical importance of these findings is uncertain.

Inotropes and Vasopressors + Cimetidine

An exaggerated hypertensive response to dobutamine occurred during anaesthetic induction in a patient taking cimetidine. Another case report describes supraventricular tachycardia, which occurred when a patient receiving dobutamine and dopamine was given cimetidine.

Clinical evidence, mechanism, importance and management

A patient about to undergo coronary artery bypass grafting was anaesthetised with midazolam, fentanyl, vecuronium and oxygen. When a 5 micrograms/kg per minute infusion of **dobutamine** was given the patient developed unexpectedly marked hypertension of 210/100 mmHg. The infusion was stopped and over the next 15 minutes the blood pressure fell to 90/50 mmHg. A new infusion had the same hypertensive effect, and the patient's blood pressure was subsequently controlled at 120/80 mmHg with **dobutamine** 1 microgram/kg per minute.[1] The authors of the report suggest that this exaggerated response to **dobutamine** may have been due to cimetidine 1 g daily, which the patient was also taking. They postulate that the cimetidine may possibly have inhibited the metabolism and clearance of the **dobutamine** by the liver, thereby increasing its effects.[1]

A post-operative patient receiving **dopamine** and **dobutamine** infusions developed a supraventricular tachycardia 30 seconds after an intravenous injection of cimetidine. Similar episodes of tachycardia occurred on rechallenge with both drugs, but not when each drug was given separately.[2]

These are isolated cases and the general importance is not known but it seems likely to be small.

Inotropes and Vasopressors + Clonidine

Studies suggest that pretreatment with clonidine decreases the blood pressure response to small doses of dopamine; does not affect the blood pressure response to noradrenaline (norepinephrine); and can increase the blood pressure responses to

dobutamine, ephedrine, isoprenaline (isoproterenol) and phenylephrine.

Clinical evidence

In a study in 70 patients undergoing elective surgery, 35 patients were given clonidine 5 micrograms/kg 90 minutes before the induction of anaesthesia and 35 patients were used as a control group. While under anaesthesia, and when haemodynamically stable for at least 10 minutes, all patients were given a 10-minute infusion of **dopamine** 3 or 5 micrograms/kg per minute or **dobutamine** 0.5, 1, or 3 micrograms/kg per minute.[1] Clonidine attenuated the response to the 5 micrograms/kg per minute dose of **dopamine** (blood pressure rise 19/10 mmHg in the control group but only 4/0 mmHg in the clonidine group). However, **dopamine** 3 micrograms/kg per minute did not significantly affect blood pressure in either the control group or the clonidine group. Conversely, clonidine enhanced the response to **dobutamine** at all 3 doses. The study had to be stopped after 2 minutes in the clonidine group receiving the highest dose of **dobutamine** as the rise in blood pressure exceed the study limits (rise 45/24 mmHg compared with 16/7 mmHg in the control group).[1] In a study of the same design, 20 clonidine-treated patients and 20 controls were given a bolus infusion of **phenylephrine** 3 micrograms/kg or **isoprenaline** (**isoproterenol**) 0.02 micrograms/kg. Those who received clonidine had a greater and more prolonged increase in arterial pressure and heart rate with **phenylephrine** (10 minutes compared with 2 to 3 minutes) and increase in heart rate (but not arterial pressure) with **isoprenaline** (**isoproterenol**).[2]

In another similar study, 77 patients (38 premedicated with clonidine 5 micrograms/kg and famotidine 20 mg, 90 minutes before anaesthetic induction, and a control group of 39 given only famotidine) were given **noradrenaline** (**norepinephrine**) 0.5 micrograms/kg or **phenylephrine** 2 micrograms/kg. It was found that the overall response to **noradrenaline** (**norepinephrine**) was not significantly affected by clonidine, although 2 to 4 minutes after administration the mean arterial blood pressure was raised in the clonidine group. The blood pressure rise in response to **phenylephrine** was found to be augmented. There were no significant differences between the groups in terms of the incidence of hypertension, arrhythmias or bradycardia.[3] Similar results have been reported with **phenylephrine** in other studies (see below). The same group of workers repeated this study using two doses of **ephedrine** 100 micrograms/kg as the vasopressor. Clonidine prolonged the response to **ephedrine** by 2 minutes and increased the rise in blood pressure (rise in mean blood pressure in response to **ephedrine** at 3 minutes of 12.7 mmHg with clonidine, compared with 6.6 mmHg without clonidine). The rise in blood pressure was greater in both groups after a second dose of **ephedrine** was given but the effect in the clonidine group was still greater (rise in mean blood pressure in response to **ephedrine** at 4 minutes of 15 mmHg with clonidine compared with 9.4 mmHg without clonidine).[4]

Additional effects on blood pressure were found in another group of patients who were anaesthetised with enflurane and nitrous oxide/oxygen, and given intravenous **ephedrine** 100 micrograms/kg after pretreatment with clonidine (about 5 micrograms/kg).[5] A study in patients anaesthetised with propofol found premedication with clonidine enhanced the pressor and tachycardic effects of **ephedrine**, especially in elderly patients (over 60 years old) given standard dose of propofol (1 mg/kg at induction followed by 6 mg/kg per hour as maintenance).[6] In another study, 21 patients were premedicated with oral clonidine (about 5 micrograms/kg) and famotidine 20 mg, 90 minutes before spinal anaesthesia with tetracaine and a further 20 patients were given famotidine alone as premedication. All patients were given intravenous **ephedrine** 200 micrograms/kg when their systolic pressure decreased to below 100 mmHg or to less than 80% of pre-anaesthetic value. Premedication with clonidine enhanced the pressor response of **ephedrine** and its duration.[7]

Further study, using enflurane and nitrous oxide/oxygen for anaesthesia, found that the mean maximum blood pressure increased in a group of patients premedicated with clonidine and given intravenous **phenylephrine** 2 micrograms/kg by 26% and 32%, for awake and anaesthetised subjects, respectively. This was greater than the blood pressure rises seen in a group not given clonidine, which were 13% and 18%, for awake and anaesthetised subjects, respectively.[8] In a placebo-controlled study, patients with hypertension were given intravenous **phenylephrine** in increasing bolus doses or 30 to 300 micrograms on the day before surgery, before induction of anaesthesia and one and 3 hours postoperatively. Oral clonidine 6 micrograms/kg, was given 2 hours before surgery and a further dose of 3 micrograms/kg intravenously during the last hour of surgery. The pressor response calculated for a dose of **phenylephrine** 1.5 micrograms/kg was 42 mmHg in patients given clonidine before surgery compared with 27 mmHg for those given placebo. The postoperative pressor response to **phenylephrine** was 37 mmHg and 26 mmHg for the clonidine and placebo groups, respectively.[9]

Mechanism

Not understood. Clonidine is an alpha$_2$ agonist, which blocks the release of noradrenaline (norepinephrine) from the nerve endings, and most suggested mechanisms consider noradrenaline release to be involved in some way.

Importance and management

An interaction is established, although the exact outcome of the concurrent use of clonidine and these sympathomimetic vasopressors is not clear. It has been suggested that the effects may be different at different doses of dopamine.[8] The authors of the one report,[3] studying phenylephrine and noradrenaline (norepinephrine) with clonidine, suggested that the increase in pressor response was unlikely to be clinically significant.

Be aware that dobutamine, ephedrine, and phenylephrine may have a greater than expected effect if clonidine has been taken. Some of these drugs may also be used as nasal decongestants (e.g. ephedrine, and phenylephrine). The outcome of the concurrent use of clonidine in these circumstances is unclear, but a rise in blood pressure seems possible. However, note that these products are usually cautioned in patients with hypertension.

Inotropes and Vasopressors + Ergometrine (Ergonovine)

An isolated report attributes the development of gangrene and subsequently fatal septicaemia to the use of dopamine following the use of ergometrine. A similar case has been reported with ergometrine and noradrenaline (norepinephrine).

Clinical evidence, mechanism, importance and management

One patient developed gangrene of the hands and feet after being given an infusion of **dopamine** (10 micrograms/kg per minute, later doubled) started approximately 2 hours after the use of ergometrine (two 400-microgram doses).[1] This would seem to have resulted from the additive peripheral vasoconstrictor effects of both drugs, which reduced the circulation to such an extent that gangrene and then fatal septicaemia developed. Note that gangrene has been reported with the use of both drugs alone, and it is recommended that peripheral tissue perfusion should be monitored in elderly patients or patients with a history of peripheral vascular disease receiving **dopamine**.[2] This would also seem to be a prudent precaution in those who have previously received ergometrine.

A similar case report describes a pregnant woman (24-weeks gestation) with severe burns who received ergometrine to treat post-partum bleeding after spontaneous abortion and **noradrenaline** (**norepinephrine**) to treat hypotensive septic shock. The combination of these two vasoconstrictors is thought to have contributed to ischaemia of the fingers, resulting in loss of some digits.[3]

In the rare circumstances when it may be necessary to use both of these drugs, close attention should be paid to peripheral tissue perfusion.

Inotropes and Vasopressors + Guanethidine

The increase in blood pressure in response to noradrenaline (norepinephrine), phenylephrine, and metaraminol can be enhanced in the presence of guanethidine. These drugs can also be used as eye drops, and in this situation their mydriatic effects are similarly enhanced and prolonged by guanethidine.

Clinical evidence

(a) Blood pressure response

A study in 6 normotensive subjects given guanethidine 200 mg on the first day of the study and 100 mg daily for the next 2 days, found that their mean arterial blood pressure in response to a range of doses of **noradrenaline** (**norepinephrine**), was increased by 6 to 18% (a 6 to 20 mmHg increase). Moreover, cardiac arrhythmias appeared at lower doses of **noradrenaline** and with greater frequency than in the absence of guanethidine, and were more serious in nature.[1]

In another report, a patient taking guanethidine 20 mg daily was given intramuscular **metaraminol** 10 mg, which rapidly caused the blood pressure to rise to 220/130 mmHg accompanied by severe headache and extreme angina.[2] An increase in blood pressure from 165/90 mmHg to 170/110 mmHg was also seen in a patient taking guanethidine who, before surgery, was given **phenylephrine** eye drops.[3]

(b) Mydriatic response

The mydriasis due to **phenylephrine** given as a 10% eye drop solution was prolonged for up to 10 hours in a patient taking guanethidine for hypertension.[4] This enhanced mydriatic response has been described in another study using guanethidine eye drops with **adrenaline** (**epinephrine**), **phenylephrine** or **methoxamine** eye drops.[5]

Mechanism

By preventing the release of noradrenaline from adrenergic neurones, guanethidine and other adrenergic neurone blockers cause a temporary drug-induced sympathectomy, which is also accompanied by hypersensitivity of the receptors. This results in the increased response to the stimulation of the receptors by directly-acting sympathomimetics such as noradrenaline (norepinephrine) and phenylephrine.

Importance and management

An established, well-documented and potentially serious interaction. As the increase in blood pressure can be grossly exaggerated, doses of inotropes or vasopressors with directly-acting sympathomimetic actions (alpha-agonists) should be reduced appropriately. In addition it should be remembered that the incidence and severity of cardiac arrhythmias is increased.[1] Considerable care is required. Direct evidence seems to be limited to noradrenaline (norepinephrine), phenylephrine, metaraminol, and methoxamine. **Dopamine** also possesses direct sympathomimetic activity and may be expected to interact similarly. If as a result of this interaction the blood pressure becomes grossly elevated, it can be controlled by giving an alpha-adrenergic blocker such as phentolamine.[6] Phenylephrine, which is used as a vasopressor, is also contained in a number of non-prescription cough and cold preparations, which may contain 12 mg in a dose. A single dose of this size is only likely to cause a moderate blood pressure rise. However, this requires confirmation, particularly as the non-prescription products may be taken up to four times daily for up to 7 days, and higher doses may be available in some countries.

An exaggerated pressor response is clearly much more potentially serious than enhanced and prolonged mydriasis, but the latter is also possible and undesirable. The same precautions apply with the use of smaller amounts of these drugs.

Inotropes and Vasopressors + Lithium

The pressor effects of noradrenaline (norepinephrine) and phenylephrine are slightly reduced by lithium carbonate.

Clinical evidence, mechanism, importance and management

A study in 8 patients with manic depression found that after taking lithium carbonate for 7 to 10 days (serum level range 0.72 to 1.62 mmol/L) the dose of a **noradrenaline** (**norepinephrine**) infusion had to be increased by 1.8 micrograms in 7 patients to maintain a blood pressure increase of 25 mmHg. This equated to a 22% reduction in the pressor effect of **noradrenaline**.[1] Another study in 17 depressed patients with serum lithium levels in the range 0.8 to 1.2 mmol/L found that 12% more **noradrenaline** and 31% more **phenylephrine** were needed to raise the blood pressure by 30 mmHg.[2] The reasons for this interaction are not known. Results from an *animal* study suggest that lithium may increase the inactivation of **noradrenaline** and decrease the **noradrenaline** available for adrenergic receptors.[3]

These decreases in the pressor response to **noradrenaline** and to **phenylephrine** in the presence of lithium carbonate are both relatively small and it seems unlikely that they will present any problems in practice.

3. Sastre E, Nicolay A, Bruguerolle B, Portugal H. Effect of lithium on norepinephrine metabolic pathways. *Life Sci* (2005) 77, 758–67.

Inotropes and Vasopressors + Reserpine

The effects of adrenaline (epinephrine), noradrenaline (norepinephrine) and other related drugs are slightly increased in the presence of reserpine.

Clinical evidence

In 11 patients taking reserpine, pretreatment with **phenylephrine** 10% eye drops caused a blood pressure increase of 30/12 mmHg, whereas no significant increase in blood pressure occurred in 176 patients who were given **phenylephrine** eye drops and who were not taking reserpine.[1] After 7 healthy subjects took reserpine 0.25 to 1 mg daily for 2 weeks the increase in the blood pressure in response to **noradrenaline** (**norepinephrine**) was increased by 20 to 40%.[2] A man taking reserpine who became hypotensive while undergoing surgery did not respond to an intravenous injection of **ephedrine**, but did so after 30 minutes treatment with **noradrenaline**, presumably because the stores of **noradrenaline** at adrenergic neurones had become replenished.[3] The mydriatic effects of **ephedrine** have also been found to be antagonised by pretreatment with reserpine.[4] However, in contrast, one report claimed that **ephedrine** 25 mg given orally or intramuscularly, once or twice daily, proved to be an effective treatment for reserpine-induced hypotension and bradycardia in patients with schizophrenia.[5]

Studies in *dogs* have demonstrated that **adrenaline** (**epinephrine**), **noradrenaline** and **phenylephrine** (all sympathomimetics with direct actions) remain effective vasopressors after treatment with reserpine, and their actions are enhanced to some extent.[6-8] **Metaraminol** has also been successfully used to raise blood pressure in reserpine-treated patients.[9]

Mechanism

The rauwolfia alkaloids (e.g. reserpine) cause adrenergic neurones to lose their stores of noradrenaline (norepinephrine), so that they can no longer stimulate adrenergic receptors and transmission ceases. Indirectly-acting sympathomimetics, which work by stimulating the release of stored noradrenaline, may therefore be expected to become ineffective. In contrast, the effects of directly-acting sympathomimetics should remain unchanged. However, their effects may be enhanced (as described above) because when the receptors are deprived of stimulation by noradrenaline for any length of time they can become supersensitive. Drugs with mixed direct and indirect actions, such as ephedrine, should fall somewhere between the two, although the reports cited seem to indicate that ephedrine has predominantly indirect activity.[3,4]

Importance and management

These are established interactions, but the paucity of clinical information suggests that in practice they do not present many problems, perhaps because the effects of these vasopressors are so closely monitored, and titrated to effect. If a pressor drug is required, a directly-acting drug such as noradrenaline (norepinephrine) or phenylephrine may be expected to be effective. The receptors may show some supersensitivity so that a dose reduction may be required. 'Table 24.1', (p.1048) gives a classification of the sympathomimetics.

Inotropes and Vasopressors; Dobutamine + Dipyridamole

The addition of dipyridamole to dobutamine for echocardiography can cause potentially hazardous hypotension.

Clinical evidence, mechanism, importance and management

Ten patients with a low probability of coronary artery disease underwent dobutamine echocardiography. Five were given dobutamine alone, while the other 5 were given a low intravenous dose of dipyridamole with the maximum dose of dobutamine, to see whether the sensitivity of the test could be improved. Four of the patients given both drugs experienced severe hypotension while no hypotension was seen in the control group. The conclusion was reached that this combination of drugs can be hazardous and should not be used in patients suspected of coronary heart disease.[1] Note that, although both of these drugs are commonly used in stress echocardiography, they are not given together.

Inotropes and Vasopressors; Dopamine + Phenytoin

Some limited evidence suggests that patients needing dopamine to support their blood pressure can become severely hypotensive if they are also given intravenous phenytoin.

Clinical evidence, mechanism, importance and management

Five critically ill patients treated with a number of different drugs, were given dopamine to maintain an adequate blood pressure. When seizures developed they were given intravenous phenytoin at an infusion rate of 5 to 25 mg/minute. Their previously stable blood pressures then fell rapidly, one patient became bradycardic, and 2 patients died from cardiac arrest. A similar reaction was found in *dogs* made hypovolaemic and hypotensive by bleeding, and then given dopamine followed by a phenytoin infusion.[1] However, another study in *dogs* was unable to find evidence of this serious adverse interaction,[2] and no evidence of marked hypotension occurred when a patient with cardiogenic shock was given a phenytoin infusion while receiving dopamine and dobutamine.[3]

The documentation of this adverse interaction therefore appears to be limited to this single report. However, intravenous phenytoin is known to cause hypotension if it is given rapidly, particularly in gravely ill patients. Blood pressure is doubtless being monitored in patients receiving dopamine, and should be monitored when phenytoin is given intravenously. However, more frequent monitoring may be necessary initially, as any interaction appears to develop rapidly.

Inotropes and Vasopressors; Dopamine + Selegiline

A case report describes a hypertensive reaction attributed to the concurrent use of dopamine and selegiline.

Clinical evidence, mechanism, importance and management

A 75-year-old man, who was taking selegiline 5 mg twice daily for Parkinson's disease, was given intravenous dopamine 3.5 micrograms/kg per minute because of a decline in blood pressure and urine output following a serious road traffic accident. Twenty minutes after the infusion was started his blood pressure had hardly changed, but 30 minutes later it had risen from 108/33 mmHg to 228/50 mmHg. The dopamine infusion was discontinued and the blood pressure decreased to 121/40 mmHg over the next 30 minutes. The dopamine infusion was reinstituted twice more at lower doses (1.03 and 0.9 micrograms/kg per minute), but each time similar reactions occurred. The exaggerated vasopressor response was thought to be due to inhibition of dopamine metabolism by selegiline.[1]

The authors of the report[1] and the manufacturers of selegiline recommend that dopamine should be used cautiously,[2] and only after careful risk-benefit assessment,[3] in patients who are currently taking selegiline or who have taken selegiline in the 2 weeks before dopamine is required. In addition, the manufacturers of dopamine warn that in patients who have received MAOIs within the previous 2 to 3 weeks, the initial dose of dopamine should be no greater than 10% of the usual dose.[4]

Inotropes and Vasopressors; Dopamine + Tolazoline

Acute and eventually fatal hypotension occurred in a patient given dopamine and tolazoline.

Clinical evidence

A patient receiving ventilatory support following surgery was given **dopamine** on the third postoperative day. Pulmonary arterial pressure had been steadily rising since the surgery, so on day 4 he was given a slow 2-mg/kg bolus injection of tolazoline. Systemic arterial pressure immedi-

ately fell to 50/30 mmHg so the **dopamine** infusion was increased but, contrary to the expected effect, the arterial pressure then fell even further to 38/15 mmHg. The **dopamine** was stopped and ephedrine, methoxamine and fresh frozen plasma were given. Two hours later his blood pressure was 70/40 mmHg. Two further attempts were made to give **dopamine**, but the arterial pressure fell to 40/15 mmHg on the first occasion, and to 38/20 mmHg on the second, which resulted in a fatal cardiac arrest.[1]

Mechanism

The interaction between dopamine and tolazoline is not fully understood. Dopamine has both alpha (vasoconstrictor) and beta (vasodilator) activity. With the alpha effects on the systemic circulation competitively blocked by the tolazoline, its vasodilatory actions would predominate, resulting in paradoxical hypotension.

Importance and management

Information on the interaction between dopamine and tolazoline is limited but this interaction would appear to be established. The authors of this report warn that an infusion of dopamine should not be considered for several hours after even a small single dose of tolazoline has been given. They point out that impaired renal function often accompanies severe respiratory failure, which may significantly prolong the effects of tolazoline.

Ivabradine + CYP3A4 inducers

The manufacturers advise that patients taking CYP3A4 inducers (they specifically name barbiturates, phenytoin, and rifampicin (rifampin)) may need dose increases of ivabradine.[1] This would seem prudent as St John's wort, a known CYP3A4 inducer, reduces ivabradine levels, see 'Ivabradine + St John's wort (*Hypericum perforatum*)', p.1066. See also 'Table 1.4', (p.6), for a list of known CYP3A4 inducers. Monitor the concurrent use of these drugs for ivabradine efficacy and adjust the dose as necessary. Remember to re-adjust the dose of ivabradine if concurrent use of these drugs is stopped.

1. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, October 2009.

Ivabradine + CYP3A4 inhibitors

Ivabradine is metabolised by CYP3A4 and its levels may therefore be increased significantly in the presence of inhibitors of this isoenzyme, such as some azoles, diltiazem, grapefruit juice, some macrolides, nefazodone, protease inhibitors, or verapamil.

Clinical evidence

A study found that **ketoconazole** 200 mg daily or **josamycin** 1 g twice daily increased ivabradine plasma levels by seven- to eightfold. Studies in healthy subjects and patients given **diltiazem** or **verapamil** have resulted in an increase in the AUC of ivabradine of two to threefold, and an additional heart rate reduction of 5 bpm.[1]

Mechanism

Ivabradine is a substrate of the cytochrome P450 isoenzyme CYP3A4, and its metabolism is reduced by inhibitors of CYP3A4, resulting in increased plasma levels and increased therapeutic effects.[1]

Importance and management

The manufacturer contraindicates the use of potent inhibitors of CYP3A4 with ivabradine, (they specifically mention **clarithromycin**, **oral erythromycin**, **itraconazole**, josamycin, ketoconazole, **nefazodone**, **nelfinavir**, **ritonavir**, and **telithromycin**).The manufacturer suggests that if moderate inhibitors of CYP3A4 are given (they name **fluconazole**), ivabradine may be used, but at a lower starting dose of 2.5 mg twice daily, with consideration of heart rate monitoring.[1] Diltiazem and verapamil are also moderate inhibitors of CYP3A4, but their use is not recommended because of their effects on heart rate. Note that clinically relevant inhibitors of CYP3A4 are listed in 'Table 1.4', (p.6). The manufacturers of ivabradine[1] also state that **grapefruit juice** (an inhibitor of CYP3A4 in the intestine) increases the exposure to ivabradine twofold, and they therefore recommend that the intake of grapefruit juice by patients also taking ivabradine is restricted. Note that this increase is similar to that seen with moderate inhibitors of CYP3A4, for which an ivabradine dose reduction has been suggested.

1. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, October 2009.

Ivabradine + Drugs that prolong the QT interval

The manufacturers advise that ivabradine should not be taken with drugs that prolong the QT interval, but also advise that if concurrent use with such drugs appears necessary, close cardiac monitoring is needed. Bradycardia is a pharmacological effect of ivabradine, and QT prolongation may be exacerbated by heart rate reductions.[1] For a list of drugs known to affect the QT interval see 'Table 9.2', (p.290).

1. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, October 2009.

Ivabradine + St John's wort (*Hypericum perforatum*)

The metabolism of ivabradine is increased by St John's wort.

Clinical evidence

Twelve healthy subjects were given a single oral dose of ivabradine 10 mg 24 hours before St John's wort (*Jarsin* tablets) 300 mg three times daily was given for 14 days. On day 16, they were given a further dose of ivabradine 10 mg with a single 300-mg dose of St John's wort. The maximum levels and AUC of ivabradine were reduced by more than half by St John's wort. The maximum levels and AUC of its active metabolite were reduced by 25% and 32%, respectively. No adverse effects were reported, and the heart rate and blood pressure remained unchanged.[1] Similar findings are also reported by the manufacturers of ivabradine.[2]

Mechanism

St John's wort is a known inducer of the cytochrome P450 isoenzyme CYP3A4, by which ivabradine is metabolised. Concurrent use therefore increases the metabolism of ivabradine, which results in a reduction in its plasma levels, and a potential reduction in effects.

Importance and management

Evidence is limited to the study above, and despite the lack of change in pharmacodynamic effects seen in this study, the pharmacokinetic changes may be large enough to affect individual patients. Monitor concurrent use for ivabradine efficacy and adjust the dose as necessary. Remember to re-adjust the dose of ivabradine if the concurrent use of these drugs is stopped. The UK manufacturer suggests that the use of St John's wort should be restricted in patients taking ivabradine.[2]

2. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, October 2009.

Ivabradine + Miscellaneous

The manufacturers say that in specific drug-drug interaction studies, ivabradine was also found not to interact with sildenafil, statins (simvastatin), dihydropyridine calcium-channel blockers (amlodipine, lacidipine), digoxin and warfarin. During clinical studies, ivabradine was taken with ACE inhibitors, angiotensin II

receptor antagonists, diuretics, short and long acting nitrates, statins, fibrates, proton pump inhibitors, oral antidiabetics, aspirin and other antiplatelet drugs, and there was no evidence of safety concerns.[1] A specific drug interaction study in 12 healthy subjects found that omeprazole 40 mg daily or lansoprazole 60 mg daily for 5 days did not significantly affect the pharmacokinetics of a single 10-mg dose of ivabradine.[2]

1. Procoralan (Ivabradine hydrochloride). Servier Laboratories Ltd. UK Summary of product characteristics, October 2009.

Lack of pharmacokinetic interaction between omeprazole or lansoprazole and ivabradine in healthy volunteers: an open-label, randomized, crossover, pharmacokinetic interaction clinical trial. *J Clin Pharmacol* (2006) 46, 1195–203.

Ketanserin + Beta blockers

There is no pharmacokinetic interaction between ketanserin and propranolol, but additive hypotensive effects may occur. Very marked acute hypotension has been seen in two patients taking atenolol when they were first given ketanserin.

Clinical evidence, mechanism, importance and management

A study in 6 patients and 2 healthy subjects given ketanserin 40 mg twice daily for 3 weeks found that **propranolol** 80 mg twice daily for 6 days did not significantly alter the steady-state plasma levels of ketanserin.[1] Another study in healthy subjects, using single doses of both drugs, found that neither drug affected the pharmacokinetics of the other.[2] In a third study, **propranolol** 80 mg twice daily had no effect on the pharmacokinetics of a single 10-mg intravenous dose of ketanserin. However, ketanserin 40 mg twice daily modestly decreased the clearance of a single 160-mg dose of **propranolol** by 29% and increased its maximum serum level by 38%, although neither of these changes were statistically significant.[3] The hypotensive effects of ketanserin were slightly increased by **propranolol** in the first study,[1] and additive hypotensive effects were seen in another study in patients with essential hypertension.[4]

Acute hypotension is reported to have occurred in 2 patients taking **atenolol** within an hour of taking a 40-mg oral dose of ketanserin. One of them briefly lost consciousness.[5]

The concurrent use of ketanserin and beta blockers can be valuable and uneventful, but a few patients may experience marked hypotensive effects when first given ketanserin. Patients should be warned.

Ketanserin + Diuretics

Sudden deaths, probably from cardiac arrhythmias, were markedly increased in patients taking potassium-depleting diuretics and high doses of ketanserin. No interaction occurred with low doses of ketanserin in those with normal potassium levels. Potassium-sparing diuretics do not interact in this way.

Clinical evidence

A large multi-national study[1] in 3899 patients found that a harmful and potentially fatal interaction could occur in those given ketanserin 40 mg three times daily and **potassium-depleting diuretics**. Of 249 patients taking both drugs, 35 patients (14%) died (16 suddenly) compared with only 15 patients (6%, with 5 sudden deaths) of 260 patients taking a placebo and **potassium-depleting diuretics**. No significant increase in the number of deaths occurred in those taking ketanserin and **potassium-sparing diuretics**. A further analysis of the results found that in patients given ketanserin, the relative mortality was 87% for those not taking diuretics, 76% for those taking **potassium-sparing diuretics** and 313% for those taking **potassium-depleting diuretics**.[2]

It was found that the corrected QT interval was prolonged as follows: ketanserin alone 18 milliseconds, ketanserin with **potassium-sparing diuretics** 24 milliseconds, ketanserin with **potassium-depleting diuretics** 30 milliseconds. Preliminary results of a later study in 33 patients using a smaller dose of ketanserin (20 mg twice daily) with **potassium-depleting diuretics** (**furosemide**, **thiazides**) found no evidence of a prolonged QTc interval in patients with normal potassium levels.[3] The pharmacokinetics of a single 20-mg dose of ketanserin were not altered by single 25-mg doses of **hydrochlorothiazide**.[4]

Mechanism

Potassium-depleting diuretics may cause hypokalaemia, which increases the risk of QT-prolongation and torsade de pointes, which can result in sudden death. Ketanserin also prolongs the QT interval in a dose-related way, and its effects would be expected to be additive with that of diuretic-induced hypokalaemia. See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Importance and management

The use of potassium-depleting diuretics (see 'Table 26.1', (p.1121)) with ketanserin 40 mg three times daily should be avoided. Lower doses of ketanserin (20 mg twice daily) have less effect on the QT interval, and can probably be used cautiously with potassium-depleting diuretics, as long as serum potassium levels are maintained. Potassium-sparing diuretics do not interact.

Ketanserin + Miscellaneous

Ketanserin should not be given with certain antiarrhythmics, naftidrofuryl, or tricyclic antidepressants because of the risk of potentially fatal cardiac arrhythmias. Drowsiness and dizziness are common adverse effects, which may possibly be additive with the effects of other CNS depressants.

Clinical evidence, mechanism, importance and management

Ketanserin has weak class III antiarrhythmic activity and can prolong the QT_c interval. For safety reasons it has therefore been advised that it should be avoided in patients with existing QT_c prolongation, atrioventricular or sinoauricular block of higher degree, or severe bradycardia of less than 50 bpm.[1] For the same reason the concurrent use of drugs that affect repolarisation (**class Ia**, **class Ic** and **class III arrhythmics**) or drugs that cause conduction disturbances (**naftidrofuryl**, **tricyclic antidepressants**) should be avoided.[1] See also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, and 'Ketanserin + Diuretics', above.

Dizziness and drowsiness are common adverse effects of ketanserin and therefore it seems likely that these will be additive with other **CNS depressants** and **alcohol**, which may possibly make driving more hazardous, but this needs confirmation.

1. Distler A. Clinical aspects during therapy with the serotonin antagonist ketanserin. *Clin Physiol Biochem* (1990) 8 (Suppl 3), 64–80.

Ketanserin + Nifedipine

Two patients experienced an increase in cardiac arrhythmias when they were given ketanserin with nifedipine.

Clinical evidence, mechanism, importance and management

A study in 20 subjects aged 60 years or more, with normal or slightly raised blood pressures, found that the concurrent use of ketanserin and

nifedipine for a week did not, on average, affect their blood pressures, heart rates, or QT intervals, but two of the subjects monitored over 24 hours had a marked increase in the frequency of ectopic beats, couplets and ventricular tachycardia.[1] The reasons are not understood. The authors of this study say that their findings do not exclude the possibility that the concurrent use of these two drugs might therefore increase arrhythmia in some elderly patients.[1] Concurrent use should be monitored.

1. Alberio L, Beretta-Piccoli C, Tanzi F, Koch P, Zehender M. Kardiale Interaktionen zwischen Ketanserin und dem Calcium-Antagonisten Nifedipin. *Schweiz Med Wochenschr* (1992) 122, 1723–7.

Levosimendan + ACE inhibitors

The haemodynamic effects of levosimendan were not significantly altered by captopril in one study.

Clinical evidence, mechanism, importance and management

Captopril, in doses of up to 50 mg twice daily, did not change the haemodynamic effects of a single 1-mg or 2-mg intravenous dose of levosimendan in 24 patients with heart failure. No additional decrease in blood pressure was observed.[1] No special precautions appear to be required if levosimendan is given to patients taking captopril. Other ACE inhibitors do not appear to have been studied, but they would be expected to behave in the same way as captopril.

1. Antila S, Eha J, Heinpalu M, Lehtonen L, Loogna I, Mesikepp A, Planken U, Sandell E-P. Haemodynamic interactions of a new calcium sensitizing drug levosimendan and captopril. *Eur J Clin Pharmacol* (1996) 49, 451–8.

Levosimendan + Beta blockers

The haemodynamic effects of levosimendan were not significantly altered by carvedilol or other unnamed beta blockers.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, carvedilol 25 mg twice daily for 7 to 9 days did not alter the effects of a single 2-mg intravenous dose of levosimendan on cardiac contractility. In addition, the heart rate and diastolic blood pressure responses were not altered, but the systolic blood pressure response was blunted.[1] In a study to compare levosimendan with dobutamine in patients with severe, low-output heart failure, 33 of the 102 patients receiving levosimendan were also given unnamed beta blockers. The use of a beta blocker was found not to reduce the haemodynamic effects of levosimendan. The authors say this suggests that there may be a place for levosimendan in the management of exacerbations of heart failure not controlled by beta blockers.[2] In another study in elderly patients with acute decompensated systolic heart failure, beta blockers did not reduce the beneficial haemodynamic effects of levosimendan.[3]

1. Lehtonen L, Sundberg S. The contractility enhancing effect of the calcium sensitiser levosimendan is not attenuated by carvedilol in healthy subjects. *Eur J Clin Pharmacol* (2002) 58, 449–52.

Levosimendan + CYP3A4 inhibitors

Itraconazole does not alter the pharmacokinetics of levosimendan and therefore interactions with other CYP3A4 inhibitors are unlikely.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that the pharmacokinetics of a single 2-mg oral dose of levosimendan were unchanged by **itraconazole** 200 mg daily for 5 days, and there was no change in heart rates or ECGs (including the QTc interval). It was concluded that because **itraconazole**, a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, does not interact significantly with levosimendan, interactions with other CYP3A4 inhibitors, by this mechanism, are unlikely.[1] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

1. Antila S, Honkanen T, Lehtonen L, Neuvonen PJ. The CYP3A4 inhibitor itraconazole does not affect the pharmacokinetics of a new calcium-sensitizing drug levosimendan. *Int J Clin Pharmacol Ther* (1998) 36, 446–9.

Levosimendan + Felodipine

The haemodynamic effects of levosimendan were not significantly altered by felodipine.

Clinical evidence, mechanism, importance and management

A study of the use of oral levosimendan 500 micrograms four times daily and felodipine 5 mg daily in 24 men with coronary heart disease found that concurrent use was well tolerated. Felodipine did not antagonise the positive inotropic effects of levosimendan and had no effect on exercise capacity. Both drugs increased heart rate during exercise, and there was a slight additional effect with concurrent use (5 to 8 bpm for levosimendan alone versus 6 to 10 bpm for the combination).[1] There would appear to be no reason for avoiding concurrent use.

1. Pöder P, Eha J, Antila S, Heinpalu M, Planken Ü, Loogna I, Mesikepp A, Akkila J, Lehtonen L. Pharmacodynamic interactions of levosimendan and felodipine in patients with coronary heart disease. *Cardiovasc Drugs Ther* (2003) 17, 451–8.

Levosimendan + Nitrates

Orthostatic hypotension occurred when levosimendan was given with isosorbide mononitrate.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects at rest, giving an infusion of levosimendan (12 micrograms/kg over 10 minutes, then 0.2 micrograms/kg per minute for 110 minutes) with a single 20-mg oral dose of **isosorbide mononitrate** had no additional effects on haemodynamic parameters (heart rate, blood pressure, leg blood flow, cardiac output) to the use of levosimendan alone. However, during an orthostatic test, the circulatory response of the combination was significantly potentiated, and three subjects were unable to remain standing for the stipulated time.[1] Care is therefore required when levosimendan and **isosorbide mononitrate**, or similar drugs, are used concurrently. Whether a similar effect occurs with oral levosimendan is unclear, but as with other drugs that cause postural hypotension, patients should be warned.

1. Sundberg S, Lehtonen L. Haemodynamic interactions between the novel calcium sensitiser levosimendan and isosorbide-5-mononitrate in healthy subjects. *Eur J Clin Pharmacol* (2000) 55, 793–9.

Methyldopa + Barbiturates

Methyldopa levels are not altered by the use of phenobarbital.

Clinical evidence, mechanism, importance and management

Indirect evidence from one study in hypertensive patients suggested that phenobarbital could reduce methyldopa levels,[1] but later work, which directly measured the plasma levels of methyldopa, did not find any evidence of a pharmacokinetic interaction.[2,3]

1. Káldor A, Juvancz P, Demeczky M, Sebestyen, Palotas J. Enhancement of methyldopa metabolism with barbiturate. *BMJ* (1971) 3, 518–19.

Plasma concentration of alfamethyldopa and its main metabolite, methyldopa-O-sulphate, during long term treatment with alfamethyldopa with special reference to possible interaction with other drugs given simultaneously. *Clin Pharmacol Ther* (1973) 14, 139–40.
3. Kristensen M, Jørgensen M, Hansen T. Barbiturates and methyldopa metabolism. *BMJ* (1973) 1, 49.

Methyldopa + Bile-acid binding resins

Colestyramine and colestipol are reported to have no important effect on the absorption of methyldopa.[1]

1. Hunninghake DB, King S. Effect of cholestyramine and colestipol on the absorption of methyldopa and hydrochlorothiazide. *Pharmacologist* (1978) 20, 220.

Methyldopa + Cephalosporins

Pustular eruptions developed in two women taking methyldopa and cefradine or cefazolin. The use of methyldopa may have been coincidental.

Clinical evidence, mechanism, importance and management

A 74-year-old black woman taking methyldopa and insulin developed pruritus on her arms and legs within 2 hours of starting to take **cefradine** 250 mg every 6 hours. **Cefradine** was stopped after 7 doses. Over the next 2 days, fever and a widespread pustular eruption developed.[1] Another 65-year-old black woman taking methyldopa and furosemide experienced severe pruritus within 8 hours of starting to receive intravenous **cefazolin sodium** 1 g every 12 hours. Over the next 2 days superficial and coalescing pustules appeared on her trunk, arms and legs.[2] The authors of the first report attributed the reaction to **cefradine**.[1] The authors of the second report note that the concurrent use of methyldopa may or may not have been a contributing factor in both reports.[2] There seem to be no other reports of this reaction.

Methyldopa + Disulfiram

An isolated report describes a patient with hypertension, which was unresponsive to methyldopa in the presence of disulfiram.

Clinical evidence, mechanism, importance and management

An alcoholic patient taking disulfiram did not respond to moderate to high doses of intravenous methyldopa, given to control his hypertension, but responded to oral low-dose clonidine. The suggested reason for this lack of response to methyldopa is that disulfiram blocks the activity of dopamine beta-hydroxylase, the enzyme responsible for the conversion of the methyldopa to its active form.[1] The general importance of this apparent interaction is uncertain.

1. McCord RW, LaCorte WS. Hypertension refractory to methyldopa in a disulfiram-treated patient. *Clin Res* (1984) 32, 923A.

Methyldopa + Haloperidol

Two cases of marked CNS adverse effects have been attributed to the use of methyldopa and haloperidol. Another patient taking both drugs became irritable and aggressive. In a small pilot study, the concurrent use of methyldopa and haloperidol lowered blood pressure, and symptomatic hypotension occurred in one patient. The combination also caused marked sedation.

Clinical evidence

Two patients who had been taking methyldopa 1 to 1.5 g daily for hypertension, without problems, developed a dementia syndrome (cognitive disabilities, loss of memory, disorientation, etc.) within 3 days of starting to take haloperidol 6 to 8 mg daily for anxiety. The symptoms totally cleared within 72 hours of stopping the haloperidol.[1] Another patient taking haloperidol for schizophrenia, and methyldopa for hypertension, became very irritable and aggressive. When the methyldopa was replaced with hydrochlorothiazide, the patient's behaviour improved dramatically.[2]

In a pilot study of the therapeutic potential of using haloperidol 10 mg daily with methyldopa 500 mg daily for 4 weeks, in the treatment of schizophrenia, the supine diastolic blood pressure decreased significantly from 65 mmHg to 59.5 mmHg. Six of the 10 patients complained of dizziness, and one patient needed a reduction in the drug doses because of transient hypotension. Somnolence occurred in 8 of the 10 patients.[3]

Mechanism

The hypotensive effects of methyldopa and haloperidol might be expected to be additive. The CNS effects are not understood, although methyldopa can cause sedation, depression and dementia, and haloperidol can cause drowsiness, dizziness and depression.

Importance and management

Concurrent use need not be avoided, but it would be prudent to be on the alert for excessive sedation, excessive reductions in blood pressure or the development of other unexpected CNS adverse effects, particularly in the initial stages of concurrent use.

Methyldopa + Iron compounds

The antihypertensive effects of methyldopa can be reduced by ferrous sulfate. Ferrous gluconate appears to interact similarly. Ferric chloride may also interact but iron complexes such as iron polymaltose are predicted not to interact with methyldopa.

Clinical evidence

Ferrous sulfate 325 mg three times daily was given to 5 hypertensive patients who had been taking methyldopa 250 mg to 1.5 g daily for more than a year. After 2 weeks the blood pressures of all of them had risen, and the systolic pressures of 3 of them had risen by more than 15 mmHg. Four had diastolic blood pressure rises, two of them exceeding 10 mmHg.[1] The renal excretion of unmetabolised methyldopa was reduced by 88% and 79% when methyldopa was given with **ferrous sulfate** and **ferrous gluconate**, respectively.[1] A further study found that if the **ferrous sulfate** was given 2 hours before, one hour before or with the methyldopa, its bioavailability was reduced by 42%, 55%, and 83%, respectively.[2] An *in vitro* study suggests that ferric chloride but not iron polymaltose would interact with methyldopa.[3]

Mechanism

The increase in the metabolic sulfonation of the methyldopa seems to have a part to play in the interaction. However, it appears that methyldopa chelates or complexes with the iron in the gut, reducing its absorption by about 50%.[1,4,5] It has been suggested that if iron is in the form of a complex such as iron polymaltose, it will not form complexes with methyldopa.[3]

Importance and management

Information is limited, but an interaction between methyldopa and iron compounds appears to be established and clinically important. Monitor the effects of concurrent use and increase the methyldopa dose as necessary. Separating the doses by up to 2 hours apparently only partially reduces the effects of this interaction. Ferrous gluconate appears to interact like ferrous sulfate, and all iron salts would be expected to interact similarly, but iron in the form of complexes with carbohydrates such as iron polymaltose is predicted not to interact.

Methyldopa + Nasal decongestants

Phenylpropanolamine and related drugs might be expected to cause a blood pressure rise in patients taking methyldopa, and an isolated case report describes such a reaction. The mydriatic effects of ephedrine are reported to be reduced by methyldopa.

Clinical evidence, mechanism, importance and management

A man with renal hypertension, whose blood pressure was well controlled with methyldopa 250 mg twice daily and oxprenolol 160 mg three times daily, had a rise in blood pressure from under 140/80 mmHg to 200/150 mmHg within 2 days of starting to take two tablets of *Triogesic* (**phenylpropanolamine** 12.5 mg and paracetamol 500 mg) three times daily. His blood pressure fell when the *Triogesic* was withdrawn.[1]

The reason for this is uncertain. One suggestion is that the methyldopa causes the replacement of noradrenaline at adrenergic nerve endings by methylnoradrenaline, which has weaker pressor (alpha) activity but greater vasodilator (beta) activity. With the vasodilator activity blocked by the oxprenolol, the vasoconstrictor (pressor) activity of the **phenylpropanolamine** would be unopposed and exaggerated. Alternatively it could have been that he was unusually sensitive to the pressor effects of **phenylpropanolamine**.

In a study in 5 hypertensive patients taking methyldopa 2 to 3 g daily, the rise in blood pressure in response to **tyramine** was doubled.[2] In another study the pressor effect of **tyramine** was 50/16 mmHg, compared with 18/10 mmHg before methyldopa was given.[3]

Despite the information derived from the studies with tyramine and the single report cited, there seems to be nothing else in the literature to suggest that phenylpropanolamine and other indirectly-acting sympathomimetics normally cause an adverse reaction with methyldopa. One report briefly mentions that the antihypertensive effects of various drugs, including methyldopa, were not affected by **diethylpropion**.[4] In contrast, one report suggests that methyldopa may reduce the effects of other related drugs. In 9 patients with untreated hypertension, the normal mydriatic effects of **ephedrine** were reduced by 54% after they started treatment with methyldopa 500 mg to 1.5 g daily.[5] The clinical relevance of this finding is unclear.

Methyldopa + Oxazepam

A single, unsubstantiated case report suggests that blood pressure control with methyldopa may possibly be made more difficult in the presence of oxazepam.

Clinical evidence, mechanism, importance and management

A 54-year-old woman with insomnia and essential hypertension had unexplained variability in blood pressure while taking methyldopa 750 mg three times daily and a thiazide diuretic. Within a week of stopping oxazepam 60 mg at night, she developed grand mal convulsions and hypertension (190/90 mmHg standing, 240/140 mmHg lying). Her hypertension was then successfully controlled by switching to atenolol and prazosin. The authors of this report suggest that short-acting benzodiazepines such as oxazepam can cause transient hypotension after a dose, but that *hyper*tension may occur on withdrawal. These effects may complicate the management of hypertension.[1] The general importance of this possible interaction is not established, but it seems likely to be limited.

1. Stokes GS. Can short-acting benzodiazepines exacerbate essential hypertension? *Cardiovasc Rev Rep* (1989) 10, 60–1.

Methyldopa + Phenothiazines

The hypotensive adverse effects of chlorpromazine and other phenothiazines may be additive with the antihypertensive effects of methyldopa. Patients may feel faint and dizzy if they stand up quickly. An isolated report describes paradoxical hypertension in a patient given methyldopa and trifluoperazine.

Clinical evidence

In one study, 8 normotensive patients given methyldopa 500 mg to 1 g daily with **chlorpromazine** 200 to 400 mg daily for schizophrenia experienced orthostatic dizziness and had reductions in their standing systolic blood pressure.[1] In contrast, an isolated report describes a paradoxical *rise* in blood pressure in a patient with systemic lupus erythematosus and renal failure when methyldopa and **trifluoperazine** were given. When the **trifluoperazine** was stopped, the blood pressure fell.[2]

Mechanism

Simple addition of the hypotensive effects of both drugs seems to be the explanation for the increased hypotension and orthostasis. The suggested explanation for the hypertensive interaction with methyldopa and trifluoperazine is that the phenothiazine blocked the reuptake of the 'false transmitter' (alpha-methyl noradrenaline) that is produced when methyldopa is given.[2]

Importance and management

The increased hypotension and orthostasis that can occur if chlorpromazine or other phenothiazines are used with antihypertensive drugs such as methyldopa is established. Note that, of the phenothiazines, **levomepromazine** is particularly associated with postural hypotension. Warn patients that they may feel faint and dizzy particularly during the initial stages of concurrent use, and that if this occurs they should lie down, and that they should remain lying down until symptoms abate completely. Dose adjustments may be necessary.

Methyldopa + Phenoxybenzamine

An isolated case report describes a patient who had undergone bilateral lumbar sympathectomy who developed total urinary incontinence when taking methyldopa and phenoxybenzamine.

Clinical evidence, mechanism, importance and management

A woman who had previously had bilateral lumbar sympathectomy for Raynaud's disease developed total urinary incontinence when given methyldopa 500 mg to 1.5 g daily in divided doses with phenoxybenzamine 12.5 mg daily, but not when she was taking either drug alone. This would seem to be the outcome of the additive effects of the sympathectomy and the two drugs on the sympathetic control of the bladder sphincters.[1] Stress incontinence has previously been described with these drugs alone, and therefore the general importance of this interaction is probably small.

1. Fernandez PG, Sahni S, Galway BA, Granter S, McDonald J. Urinary incontinence due to interaction of phenoxybenzamine and α-methyldopa. *Can Med Assoc J* (1981) 124, 174.

Methyldopa + Tricyclic and related antidepressants

The antihypertensive effects of methyldopa are not normally adversely affected by desipramine, but an isolated report describes hypertension, tachycardia, tremor and agitation in a man taking

methyldopa and amitriptyline. The tetracyclic mianserin does not appear to interact with methyldopa to a clinically significant extent.

Clinical evidence

A man with hypertension, taking methyldopa 250 mg three times daily and a thiazide diuretic, experienced tremor, agitation, tachycardia (148 bpm) and hypertension (a rise from under 150/90 mmHg to 170/110 mmHg) within 10 days of starting to take **amitriptyline** 25 mg three times daily. A week after stopping all treatment his pulse rate was 100 bpm and his blood pressure 160/90 mmHg.[1] In contrast, a double-blind, crossover study in 5 subjects (one with mild hypertension) found that **desipramine** 25 mg three times daily for 3 days had no significant effect on the hypotensive effects of a single 750-mg dose of methyldopa.[2] Another study in 3 hypertensive patients taking methyldopa 2.5 to 3 g daily found that **desipramine** 75 mg daily for 5 to 6 days did not antagonise the action of methyldopa. In fact, the blood pressure fell slightly.[3] **Mianserin** 20 mg three times daily for 2 weeks had no effect on the control of blood pressure in 6 patients receiving methyldopa, although 2 patients developed symptomatic hypotension after the first dose of **mianserin**.[4,5]

Mechanism

Not understood. Antagonism of the antihypertensive actions of methyldopa by tricyclic antidepressants is seen in *animals* and it seems to occur within the brain.[6,7]

Importance and management

Normally no adverse interaction occurs. However, in view of the case report consider an interaction as a possible cause if a patient taking a tricyclic antidepressant appears unresponsive to methyldopa. Note that methyldopa sometimes induces depression, and so it should generally be avoided in depressed patients.

Minoxidil + Glibenclamide (Glyburide)

There is some evidence that a 5-mg dose of glibenclamide, but not a 2.5-mg dose, may reduce the hypotensive effect of minoxidil.

Clinical evidence, mechanism, importance and management

A single-dose study in 9 healthy subjects found that glibenclamide 2.5 mg did not alter the hypotensive effect of oral minoxidil 5 mg. However, in a further 4 subjects a 5-mg dose of glibenclamide appeared to cause some loss in the hypotensive effect of minoxidil, but this was not statistically significant. The authors therefore suggested that this interaction may be dose-related. The suggested reason for these effects is that these two drugs have opposing effects on the potassium channels of the smooth muscle of blood vessels.[1] In this study, subjects were pre-treated with propranolol to prevent reflex tachycardia when given minoxidil, which is how minoxidil is used clinically.[1] What is not yet clear is whether any interaction occurs between minoxidil and glibenclamide in a clinical setting.

1. Stein CM, Brown N, Carlson MG, Campbell P, Wood AJJ. Coadministration of glyburide and minoxidil, drugs with opposing effects on potassium channels. *Clin Pharmacol Ther* (1997) 61, 662–8.

Minoxidil + Miscellaneous

The manufacturer notes that excessive blood pressure reductions may occur if minoxidil is used in patients taking guanethidine, because of the adrenergic blocking effects of guanethidine.[1,2] If excessive hypotension occurs with minoxidil, this should *not* be treated with adrenaline (epinephrine) or noradrenaline (norepinephrine), because this may result in excessive tachycardia.[1]

1. Loniten Tablets (Minoxidil). Pharmacia Ltd. UK Summary of product characteristics, January 2008.
2. Minoxidil. Watson Pharmaceuticals, Inc. US Prescribing information, October 2002.

Minoxidil; Topical + Miscellaneous

The absorption of topical minoxidil is increased by topical tretinoin and also possibly by topical corticosteroids, dithranol and soft paraffin. Increased minoxidil absorption could possibly potentiate the hypotensive effects of vasodilators.

Clinical evidence, mechanism, importance and management

A study in 19 healthy subjects found that the absorption of topical minoxidil was increased by almost threefold by the use of topical **tretinoin** 0.05% applied one hour before the minoxidil.[1] In another study, in 29 male patients, the use of topical minoxidil 5% with **tretinoin** 0.01% daily in 15 patients was found to be as effective and safe as the use of minoxidil 5% alone twice daily in the other 14 patients for the treatment of male pattern baldness.[2]

The manufacturer notes that *topical* drugs that alter the stratum corneum barrier, such as **corticosteroids**, **tretinoin**, **dithranol**, or **white** or **yellow soft paraffin**, could result in increased absorption of minoxidil if both drugs are applied concurrently. They suggest that, theoretically, one possible effect of minoxidil absorption would be potentiation of orthostatic hypotension caused by **vasodilators**.[3] The exact drugs are not stated but this caution would be expected to cover drugs such as the **nitrates** and **hydralazine**.

3. Regaine for Men Gel (Minoxidil). McNeil Ltd. UK Summary of product characteristics, April 2008.

Moxisylyte + Miscellaneous

There is a theoretical possibility of increased blood pressure lowering effects if moxisylyte is used with antihypertensives or tricyclic antidepressants.

Clinical evidence, mechanism, importance and management

Moxisylyte is an alpha-1, and to a lesser extent, an alpha-2 blocker, which may be used orally as a peripheral vasodilator in Raynaud's syndrome. The manufacturer suggests that if moxisylyte is used by patients taking **antihypertensives**, it may theoretically potentiate the antihypertensive effect of these drugs, although at the recommended doses this has not been reported.[1]

The manufacturer also says that **tricyclic antidepressants** might increase any hypotensive effect of moxisylyte.[1]

For further commentary on the use of two or more drugs with antihypertensive effects, see 'Antihypertensives + Other drugs that affect blood pressure', p.1051.

1. Opilon (Moxisylyte hydrochloride). Archimedes Pharma UK Ltd. UK Summary of product characteristics, October 2008.

Moxonidine + Hydrochlorothiazide

No clinically significant pharmacokinetic interaction occurs between moxonidine and hydrochlorothiazide; however, the blood pressure lowering effects of the combination is greater than that seen with either drug alone.

Clinical evidence, mechanism, importance and management

In a study in 18 healthy subjects, no clinically relevant pharmacokinetic interaction was seen at steady state between moxonidine 200 micrograms twice daily and hydrochlorothiazide 25 mg twice daily.[1] A double-blind, placebo-controlled study found that when moxonidine 400 micrograms daily was given with hydrochlorothiazide 25 mg daily an increased blood pressure lowering effect was seen, compared with either drug alone. A mean reduction of 27/16 mmHg was noted with the combination, compared with 13/9 mmHg, 20/12 mmHg, and 22/13 mmHg for placebo, moxonidine and hydrochlorothiazide, respectively.[2] No particular precautions seem necessary on concurrent use, unless the combined effect on blood pressure is greater than desired.

2. Frei M, Küster L, Gardosch von Krosigk PP, Koch HF, Küppers H. Moxonidine and hydrochlorothiazide in combination: a synergistic antihypertensive effect. *J Cardiovasc Pharmacol* (1994) 24, (Suppl 1), S25–S28.

Moxonidine + Miscellaneous

No clinically significant pharmacokinetic interactions occur with moxonidine and digoxin, glibenclamide (glyburide), moclobemide, or quinidine.

Clinical evidence, mechanism, importance and management

(a) Digoxin

In 15 healthy subjects, no clinically relevant pharmacokinetic interaction was seen at steady state between moxonidine 200 micrograms twice daily and digoxin 200 micrograms daily.[1]

(b) Glibenclamide (Glyburide)

In 18 healthy subjects, glibenclamide 2.5 mg daily had no effect on the steady-state pharmacokinetics of moxonidine 200 micrograms twice daily. There was a minor 12% decrease in the AUC of glibenclamide, and a 14% increase in its clearance, but these changes are unlikely to be of any clinical relevance.[2]

(c) Moclobemide

A study found no pharmacokinetic interaction occurred when healthy subjects were given moxonidine 400 micrograms daily and a single 300-mg dose of moclobemide. Moxonidine alone or with moclobemide did not significantly affect cognitive function.[3]

(d) Quinidine

In a single-dose study in 6 healthy subjects, quinidine sulfate 400 mg, given one hour before moxonidine 200 micrograms, caused a minor 11% increase in the AUC of moxonidine and decreased its clearance by 10%. These small changes are unlikely to be of any clinical relevance.[4]

1. Pabst G, Weimann H-J, Weber W. Lack of pharmacokinetic interactions between moxonidine and digoxin. *Clin Pharmacokinet* (1992) 23, 477–81.
2. Müller M, Weimann H-J, Eden G, Weber W, Michaelis K, Dilger C, Achtert G. Steady state investigation of possible pharmacokinetic interactions of moxonidine and glibenclamide. *Eur J Drug Metab Pharmacokinet* (1993) 18, 277–83.

4. Wise SD, Chan C, Schaefer HG, He MM, Pouliquen IJ, Mitchell MI. Quinidine does not affect the renal clearance of moxonidine. *Br J Clin Pharmacol* (2002) 54, 251–4.

Nicorandil + Miscellaneous

Neither cimetidine nor rifampicin had any clinically relevant effect on the pharmacokinetics of nicorandil. Nicorandil did not alter the anticoagulant effects of acenocoumarol. Although *animal* studies suggest antagonism of effects, a study in patients found no pharmacodynamic interaction between nicorandil and glibenclamide. Nicorandil may potentiate the hypotensive effects of other vasodilators, tricyclic antidepressants and alcohol. Gastrointestinal perforations have been reported during the concurrent use of nicorandil and corticosteroids.

Clinical evidence, mechanism, importance and management

(a) Acenocoumarol

Nicorandil 10 mg twice daily for 4 days then 20 mg twice daily for 7 days did not alter the INR in 11 patients stabilised on acenocoumarol.[1]

(b) Cimetidine

Cimetidine 400 mg twice daily for 7 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 7 days, except that the nicorandil AUC showed a minor 10% increase, which is not clinically important.[1]

(c) Corticosteroids

Gastrointestinal perforations have been reported in patients given nicorandil and corticosteroids. Therefore, the manufacturer advises caution if concurrent use is considered.[2]

(d) Glibenclamide

Studies in *animals* have indicated that there may be antagonism between nicorandil and glibenclamide. However, in a study, 8 patients with diabetes and angina taking glibenclamide, and 11 similar patients not receiving glibenclamide, were given nicorandil 15 mg daily for more than 8 weeks. In contrast to the findings in the *animal* studies, glibenclamide did not cause inhibition of the anti-anginal effects of nicorandil, nor was there any disturbance of diabetic control.[3]

(e) Miscellaneous drugs

Combined data from clinical studies in 1 152 patients taking nicorandil found no evidence of increased adverse effects or an increased number of withdrawals in patients taking unnamed **beta blockers** (210 patients), **calcium-channel blockers** (117 patients), **long-acting nitrates** (130 patients), **diltiazem** (91 patients), **verapamil** (9 patients), **amiodarone** (23 patients) or **molsidomine** (30 patients). It has also been reported that unnamed **antihypertensives**, **antidiabetic** or **lipid-regulating drugs** do not appear to interact adversely with nicorandil.[4] No adverse ECG effects have been seen (including QT or ST segment modifications) with nicorandil.[4] However, the manufacturers suggest that nicorandil may possibly potentiate the blood pressure-lowering effects of other **vasodilators**, **tricyclic antidepressants** or **alcohol**.[2] For further discussion on additive blood pressure lowering effects, consider also 'Antihypertensives + Other drugs that affect blood pressure', p.1051. For mention that phosphodiesterase inhibitors (e.g. **sildenafil**, **tadalafil**, **vardenafil**) should not be used with nicorandil, see 'Phosphodiesterase type-5 inhibitors + Nitrates', p.1537.

(f) Rifampicin

Rifampicin 600 mg daily for 5 days had no effect on the pharmacokinetics of nicorandil 20 mg twice daily for 5 days, except for a minor 17% decrease in the elimination half-life, which is not clinically important.[1]

Pentoxifylline + Cimetidine

Cimetidine increases pentoxifylline levels to a moderate extent, which may increase the incidence of adverse effects.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects found that the mean steady-state plasma levels of controlled-release pentoxifylline 400 mg every 8 hours were raised by about 27% when cimetidine 300 mg four times daily for 7 days was added.[1] Adverse effects such as headache, nausea, and vomiting were said to be more common and bothersome while taking the cimetidine.[1]

The reason for this interaction is not known. However, cimetidine is known to inhibit the metabolism of theophylline (see 'Theophylline + H_2-receptor antagonists', p.1440, to which pentoxifylline is structurally related.

The findings of this study suggest that this interaction may be clinically relevant. If cimetidine is required in a patient taking pentoxifylline, mon-

itor for adverse effects, and decrease the pentoxifylline dose if problems occur.

1. Mauro VF, Mauro LS, Hageman JH. Alteration of pentoxifylline pharmacokinetics by cimetidine. *J Clin Pharmacol* (1988) 28, 649–54.

Pentoxifylline + Ciprofloxacin

Evidence from one study suggests that ciprofloxacin increases the levels of pentoxifylline, and may increase the incidence of adverse effects. In some clinical studies ciprofloxacin has been used to boost the levels of pentoxifylline.

Clinical evidence

Because patients taking pentoxifylline and ciprofloxacin often complained of headache, the possibility of a pharmacokinetic interaction was studied in 6 healthy subjects. The study found that ciprofloxacin 500 mg daily for 3 days increased the peak serum levels of a single 400-mg dose of pentoxifylline by almost 60% (from 114.5 to 179.5 nanograms/mL), and increased the AUC by 15%. All 6 subjects complained of a frontal headache.[1]

Mechanism

The evidence suggests that ciprofloxacin inhibits the metabolism of the pentoxifylline (a xanthine derivative) by the liver. Studies in *animals* found that ciprofloxacin inhibited the cytochrome P450 isoenzyme CYP1A2 which is involved in the metabolism of pentoxifylline.[2]

Importance and management

Information on this interaction and its clinical relevance is limited. The author of the pharmacokinetic study suggests that, if the drugs need to be used together, the dose of pentoxifylline should be halved.[1] In the absence of other information, if a short-course of ciprofloxacin is required in a patient taking pentoxifylline, this may be a sensible precaution. Alternatively, because the increase in AUC was minor, it may be sufficient to recommend a reduction in pentoxifylline dose only in those who experience adverse effects (e.g. nausea, headache). Note that ciprofloxacin has been used to boost pentoxifylline levels in studies investigating the possible therapeutic value of the ability of pentoxifylline to inhibit various cytokines. For example, ciprofloxacin 500 mg twice daily was used with pentoxifylline 800 mg three times daily for up to one year in patients with myelodysplastic syndrome.[3]

Perhexiline + SSRIs

Case reports describe an increase in perhexiline levels resulting in toxicity when citalopram, fluoxetine or paroxetine were given.

Clinical evidence, mechanism, importance and management

An 86-year-old woman taking perhexiline was admitted to hospital because of ataxia, falls, lethargy, nausea, and an inability to cope at home. She had started to take **paroxetine** 20 mg daily 5 weeks earlier. Her serum perhexiline levels were 2.02 mg/L (reference range 0.15 to 0.6 mg/L).[1] Perhexiline toxicity was also seen in two other elderly women, following the use of **paroxetine** in one case, and **fluoxetine** in the other. The perhexiline serum levels fell when both drugs were stopped, but in one case the fall was very slow.[2] Another case report describes toxicity and raised perhexiline levels in an elderly man shortly after he started taking **citalopram**.[3]

The reason for the rise in perhexiline levels is not known, but it seems likely that these SSRIs can inhibit its metabolism, probably by the cytochrome P450 isoenzyme CYP2D6, although note that citalopram is usually considered to be a weak inhibitor of this isoenzyme. The general importance of these interactions is not known, but it would seem prudent to monitor the outcome of concurrent use for perhexiline toxicity and consider monitoring perhexiline levels where possible. The perhexiline dose may need to be reduced. More study is needed.

Ranolazine + Azoles

Ketoconazole raises ranolazine levels. Other azoles are expected to interact similarly.

Clinical evidence

In a double-blind, randomised study, healthy subjects were given slow-release ranolazine 375 mg twice daily for 9 days, with ketoconazole 200 mg twice daily on days 5 to 9. The same study was repeated with ranolazine 1 g twice daily. It was found that ketoconazole increased the AUC, levels (mean, peak and trough) and half-life of ranolazine by 2.5- to 4.5-fold. The most common adverse events were headaches, dizziness and nausea. In some patients the higher dose of ranolazine with ketoconazole resulted in intolerable adverse effects.[1]

Mechanism

Ranolazine is a substrate of cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a potent inhibitor. Concurrent use therefore raises ranolazine levels. All azoles are, to a greater or lesser extent, inhibitors of this isoenzyme and may therefore interact similarly.

Importance and management

Information regarding an interaction between ranolazine and ketoconazole appears to be limited to this study, but what is known is in line with the known effects of these drugs, and is therefore established. The dose-related adverse effects of ranolazine such as nausea and dizziness are increased by ketoconazole. Further, increases in plasma levels of ranolazine may cause significant QT prolongation and the possible risk of arrhythmias (see also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

The manufacturers of ranolazine contraindicate its use with ketoconazole and other potent CYP3A4 inhibitors. Others they specifically name include **itraconazole**, **posaconazole**, and **voriconazole**.[2,3]

Fluconazole is only a moderate inhibitor of CYP3A4, and therefore the US manufacturer recommends that the dose of ranolazine should be limited to 500 mg twice daily,[2] whereas the UK manufacturer recommends careful dose titration of ranolazine. There appear to be no recommendations about **miconazole**; however, a large proportion of miconazole oral gel (both prescription and non-prescription doses) may be swallowed and therefore adequate systemic absorption may occur to produce an interaction. It would therefore seem prudent to monitor concurrent use closely. For systemic miconazole, similar precautions to those recommended for fluconazole would seem prudent.

3. Ranexa (Ranolazine). A Menarini Pharma UK SRL. UK Summary of product characteristics, August 2009.

Ranolazine + Calcium-channel blockers

Diltiazem and verapamil raise ranolazine levels, which increases the risk of ranolazine adverse effects. However, concurrent use may be beneficial.

Clinical evidence

(a) Diltiazem

In a placebo-controlled study in 12 healthy subjects, diltiazem 60 mg three times daily was given to 12 healthy subjects for 7 days with ranolazine 240 mg three times daily on days 4 to 7. Ranolazine did not alter the pharmacokinetics of diltiazem, but diltiazem increased the AUC and maximum plasma level of ranolazine by 85% and twofold, respectively. A further study using modified-release diltiazem 180 mg, 240 mg, and 360 mg daily, and a slow-release preparation of ranolazine 1 g twice daily, resulted in increases in the AUC of ranolazine of 52%, 93%, and 139%, respectively.[1] However, a clinical study in patients with angina who were taking diltiazem 180 mg daily, with amlodipine or atenolol, and were given ranolazine or placebo, found that ranolazine 750 mg or 1000 mg twice daily provided additional anti-anginal efficacy with minimal haemodynamic effects.[2]

(b) Verapamil

The plasma levels of ranolazine are reported to be increased twofold by the concurrent use of verapamil 120 mg three times daily.[3]

Mechanism

Ranolazine is a substrate of cytochrome P450 isoenzyme CYP3A4. Diltiazem and verapamil are moderate inhibitors of this isoenzyme, and therefore increase ranolazine levels. Ranolazine is also a substrate of P-glycoprotein and therefore verapamil, which also inhibits P-glycoprotein, may increase its levels by this mechanism as well.

Importance and management

Information regarding an interaction between ranolazine and diltiazem or verapamil is limited, but what is known is in line with the known effects of these drugs, and is therefore established. The dose-related adverse effects of ranolazine such as nausea and dizziness may be increased by concurrent use of drugs that increase its plasma levels. Further, increases in plasma levels of ranolazine may cause significant QT prolongation and the possible risk of arrhythmias (see also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

The US manufacturer recommends that the dose of ranolazine should be limited to 500 mg twice daily when given to patients also taking moderate CYP3A4 inhibitors including diltiazem, verapamil.[3] The UK manufacturer recommends careful dose titration of ranolazine in patients taking diltiazem, and suggests that lower ranolazine doses may be needed in the presence of verapamil.[4]

There appears to be no information about the use of ranolazine with other calcium-channel blockers, but as these drugs are not inhibitors of CYP3A4 or P-glycoprotein, a pharmacokinetic interaction would not be expected.

Ranolazine + CYP2D6 inhibitors or substrates

Paroxetine does not affect ranolazine levels to a clinically significant extent. Although drugs such as the tricyclics are predicted to affect the pharmacokinetics of ranolazine, this seems unlikely.

Clinical evidence, mechanism, importance and management

(a) CYP2D6 inhibitors

Paroxetine has been reported to increase the average steady-state plasma concentrations of ranolazine 1 g twice daily by 20%.[1,2] Ranolazine is partially metabolised by the cytochrome P450 isoenzyme CYP2D6, which **paroxetine** inhibits. Therefore, the UK manufacturer predicts that a potent inhibitor of CYP2D6, like **paroxetine**, could increase the AUC of ranolazine 500 mg twice daily (therapeutic dose) by about 62%.[1] However, as CYP2D6 is not the main route of metabolism, only very modest effects are seen, and no dose adjustment is necessary.[1,2]

(b) CYP2D6 substrates

Ranolazine is partially metabolised by cytochrome P450 isoenzyme CYP2D6. Although there are no studies on the concurrent use of CYP2D6 substrates with ranolazine, the manufacturers predict that levels of drugs metabolised by CYP2D6, such as **tricyclic antidepressants** and **antipsychotics**, may be increased and that lower doses of these drugs may be required.[1,2] However, as CYP2D6 inhibitors do not appear to have a clinically relevant effect on ranolazine, an interaction seems highly unlikely.

1. Ranexa (Ranolazine). A Menarini Pharma UK SRL. UK Summary of product characteristics, August 2009.
2. Ranexa (Ranolazine). CV Therapeutics, Inc. US Prescribing Information, March 2009.

Ranolazine + CYP3A4 inducers

Rifampicin (a CYP3A4 and P-glycoprotein inducer) markedly reduces ranolazine levels. Other CYP3A4 inducers are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Rifampicin 600 mg daily is reported to decrease the steady-state plasma levels of ranolazine 1 g twice daily by about 95%. This is due to the induction of the metabolism of ranolazine by cytochrome P450 isoenzyme CYP3A4 and possibly also by P-glycoprotein. Such a marked reduction in levels would be expected to abolish the effects of ranolazine and the manufacturers of ranolazine therefore contraindicate concurrent use.[1,2] The manufacturers recommend avoiding the concurrent use of ranolazine with other CYP3A4 inducers, including **carbamazepine**, **phenobarbital**, **phenytoin**, **rifabutin**, **rifapentine** and **St John's wort**.[1,2] In the absence of any information on the magnitude of the effect of these CYP3A4 inducers on ranolazine levels, this seems prudent.

1. Ranexa (Ranolazine). CV Therapeutics, Inc. US Prescribing Information, March 2009.
2. Ranexa (Ranolazine). A Menarini Pharma UK SRL. UK Summary of product characteristics, August 2009.

Ranolazine + Miscellaneous

Ranolazine may increase levels of ciclosporin and digoxin. Ciclosporin may also increase ranolazine levels. In theory ranolazine may increase the levels of bupropion, efavirenz and cyclophosphamide. The concurrent use of ranolazine and moderate or potent inhibitors of CYP3A4, will result in increased levels of ranolazine, and can predispose the patient to adverse effects including QT interval prolongation. Cimetidine does not interact with ranolazine to a clinically significant extent. Ranolazine may increase the levels of simvastatin.

Clinical evidence, mechanism, importance and management

(a) Ciclosporin

Ranolazine inhibits P-glycoprotein and has been shown to raise digoxin levels (see *Digoxin*, below). However, ranolazine is also a substrate of P-glycoprotein and plasma levels of ranolazine are increased by inhibitors of P-glycoprotein, such as ciclosporin. The manufacturers of ranolazine therefore advise caution if it is given to patients taking ciclosporin, which is also a P-glycoprotein inhibitor [and substrate].[1,2] The dose of ranolazine should be titrated according to clinical response and down-titration may be required.[1,2] Until more is known it may also be prudent to be alert for any changes in ciclosporin levels.

(b) Cimetidine

The manufacturers report that in healthy subjects cimetidine 400 mg three times daily does not increase levels of ranolazine.[1]

(c) CYP2B6 substrates

Although the potential for ranolazine to inhibit the cytochrome P450 isoenzyme CYP2B6 has not been evaluated, the UK manufacturer advises caution if it is given with CYP2B6 substrates and they give as examples

bupropion, **efavirenz** and **cyclophosphamide**.[2] The clinical relevance of any interaction is unknown.

(d) Digoxin

A study in healthy subjects given ranolazine 1 g twice daily and digoxin 125 micrograms found that ranolazine increased the plasma levels of digoxin by about 50%. Plasma levels of ranolazine were not significantly affected by digoxin.[1,2] Ranolazine probably raises digoxin levels by inhibiting P-glycoprotein. Digoxin levels should be monitored if ranolazine is started or stopped, and the digoxin dose may have to be adjusted.[1,2]

(e) Other drugs

Ranolazine is a substrate of the cytochrome P450 isoenzyme CYP3A4 and inhibitors of CYP3A4 increase plasma levels of ranolazine. Potent inhibitors of CYP3A4 such as ketoconazole (see 'Ranolazine + Azoles', p.1073) cause a three to fourfold increase in ranolazine levels and moderate inhibitors such as diltiazem (see 'Ranolazine + Calcium-channel blockers', p.1073) may increase levels about twofold. The dose-related adverse effects of ranolazine such as nausea and dizziness may be increased by concurrent use of drugs that increase its plasma levels. Further, increases in plasma levels of ranolazine may cause significant QT prolongation and the possible risk of arrhythmias (see also, 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

The manufacturers of ranolazine contraindicate its use with potent CYP3A4 inhibitors. They include **clarithromycin**, **nefazodone** and the **protease inhibitors** (the US manufacturer[1] names **indinavir**, **nelfinavir**, **ritonavir** and **saquinavir**). The UK manufacturer[2] also names **telithromycin**.

The US manufacturer recommends that the dose of ranolazine should be limited to 500 mg twice daily when given to patients taking moderate CYP3A4 inhibitors including **aprepitant** and **erythromycin**.[1] The UK manufacturer recommends careful dose titration of ranolazine in patients taking moderately potent CYP3A4 inhibitors, and name **erythromycin**.

While the UK manufacturers of ranolazine consider **grapefruit juice** to be a potent inhibitor of CYP3A4 and therefore contraindicate its use with ranolazine, the US manufacturer includes **grapefruit juice** and **grapefruit-containing products** as moderate inhibitors and recommends limiting the dose of ranolazine to 500 mg twice daily during concurrent use.[1]

Ranolazine is also a substrate of P-glycoprotein and therefore ritonavir, which inhibits P-glycoprotein may also increase ranolazine levels by this mechanism (see *Digoxin*, above).

2. Ranexa (Ranolazine). A Menarini Pharma UK SRL. UK Summary of product characteristics, August 2009.

Sodium nitroprusside + Miscellaneous

Smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. Clonidine does not affect the response to nitroprusside. There is a risk of severe hypotension if phosphodiesterase inhibitors (e.g. sildenafil, tadalafil and vardenafil) are used with sodium nitroprusside.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives

The manufacturer notes that smaller doses of sodium nitroprusside might be required in patients receiving antihypertensive drugs. In any event the required dose varies considerably between patients and so should be titrated to effect.[1]

In a placebo-controlled study, patients with hypertension were given intravenous sodium nitroprusside in increasing bolus doses of 30 to 300 micrograms on the day before surgery, before induction of anaesthesia and one and 3 hours postoperatively. Oral **clonidine** 6 micrograms/kg, was given 2 hours before surgery with a further dose of 3 micrograms/kg intravenously over the last hour of surgery. **Clonidine** did not affect the perioperative response to nitroprusside.[2]

When nitroprusside is used for controlled hypotension during anaesthesia, the hypotensive effect of other drugs, particularly anaesthetics, should be remembered.[1] The manufacturer specifically names **halothane** and **enflurane**. Consider also 'Antihypertensives + Other drugs that affect blood pressure', p.1051.

(b) Phosphodiesterase type-5 inhibitors

The use of phosphodiesterase inhibitors (e.g. **sildenafil**, **tadalafil** and **vardenafil**) with sodium nitroprusside is contraindicated by the manufacturers, due to the risk of severe hypotension. See also 'Phosphodiesterase type-5 inhibitors + Nitrates', p.1537. A case report describes the therapeutic use of **sildenafil** to enhance the hypotensive effect of sodium nitroprusside and other antihypertensives in a patient with a hypertensive crisis.[3]

Tirilazad + Miscellaneous

Phenobarbital and phenytoin reduce the levels of tirilazad mesilate whereas ketoconazole increases them. Finasteride inhibits the metabolism of tirilazad mesilate to its active metabolite. No pharmacokinetic interaction appears to occur between cimetidine or nimodipine and tirilazad mesilate.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

A study in 16 healthy men found that cimetidine 300 mg every 6 hours for 4 days had no effect on the pharmacokinetics of a single 2-mg/kg dose of tirilazad mesilate, given by infusion over 10 minutes on day 2, nor on U-89678, its active metabolite.[1] No special precautions would seem necessary if cimetidine is given with tirilazad mesilate.

(b) Finasteride

In a study, 8 healthy men were given finasteride 5 mg daily for 10 days, with tirilazad mesilate 10 mg/kg orally or 2 mg/kg intravenously on day 7. Finasteride increased the AUCs of intravenous and oral tirilazad by 21% and 29%, respectively. Oral finasteride reduced the AUCs of the active metabolite (U-89678) by 92% when tirilazad was given intravenously and by 75% when tirilazad was given orally. Although the metabolism of tirilazad to U-89678 was inhibited there was only a moderate effect on the overall clearance of tirilazad and the interaction was considered unlikely to be of clinical significance.[2]

(c) Ketoconazole

Tirilazad mesilate, 10 mg/kg orally or 2 mg/kg intravenously, was given to 12 healthy subjects (both men and women), either alone or on day 4 of a 7-day regimen of ketoconazole 200 mg daily. The ketoconazole more than doubled the absolute bioavailability of the oral tirilazad mesilate (from 8.7% to 20.9%), apparently because its metabolism by the cytochrome P450 isoenzyme CYP3A in the gut wall and during the first pass through the liver was inhibited.[3] The clinical importance of this interaction awaits assessment.

(d) Nimodipine

In a single-dose study in 12 healthy men, there was no pharmacokinetic or pharmacodynamic interaction between intravenous tirilazad mesilate 2 mg/kg and oral nimodipine 60 mg.[4] No special precautions would seem necessary if nimodipine is given with tirilazad mesilate

(e) Phenobarbital

The pharmacokinetics of tirilazad mesilate (1.5 mg/kg as 10 minute intravenous infusions every 6 hours for 29 doses) were studied in 15 healthy subjects before and after they took phenobarbital 100 mg daily for 8 days. Phenobarbital increased the clearance of tirilazad by 25% in the male subjects and 29% in the female, and the AUC of the active metabolite of tirilazad (U-89678) was reduced by 51% in the males and 69% in the females. This was thought to occur because phenobarbital acts as an enzyme inducer, which increases the metabolism of the tirilazad.[5] The clinical importance of these pharmacokinetic changes awaits assessment, but be alert for evidence of reduced effects if both drugs are given. It is doubtful if the full enzyme-inducing effects of the phenobarbital would have been reached in this study after only one week, so anticipate a greater effect if it is given for a longer period. Note that **primidone** is metabolised to phenobarbital, and therefore it may be expected to interact similarly.

(f) Phenytoin

In a study in 12 healthy subjects, phenytoin 200 mg every 8 hours for 11 doses then 100 mg every 8 hours for 5 doses, reduced the $AUC_{0\text{-}6}$ of tirilazad mesilate by 35%. The AUC of the active metabolite, U-89678, was reduced by 87%.[6] Another report by the same group of workers[7] found that phenytoin every 8 hours for 7 days (9 doses of 200 mg followed by 13 doses of 100 mg) reduced the clearance of tirilazad by 92% and of U-89678 by 93%. In another report the authors noted that phenytoin increased the metabolism of tirilazad and its metabolite in men and women to similar extents.[8] The clinical importance of these reductions is still to be assessed, but be alert for any evidence of reduced tirilazad effects if both drugs are given. Note that **fosphenytoin** is a prodrug of phenytoin, and may therefore be expected to interact similarly.

Tolazoline + H_2-receptor antagonists

Cimetidine and ranitidine can reduce or abolish the effects of tolazoline used as a pulmonary vasodilator in children.

Clinical evidence

A newborn infant with persistent foetal circulation was given a continuous infusion of tolazoline to reduce pulmonary hypertension. The oxygenation improved but gastrointestinal bleeding occurred. When **cimetidine** was given, the condition of the child deteriorated with a decrease in oxygen saturation and arterial pO_2 values.[1] A second case report describes a similar outcome in a 2-day-old neonate, who had an initial improvement with tolazoline alone, but then developed worsening hypoxaemia when cimetidine was given.[2]

These reports are similar to another, in which the tolazoline-induced reduction in pulmonary arterial pressure in a child was reversed when **cimetidine** was given, for acute gastrointestinal haemorrhage.[3] Another study in 12 children found that intravenous **ranitidine** 3 mg/kg abolished the tolazoline-induced reduction in pulmonary and systemic vascular.[4]

Mechanism

Tolazoline dilates the pulmonary vascular system by stimulating both H_1- and H_2-receptors. Cimetidine and ranitidine block H_2-receptors so that at least part of the effects of tolazoline are abolished. It has been suggested that this interaction is confined to children.[3]

Importance and management

An established interaction. Cimetidine and ranitidine are not suitable drugs for prophylaxis of the gastrointestinal adverse effects of tolazoline in children. Other H_2-receptor antagonists would be expected to behave similarly.

Digitalis glycosides

Plant extracts containing cardiac glycosides have been in use for thousands of years. The ancient Egyptians were familiar with squill (a source of **proscillaridin**), as were the Romans who used it as a heart tonic and diuretic. The foxglove was mentioned in the writings of Welsh physicians in the thirteenth century and features in 'An Account of the Foxglove and some of its Medical Uses', published by William Withering in 1785, in which he described its application in the treatment of 'dropsy' or the oedema that results from heart failure.

The most commonly used cardiac glycosides are those obtained from the members of the foxglove family, *Digitalis purpurea* and *Digitalis lanata*. The leaves of *D. lanata* are the source of a number of purified glycosides including **digoxin**, **digitoxin**, **acetyldigoxin**, **acetyldigitoxin**, **lanatoside C**, **deslanoside**, of gitalin (an amorphous mixture largely composed of digitoxin and digoxin), and of powdered whole leaf **digitalis lanata leaf**. *D. purpurea* is the source of **digitoxin**, **digitalis leaf**, and the standardised preparation **digitalin**. **Metildigoxin** is a semi-synthetic digitalis glycoside. Occasionally ouabain or strophanthin-K (also of plant origin) are used for particular situations, while for a number of years the Russians have exploited cardiac glycosides from lily of the valley (**convallaria**). Bufalin is a related cardioactive compound obtained from toads, and is found in a number of Chinese medicines.

Digitalisation

The cardiac glycosides have two main actions and two main applications. They reduce conductivity within the atrioventricular (AV) node, hence are used for treating supraventricular tachycardias (especially atrial fibrillation), and they have a positive inotropic effect (i.e. increase the force of contraction), and hence may be used for congestive heart failure.

Because the most commonly used glycosides are derived from digitalis, the achievement of the desired therapeutic serum concentration of any cardiac glycoside is usually referred to as digitalisation. Treatment may be started with a large loading dose so that the therapeutic concentrations are achieved reasonably quickly, but once these have been reached the amount is reduced to a maintenance dose. This has to be done carefully because there is a relatively narrow gap between therapeutic and toxic serum concentrations. Normal therapeutic levels are about one-third of those that are fatal, and serious toxic arrhythmias begin at about two-thirds of the fatal levels. The therapeutic range for digoxin levels is 0.8 to 2 nanograms/mL (or 1.02 to 2.56 nanomol/L). To convert nanograms/mL to nanomol/L multiply by 1.28, or to convert nanomol/L to nanograms/mL multiply by 0.781. Note that micrograms/L is the same as nanograms/mL.

If a patient is over-digitalised, signs of toxicity will occur, which may include loss of appetite, nausea and vomiting, and bradycardia. These symptoms are often used as clinical indicators of toxicity and a pulse rate of less than 60 bpm is usually considered to be an indication of over-treatment. Note that paroxysmal atrial tachycardia with AV block and junctional tachycardia can also occur as a result of digitalis toxicity. Other symptoms include visual disturbances, headache, drowsiness and occasionally diarrhoea. Death may result from cardiac arrhythmias. Patients given digitalis for cardiac arrhythmias can therefore demonstrate arrhythmias when they are both under- as well as over-digitalised.

Interactions of the cardiac glycosides

The pharmacological actions of these glycosides are very similar, but their rates and degree of absorption, metabolism and clearance are different. For example, digoxin is mainly renally cleared whereas digitoxin undergoes a degree of metabolism by the liver. It is therefore most important not to extrapolate a pharmacokinetic interaction seen with one glycoside and apply it uncritically to any other. Because the therapeutic ratio of the cardiac glycosides is low, a quite small change in serum levels may lead to inadequate digitalisation or to toxicity. For this reason interactions that have a relatively modest effect on serum levels may sometimes have serious consequences.

Many interactions between digoxin and other drugs are mediated by P-glycoprotein. Drugs that inhibit the activity of P-glycoprotein in the renal tubules may reduce the elimination of digoxin in the urine and this may result in toxic serum levels. Further, the induction or inhibition of P-glycoprotein in the gut may affect the oral absorption of digoxin. See also 'Drug transporter proteins', (p.8).

Digoxin and related drugs + ACE inhibitors

Most ACE inhibitors do not interact with digoxin to a clinically relevant extent. Some studies have found that serum digoxin levels rise by about 20% or more if captopril is used, but others have found no significant changes. It has been suggested that any interaction is likely to occur only in those patients who have pre-existing renal impairment. Digitoxin and captopril appear not to interact.

Clinical evidence

(a) Digitoxin and Captopril

A study in 12 healthy subjects given digitoxin 70 micrograms daily for up to 58 days found no evidence that the addition of captopril 25 mg daily had a relevant effect on the pharmacokinetics of digitoxin, or its effects on the heart.[1]

(b) Digoxin and Captopril

The serum digoxin levels of 16 patients with severe chronic congestive heart failure rose by 21% (from 1.1 to 1.3 nanograms/mL), while taking captopril (average dose 93.7 mg daily). Serum digoxin levels were above the therapeutic range at 2 nanograms/mL on 3 out of 63 occasions, but no toxicity was seen. All patients had impaired renal function and were being treated with diuretics.[2,3] Another study[4] found a rise of about 30% in serum digoxin levels in patients with congestive heart failure (NYHA class II) given captopril and a further study[5] found an approximate 60% rise in peak serum digoxin levels in patients with congestive heart failure (NYHA class IV) given captopril. Conversely, another study in 31 patients with stable congestive heart failure, given captopril 25 mg three times daily, found no significant changes in serum digoxin levels over a 6-month period.[6] Two other studies in healthy subjects[7] and patients with congestive heart failure[8] also found no evidence of an interaction.

(c) Digoxin and Other ACE inhibitors

In general no significant interactions have been seen between ACE inhibitors and digoxin.

- **Cilazapril** 5 mg for 14 days did not alter the trough plasma digoxin levels in healthy subjects.[9]
- **Enalapril** 20 mg daily for 30 days had no significant effect on the pharmacokinetics of digoxin 250 micrograms daily in 7 patients with congestive heart failure.[10]
- **Imidapril** 10 mg daily had no effect on the serum digoxin levels of 12 healthy subjects, but slight reductions in levels of the active form imidaprilat and in ACE inhibition of about 15% were seen, which were of uncertain clinical relevance.[11]
- **Lisinopril** 5 mg daily for 4 weeks had no significant effect on the serum digoxin levels of 9 patients.[12] This confirms the findings of a single-dose study.[13]
- **Moexipril** has been reported, by the manufacturer, to have had no important pharmacokinetic interaction with digoxin in healthy subjects.[14] The manufacturer also has clinical studies that show no evidence of clinically important adverse interactions when moexipril was used with digoxin.[15]
- **Perindopril** 2 to 4 mg daily for a month had no effect on the steady-state serum digoxin levels of 10 patients with mild chronic heart failure.[16]
- **Quinapril** is also reported not to alter the steady-state levels of digoxin in healthy subjects,[17] and patients with congestive heart failure.[18]
- **Ramipril** 5 mg daily for 14 days had no effect on the serum digoxin levels of 12 healthy subjects.[19]
- **Spirapril** 12 to 48 mg daily did not significantly affect the pharmacokinetics nor the steady-state serum levels of digoxin in 15 healthy subjects taking digoxin 250 micrograms twice daily.[20]
- **Trandolapril** has been shown to have no significant pharmacokinetic interaction with digoxin in healthy subjects.[21] The manufacturers also note that, in patients with left ventricular dysfunction after myocardial infarction, no clinical interactions have been found between trandolapril and digoxin.[22,23]

Mechanism

Not fully understood. It has been suggested that an interaction is only likely to occur in those who have renal impairment because the glomerular filtration rate of these patients may be maintained by the vasoconstrictor action of angiotensin II on the post-glomerular blood vessels, which would be impaired by ACE inhibition. As a result some of the loss of digoxin through the tubules is reduced.[7]

Importance and management

The overall picture is that no clinically important adverse interaction occurs between digoxin and ACE inhibitors in patients with normal renal function, and that serum digoxin monitoring is only needed in those who have a high risk of reversible ACE inhibitor-induced renal failure (e.g. patients with congestive heart failure during chronic diuretic treatment, with bilateral renal artery stenosis or unilateral renal artery stenosis in a solitary kidney);[7] however, note these latter two conditions are contraindications to the use of ACE inhibitors. The critical factor does not seem to be the particular ACE inhibitor used but the existence of abnormal renal function or conditions that increase the risk of renal impairment. This needs confirmation.

No interaction apparently occurs between digitoxin and captopril in healthy subjects, but this ideally needs confirmation in patients.

Digoxin + Acipimox

One study suggests that acipimox does not interact with digoxin.

Clinical evidence, mechanism, importance and management

In 6 elderly patients acipimox 250 mg three times daily for a week was found to have no significant effect on plasma digoxin levels, clinical con-

dition, ECGs, plasma urea or electrolyte levels.[1] No special precautions would seem necessary during concurrent use.

1. Chijioke PC, Pearson RM, Benedetti S. Lack of acipimox-digoxin interaction in patient volunteers. *Hum Exp Toxicol* (1992) 11, 357–9.

Digoxin + Allopurinol

Allopurinol does not appear to affect digoxin levels.

Clinical evidence, mechanism, importance and management

No significant changes in the serum digoxin levels of 5 healthy subjects occurred over a 7-day period while they were taking allopurinol 300 mg daily.[1] No digoxin dose adjustments would appear to be necessary on concurrent use.

1. Havelund T, Abildtrup N, Birkebaek N, Breddam E, Rosager AM. Allopurinols effekt på koncentrationen af digoksin i serum. *Ugeskr Laeger* (1984) 146, 1209–11.

Digoxin + Alpha blockers

A rapid and marked rise in serum digoxin levels occurred in one study when prazosin was also given, whereas a decrease in digoxin levels was reported in another study with prazosin. Alfuzosin, doxazosin, tamsulosin and terazosin appear not to interact with digoxin.

Clinical evidence, mechanism, importance and management

(a) Alfuzosin

The manufacturers of alfuzosin report that no pharmacodynamic or pharmacokinetic interaction was observed in healthy subjects given alfuzosin 10 mg [daily] with digoxin 250 micrograms daily for 7 days.[1,2]

(b) Doxazosin

Doxazosin is highly bound to plasma proteins (98%), but the manufacturer notes that *in vitro* data in human plasma indicated that doxazosin did not affect the protein binding of digoxin.[3,4] Although there appears to be no clinical evidence of an interaction between digoxin and doxazosin, an *in vitro* study found that doxazosin inhibited the P-glycoprotein-mediated transcellular transport of digoxin, suggesting that an interaction is possible, as digoxin renal transport may be inhibited.[5] More study is needed.

(c) Prazosin

In 20 patients prazosin 2.5 mg twice daily increased the mean steady-state plasma digoxin level by 43% (from 0.94 to 1.34 nanograms/mL) after one day, and by 60% (from 0.94 to 1.51 nanograms/mL) after 3 days, although the individual response varied from an increase to a decrease, or no effect. Three days after the prazosin was stopped, by which time it would be totally cleared from the body, the serum digoxin concentrations had fallen to their previous levels.[6] Another study found that prazosin shortened the half-life of digoxin, decreased serum levels and increased its clearance, but did not affect digoxin bioavailability.[7]

The reason for this response is not understood. There do not appear to be any other reports in the literature, and the manufacturer notes that, in clinical experience, prazosin has been given with digoxin (and **digitalis**) without any adverse drug interaction.[8] However, bear this interaction in mind in case of an unexpected response to treatment.

(d) Tamsulosin

A placebo-controlled study in 10 healthy subjects found that tamsulosin 800 micrograms daily had no effect on the pharmacokinetics of a single 500-microgram intravenous dose of digoxin. The most frequently reported adverse effect was dizziness and the safety profile was considered acceptable.[9] The manufacturers note that dose adjustments are not necessary when tamsulosin is given with digoxin.[10]

(e) Terazosin

The manufacturer of terazosin states that terazosin has been given with cardiac glycosides without evidence of an interaction.[11]

Digoxin + Alpha-glucosidase inhibitors

Some but not all studies have found that digoxin levels can be markedly reduced by acarbose. Miglitol modestly reduced digoxin levels in healthy subjects, but no change was seen in diabetic patients. Voglibose does not appear to interact adversely with digoxin.

Clinical evidence, mechanism, importance and management

(a) Acarbose

A woman taking digoxin 250 micrograms daily, insulin, nifedipine, isosorbide dinitrate, clorazepate and nabumetone had subtherapeutic plasma digoxin levels of 0.48 to 0.64 nanograms/mL while taking acarbose, even when her digoxin dose was increased by adding 125 micrograms on 2 days of the week. Later, in the absence of acarbose and with the original digoxin dose, her plasma levels were 1.9 nanograms/mL.[1,2] Similarly, two other patients had markedly reduced plasma digoxin levels while taking acarbose. When the acarbose was stopped, the plasma digoxin levels rose from 0.23 nanograms/mL to 1.6 nanograms/mL and from 0.56 nanograms/mL to 1.9 nanograms/mL, respectively.[3] Another patient with heart failure and type 2 diabetes taking digoxin and voglibose, was found to have subtherapeutic levels of digoxin when his treatment was changed from voglibose (see below) to acarbose. The serum levels unexpectedly remained subtherapeutic for at least a month when treatment was switched back to voglibose.[4]

A pharmacokinetic study in 7 healthy subjects, using either a 200-mg dose of acarbose or pretreatment with acarbose 100 mg doses three times daily, similarly found that the serum levels and AUC of a single 500-microgram dose of digoxin were reduced. Maximum digoxin serum levels were reduced by about 30 to 40% and the AUC was reduced by about 40%.[5] The reasons for this interaction are not understood but a reduction in the absorption of the digoxin from the gut has been suggested.[5] These reports contrast with other studies that found no significant interaction between single-dose digoxin and acarbose in healthy subjects.[6,7] Just why there is an inconsistency between these reports is not understood but it would clearly be prudent to consider monitoring digoxin levels if both drugs are used, being alert for any evidence of reduced levels.

(b) Miglitol

The manufacturer of miglitol notes that in a study in healthy subjects, miglitol 50 mg or 100 mg three times daily reduced the average plasma concentrations of digoxin by 19% and 28%, respectively. However, in diabetic patients plasma digoxin levels were not altered by the concurrent use of miglitol 100 mg three times daily for 14 days.[8] The effects in healthy subjects are modest, and the lack of effect in patients suggests that no interaction is likely, but this needs confirmation.

(c) Voglibose

A randomised, crossover study in 8 healthy subjects taking digoxin 250 micrograms daily after breakfast for 8 days found that voglibose 200 micrograms three times daily had no effect on the pharmacokinetics of the digoxin.[9] No dose adjustment of digoxin therefore seems necessary if voglibose is given.

Digoxin + 5-Alpha reductase inhibitors

Dutasteride and finasteride do not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 20 healthy subjects taking digoxin found that its steady-state pharmacokinetics were unchanged by **dutasteride** 500 micrograms daily for 3 weeks.[1] Similarly, in a randomised study, 17 healthy subjects were given a single 400-microgram dose of digoxin while taking **finasteride** 5 mg daily for 10 days. Finasteride had no significant effect on the single-dose pharmacokinetics of digoxin.[2] No digoxin dose adjustment would be expected to be necessary on concurrent use of either of these 5-alpha reductase inhibitors.

2. Gregoire S, Williams R, Gormley G, Lin E. Effect of finasteride (MK-906) on the disposition of digoxin. *J Clin Pharmacol* (1990) 30, 847.

Digoxin and related drugs + Aminoglutethimide

The clearance of digitoxin is markedly increased by aminoglutethimide and a reduction in its effects would be expected.

Clinical evidence, mechanism, importance and management

The clearance of digitoxin was increased by a mean of 109% in 5 patients who took aminoglutethimide (250 mg four times a day in 4 patients, and 125 mg twice daily in one patient).[1,2] The likely reason for this effect is that aminoglutethimide increases the metabolism of digitoxin by the liver.

This increase in clearance would be expected to be clinically important, but this does not appear to have been assessed. Check that patients do not become under-digitalised during concurrent use. No interaction would be expected with digoxin because it is largely excreted unchanged in the urine and therefore metabolism by the liver has little part to play in its clearance.

Digoxin + Aminoglycosides

Digoxin levels can be reduced by oral neomycin and increased by intramuscular gentamicin.

Clinical evidence

(a) Gentamicin

In a study in 12 patients with congestive heart failure taking digoxin 250 micrograms daily, the addition of gentamicin 80 mg intramuscularly twice daily for 7 days was found to increase serum digoxin levels by 129%. In a further 12 patients with congestive heart failure and diabetes, the same dose of gentamicin increased digoxin levels more than twofold, to 2 nanograms/mL. However, no symptoms of digoxin toxicity were seen. It should be noted that serum creatinine levels were higher in both groups than those in healthy controls even before receiving gentamicin, and were further increased after gentamicin.[1]

An earlier study similarly found that gentamicin prolonged the half-life of digoxin and increased its serum levels by 47% (from 1.9 to 2.8 nanograms/mL).[2]

(b) Neomycin

Neomycin 1 to 3 g orally was found to delay and reduce the absorption of a single 500-microgram dose of digoxin in healthy subjects.[3] The AUC of digoxin was reduced by 41 to 51%. Absorption was affected even when neomycin was given 3 to 6 hours before digoxin. In a steady-state study, neomycin 2 g given with digoxin 250 to 500 micrograms daily reduced the serum level of digoxin by 8 to 49% (mean 28%).[3]

Mechanism

Gentamicin impairs renal function, so decreasing digoxin clearance.[2] Higher digoxin levels and serum creatinine levels in diabetic compared with non-diabetic patients may be due to differences in renal function,[1] with concurrent gentamicin causing a further impairment of renal function and even higher digoxin levels. The reduction in digoxin toxicity is not fully understood but changes in ionic transport may be involved. The inhibition by gentamicin of Na^+/K^+ ATPase, which acts as a specific receptor for digoxin, may also be a factor.[1]

Neomycin can cause a general but reversible malabsorption syndrome, which affects the absorption of several drugs. The extent of this is probably offset in some patients, because the neomycin also reduces the breakdown of digoxin by the bacteria in the gut.[4]

Importance and management

Information is limited, but patients should be monitored for increased digoxin effects if gentamicin is given, especially those with diabetes or any other patient with renal impairment. Initially, checking pulse rate is probably adequate. There seems to be no information about other parenteral aminoglycosides.

Patients should be monitored for reduced digoxin effects if neomycin is given and suitable dose adjustments made if necessary. Separating administration of the two drugs does not prevent this interaction. Other aminoglycosides that can be given orally such as **kanamycin** and **paromomycin** might possibly interact similarly to neomycin, but this requires confirmation.

Digoxin + 5-Aminosalicylates

Digoxin levels can be reduced by sulfasalazine. The manufacturers of balsalazide suggest that it may interact similarly.

Clinical evidence, mechanism, importance and management

The observation that a patient taking **sulfasalazine** 8 g daily had low serum digoxin levels, prompted a crossover study in 10 healthy subjects. In this study a single 500-microgram dose of digoxin syrup was given alone, and the subjects had taken **sulfasalazine** 2 to 6 g daily for 6 days. Digoxin absorption was reduced, ranging from 0 to 50% depending on the dose of **sulfasalazine** used.[1] Serum digoxin levels were reduced accordingly.[1] The reasons for this effect are not understood. This seems to be the only report of this interaction. Concurrent use need not be avoided, but it would be prudent to check for under-digitalisation, initially by checking symptoms and pulse rate, and then taking digoxin levels if an interaction is suspected. In the initial patient, separating the doses did not appear to prevent this interaction.[1]

Although no interaction involving digoxin and **balsalazide** has been reported, based on the information with sulfasalazine, the manufacturer of **balsalazide** recommend that plasma levels of digoxin should be monitored in digitalised patients starting **balsalazide**.[2]

Digoxin + Aminosalicylic acid

Aminosalicylic acid causes a small reduction in digoxin levels in healthy subjects.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects, the bioavailability of a single 750-microgram dose of digoxin, using urinary excretion as a measure, was reduced by 20% by aminosalicylic acid 2 g four times daily for 2 weeks.[1] This seems to be just another aspect of the general malabsorption caused by aminosalicylic acid. The importance of this interaction in patients is not known, but it would be expected to be small.

1. Brown DD, Juhl RP, Warner SL. Decreased bioavailability of digoxin due to hypocholesterolemic interventions. *Circulation* (1978) 58, 164–72.

Digoxin and related drugs + Amiodarone

Digoxin levels can be approximately doubled by amiodarone. Some individuals may show even greater increases. The same interaction also appears to occur with digitoxin.

Clinical evidence

(a) Acetyldigoxin

Torsade de pointes developed in one patient 3 days after the amiodarone dose was increased to 600 mg daily, and beta-acetyldigoxin 100 micrograms and bisoprolol 1.25 mg daily were added, for persistent atrial fibrillation. Serum levels of digoxin and amiodarone were normal. Withdrawal of all medications and treatment with intravenous magnesium resolved the arrhythmias.[1]

(b) Digitoxin

Two elderly patients (aged 77 years and 78 years) taking digitoxin 100 micrograms daily were given loading doses of amiodarone followed by maintenance doses of 200 to 400 mg daily. Within 2 months in one case, and within 4 months in the other, they were hospitalised because of bradycardia, dyspnoea, nausea and malaise. One of them had total AV block (38 bpm). The serum digitoxin levels of both of them were found to be elevated (54 nanograms/mL and 45 nanograms/mL, respectively) well above the therapeutic range of 9 to 30 nanograms/mL. Serum amiodarone and desethylamiodarone levels were normal. Both patients recovered when the digitoxin was stopped.[2]

(c) Digoxin

The observation that patients taking digoxin developed digoxin toxicity when given amiodarone[3] prompted a study of this interaction. Seven patients receiving digoxin had a mean rise in their plasma digoxin levels of 69% (from 1.17 to 1.98 nanograms/mL), when they were given amiodarone 200 mg three times daily. Two other patients similarly treated also developed this interaction.[3]

Numerous studies in patients have confirmed this interaction with reported increases in serum digoxin levels of 75% to 158%.[4-8] The occasional patient may show three- to fourfold increases, whereas others may show little or no change.[6,9] Children seem particularly sensitive, with threefold, and even as much as ninefold rises reported.[10] Other reports confirm that the digoxin levels are markedly increased or roughly doubled, and toxicity can occur.[9,11-20] In contrast, one group of workers state that they observed no change in serum digoxin levels in 5 patients given amiodarone.[21,22] There is also a case report of a 31-year-old man with dilated cardiomyopathy who had his dose of digoxin reduced from 250 to 125 micrograms daily, four days before starting an oral loading-dose regimen of amiodarone 600 mg daily. Before starting amiodarone, his digoxin levels were 1.27 nanograms/mL, and these increased to 1.79 nanograms/mL 10 hours post-dose on day 2, and 2.93 nanograms/mL 8.4 hours post-dose on day 3. Digoxin was stopped and 15.5 hours later the level was 1.8 nanograms/mL. However, on day 4, 9.25 hours after amiodarone was given, the digoxin level had increased to 2.52 nanograms/mL. Twice daily monitoring of digoxin over the next 3 days found that levels rose and fell, with the highest levels occurring between 8 and 10 hours after amiodarone administration. The patient did not develop any signs of digoxin toxicity.[23]

There is also some evidence that, in the treatment of resistant atrial tachyarrhythmias, the risk of arrhythmias may be increased by the concurrent use of digoxin and amiodarone,[19,24] and another study found that concurrent use had an unfavourable effect on survival in patients with atrial fibrillation and sinus rhythm.[25]

A review of prescribing in an Australian hospital revealed 42 patients who had taken amiodarone with digoxin (both long-term (16), either drug recently started (21), or both drugs recently started (5)). Of 31 patients who had digoxin levels monitored, 12 required a change in dose of the digoxin, and in 3, digoxin was stopped.[26] It is unclear whether this was purely on the basis of serum levels, or whether patients experienced adverse effects.

Mechanism

Not fully understood. Amiodarone reduces both the renal and non-renal excretion of digoxin.[27] *In vitro* studies have found that amiodarone (and possibly desethylamiodarone) inhibits P-glycoprotein-mediated transcellular transport of digoxin. This suggests that any interaction may occur, at least in part, by inhibiting digoxin renal tubular secretion.[28,29]

Another possible mechanism that has been suggested involves changes in thyroid function. Serum digoxin levels have been found to be lower in hyperthyroidism and higher in hypothyroidism, when compared to those found when thyroid function is normal. It has been suggested that amiodarone-induced hypothyroidism may precipitate digoxin toxicity.[30]

Protein-binding displacement has also been suggested as a possible mechanism.[31,32] and the lack of digoxin toxicity in some studies where high plasma digoxin levels were reported is thought to be due to redistribution of digoxin from tissue-binding sites to plasma in the presence of amiodarone.[23,31,32]

Another study in healthy subjects found that amiodarone increased the plasma levels and the AUC of digoxin given orally but had no effect on digoxin given intravenously. It was suggested that amiodarone may increase the bioavailability of orally digoxin, by prolonging intestinal transit time which may enhance absorption.[4]

It is thought that amiodarone can also inhibit the metabolism of digitoxin by the liver, which would explain why its serum levels are increased.[2]

Importance and management

The pharmacokinetic interaction between **digoxin** and amiodarone is well documented, well established and of considerable clinical importance. It occurs in most patients. It is clearly evident after a few days and develops over the course of one to 4 weeks.[7] If no account is taken of this interaction the patient may develop digitalis toxicity. Reduce the digoxin dose by between one-third to one-half when amiodarone is added,[3-5,14] with further adjustment of the dosage after a week or two, and possibly a month or more,[14] depending on digoxin levels. Particular care is needed in children, who may have much larger rises in digoxin levels than adults. Amiodarone has a long half-life so that the effects of this interaction will persist for several weeks after its withdrawal.[18] A synergistic effect on heart rate and atrioventricular conduction is also possible, which may result in the development of new arrhythmias. Also note that some authors suggest that concurrent use may possibly worsen the prognosis in some patients.[24,25]

Far less is known about the interaction between **digitoxin** and amiodarone but the limited evidence available suggests that all of the precautions appropriate for digoxin should be used for digitoxin as well. Note that the interaction may possibly take months to develop.

Digoxin + Angiotensin II receptor antagonists

Candesartan, eprosartan, irbesartan, losartan, olmesartan, and valsartan do not appear to affect the pharmacokinetics of digoxin, but telmisartan may cause a rise in serum digoxin levels.

Clinical evidence

(a) Candesartan

In a study in 12 healthy subjects there was no pharmacokinetic interaction between candesartan 16 mg daily and digoxin, given as a loading dose of 750 micrograms then 250 micrograms daily.[1]

(b) Eprosartan

A study in 12 healthy men given a single 600-microgram dose of digoxin found that eprosartan 200 mg every 12 hours for 4 days had no significant effect on the pharmacokinetics of digoxin.[2]

(c) Irbesartan

A study in 10 healthy subjects taking digoxin for 2 weeks found no changes in the AUC or maximum serum levels of digoxin, when, during the second week, they also took irbesartan 150 mg daily.[3]

(d) Losartan

In 13 healthy subjects the pharmacokinetics of a single 500-microgram oral or intravenous dose of digoxin were not affected by losartan 50 mg daily for a week.[4]

(e) Olmesartan

In a study in 24 healthy subjects given digoxin 375 micrograms daily after a loading dose of 1.125 mg on day one and olmesartan medoxomil 20 mg daily for 7 days there were no clinically significant pharmacokinetic interactions.[5]

(f) Telmisartan

A study in 12 healthy subjects given a 500-microgram loading dose of digoxin followed by 250 micrograms daily found that the maximum serum concentration, the trough serum concentration and the AUC were increased by 50%, 13%, and 22%, respectively, when telmisartan 120 mg daily was given for 7 days.[6] No clinically relevant changes in vital signs or ECGs were noted.

(g) Valsartan

In a study in 12 healthy subjects there was no adverse interaction between a single 160-mg dose of valsartan and digoxin 250 micrograms.[7]

Mechanism

It has been suggested that telmisartan may have caused digoxin to be more rapidly absorbed.[6] An *in vitro* study found that candesartan and losartan do not appear to inhibit P-glycoprotein-mediated transcellular transport. Therefore interactions resulting in reduced digoxin renal excretion are unlikely.[8]

Importance and management

No special precautions seem to be necessary when digoxin is used with candesartan, eprosartan, irbesartan, losartan, or valsartan. However, note that information for eprosartan, losartan, and valsartan is from single-dose studies, although the authors of the eprosartan study consider that a clinically relevant interaction with multiple doses of digoxin is unlikely.[2] The small increase in trough serum digoxin level with telmisartan suggests that the dose of digoxin need not automatically be reduced when telmisartan is started, but consideration should be given to monitoring digoxin effects (e.g. monitor for bradycardia) and take digoxin levels if necessary.

Digoxin and related drugs + Antacids

Although some studies suggest that antacids can reduce the bioavailability of digoxin and digitoxin, there is other evidence suggesting that no clinically relevant interactions occur.

Clinical evidence

(a) Digoxin

1. Evidence of an interaction. A study in 10 healthy subjects given digoxin 750 micrograms with 60 mL of either 4% **aluminium hydroxide gel**, 8% **magnesium hydroxide gel** or **magnesium trisilicate** found that the cumulative 6-day urinary excretion of digoxin, expressed as a percentage of the original dose, was 40% for control; 31% for **aluminium hydroxide**; 27% for **magnesium hydroxide**; and 29% for **magnesium trisilicate**.[1] Other studies describe reductions in digoxin absorption of 11% with **aluminium hydroxide**, 15% with **bismuth carbonate** and **light magnesium carbonate**, and 99.5% with **magnesium trisilicate**.[2]
When digoxin was given with 30 mL of an **aluminium/magnesium hydroxide** antacid and mexiletine, the digoxin AUC was approximately halved. As mexiletine (see 'Digoxin + Mexiletine', p.1106) does not appear to interact with digoxin the interaction was attributed to the antacid.[3]

2. Evidence of no interaction. A study in 4 patients taking long-term digoxin 250 to 500 micrograms daily, found that the concurrent use of either 10 mL of **aluminium hydroxide mixture BP** or **magnesium trisilicate mixture BP**, three times daily, did not reduce the bioavailability of the digoxin and none of the patients had any reduction in the control of their symptoms.[4] Other bioavailability studies have not found a significant interaction between digoxin capsules and **aluminium/magnesium hydroxide**.[5]

(b) Other cardiac glycosides

In vitro studies with **digitoxin** suggest that it might possibly be absorbed by various antacids,[6] but **lanatoside C** probably does not interact.[7] A study in 10 patients with heart failure found that their steady-state serum **digitoxin** levels were slightly, but not significantly raised by 11% (from 13.6 to 15.1 nanograms/mL) while taking 20 mL of **aluminium/magnesium hydroxide** gel three or four times daily, separated from the **digitoxin** dosage by at least one to 2 hours.[8] Bioavailability studies have not found a significant interaction between **beta-acetyldigoxin** and **aluminium/magnesium hydroxide**.[9]

Mechanism

Not established. One suggestion is that the digoxin can become adsorbed onto the antacids and therefore unavailable for absorption.[1,6] This is probably also true for digitoxin. However, some results are not consistent with this idea.

Importance and management

The interactions between digoxin or digitoxin and antacids are only moderately well documented, and the evidence is inconsistent. Nevertheless, the findings of most studies is of a modest interaction, at worst, and no clearly clinically relevant interactions have been reported. Separating the doses by one to 2 hours to minimise admixture is effective with many other drugs that interact with antacids in this way, and seems to work with digitoxin. However, unless further information becomes available it seems unlikely that separating administration is necessary, although it may be worth bearing in mind if, on rare occasions, a patient experiences an interaction.

Digoxin and related drugs + Anticholinesterases; Centrally acting

There is no pharmacokinetic interaction between digoxin and tacrine or donepezil. The bradycardic effects of centrally-acting anticholinesterases and digoxin may possibly be additive.

Clinical evidence

(a) Donepezil

A single-dose study in 12 healthy subjects found that the pharmacokinetics of donepezil 5 mg and digoxin 250 micrograms were not affected by concurrent use and no clinically relevant changes in cardiac conduction parameters occurred.[1] In a study in patients with Alzheimer's disease who were given donepezil for 12 weeks, the risk of bradycardia was not significantly increased by the concurrent use of digoxin.[2]

(b) Galantamine

In a study in healthy subjects, galantamine 24 mg daily had no effect on the pharmacokinetics of digoxin 375 micrograms daily. However, one subject was hospitalised for second-and third-degree heart block and bradycardia.[3]

(c) Rivastigmine

The manufacturers of rivastigmine[4,5] say that the combination has no pharmacokinetic interaction, nor does it appear to interfere with cardiac conduction.[4]

(d) Tacrine

In one study in healthy subjects given a single 500-microgram dose of digoxin, the pharmacokinetics of the digoxin were unchanged by tacrine 20 mg every 6 hours.[6]

Mechanism

No pharmacokinetic interaction appears to occur. Both the centrally-acting anticholinesterases and digoxin (and indeed other **digitalis glycosides**) can slow the heart rate, and the bradycardia seen in the isolated case may have simply been due to the additive effects of both drugs.

Importance and management

No pharmacokinetic interaction appears to occur between any of the centrally-acting anticholinesterases and digoxin, and therefore no dose adjustments are needed on a pharmacokinetic basis. However, the digitalis glycosides are known to slow the heart rate, and in clinical studies, bradycardia was reported in 2 to 3% of patients taking galantamine compared with less than 1% of those given placebo.[3] Therefore the UK manufacturers of galantamine[7] caution about the possibility of a pharmacodynamic interaction that may result in bradycardia. This seems logical. Nevertheless, few cases appear to have been reported. The manufacturer of tacrine suggests that patients with conduction abnormalities or bradyarrhythmias, may be at particular risk of an interaction.[8] Therefore it may be prudent to be alert for bradycardia if any of these centrally-acting anticholinesterases are given with a digitalis glycoside.

Digoxin and related drugs + Antiepileptics; Miscellaneous

There is little evidence to suggest that carbamazepine interacts with digoxin, and topiramate causes only a small reduction in digoxin serum levels. Levetiracetam and tiagabine do not appear to interact with digoxin.

Clinical evidence, mechanism, importance and management

(a) Carbamazepine

In an early clinical study, bradycardia seen in 3 patients taking **digitalis** and carbamazepine was tentatively attributed to their concurrent use.[1]There appear to be no other reports to confirm or refute this.

(b) Levetiracetam

In a placebo-controlled study, 11 healthy subjects were given an initial loading dose of digoxin 500 micrograms followed by 250 micrograms daily with levetiracetam 1 g twice daily for one week. Levetiracetam did not significantly affect the pharmacokinetics or pharmacodynamics of digoxin, and the pharmacokinetics of levetiracetam were not significantly altered by digoxin.[2] No additional precautions seem necessary on concurrent use.

(c) Tiagabine

In a crossover study, 13 healthy subjects were given a loading dose of digoxin 500 micrograms twice daily for one day then 250 micrograms daily for 8 days, either alone or with tiagabine 4 mg three times daily for 9 days. It was found that the pharmacokinetics of digoxin were not significantly altered by tiagabine.[3]

(d) Topiramate

In a study in 12 healthy subjects, topiramate 100 mg twice daily for 9 days caused a small reduction in serum digoxin levels. The maximum serum levels and the AUC were reduced by 16% and 12%, respectively, and the oral digoxin clearance was increased by 13%.[4-6] The manufacturers suggest good monitoring of digoxin if topiramate is added or withdrawn,[5] but changes in the pharmacokinetics of digoxin of this magnitude seem unlikely to be clinically relevant in most patients.

Digoxin and related drugs + Antiepileptics; Phenytoin

Phenytoin reduces the levels of digoxin and digitoxin. Cases of bradycardia have been seen in digitalised patients given phenytoin. Phenytoin was formerly used for the treatment of digitalis-induced cardiac arrhythmias, but sudden cardiac arrest has been reported.

Clinical evidence

(a) Acetyldigoxin

A study in 6 healthy subjects given beta-acetyldigoxin 400 micrograms daily found that the half-life of digoxin was reduced by 30% (from 33.9 to 23.7 hours) and the AUC was reduced by 23% after they took phenytoin 200 mg twice daily for a week. Total digoxin clearance increased by 27%.[1]

(b) Digitoxin

The plasma digitoxin levels of a man were reduced on three occasions when he was given phenytoin. On the third occasion, while taking digitoxin 200 micrograms daily, the addition of phenytoin 900 mg daily caused a 60% fall in digitoxin levels (from 25 to 10 nanograms/mL) over 7 to 10 days.[2]

(c) Digoxin

A patient with Down's syndrome and mitral valve insufficiency taking digoxin 250 micrograms daily developed bradycardia of 34 bpm and complete heart block when his phenytoin dose was increased from 200 to 300 mg daily.[3]

(d) Unnamed digitalis glycosides

A patient with suspected digitalis-induced cardiac arrhythmias developed bradycardia, then became asystolic and died, following an intravenous injection of phenytoin.[4] The discussion of this case briefly mentions a further 6 fatalities in patients similarly treated.[4]

Mechanism

Phenytoin has a stabilising effect on the myocardial cells so that the toxic threshold of digoxin at which arrhythmias occur is raised. However, the bradycardic effects of the digitalis glycoside are not opposed and the lethal dose is unaltered, so that the cardiac arrest reported would appear to be the result of excessive bradycardia. It seems possible that the fall in plasma digitoxin levels may be due to a phenytoin-induced increase in the metabolism of the digitoxin by the liver.[5]

Importance and management

Phenytoin was formerly used for treating digitalis-induced arrhythmias, but this use now appears to be obsolete. Intravenous phenytoin should not be used in patients with a high degree of heart block or marked bradycardia because of the risk that cardiac arrest may occur. Information about the effects of phenytoin on digitalis glycoside levels seems to be confined to these single reports, but it may be prudent to check that patients who are taking digitoxin (and possibly digoxin), and are subsequently given phenytoin, do not become under-digitalised.

Digoxin and related drugs + Antineoplastics; Cytotoxic

Treatment with radiation and/or antineoplastic cytotoxics can damage the lining of the intestine so that digoxin (given as tablets) is much less readily absorbed. This appears to be resolved by giving the digoxin in liquid or liquid-in-capsule form, or by substituting digitoxin.

Clinical evidence

A study in 13 patients with various forms of neoplastic disease found that radiation therapy and/or various high-dose cytotoxic regimens (including **carmustine**, **cyclophosphamide**, **melphalan**, **cytarabine** and **methotrexate**) reduced the absorption of digoxin from tablets (*Lanoxin*) by almost 46%, but the reduction was not significant (15%) when the digoxin was given as capsules (*Lanoxicaps*).[1]

Other studies confirm that a 50% reduction in serum digoxin levels (using **beta-acetyldigoxin**) occurred in patients given **cyclophosphamide**, **vincristine**, **procarbazine** and prednisone (COPP); **cyclophosphamide**, **vincristine** and prednisone (COP); **cyclophosphamide**, **vincristine**, **cytarabine** and prednisone (COAP); and **doxorubicin**, **bleomycin** and prednisone (ABP). These effects disappeared about a week after cytotoxic therapy finished.[2] Radiation has a smaller effect.[3] **Digitoxin** absorption does not seem to be affected by antineoplastics.[4]

Mechanism

The reduced absorption is thought to result from damage to the intestinal epithelium caused by the antineoplastic cytotoxics.[5]

Importance and management

The interaction appears to be established. Patients taking digoxin and receiving treatment with these antineoplastic cytotoxics (cyclophosphamide and vincristine appear to be the most frequently implicated) should be monitored for signs of under-digitalisation. The problem appears to be overcome by replacing digoxin tablets with digoxin in liquid form or in solution inside a capsule. The effects of the interaction are short-lived so that a downward readjustment may be necessary about a week after treatment is withdrawn. An alternative is to use digitoxin, which does not appear to be affected.

Digoxin + Aprepitant

Aprepitant does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised, study in 11 healthy subjects found that the pharmacokinetics of digoxin 250 micrograms daily were not affected by aprepitant (125 mg given on day 7 and 80 mg given daily on days 8 to 11).

In vitro evidence indicates that aprepitant is a substrate and weak inhibitor of P-glycoprotein. However, at the doses used for the prevention of chemotherapy-induced nausea and vomiting, it appears unlikely to interact with P-glycoprotein substrates such as digoxin.[1] **Fosaprepitant** is a prodrug of aprepitant, and it would therefore be expected to behave in the same way.

Digoxin + Argatroban

No significant pharmacokinetic interaction occurs between digoxin and argatroban.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 12 healthy subjects found that the pharmacokinetics of steady-state digoxin 375 micrograms daily were not affected by an infusion of argatroban 2 micrograms/kg per minute for 120 hours. Steady-state argatroban levels were obtained within 3 hours and maintained throughout the infusion. Dose adjustments should not be necessary during concurrent use.[1]

Digoxin + Aspirin

Aspirin, in analgesic doses, may cause a moderate rise in digoxin levels.

Clinical evidence, mechanism, importance and management

Although aspirin can double the serum concentrations of digoxin in *dogs*, a study in 8 healthy subjects found no interaction, even when high doses of aspirin (975 mg three times daily) were given.[1] However, in another study in 9 healthy subjects given aspirin 1.5 g daily for 10 days, the serum levels of digoxin were increased by 31%.[2] A further study found a 49% increase in digoxin levels when it was given with aspirin 1.5 g daily.[3] Bearing in mind that both drugs have been in use for a very considerable number of years, the lack of reports in the literature describing problems suggests that no clinically important interaction normally occurs.

Digoxin + Azoles; Itraconazole

Itraconazole causes a marked increase in digoxin levels. Toxicity may occur unless the digoxin dose is suitably reduced. Theoretically, itraconazole might also oppose the positive inotropic effects of digoxin.

Clinical evidence

In a placebo-controlled, crossover study, 10 healthy subjects taking digoxin 250 micrograms daily were given itraconazole 200 mg daily for 10 days. The serum digoxin levels increased by about 80% (from 1 to 1.8 nanograms/mL). New steady-state digoxin levels were not fully achieved during the 10-day period with itraconazole, so greater rises might occur on longer-term use.[1] A study in 3 patients with congestive heart failure taking digoxin found that itraconazole decreased digoxin clearance by 50% and increased digoxin levels: ECG changes (premature ventricular contractions, AV block and ST depression) occurred.[2]

A 68-year-old man taking digoxin 250 micrograms twice daily and ibuprofen developed nausea and fatigue (interpreted later as digoxin toxicity) after starting to take itraconazole 400 mg daily for an infected elbow. The symptoms disappeared when both itraconazole and ibuprofen were stopped, but returned when itraconazole was restarted. After 7 days his heart rate had fallen, from 60 bpm to 40 bpm, and his digoxin level had doubled (from 1.6 to 3.2 nanograms/mL). He was later satisfactorily restabilised on a quarter of the digoxin dose while taking the same dose of itraconazole.[3] Several other patients developed digoxin toxicity (a sixfold increase in serum digoxin level in one case) within 3 to 13 days of starting to take itraconazole,[4-10] and after 4 weeks in one case.[11] A possible case of digoxin toxicity has also occurred with itraconazole pulse therapy.[12] Two cases of digoxin toxicity have been reported when itraconazole was given to renal transplant patients, but other factors may have contributed to the high levels of digoxin in these 2 patients.[13]

Mechanism

Itraconazole inhibits P-glycoprotein, which transports digoxin out of kidney tubule cells into the urine,[14-17] and therefore digoxin urinary clearance is reduced and serum levels are increased.[5,10]

Importance and management

An established and clinically important pharmacokinetic interaction. Monitor the effects of digoxin (e.g. bradycardia, nausea, vomiting) if itraconazole is started, anticipating the need to reduce the digoxin dose. Halving the dose was suggested in one study.[2] Two of the patients cited above were restabilised with a quarter of the digoxin dose[3,4] and another with about one-third of the original digoxin dose[5] while taking itraconazole. More recent findings suggest that itraconazole may possess significant negative inotropic properties, and the CSM in the UK suggests that it should be used with caution in patients at risk of heart failure.[18] This suggests that itraconazole might oppose the pharmacological effects of digoxin.

Digoxin + Azoles; Posaconazole

Posaconazole may increase digoxin levels.

Clinical evidence, mechanism, importance and management

The US manufacturers of posaconazole caution that increased plasma concentrations of digoxin have been found in patients taking digoxin and posaconazole, and advises monitoring during concurrent use.[1] Although the UK manufacturers of posaconazole do not mention a specific interaction between the two drugs, they do advise that digoxin levels should be monitored when initiating or discontinuing posaconazole, in the light of

the rise in digoxin levels seen when it has been given with other azoles.[2] See 'Digoxin + Azoles; Itraconazole', p.1085.

Digoxin + Azoles; Voriconazole

Voriconazole did not affect the steady-state pharmacokinetics of digoxin in a study in healthy patients. Another study briefly mentions increased digoxin levels in two patients receiving voriconazole.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in healthy subjects given a digoxin loading dose over 2 days, then digoxin 250 micrograms daily for 20 days, found that voriconazole 200 mg twice daily for the last 12 days had no significant effect on the steady-state pharmacokinetics of digoxin.[1] Unlike itraconazole (see 'Digoxin + Azoles; Itraconazole', p.1085), voriconazole appears not to alter the P-glycoprotein-mediated transport of digoxin.

However, a clinical study in severely ill patients with invasive mycosis briefly mentions that 2 patients receiving voriconazole developed high trough digoxin levels, which required the digoxin to be withdrawn. One patient was symptomatic with an arrhythmia and ECG changes.[2] These cases appear to be the only ones reported, nevertheless, they introduce a note of caution, and it may be prudent to consider an interaction as a possible cause, if bradycardia or other digoxin adverse effects develop in a patient given voriconazole.

Digoxin and related drugs + Barbiturates

Digitoxin levels can be halved by phenobarbital and its effects may be expected to be reduced accordingly. However, another study found that phenobarbital did not affect digitoxin, digoxin or acetyldigitoxin pharmacokinetics.

Clinical evidence

Phenobarbital 60 mg three times daily for 12 weeks, halved the steady-state plasma levels of **digitoxin** 100 micrograms daily.[1] In associated studies the half-life of **digitoxin** decreased from 7.8 days to 4.5 days during the use of **phenobarbital**.[1] In another study[2] the rate of conversion of **digitoxin** to digoxin increased from 4% to 27% in one patient who took **phenobarbital** 96 mg daily for 13 days.

In contrast, a study in groups of 10 healthy subjects given either **digitoxin** 400 micrograms, digoxin 1 mg or **acetyldigitoxin** 800 micrograms daily did not find any changes in the serum concentrations of any of these digitalis glycosides when **phenobarbital** 100 mg was given three times daily for 7 to 9 days.[3]

Mechanism

Phenobarbital and other barbiturates are well-known potent liver enzyme inducers which, it would seem, can increase the metabolism and conversion of digitoxin to digoxin.[1,2] The lack of interaction in one study may possibly have been because the barbiturate was taken for a relatively short time.[3]

Importance and management

An established interaction, although its clinical importance is somewhat uncertain because there seem to be few reports of the effects of using digitoxin with phenobarbital, or of problems in practice. Nevertheless, patients taking both drugs should be monitored for possible underdigitalisation and the dose of digitoxin increased if necessary. Other barbiturates would be expected to behave like phenobarbital. It seems unlikely that digoxin will be affected by the barbiturates because it is largely excreted unchanged in the urine.

Digoxin and related drugs + Benzodiazepines and related drugs

Digoxin toxicity occurred in two elderly patients, and rises in digoxin levels have been seen in others, when they were given alprazolam. A reduction in the urinary clearance of digoxin has been described during the use of diazepam. No pharmacokinetic interaction seems to occur with digoxin and eszopiclone, zaleplon, or zolpidem.

Clinical evidence

(a) Benzodiazepines

1. Alprazolam. An elderly woman taking digoxin, maprotiline, isosorbide dinitrate, furosemide and potassium chloride had signs of digoxin toxicity during the second week of taking alprazolam 1 mg daily. Her serum digoxin levels were later found to have risen almost 300% (from 1.6 to 4.3 nanograms/mL), and her apparent digoxin clearance had fallen by about 60%.[1] A later study in 12 patients confirmed that digoxin levels can be significantly raised by alprazolam, particularly in those over 65 years old. One elderly man developed clinical digoxin toxicity.[2] In contrast, a study in 8 healthy subjects found no changes in the clearance of digoxin after they took alprazolam 1.5 mg daily.[3]

2. Diazepam. The observation that 3 patients developed raised digoxin levels while also taking diazepam prompted a further study in 7 healthy subjects.[4] After taking diazepam 5 mg with a single 500-microgram dose of digoxin, and diazepam 5 mg every 12 hours thereafter, all of them had a substantial reduction in the urinary excretion of digoxin and 5 of them had a moderate increase in the digoxin half-life. No further details were given.[4]

3. Metaclazepam. No statistically significant interaction was seen in 9 patients taking **beta-acetyldigoxin** when they were given metaclazepam.[5]

(b) Non-benzodiazepine hypnotics

1. Eszopiclone. In a study in 12 healthy subjects, a 3-mg single dose of eszopiclone did not alter the pharmacokinetics of digoxin, given for 7 days.[6]

2. Zaleplon. Zaleplon 10 mg daily, given to 20 healthy subjects for 5 days, had no significant effects on the steady-state pharmacokinetics of digoxin 375 micrograms daily. There were no significant differences in QTc or PR intervals.[7]

3. Zolpidem. No significant pharmacokinetic interaction occurs between zolpidem and digoxin.[8]

Mechanism

Uncertain. It has been suggested that diazepam and some other benzodiazepines may possibly alter the extent of the protein binding of digoxin within the plasma, which may have some influence on the renal tubular excretion.[4] However, see comments on protein binding interactions in 'Drug distribution interactions', (p.3). The reason for the interaction between digoxin and alprazolam is not understood.

Importance and management

Information on the interaction between digoxin and alprazolam is limited, but it may be prudent to monitor the effects of digoxin (e.g. bradycardia) in any patient if alprazolam is added, and reduce the digoxin dose as necessary. What is known suggests that an adverse interaction is more likely in the elderly. Other benzodiazepines and digoxin have been used for a considerable time but there seem to be no other reports of adverse interactions. The newer non-benzodiazepine hypnotics, eszopiclone, zaleplon and zolpidem do not appear to affect the pharmacokinetics of digoxin.

Digoxin and related drugs + Beta-agonist bronchodilators

Oral salbutamol (albuterol) causes a small reduction in digoxin levels. Beta agonists can cause hypokalaemia, which could lead to the development of digitalis toxicity.

Clinical evidence, mechanism, importance and management

A study in 10 healthy subjects who had taken digoxin 500 micrograms daily for 10 days[1] found that, 3 hours after taking oral **salbutamol** (albuterol) 3 to 4 mg, their serum digoxin levels had fallen by 0.23 nanograms/mL and their serum potassium levels had fallen by 0.58 mmol/L. A follow-up study suggested that the digoxin distribution to skeletal muscle may have been increased.[2]

Note that all $beta_2$ agonists can cause a fall in serum potassium, which could possibly affect the response of patients to digoxin of other **digitalis glycosides**. The clinical importance of these changes is uncertain but concurrent use should be monitored. Consider monitoring potassium levels if the effects of digoxin seem excessive.

Digoxin and related drugs + Beta blockers

In general there appears to be no pharmacokinetic interaction between digoxin and beta blockers, although talinolol and carvedilol appear to increase the bioavailability of digoxin. Pharmacodynamic interactions, resulting in additive bradycardia, are possible. A few cases of excessive bradycardia have been reported when propranolol was used to control digitalis-induced arrhythmias.

Clinical evidence

(a) Carvedilol

A 12-year-old boy with dilated cardiomyopathy taking digoxin 250 micrograms in the morning and 125 micrograms in the evening was subsequently given carvedilol 70 micrograms/kg twice daily. Several days later he lost his appetite and started vomiting, and his digoxin serum level was found to have increased from 1.6 to 2.3 nanograms/mL up to 4.2 nanograms/mL. Digoxin was stopped and subsequently restarted at half the original dose.[1] In one study, 8 children aged 2 weeks to 8 years were given digoxin for ventricular failure secondary to congenital heart disease. When they were also given carvedilol 0.06 to 1.06 mg/kg daily the clearance of digoxin was approximately halved and 2 children developed digoxin toxicity.[1]

A single-dose study in healthy adults given carvedilol 25 mg found that the maximum plasma levels of a 500-microgram dose of digoxin were increased by 0.97 nanograms/mL (60%) and the AUC was increased by about 20%, but the clinical effects of these changes were considered likely to be small.[2] No significant pharmacokinetic interaction was found in other single-dose studies in adults given carvedilol and **digitoxin**,[3] or carvedilol and intravenous digoxin.[2]

In a multiple-dose study in adult patients with hypertension, carvedilol raised the maximum serum levels and AUC of digoxin 250 micrograms daily by 32% and 14%, respectively, after 2 weeks of concurrent use. Again, these changes were considered unlikely to be clinically significant.[4] In another study in 12 male and 12 female patients taking digoxin 62.5 to 250 micrograms daily for heart failure, the addition of carvedilol 6.25 mg twice daily for 7 days increased the maximum concentration and the AUC_{0-16} of digoxin by 37% and 56%, respectively, in the men, but no significant changes to the pharmacokinetics of digoxin were noted in the women.[5]

(b) Esmolol

A single dose of intravenous esmolol did not affect the pharmacokinetics of multiple-dose digoxin, except that a small increase was seen in the AUC_{0-6} of digoxin.[6]

(c) Propranolol

Two cases, where propranolol 10 mg orally was used to treat arrhythmias associated with digoxin toxicity, are reported.[7] The first patient (who had heart failure) became bradycardic, asystolic and then died, while the second patient became bradycardic (30 bpm) but recovered after being given atropine. A further fatality was reported when intravenous propranolol was used.[8]

(d) Sotalol

In a placebo-controlled study of the use of sotalol in digitalised patients with chronic atrial fibrillation, 2 of 24 sotalol recipients were withdrawn due to bradycardia compared with none of 10 given placebo. However, the combination was still considered valuable.[9] In this study, the pharmacokinetics of multiple-dose digoxin were unaffected by sotalol 80 to 320 mg daily.[9]

(e) Talinolol

In healthy subjects talinolol 100 mg orally substantially increased the bioavailability of a single 500-microgram dose of digoxin. The AUC_{0-72} and the maximum serum levels of digoxin were increased by 23% and 45%, respectively.[10] Conversely, intravenous talinolol 30 mg had no effect on digoxin pharmacokinetics.[10]

(f) Timolol

There is a report of marked bradycardia of 35 to 50 bpm in a 91-year-old patient taking **digoxin** and using timolol 0.25% eye drops.[11] Bradycardia persisted on withdrawal of **digoxin**, and improved only after discontinuation of the timolol as well.

(g) Miscellaneous

The pharmacokinetics of multiple-dose digoxin have been shown to be unaffected by **acebutolol**,[12] **atenolol**,[13] **bevantolol** 200 mg daily,[14] **bisoprolol** 10 mg daily,[15] or **nebivolol** 10 mg daily.[16]

In a prospective analysis of adverse drug reactions leading to hospital admission over a 4-year period, 83 patients were identified who had been admitted with bradycardia. Of these, 62 were taking **digitalis glycosides**, and 14 were also taking a beta blocker.[17] Increased bradycardia may occur on the concurrent use of a digitalis glycoside and a beta blockers, but reports of this becoming a problem seem rare (although see *Propranolol*, *Sotalol*, and *Timolol*, above).

In healthy subjects, the pharmacodynamics of digoxin were unaffected by **bevantolol**,[14] and **esmolol**,[6] with no significant changes in heart rate or blood pressure occurring. A study in healthy subjects found that **atenolol** did not affect digoxin-induced inotropism.[13]

Mechanism

In most cases where the situation has had an adverse outcome the interaction seems to be due to the additive effects of the digitalis glycoside and the beta blocker on the slowing of the heart.

It has been suggested that the pharmacokinetic interaction with talinolol is due to competition with digoxin for *intestinal* P-glycoprotein, although this needs confirmation.[10] It would seem possible that this mechanism also accounts for the interaction between digoxin and carvedilol, and an *in vitro* study found that carvedilol (but not atenolol or metoprolol) inhibits P-glycoprotein-mediated transcellular transport of digoxin,[18] which may mean *renal* tubular secretion of digoxin is inhibited. It is conceivable that P-glycoprotein inhibition by carvedilol enhances the intestinal absorption of digoxin and also decreases its renal excretion. This may explain why the interaction is possibly more significant in children, as they have a higher renal clearance rate of digoxin than adults.[1] Women have lower P-glycoprotein activity in the gut than men, which may account for the gender differences seen with the interaction of carvedilol and digoxin.[5]

Importance and management

On the whole, the concurrent use of a digitalis glycoside and a beta blocker appears to be beneficial, but the potential for additive bradycardia should be borne in mind. However, any adverse effect appears rare with digoxin, and there appear to be no reports of additive bradycardia with beta blockers and digitoxin, although this is perhaps due to a lack of reporting, as this is an expected effect of concurrent use. In addition, it may be prudent to monitor digoxin levels with talinolol, and also with carvedilol, particularly in children. It has been suggested that the dose of digoxin should be reduced by at least 25% in children given carvedilol, with further adjustments as required.[1]

Digoxin and related drugs + Beta-lactam antibacterials

No interaction normally occurs between digoxin and amoxicillin, cefazolin, cefuroxime, flucloxacillin, phenoxymethylpenicillin or ticarcillin with clavulanic acid. No pharmacokinetic interaction occurs between ampicillin and digitoxin. In contrast, one early study found that cefradine increased digoxin levels.

Clinical evidence

In 6 healthy subjects, **ampicillin** 500 mg four times daily for 5 days had no significant effect on the pharmacokinetics of a single 1-mg dose of **digitoxin**.[1] No significant changes in digoxin serum concentrations were found in 16 elderly patients given **amoxicillin** (2 patients also took erythromycin and one **flucloxacillin**), and 2 patients who took **flucloxacillin** and **phenoxymethylpenicillin**. However, a few patients complained of some 'toxic' symptoms (nausea, vomiting, anorexia, headache, fatigue, blurred vision, confusion), which the authors of the report attributed to the underlying illness or the antibacterials rather than to an interaction.[2] In a study in 15 healthy subjects, **ticarcillin/clavulanic acid** 1 g/200 mg intramuscularly every 12 hours for one week did not affect the pharmacokinetics of digoxin.[3] In another study, there was no reduction in the excretion of digoxin metabolites from the gut in 3 patients taking **cefazolin**, and a reduction occurred in only 1 of 10 patients taking penicillins (**ampicillin** 6, **oxacillin** 3, **penicillin** 1).[4]

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1051 patients who had been admitted to hospital with digoxin toxicity. Of these, 5 patients (0.5%) had been exposed to **cefuroxime** in the preceding 3 weeks when compared with 0.3% of controls, suggesting that digoxin toxicity was not significantly related to **cefuroxime** exposure.[5]

In an early study, **cefradine** prolonged the half-life of digoxin and increased its serum levels from 1.8 nanograms/mL to 2.6 nanograms/mL. This effect was considered to occur as a result of reduced renal clearance.[6]

Mechanism

Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be due to gut flora,[7] in particular *Eubacterium lentum*, which is anaerobic and Gram positive. It was suggested that inhibition of digoxin metabolism by gut flora was responsible for any interaction, but doubt has been thrown on this theory, (see *Mechanism* under 'Digoxin and related drugs + Macrolides', p.1103).

Importance and management

The silence of the literature on adverse interactions between digoxin and beta-lactam antibacterials, and the limited evidence for a plausible mechanism suggest that interactions are unlikely.

Digoxin and related drugs + Bufalin

Bufalin can interfere with the assay of cardiac glycosides.

Clinical evidence, mechanism, importance and management

Bufalin, a cardioactive substance of amphibian origin, and Chinese medicines such as Chan Su, Lu-Shen-Wan and Kyushin that contain bufalin, can interfere with some immunoassay methods of **digitoxin** and digoxin, particularly the fluorescence polarisation immunoassay.[1-4] The digoxin-like immunoreactivity of Kyushin was found to be equivalent to varying amounts of digoxin because of differences in the cross-reactivity of the antibody used in different immunoassays.[3] A chemiluminescent assay for **digitoxin**[2,5] and digoxin[2] did not cross-react with bufalin.

Bufalin and an extract of Chan Su displaced **digitoxin** from protein-binding sites *in vitro*.[5] Whether this would result in elevated free **digitoxin** levels and toxicity *in vivo* is not known. However, this is probably unlikely, since *in vivo* the free drug would be available for metabolism (see 'protein-binding interactions', (p.3)).

Another possibility, given the similarities between bufalin and digitalis glycosides, is that toxicity could result from additive cardiac effects. Cases of cardiotoxicity following the ingestion of bufalin (or toads) alone have been reported. In one case, the symptoms seen were very similar to those of digoxin toxicity, with nausea, vomiting, blurred vision, mental confusion, cardiopulmonary arrest and severe bradyarrhythmia. Assay for digoxin was positive (2.1 nanograms/mL) when measured by the fluorescence energy transfer immunoassay. The patient had ingested a bowl of toad soup (Bufo melanosticus Schneider) shortly before his symptoms developed.[6]

Digoxin and related drugs + Calcium-channel blockers; Dihydropyridines

The concurrent use of digoxin and calcium-channel blockers can be valuable. Felodipine, lacidipine, nicardipine and nisoldipine cause small increases in digoxin levels, while amlodipine, isradipine and nimodipine appear not to interact. The situation with nitrendipine is uncertain but it possibly causes only a small rise in digoxin levels.

Clinical evidence

(a) Amlodipine

In a study in 21 healthy subjects, amlodipine 5 mg daily had no significant effect on the serum levels or renal clearance of digoxin 375 micrograms daily.[1]

(b) Felodipine

Felodipine 10 mg twice daily for 8 weeks raised the serum digoxin levels in 11 patients by 15%, which was not clinically significant.[2] In another study, 14 patients were given felodipine 10 mg daily for a week. Plain tablets raised the steady-state digoxin serum levels by 11%, but extended-release tablets had no significant effect.[3] A third study found that, when taking felodipine, peak plasma digoxin levels were transiently raised by about 40% one hour after intake, but that digoxin AUCs were not significantly increased.[4]

(c) Isradipine

Isradipine (given as 2.5 mg every 12 hours for 2 days, 5 mg every 12 hours for 2 days and then 5 mg three times daily for 10 days) did not interact significantly with a single 1-mg intravenous dose of digoxin given to 24 healthy subjects.[5] A similar study by the same group found that the same dosage regimen of isradipine given with oral digoxin 250 micrograms twice daily caused a small increase in peak serum digoxin levels but no changes in its steady-state levels or AUC.[6]

(d) Lacidipine

In 12 healthy subjects, a single 4-mg oral dose of lacidipine did not affect the AUC or minimum serum levels of digoxin 250 micrograms daily for 7 days, but the maximum serum levels of digoxin were increased by 34%. These changes were not considered to be clinically significant.[7]

(e) Lercanidipine

The maximum serum levels of digoxin rose by 33% in healthy subjects also given lercanidipine. However, there was no evidence of a pharmacokinetic interaction in patients given **metildigoxin** with lercanidipine.[8]

(f) Nicardipine

In 10 patients given nicardipine 20 mg three times daily for 14 days the plasma levels of digoxin 130 to 250 micrograms daily were increased by 15%, but this was not statistically significant.[9] Another 20 patients with congestive heart failure also had no significant changes in steady-state serum digoxin levels while taking nicardipine 30 mg three times daily for 5 days.[10] Yet another study in 9 patients confirmed the absence of an interaction.[11]

(g) Nifedipine

For the interaction between digoxin or digitoxin and nifedipine, see 'Digoxin and related drugs + Calcium-channel blockers; Nifedipine', p.1090.

(h) Nimodipine

In a study in 12 healthy subjects, nimodipine 30 mg twice daily caused no change in the pharmacokinetics or haemodynamic effects of **beta-acetyldigoxin**.[12]

(i) Nisoldipine

In 10 patients with heart failure nisoldipine 20 mg daily increased the plasma trough digoxin levels by about 15%.[13,14] In 8 healthy subjects, nisoldipine 10 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of digoxin.[12]

(j) Nitrendipine

A study in 8 healthy subjects who had been taking digoxin 250 micrograms twice daily for 2 weeks, found that nitrendipine 10 mg daily caused a slight but insignificant rise in plasma digoxin levels. Nitrendipine 20 mg daily increased the AUC of digoxin by 15%, its maximum plasma levels rose from 1.34 nanograms/mL to 2.1 nanograms/mL, and its clearance fell by 13%. One subject dropped out of the study because of dizziness, nausea and vomiting, palpitations, insomnia and nervousness.[15,16]

Another study found that plasma digoxin levels were approximately doubled when nitrendipine was given,[17] but other studies in healthy subjects and patients found that nitrendipine 20 mg twice daily caused no changes in the pharmacokinetics or haemodynamic effects of digoxin,[12,18] or **beta-acetyldigoxin**.[19]

Mechanism

Where an interaction occurs it is probably due to changes in the renal excretion of the digoxin. An *in vitro* study found that several calcium-channel blockers including nicardipine, and to a lesser extent nisoldipine (as well as barnidipine, manidipine, nilvadipine, and verapamil) inhibited the P-glycoprotein-mediated transcellular transport of digoxin. This suggests that any interaction may occur, at least in part, by affecting digoxin renal tubular excretion. Nitrendipine only weakly inhibited the transcellular transport of digoxin.[20]

Importance and management

The extent of the information varies from drug to drug, but the concurrent use of digoxin and calcium-channel blockers can be therapeutically valuable. Monitor the effects of digoxin (e.g. bradycardia) in patients given digoxin and lercanidipine, and consider measuring levels if the effects of digoxin seem excessive. Reduce the digoxin dose as necessary. The other calcium-channel blockers listed here either cause only minimal increases in digoxin levels, which are unlikely to be clinically important in most patients, or do not interact at all. The situation with nitrendipine needs clarification.

Digoxin and related drugs + Calcium-channel blockers; Diltiazem

Digoxin levels are reported to be unchanged by diltiazem in a number of studies but others describe increases ranging from 20 to 85%. Serum digitoxin levels have also been reported to rise in some patients, but only by about 20%. There is a risk of additive bradycardia when digitalis glycosides are given with diltiazem.

Clinical evidence

(a) Digitoxin

Five out of 10 patients taking digitoxin had a 6 to 31% (mean 21%) rise in plasma digitoxin levels while taking diltiazem 180 mg daily for 4 to 6 weeks.[1]

(b) Digoxin

Diltiazem 30 or 60 mg four times daily had no significant effect on the serum levels of digoxin 250 micrograms daily in 9 patients with cardiac diseases.[2] Two similar studies in 12 patients[3] and 8 healthy subjects,[4] taking digoxin with diltiazem 120 to 360 mg daily confirmed the absence of an interaction. Two further studies in healthy subjects,[5,6] found that diltiazem 120 mg daily did not affect the pharmacokinetics of a single 1-mg intravenous dose of digoxin. In contrast, a study in 17 Japanese patients (some with rheumatic valvular disease) taking either digoxin or **metildigoxin** found that diltiazem 60 mg three times daily for 2 weeks increased their serum digoxin levels measured at 24 hours by 36% and 51%, respectively.[7] Another study in 8 patients with chronic heart failure secondary to ischaemic disease, taking digoxin 250 micrograms daily, found that diltiazem 60 mg three times daily increased the digoxin AUC and mean steady-state serum levels by about 50%, its peak serum level by 37% and elimination half-life by 29%, but there was no evidence of any haemodynamic changes.[8]

Other studies in Western patients[9,10] and healthy subjects[11-14] have found rises of 20 to 85% in plasma digoxin levels during diltiazem use. In one case report a 143% increase was seen.[15] The authors of two of these studies noted that the effect was highly individual with some subjects having no increase and some a large increase.[10,12] There is also a case report of raised serum digoxin levels and toxicity in a man taking digoxin when given diltiazem with or without nifedipine.[16]

In addition to these pharmacokinetic changes, a pharmacodynamic interaction has also been seen. A study in patients without sinoatrial (SA) or atrioventricular (AV) node dysfunction, found that intravenous diltiazem alone depressed SA and AV node function and slightly shortened atrial refractoriness. These effects were amplified by subsequent administration of intravenous digoxin 0.018 mg/kg. However, concurrent use did not cause any notable adverse effects in this group of patients.[17] A study identified 62 patients who had been admitted to hospital with bradycardia over a 4-year period, 18 of whom had been taking digoxin and a non-dihydropyridine calcium-channel blocker, and 12 patients who had been taking digoxin, a beta blocker and a non-dihydropyridine calcium-channel blocker. However, the specific calcium-channel blockers were not named.[18]

Mechanism

Not understood. In those individuals showing a pharmacokinetic interaction, falls in total digoxin clearance of about 25% have been described.[8,10,11,19,20] Although several calcium-channel blockers may inhibit the P-glycoprotein-mediated renal clearance of digoxin, the results of an *in vitro* study[21] suggest that this may not occur with diltiazem. A synergistic effect on heart rate and atrioventricular conduction is also possible.

Importance and management

A thoroughly investigated and well documented pharmacokinetic interaction but there is no clear explanation for the inconsistent results. All patients taking digoxin given diltiazem should be well monitored for signs of over-digitalisation (e.g. bradycardia) with digoxin levels measured as necessary. Dose reductions may be necessary. Those most at risk are patients with digoxin levels near the top end of the range. Similar precautions would appear to be necessary with digitoxin, although the documentation of this interaction is very limited and the expected rise in levels only small.

The potential for additive bradycardia and heart block should be borne in mind when using diltiazem with any digitalis glycoside.

Digoxin and related drugs + Calcium-channel blockers; Nifedipine

Serum digoxin levels are normally unchanged or increased only to a small extent by nifedipine. However, one unexplained and conflicting study indicated that a 45% rise could occur. Digitoxin appears not to interact.

Clinical evidence

(a) Digitoxin

A study in 18 subjects showed that nifedipine 40 to 60 mg daily had no significant effect on their steady-state plasma digitoxin levels over a 6-week period.[1] This study has also been published elsewhere.[2]

(b) Digoxin

1. Serum digoxin levels unchanged. Studies in 25 patients[3-5] and 28 healthy subjects[6-8] found that serum digoxin levels were not significantly altered by nifedipine 30 to 60 mg daily. Similarly no significant changes in the pharmacokinetics of a single intravenous dose of digoxin were found in 6 patients[9] or 16 healthy subjects[10,11] taking nifedipine 40 to 90 mg daily. Furthermore, no changes in the pharmacokinetics of nifedipine were seen.[10]

2. Serum digoxin levels increased. in 12 healthy subjects nifedipine 30 mg increased the plasma levels of digoxin 375 micrograms daily by 45% (from 0.505 to 0.734 nanograms/mL) over 14 days.[12] In a study in 7 healthy subjects, nifedipine 15 to 60 mg daily increased the levels of digoxin 250 micrograms twice daily by a modest 15%.[13] These studies have been reported elsewhere.[14,15]

Nifedipine 20 mg twice daily increased the steady-state serum digoxin levels of 9 patients by 15% (from 0.87 to 1.04 nanograms/mL).[16] A 61% increase in serum digoxin levels was found in a study involving nifedipine in daily doses of 30 mg.[17]

In a study in 10 patients with congestive heart failure given **metildigoxin**

200 micrograms daily for 9 days, the concurrent use of nifedipine 60 mg for a further 7 days, increased levels of digoxin by about 25%. In another 10 patients given both nifedipine 60 mg and verapamil 320 mg daily for 7 days, digoxin levels were increased by about 66%.[18]

Mechanism

Not understood. Changes and lack of changes in both the renal and non-renal excretion of digoxin have been reported. A retrospective analysis of pharmacokinetic data suggests that clearance of digoxin may be reduced by 10% in patients also taking nifedipine.[19] Although several calcium-channel blockers may inhibit the P-glycoprotein mediated renal clearance of digoxin, the results of an *in vitro* study[20] suggest that this may not occur with nifedipine.

Importance and management

The pharmacokinetic interaction between digoxin and nifedipine is well documented but the findings are inconsistent. The weight of evidence appears to be that serum digoxin levels are normally unchanged or only modestly increased by nifedipine. Concurrent use appears normally to be safe and effective.[21] One report suggests that nifedipine has some attenuating effect on the digoxin-induced inotropism.[22] Another points out that under some circumstances (renal impairment or pre-existing digoxin overdosing) some risk of an undesirable interaction still exists.[13] If undesirable bradycardia occurs in a patient taking digoxin and nifedipine consider measuring digoxin levels, and adjust the dose accordingly. Nifedipine does not appear to interact with digitoxin to a clinically significantly extent.

Digoxin and related drugs + Calcium-channel blockers; Verapamil

Serum digoxin levels are increased by about 40% by verapamil 160 mg daily, and by about 70% by verapamil 240 mg daily. Digoxin toxicity may develop, and deaths have occurred. Verapamil causes a rise of about 35% in digitoxin levels. There is a risk of additive bradycardia and conduction disturbances when cardiac glycosides are given with verapamil. Gallopamil, a drug chemically related to verapamil, does not appear to affect digoxin levels to a clinically relevant extent.

Clinical evidence

(a) Digitoxin

Eight out of 10 patients had a mean 35% rise (range 14 to 97%) in plasma digitoxin levels over a 4 to 6 week period while taking verapamil 240 mg daily, in three divided doses. In 2 patients (and 3 other healthy subjects given a single dose of digitoxin) the pharmacokinetics of digitoxin were not affected by verapamil.[1,2]

(b) Digoxin

After 2 weeks of treatment with verapamil 240 mg daily, in three divided doses, the mean serum digoxin levels of 49 patients with chronic atrial fibrillation had risen by 72%. The rise was seen in most patients, and it occurred largely within the first 7 days. A rise of about 40% has been seen with verapamil 160 mg daily.[3,4]

Reports in a total of 21 healthy subjects,[5,6] and 54 patients[7-9] describe rises in serum digoxin levels of 22 to 147% when verapamil 240 to 360 mg daily was added to digoxin. Similar rises are reported elsewhere.[4,10-12]

A rise in digoxin levels of about 50% was seen in chronic haemodialysis patients given verapamil 120 to 240 mg daily.[13] Nine healthy subjects had a 53% rise in their digoxin levels while taking verapamil 240 mg three times daily for 2 weeks.[5] Toxicity[14] and a fatality[15] occurred in patients whose digoxin levels became markedly increased by verapamil. Both asystole and sinus arrest have been described.[16,17] A single-dose study indicated that cirrhosis magnifies the extent of this interaction.[18]

In a study in 10 patients with congestive heart failure given **metildigoxin** 200 micrograms daily for 9 days, the concurrent use of verapamil 320 mg for a further 7 days, increased levels of digoxin by about 35%. In another 10 patients given both verapamil 320 mg and nifedipine 60 mg daily for 7 days, digoxin levels were increased by about 66%.[19]

A study identified 62 patients who had been admitted to hospital with bradycardia over a 4-year period, 18 of whom had been taking a combination of digoxin and a non-dihydropyridine calcium-channel blocker, and 12 patients who had been taking digoxin, a beta blocker and a non-dihydropyridine calcium-channel blocker. However, the specific calcium-channel blockers were not named.[20]

In 12 healthy subjects, **gallopamil** (a calcium-channel blocker that is chemically related to verapamil), in a dose of 50 mg three times daily for 2 weeks, raised the serum levels of digoxin 375 micrograms daily by 16% (from 0.58 to 0.67 nanograms/mL).[21] This change would not be expected to be clinically relevant.

Mechanism

The rise in serum digoxin levels with verapamil is due to reductions in renal and especially extra-renal (biliary) clearance; a diminution in the volume of distribution also takes place.[4,9,10,22] It has been suggested that P-glycoprotein may be involved.[23] An *in vitro* study found that verapamil can inhibit the P-glycoprotein-mediated transcellular transport of digoxin,[24] which suggests that any interaction may occur, at least in part, by inhibiting the renal tubular excretion of digoxin. Impaired extra-renal excretion is suggested as the reason for the rise in serum digitoxin levels.[1]

The increased plasma levels of digoxin caused by verapamil are reported to increase both inotropism[25] and toxic effects.[26] Verapamil may enhance the digoxin-induced elevation of intracellular sodium, which may increase the risk of arrhythmias.[26,27] A synergistic effect on heart rate and atrioventricular conduction is also possible.

Importance and management

The pharmacokinetic interaction between digoxin and verapamil is well documented, well established and occurs in most patients.[10,28] Serum digoxin levels should be well monitored and downward dose adjustments made to avoid digoxin toxicity (deaths have occurred[15]). An initial 30 to 50% dose reduction has been recommended.[29-31] The interaction develops within 2 to 7 days, approaching or reaching a maximum within 14 days or so.[3,8] The magnitude of the rise in serum digoxin is dose-dependent[32] with a significant increase if the verapamil dose is increased from 160 to 240 mg daily,[3] but with no further significant increase if the dose is raised any higher.[6] The mean rise with verapamil 160 mg daily is about 40%, and

with 240 mg or more is about 60 to 80%, but the response is variable. Some patients may have rises of up to 150% while others have only a modest increase. One study found that although the rise in serum digoxin levels was 60% within a week, this had lessened to about 30% five weeks later.[10] Large interpatient variability in the reduction in digoxin clearance has been reported.[31] Initial individual digoxin dose titration, regular monitoring and dose adjustments would seem to be necessary. Note that the potential for additive bradycardia and heart block should also be borne in mind.

The documentation of the digitoxin and verapamil interaction is limited, but the interaction appears to be established. Downward dose adjustments may be necessary, particularly in some patients.[1]

Digoxin + Chloroquine or Hydroxychloroquine

The levels of digoxin were found to be increased by over 70% in two elderly patients when they were given hydroxychloroquine. A similar increase has been seen with chloroquine in *dogs*.

Clinical evidence, mechanism, importance and management

Two women aged 65 years and 68 years who had been taking digoxin 250 micrograms daily for 2 to 3 years for arrhythmias were given hydroxychloroquine 250 mg twice daily for rheumatoid arthritis. When the hydroxychloroquine was withdrawn the plasma digoxin levels of both women fell by 70 to 75% (from 2.3 to 0.5 nanograms/mL and from 2.4 to 0.7 nanograms/mL, respectively). Neither patient had any evidence of toxicity during concurrent use, and one of them claimed that the regularity of her heart rhythm had been improved.[1] The reason for this apparent interaction is not understood and its general significance is uncertain.

No interaction between digoxin and chloroquine has been described clinically, but increases in peak serum digoxin levels of about 77% have been seen in *dogs*.[2]

Digoxin + Cibenzoline (Cifenline)

Cibenzoline does not appear to affect plasma digoxin levels.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects taking digoxin 250 to 375 micrograms daily found that cibenzoline 160 mg twice daily for 7 days had no effect on the pharmacokinetics of digoxin.[1] A study in 22 patients taking digoxin 250 micrograms daily found that the addition of cibenzoline 65 or 130 mg twice daily for 4 weeks did not affect the plasma levels of digoxin. Concurrent use was well-tolerated in 16 of 21 patients available for evaluation and no significant changes in vital signs occurred during the study period.[2] An *in vitro* study found that cibenzoline only slightly inhibited the P-glycoprotein-mediated transcellular transport of digoxin and therefore inhibition of the renal tubular secretion of digoxin is unlikely.[3] There appears to be no pharmacokinetic reason to adjust the dose of digoxin in patients given cibenzoline.

Digoxin + Ciclosporin

Ciclosporin causes a marked rise in digoxin levels in some patients.

Clinical evidence

Digoxin toxicity developed in 4 patients when they were given ciclosporin before a heart transplant. In the two cases described in detail, ciclosporin 10 mg/kg daily was given to patients taking digoxin 375 micrograms daily. Fourfold rises in digoxin levels, from 1.2 nanograms/mL to 4.5 nanograms/mL and from 2 nanograms/mL to 8.3 nanograms/mL, were seen within 2 to 3 days. This was accompanied by rises in serum creatinine levels from 110 micromol/L to 120 micromol/L and from 84 micromol/L to 181 micromol/L, respectively, which were considered insufficient to explain the rise in digoxin levels. As a consequence of these findings, the same authors conducted a study in 4 patients given ciclosporin and digoxin. Two patients developed acute renal failure. In the other 2 patients, the volume of distribution of digoxin was decreased by 69% and 72%, while the clearance was reduced by 47% and 58%, respectively.[1] In a further 7 patients, digoxin pharmacokinetics were assessed before heart transplant, then after transplantation during the use of maintenance ciclosporin.[2] The total body clearance of digoxin remained unchanged, which appeared to be at odds with the earlier results.[1] It was suggested that haemodynamic improvements brought about by a successful heart transplant may have counterbalanced any inhibitory effect ciclosporin had on renal clearance.[2]

Mechanism

Not fully understood. The authors of the studies concluded that ciclosporin has no specific inhibitory effect on the renal elimination of digoxin, but that it causes a non-specific reduction in renal function after acute use, which reduces digoxin elimination.[2] Conversely, another study in *animals* suggested that ciclosporin can reduce the secretion of digoxin by the kidney tubular cells by inhibiting P-glycoprotein.[3]

Importance and management

Information seems limited to the studies cited. Nevertheless, the effects of concurrent use should be monitored very closely, and the digoxin dose should be adjusted as necessary.

Digoxin + Colesevelam

The absorption of a single dose of digoxin is not affected by colesevelam.

Clinical evidence, mechanism, importance and management

A single-dose study in which 26 healthy subjects were given digoxin 250 micrograms with or without colesevelam 4.5 g, followed by a standard meal, found that colesevelam did not significantly affect the absorption of digoxin.[1]

1. Donovan JM, Stypinski D, Stiles MR, Olson TA, Burke SK. Drug interactions with colesevelam hydrochloride, a novel, potent lipid-lowering agent. *Cardiovasc Drugs Ther* (2000) 14, 681–90.

Digoxin and related drugs + Colestipol

Colestipol appears not to interfere with the absorption of either digoxin or digitoxin if it is given at least 1.5 hours after the digitalis glycoside.

Clinical evidence

(a) Digitoxin

Four patients with digitoxin toxicity were given colestipol 10 g at once and 5 g every 6 to 8 hours thereafter to reduce their digitoxin serum levels. The average digitoxin half-life fell to 2.75 days compared with an untreated control patient in whom the digitoxin half-life was 9.3 days.

A comparative study in 11 patients with plasma digitoxin levels greater than 40 nanograms/mL found that when the digitoxin was stopped and colestipol 5 g four times daily was given before meals, the digitoxin half-life (6.3 days) was unaffected, when compared with 11 other patients not given colestipol (6.8 days).[1] For another study in which the levels of digitoxin were not affected by colestipol, see under *Digoxin*, below.

(b) Digoxin

In a patient with digoxin toxicity who was given colestipol in an attempt to reduce digoxin levels, the digoxin half-life was 16 hours compared with 1.8 to 2 days in two other control patients.[2] A digoxin elimination half-life of 55 hours was reported in a second patient with digoxin toxicity who was given colestipol, and this compared with a predicted time of at least 85 hours for digoxin alone.[3] Other reports also found colestipol reduced the half-life of digoxin in patients with digoxin toxicity.[4,5] In contrast, a study in healthy subjects found that colestipol 10 g given immediately after a single 250-microgram dose of digoxin did not reduce the absorption of digoxin.[6] Furthermore, 10 patients receiving long-term treatment with either digoxin 125 to 250 micrograms daily or **digitoxin** 100 to 200 micrograms daily were given colestipol 15 g daily or a placebo, taken 1.5 hour after the digitalis. Their serum digitalis levels were not significantly altered over a 1-year period by the colestipol.[7]

Mechanism

Colestipol is an ion-exchange resin, which can bind to digoxin and digitoxin.[2] In cases of toxicity, colestipol may possibly reduce serum digitalis levels because under these circumstances the excretion of digitalis in the bile increases and more becomes available for binding in the gut.[7]

Importance and management

This interaction is not well established. Giving either digoxin or digitoxin 1.5 hours before colestipol appears to avoid any possible interaction in the gut.[7] Note that it is usually recommended that other drugs are given one hour before or 4 hours after colestipol.

Digoxin and related drugs + Colestyramine

The levels of both digoxin and digitoxin can be reduced by colestyramine.

Clinical evidence

A study in 12 healthy subjects given digoxin 750 micrograms found that the cumulative 6-day recovery of digoxin from the urine was reduced by almost 20% (from 40.5 to 33.1%) when colestyramine 4 g was given.[1] Two patients with congestive heart failure and toxic serum levels of digoxin of 3 nanograms/mL and 4 nanograms/mL were given colestyramine 4 g every 4 hours for 4 doses. The levels of digoxin fell to therapeutic levels within 13 to 24 hours.[2]

Other reports describe a fall in serum digoxin levels during the concurrent use of colestyramine[3-6] and an increase in the loss of digoxin and its metabolites in the faeces during long-term use.[7] Another study found that giving digoxin as a solution in a capsule reduced the effects of this interaction.[5]

Some studies have found that colestyramine reduces the half-life of **digitoxin** by 35 to 40%.[8,9] There are reports of colestyramine successfully being used in patients with **digitoxin** toxicity to increase its elimination.[10-12] However, not all studies and cases have found pronounced interactions with digoxin and **digitoxin**. In one case report of **digitoxin** overdose, the effects of colestyramine on digitoxin appeared to be delayed for 48 hours and the reduction in half-life of digitoxin from 7.4 days to 6 days was less pronounced than noted in other studies.[13] Furthermore, a study in 10 patients receiving long-term treatment with either digoxin 125 to 250 micrograms daily or **digitoxin** 100 to 200 micrograms daily were given colestyramine 12 g daily or a placebo taken 1.5 hour after the digitalis. Their plasma digitalis levels were not significantly altered by the colestyramine over a 1-year period.[14] In another study, the half-life of **digitoxin** is reported to have remained unchanged when colestyramine was given,[15] and one study suggested that **metildigoxin** may be minimally affected by colestyramine.[16]

Mechanism

Not totally understood. Colestyramine appears to bind with digitoxin in the gut, thereby reducing its bioavailability and interfering with enterohepatic recirculation so that its half-life is shortened. Digoxin may interact similarly.[2]

Importance and management

The overall picture is far from clear. Some interaction between colestyramine and digoxin or digitoxin seems possible but the extent to which it impairs the treatment of patients receiving these drugs is uncertain. Be alert for any evidence of under-digitalisation if digoxin or, more particularly, digitoxin is given with colestyramine. The studies suggest that coles-

tyramine should not be given less than 1.5 to 2 hours after the digitalis glycoside to minimise the possibility of an interaction.[14] Note that the standard recommendation is to give other drugs one hour before or 4 to 6 hours after colestyramine.

Digoxin + Danaparoid

No clinically significant interaction appears to occur between digoxin and danaparoid.

Clinical evidence, mechanism, importance and management

In a study, 6 healthy subjects were given digoxin 250 micrograms daily for 8 days, with a single 3250 anti-Xa-unit-bolus dose of danaparoid during day 7. The AUC of digoxin was slightly decreased by danaparoid, although this did not appear to be clinically significant. Digoxin did not alter the effects of danaparoid on clotting tests (including aPTT).[1]

Digoxin and related drugs + Danshen (*Salvia miltiorrhiza*)

Danshen can falsify the results of serum immunoassay methods for digoxin.

Clinical evidence, mechanism, importance and management

Danshen can falsify some laboratory measurements of digoxin because it contains digoxin-like immunoreactive components. A study found that a fluorescent polarization immunoassay method (Abbott Laboratories) for digoxin gave falsely high readings in the presence of danshen, whereas a microparticle enzyme immunoassay (Abbott Laboratories) gave falsely low readings. These, or similar findings have been reported elsewhere.[1] These false readings could be eliminated by monitoring the free (i.e. unbound) digoxin concentrations[2] or by choosing assay systems that are unaffected by the presence of danshen (said to be the Roche and Beckman systems[3] or an enzyme linked chemiluminescent immunosorbent digoxin assay by Bayer HealthCare[1,4]). Similarly, when assaying serum from patients taking digoxin, to which a variety of danshen extracts were added, the use of a fluorescent polarization immunoassay gave variable results, whereas the results were more consistent with a chemiluminescent assay, the EMIT 2000 digoxin assay and the Randox digoxin assay.[5] It would therefore seem prudent, wherever possible, to use a chemiluminescent assay for digoxin in patients also taking danshen.

Digoxin + Darifenacin or Solifenacin

Darifenacin increased digoxin exposure by a modest 16% in one study. Solifenacin does not appear to alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

(a) Darifenacin

The manufacturers note that the concurrent use of digoxin 250 micrograms and darifenacin 30 mg daily (twice the recommended dose) increased steady-state digoxin levels and AUC by a modest 20% and 16%, respectively.[1,2] The increase in digoxin exposure could be due to competition between digoxin and darifenacin for P-glycoprotein.[2] This small increase would generally not be expected to be clinically relevant but the manufacturers advise monitoring digoxin[1,2] with the UK manufacturer specifying monitoring when starting or ending darifenacin treatment or when changing darifenacin dose.[2]

(b) Solifenacin

In a crossover study in 24 healthy subjects, solifenacin 10 mg daily for 10 days had no effect on the pharmacokinetics of digoxin 125 micrograms daily.[3]

This study suggests that no pharmacokinetic interaction occurs, and that no digoxin dose adjustment would be expected to be needed on concurrent use.

Digoxin + Dexmedetomidine

An isolated report describes bradycardia when an infant receiving digoxin was given dexmedetomidine.

Clinical evidence, mechanism, importance and management

A 5-week-old infant with an atrioventricular septal defect, taking digoxin 10 micrograms twice daily and furosemide for mild congestive heart failure, developed respiratory failure requiring intubation and mechanical ventilation. She was given dexmedetomidine for sedation and received a loading dose of 0.5 micrograms/kg over 15 minutes, followed by an infusion of 0.44 micrograms/kg per hour. During the loading dose period her heart rate decreased from 133 bpm to 116 bpm. Throughout the next 13 hours the rate continued to decrease to about 90 bpm, with episodes of sinus bradycardia (heart rate around 50 bpm). Within one hour of discontinuing dexmedetomidine, the heart rate increased to its baseline value and no further episodes of bradycardia were observed. The reasons for the interaction are not known, but the authors of the report suggested that caution is warranted if dexmedetomidine is used for sedation in patients receiving digoxin.[1]

1. Berkenbosch JW, Tobias JD. Development of bradycardia during sedation with dexmedetomidine in an infant concurrently receiving digoxin. *Pediatr Crit Care Med* (2003) 4, 203–5.

Digoxin + Dietary fibre or Laxatives

Bisacodyl reduces digoxin levels. Large amounts of dietary fibre, guar gum and bulk-forming laxatives containing ispaghula or psyllium appear to have no significant effect on the absorption of digoxin. Single-dose studies show that macrogol 4000, a laxative polymer, reduces digoxin levels.

Clinical evidence

(a) Bisacodyl

Bisacodyl reduced the mean serum digoxin levels of 11 healthy subjects by about 12%. When the bisacodyl was taken 2 hours before the digoxin, serum digoxin levels were slightly raised, but not to a statistically significant extent.[1] Another study in 10 patients taking **alpha-acetyldigoxin** found that bisacodyl 30 mg daily reduced plasma digoxin levels from a peak of just over 1.6 nanograms/mL, to a low of about 1.25 nanograms/mL.[2]

(b) Fibre

The serum digoxin levels of 12 patients taking digoxin 125 to 250 micrograms daily 15 to 30 minutes before breakfast were unchanged over a 10-day period when they were given a diet supplemented each day with 22 g of dietary fibre. The fibre was given in this way to simulate the conditions that might be encountered clinically (for example to reduce the symptoms of diverticular disease).[3]

Wheat bran 7.5 g twice daily caused a small 10% reduction in the plasma digoxin levels of 14 geriatric patients after 2 weeks, but there was no significant change after 4 weeks.[4] Bran fibre 11 g caused a 6 to 7% reduction in the absorption and the steady-state serum levels of digoxin in 16 healthy subjects.[5] The cumulative urinary recovery of a single oral dose of digoxin in healthy subjects was reduced almost 20% by 5 g of fibre, whereas 0.75 g of fibre had no effect.[6]

(c) Guar gum

In 10 healthy subjects *Guarem* (95% guar gum) 5 g reduced the peak serum levels of a single 500-microgram oral dose of digoxin by 21% and the AUC_{0-6} was reduced by 16%, but the amount excreted in the urine over 24 hours was only minimally reduced.[7] Guar gum 18 g with a test meal did not affect steady-state plasma digoxin levels in 11 healthy subjects given digoxin 1 mg on day one, 750 micrograms on day 2, and then 500 micrograms daily for 3 days.[8]

(d) Ispaghula

An ispaghula preparation (*Vi-Siblin S*) was found to have no significant effect on the serum digoxin levels of 16 geriatric patients.[4] The same lack of effect was seen in another study in 15 patients given 3.6 g of a psyllium preparation (*Metamucil*) three times daily.[9]

(e) Macrogol 4000

A randomised, crossover study in 18 healthy subjects found that 20 g of macrogol 4000 daily over an 8-day period reduced the maximum serum levels of a single 500-microgram dose of digoxin by 40%, and reduced its AUC by 30%. Heart rate and the PR interval were unchanged.[10] More study is needed to assess the effects of this interaction on steady-state digoxin levels.

Mechanism

Not established. Digoxin can bind to some extent to fibre within the gut.[11] However, *in vitro* studies (with bran, carrageenan, pectin, sodium pectinate, xylan and carboxymethylcellulose) have shown that most of the binding is reversible.[12]

Importance and management

Information seems to be limited to these reports. The reduction in serum digoxin levels caused by bisacodyl is small, and not expected to be of clinical importance, and apparently preventable by giving the bisacodyl 2 hours before the digoxin. Neither dietary fibre (bran), guar gum nor the two bulk-forming laxatives (*Vi-Siblin* and *Metamucil*) have a clinically important effect on serum digoxin levels. No special precautions would appear to be necessary. The importance of the interaction between digoxin and macrogol 4000 awaits further assessment, but on the available evidence it would be prudent to be alert for the need to increase the digoxin dose.

Digoxin and related drugs + Digoxin-like herbal medicines

Many herbal remedies contain digitalis glycosides, which could in theory have additive effects with digoxin or related digitalis glycosides, or interfere with their assays. However, there appear to be few such interactions reported.

Clinical evidence, mechanism, importance and management

(a) Additive effects possible

A 26-year-old woman developed severe and unexplained chest pain, and was later noted to have a heart rate of 39 bpm and a blood pressure of 59/36 mmHg, but these rose to normal with conservative management. She was found to have a digoxin level of 0.9 nanograms/mL and was diagnosed as having digoxin toxicity, despite not taking any prescribed digoxin. The digoxin-like digitalis glycosides were thought to have come from an unnamed herbal remedy for stress, which contained **black cohosh root** (*Cimicifuga racemosa*), **cayenne pepper fruit** (*Capsicum annuum*), **hops flowers** (*Humulus lupulus*), **skullcap herb** (*Scutellaria lateriflora*), **valerian root** (*Valeriana officinalis*) and **wood betony herb** (*Pedicularis canadensis*).[1] All of these had previously been shown to contain small amounts of digoxin-like compounds, which were only partially detected by digoxin antibody immunoassays.[1,2] In this previous *in vitro* study, 46 commercially packaged herb teas and 78 teas prepared from herbs were assayed for digoxin-like factors by their cross-reactivity with digoxin antibody or inhibition of ouabain binding, and these values were used to give approximate equivalent daily doses of digoxin. Three packaged teas (***Breathe Easy***, **blackcurrant**, and **jasmine**) and 3 herbs (**pleurisy root**, **chaparral**, **peppermint**) were found to contain greater than 30 micrograms of digoxin equivalents per cup and were postulated to provide a therapeutic daily dose of digoxin if 5 cups a day were drunk.[2] However, note that some common teas sampled in this study (e.g. English Breakfast, Earl Grey) contained over 20 micrograms of digoxin equivalents per cup, and tea drinking has not been associated with adverse cardiovascular risk.[3] Therefore the interpretation of the findings of this study is unclear.

Theoretical interactions with herbal remedies are not always translated into practice, and there do not appear to be any cases of herbals interacting with digoxin because of their cardiac glycoside content.

(b) Effects on digoxin or digitoxin assays

A 68-year-old woman who was given a loading dose of digitoxin 750 micrograms then 100 micrograms on the second day was found to have markedly elevated levels of digitoxin (greater than 100 nanograms/mL), but no clinical signs of toxicity. Two days before admission she had ingested 90 drops of **Uzara**, a preparation from *Xysmalobium undulatum*, which contains weak digitalis glycosides. Later investigations in 4 healthy subjects given 30 drops of **Uzara** confirmed that assays for **digitoxin** (CEDIA digitoxin test, Roche Diagnostics, Ger-

many) and digoxin (Tina-quant digoxin test, Roche Diagnostics, Germany) were markedly elevated by **Uzara** to levels well above usual therapeutic concentrations, but that there were no clinically relevant changes in heart rate and blood pressure.[4]

In an *in vitro* study, **plantain** (*Plantago major*) extract from capsules, liquid extract, or dry leaf did not affect the results of digoxin assays when using fluorescence polarization immunoassay or microparticle enzyme immunoassay.[5] Note that contamination of **plantain** with *Digitalis lanata* has been reported.[6]

Digoxin + Dihydroergocryptine

Dihydroergocryptine does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study in 12 healthy subjects, dihydroergocryptine 20 mg did not affect the pharmacokinetics of a single 500-microgram dose of digoxin. No clinically significant changes were seen in the ability of the heart to initiate and conduct impulses, or repolarise. The slight drop in blood pressure during the first 2 to 4 hours after digoxin was more pronounced in the presence of dihydroergocryptine, but there was no evidence of impaired orthostatic blood pressure control.[1] No special precautions would seem necessary during concurrent use.

1. Retzow A, Althaus M, de Mey C, Mazur D, Vens-Cappell B. Study on the interaction of the dopamine agonist α-dihydroergocryptine with the pharmacokinetics of digoxin. *Arzneimittelforschung* (2000) 50, 591–6.

Digoxin + Dipeptidylpeptidase-4 inhibitors

There appears to be no pharmacokinetic interaction between digoxin and saxagliptin or vildagliptin. Sitagliptin very slightly raised digoxin levels, but this is not likely to be clinically relevant.

Clinical evidence

(a) Saxagliptin

In a study in 14 healthy subjects, there was no change in the pharmacokinetics of digoxin or saxagliptin when digoxin (loading dose over 2 days then 250 micrograms daily for 5 days) was given with saxagliptin 10 mg daily, when compared with either drug alone.[1]

(b) Sitagliptin

The manufacturers describe a study in which digoxin 250 micrograms daily was given with sitagliptin 100 mg daily for 10 days. The AUC and maximum plasma levels of digoxin were increased by 11% and 18%, respectively.[2,3]

(c) Vildagliptin

In a study, 18 healthy subjects were given either vildagliptin 100 mg daily for 7 days or digoxin 500 micrograms on the first day then 250 micrograms for 6 days then both drugs together. No changes in the pharmacokinetics of either drug occurred.[4]

Mechanism

Sitagliptin may be a weak inhibitor of P-glycoprotein, thereby slightly raising digoxin levels.

Importance and management

The small rise in digoxin exposure with sitagliptin is unlikely to be clinically relevant, and no digoxin dose adjustment is needed when sitagliptin is started. However, the manufacturer recommends that patients at risk of digoxin toxicity should be monitored for this when sitagliptin is used,[2,3] which is a cautious approach.

Saxagliptin and vildagliptin do not alter digoxin levels, and no dose adjustment is required on concurrent use.

Digoxin + Dipyridamole

Dipyridamole may cause a minor increase in the absorption of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that dipyridamole 150 mg twice daily for 5 doses increased the AUC_{0-4} and the AUC_{0-24} of a single 500-microgram oral dose of digoxin by 20% and 13%, respectively. This was attributed to an increase in digoxin absorption possibly mediated by intestinal P-glycoprotein inhibition.[1] *In vitro* studies[1,2] found that dipyridamole inhibits the P-glycoprotein-mediated transport of digoxin, but in one study this was only at higher levels than those achieved clinically.[2] Therefore these minor changes are not fully explained. Nevertheless, the changes in digoxin pharmacokinetics in the presence of dipyridamole are small and unlikely to be of clinical significance.

Digoxin and related drugs + Disopyramide or Procainamide

Neither disopyramide nor procainamide normally cause a significant change in digoxin levels. A single report describes toxicity in a patient taking digitoxin and disopyramide.

Clinical evidence, mechanism, importance and management

(a) Disopyramide

A number of studies have clearly shown that disopyramide causes only a very small increase or no increase at all in the serum levels of digoxin.[1-6] A small but insignificant reduction in heart rate has been seen,[7] but the weight of evidence suggests that no adverse interaction occurs if digoxin and disopyramide are used together. However, a very brief report describes toxicity and serious arrhythmia in one patient given **digitoxin** and disopyramide.[8]

(b) Procainamide

A study in patients who had been taking digoxin for at least 7 days found that procainamide did not affect their serum digoxin levels.[2]

Digoxin and related drugs + Diuretics; Potassium-depleting

The potassium loss caused by potassium-depleting diuretics increases the toxicity of the digitalis glycosides.

Clinical evidence

A comparative study[1] of the medical records of 418 patients taking digitalis over the period 1950 to 1952, and of 679 patients over the period 1964 to 1966, found that the incidence of digitalis toxicity had more than doubled. Of the earlier group 8.6% developed toxicity (58% taking diuretics, mainly of the **organomercurial type**) compared with 17.2% of the latter group (81% taking diuretics, mainly **chlorothiazides**, **furosemide**, **etacrynic acid**, **chlortalidone**). It was concluded that the increased toxicity was related to the increased usage of potassium-depleting diuretics.

A retrospective study of over 400 patients taking digoxin found that almost one in five had some toxic reactions attributable to the use of the digoxin. Of these, 16% had demonstrable hypokalaemia (defined as serum potassium less than 3.5 mmol/L). Almost half of the patients who had toxicity were taking potassium-depleting diuretics, notably **hydrochlorothiazide** or **furosemide**.[2] Similar results were found in other studies in a considerable number of patients.[3-9]

In contrast, a retrospective study of patients who developed digitalis toxicity showed that the likelihood of its development in those with potassium levels below 3.5 mmol/L was no greater than those with normal potassium levels.[10] Two other studies in a total of almost 200 patients did not detect any association between the development of digitalis toxicity and the use of diuretics or changes in potassium levels.[11,12]

A pharmacokinetic study in 6 patients found that single 50-mg and 100-mg doses of **cicletanine** had no effect on the plasma levels of digoxin 125 to 250 micrograms daily.[13] In addition there is also some evidence that **furosemide** may raise serum digoxin levels,[14] although two other studies found no evidence that **furosemide** affects the urinary excretion of digoxin.[15,16]

Mechanism

Not fully understood. The cardiac glycosides inhibit sodium-potassium ATP-ase, which is concerned with the transport of sodium and potassium ions across the membranes of the myocardial cells. This is associated with an increase in the availability of calcium ions concerned with the contraction of the cells. Potassium loss caused by these diuretics exacerbates the potassium loss from the myocardial cells, thereby increasing the activity and the toxicity of the digitalis. Some loss of magnesium may also have a part to play. The mechanism of this interaction is still being debated.

Importance and management

A direct link between the use of these potassium-depleting diuretics and the development of digitalis toxicity is not established beyond doubt, but concurrent use can result in digitalis toxicity. It is therefore important that potassium levels remain within the accepted normal range during the use of a digitalis glycoside. Potassium levels should be routinely monitored when diuretics are given and it may be prudent to recheck levels if patients develop symptoms of digitalis toxicity. See 'Table 26.1', (p.1121) for a list of potassium-depleting diuretics.

Digoxin and related drugs + Diuretics; Potassium-sparing

Digoxin levels may be increased by 25% by spironolactone, but because spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods, the evaluation of this interaction is difficult. Eplerenone may also cause a minor increase in digoxin levels. Amiloride has little effect on digoxin levels in healthy subjects, but it may reduce its inotropic effects, and in patients with renal impairment it possibly raises digoxin levels.
The effects of digitoxin are reported to be both increased and decreased by spironolactone.

Clinical evidence

(a) Digitoxin

A study in 6 healthy subjects who had been taking digitoxin 100 or 150 micrograms daily for 30 days found that **spironolactone** 300 mg daily increased the digitoxin half-life by one-third (from 142 to 192 hours).[1]

In contrast, other studies have found that the digitoxin half-life was reduced (from 256 to 205 hours) by **spironolactone**.[2]

(b) Digoxin

1. Amiloride. In 6 healthy subjects amiloride 5 mg twice daily for 8 days almost doubled the renal clearance of digoxin (from 1.3 to 2.4 mL/kg per minute), but reduced the extra-renal clearance (from 2.1 to 0.1 mL/kg per minute). The balance of the two effects was to cause a small fall in total clearance and a small rise in plasma digoxin levels.[3] The positive inotropic effects of digoxin were reduced, but whether this is clinically important is uncertain. In contrast, a later study in 8 healthy subjects found that a single 75-mg [sic] oral dose of amiloride given 3 hours before an infusion of digoxin did not reduce the inotropic effects of digoxin.[4]

2. Eplerenone. In one study, the steady-state AUC of digoxin 200 micrograms daily increased by 16% (90% confidence interval: 4% to 30%) when it was given with eplerenone.[5,6]

3. Spironolactone. The plasma digoxin levels of 9 patients were increased by about 20% (from 0.8 to 1 nanograms/mL) when they were given spironolactone 100 mg daily. One patient had a three to fourfold rise in digoxin levels.[7]

The clearance of a single 750-microgram intravenous dose of digoxin was reduced by about 25% in 4 patients and 4 healthy subjects following 5 days of treatment with spironolactone 100 mg twice daily.[8] A marked fall in serum digoxin levels occurred in an elderly patient when spironolactone was withdrawn,[9] but the accuracy of the assay method used is uncertain (see *Importance and management* below). One study found that no clinically important reduction in digoxin clearance occurred when *Aldactazide* (spironolactone-hydrochlorothiazide) was also given.[10]

Mechanism

Not fully understood. Spironolactone inhibits the excretion of digoxin by the kidney (by 13%) but does not affect its biliary clearance.[11] *Animal* studies have suggested that spironolactone may induce P-glycoprotein expression, resulting in reduced intestinal absorption of substrates such as digoxin.[12] Spironolactone probably also causes a reduction in the volume of distribution of digoxin.

It has been suggested that amiloride may have increased the production of aldosterone, which suppressed the positive inotropic effects of digoxin.[3] Studies in patients with congestive heart failure are needed.

Importance and management

The pharmacokinetic interaction between digoxin and **spironolactone** appears to be established. What is known suggests that a rise in digoxin levels of up to 25% is likely to occur, although much greater increases can apparently occur in some patients.[7] Monitor concurrent use carefully for signs of over-digitalisation. Note that spironolactone or its metabolite, canrenone, can interfere with some digoxin assay methods.[13] In one report, radioimmunoassay (RIA) and affinity-column-mediated immunoassay (ACMIA) were particularly affected by spironolactone and its metabolites.[14] Conversely, falsely low digoxin readings with the AxSym MEIA assay method led to digoxin overdose and toxicity in one patient.[15] This means that monitoring is difficult unless the digoxin assay method is known to be reliable. Measurement of free digoxin levels or use of a chemiluminescent assay (CLIA) or turbidometric immunoassay for digoxin has been reported to mostly eliminate interference from spironolactone, potassium canrenoate and canrenone.[16,17]

Eplerenone also appears to cause a small increase in digoxin levels. The UK manufacturers recommend that caution is warranted when digoxin is dosed near the upper limit of therapeutic range.[5] However, the US manufacturer states that the pharmacokinetic interaction is not clinically significant.[18]

The situation with digitoxin and spironolactone is confusing because the reports are contradictory and the outcome uncertain. Concurrent use should be well monitored.

Patients with poor renal function would be expected to have a rise in digoxin levels when given **amiloride** (due to the increased reliance on renal clearance) but the clinical importance of this awaits confirmation.

Digoxin + Dofetilide

Dofetilide does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 13 subjects, dofetilide 250 micrograms twice daily for 5 days had no effect on the steady-state pharmacokinetics of digoxin, given at a dose of 250 micrograms daily after a loading dose.[1]

1. Kleinermans D, Nichols DJ, Dalrymple I. Effect of dofetilide on the pharmacokinetics of digoxin. *Am J Cardiol* (2001) 87, 248–50.

Digoxin and related drugs + Drugs that affect calcium

The effects of digitalis glycosides might be increased by rises in blood calcium levels, and the use of intravenous calcium may result in the development of potentially life-threatening digitalis-induced arrhythmias. The use of digitalis glycosides in the presence of hypercalcaemia due to vitamin D administration could result in arrhythmias. Teriparatide appears not to affect the calcium-mediated effects of digoxin.

Clinical evidence

(a) Calcium

Two patients developed cardiac arrhythmias and died after being given digitalis intramuscularly and either **calcium chloride** or **calcium gluconate** intravenously. No absolutely certain causative relationship was established.[1]

There is some evidence that increases or decreases in blood **calcium** levels can increase or decrease, respectively, the effects of digitalis. A patient with congestive heart failure and atrial fibrillation was resistant to the actions of digoxin (serum levels of 1.5 to 3 nanograms/mL) until his serum **calcium** levels were raised from 1.68 mmol/L to about 2.13 mmol/L by oral **calcium and vitamin D**.[2]

(b) Teriparatide

A placebo-controlled study in 15 healthy subjects given digoxin 500 micrograms daily, adjusted to maintain steady-state serum levels in the range 1 to 2 nanograms/mL, found that a single 20-microgram subcutaneous dose of teriparatide on day 15 or 16 did not alter the calcium-mediated effects of digoxin (systolic time interval), or heart rate. Serum calcium increased slightly, with a maximum increase of 0.05 mmol/L.[3]

Mechanism

The actions of the cardiac glycosides (even now not fully understood) are closely tied up with movement of calcium ions into heart muscle cells. Increased concentrations of calcium outside these cells increase the inflow of calcium and this enhances the activity of the glycosides. This can lead to effective over-digitalisation and even potentially life-threatening arrhythmias. Conversely, a drop in calcium levels can attenuate the activity of the glycosides: **disodium edetate**,[4-6] which lowers blood calcium levels, has been used successfully in the treatment of digitalis toxicity, although less toxic drugs are generally preferred.

Importance and management

The report of deaths associated with digitalis and calcium compounds (published in 1936) seems to be the only direct clinical evidence of a serious adverse interaction, although there is plenty of less direct evidence that an interaction is possible. Intravenous calcium should be avoided in patients receiving cardiac glycosides. If that is not possible, it has been suggested[7] that it should be given slowly or only in small amounts in order to avoid transient serum calcium levels higher than 7.5 mmol/L, but it seems likely that very large doses of calcium would be required to reach this level, even transiently.

Hypercalcaemia is one of the most common adverse effects of **alfacalcidol** and **paricalcitol**, and is reported to be a common adverse effect of **calcitriol** and **ergocalciferol** usually occurring with excessive doses. Although calcium levels should be monitored in patients taking these drugs, it is particularly important to ensure that this is done in patients also taking cardiac glycosides.

The very slight increases in calcium observed with teriparatide were considered insufficient to increase cardiac sensitivity to digoxin.[3] Nevertheless, the manufacturer of teriparatide still advises caution in patients taking digitalis, because of the possibility for transiently raised calcium levels.[8,9]

Digoxin and related drugs + Drugs that lower potassium levels

A number of drugs, including amphotericin B, carbenoxolone, and the corticosteroids, cause potassium loss, which could lead to the development of digitalis toxicity.

Clinical evidence, mechanism, importance and management

Among the well-recognised adverse effects of **amphotericin B** is hypokalaemia, which can be severe. Although there seem to be no reports of adverse interactions, it would be logical to expect that digitalis toxicity could develop in patients given both drugs if the potassium levels fall. Amiloride has been successfully used to counteract the potassium loss caused by **amphotericin B**.[1]

The adverse effects of **carbenoxolone** include an increase in blood pressure (both systolic and diastolic), fluid retention and reduced serum potassium levels. The incidence of these adverse effects is said in some reports to be as high as 50%; others quote lower figures. Hypertension and fluid retention occur early in **carbenoxolone** treatment, whereas the hypokalaemia develops later and may occur in the absence of the other two adverse effects.[2-5] **Carbenoxolone** is therefore unsuitable for patients with congestive heart failure, or those taking digitalis glycosides, unless measures to avoid hypokalaemia are taken.

Systemic corticosteroids can increase the loss of potassium, particularly those that are naturally occurring (**cortisone**, **deoxycortone**, **hydrocortisone**) whereas the synthetic derivatives (**betamethasone**, **dexamethasone, methylprednisolone**, **prednisolone**, **prednisone**, **triamcinolone**) have much less mineralocorticoid activity. There is therefore the possibility of potassium depletion, particularly when corticosteroids are used long-term, which may increase the risk of digitalis toxicity. These corticosteroids also cause sodium and water retention, resulting in oedema and hypertension, which can lead to cardiac failure in some individuals.

It is therefore important to monitor the use of digoxin and any of these drugs well. Potassium levels should be routinely monitored in any patient taking **amphotericin B**, but it is particularly important in those taking digoxin. With other drugs where potassium monitoring is not routine, it would seem prudent to watch for signs of digoxin adverse effects (e.g. bradycardia) and consider measuring potassium levels if these develop. No problems of this kind would be expected with corticosteroids used topically or by inhalation, because the amounts absorbed are likely to be relatively small.

For reports of digoxin toxicity or increased sensitivity to digoxin associated with other drugs that cause hypokalaemia, see 'Digoxin and related drugs + Diuretics; Potassium-depleting', p.1097, and 'Digoxin and related drugs + Beta-agonist bronchodilators', p.1087.

Digoxin and related drugs + Edrophonium

Excessive bradycardia and AV-block may occur if patients taking digitalis glycosides are given edrophonium.

Clinical evidence, mechanism, importance and management

The rapid intravenous injection of edrophonium 10 mg has been used in the differentiation of cardiac arrhythmias, but in one study, 4 of 10 digitalised patients given edrophonium developed atrial tachycardia with AV block. The effect was transient; recovery of baseline ECGs occurred 15 to 20 minutes after administration.[1] Nevertheless, the authors recommended that edrophonium should not be given to patients with atrial flutter or tachycardia who are taking **digitalis glycosides**. This recommendation is reinforced by the case of an elderly woman[2] who developed bradycardia, AV block and asystole following concurrent use. She recovered after being given atropine 1 mg.

Digoxin + Endothelin receptor antagonists

Bosentan does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

(a) Ambrisentan

A study in 15 healthy subjects found that multiple doses of ambrisentan 10 mg daily (duration not stated) slightly increased the trough concentration and AUC of a single dose of digoxin (dose not stated), and modestly increased the maximum concentration digoxin, by 29%. These changes are not expected to be clinically relevant and therefore no digoxin dose adjustments are needed if ambrisentan is also given.[1]

(b) Bosentan

In a study in 18 healthy subjects, bosentan 500 mg twice daily for a week did not significantly affect the steady-state peak or trough levels of digoxin 375 micrograms daily. There was a small reduction of about 12% in the AUC of digoxin, which may have been due to induction of P-glycoprotein by bosentan. There were no changes in ECG recordings and vital signs. The results suggest that bosentan does not interact with digoxin to a clinically relevant extent and that concurrent use need not be avoided. However, the authors of the report note that further studies over the longer term, and in patients with renal impairment, may be necessary to confirm this.[2]

(c) Sitaxentan

The manufacturers of sitaxentan note that it does not alter the pharmacokinetics of digoxin.[3]

Digoxin and related drugs + Enoximone

Studies in patients receiving long-term treatment with digoxin or digitoxin found that *oral* enoximone 100 mg three times daily for a week had no significant effect on the plasma levels of either of these digitalis glycosides.[1,2] Cardiac function was improved. There dose adjustments of these cardiac glycosides would not be expected to be necessary if enoximone is also given.

2. Trenk D, Hertrich F, Winkelmann B, Glauner T, Dieterich HA, Jähnchen E. Lack of effect of enoximone on the pharmacokinetics of digoxin in patients with congestive heart failure. *J Clin Pharmacol* (1990) 30, 235–40.

Digoxin + Etanercept

No clinically significant interaction appears to occur between digoxin and etanercept.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given an oral loading dose of digoxin 500 micrograms twice daily on day one, followed by 250 micrograms daily, found that subcutaneous etanercept 25 mg twice weekly did not significantly affect the pharmacokinetics of digoxin. The maximum serum levels and AUC of etanercept were 4% and 13% lower, respectively, during concurrent use but this was not considered to be clinically significant. The combination was well tolerated and there were no changes in ECG parameters.[1] No special precautions therefore seem necessary if both drugs are given.

Digoxin + Exenatide

Exenatide delays the time to peak plasma digoxin levels.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study, 21 healthy subjects were given an oral loading dose of digoxin 500 micrograms twice daily on day one, then 250 micrograms daily for 11 days, with subcutaneous exenatide 10 micrograms twice daily on days 8 to 12. The median time to maximum plasma concentration of digoxin was increased from 1.5 hours to 4 hours, and there was a reduction of 17% in its maximum levels. There was no change in AUC and trough digoxin levels, and the renal clearance of digoxin was not altered. It is thought that the changes in digoxin pharmacokinetics occurred as a result of altered gastric emptying caused by exenatide.[1] Evidence for an interaction between digoxin and exenatide appears to be limited to this study, which suggests that the changes in digoxin pharmacokinetics are small, and unlikely to be clinically relevant. No digoxin dose adjustment is likely to be required on concurrent use.

1. Kothare AP, Soon DKW, Linnebjerg H, Park S, Chan C, Yeo A, Lim M, Mace KF, Wise SD. Effect of Exenatide on the steady-state pharmacokinetics of digoxin. *J Clin Pharmacol* (2005) 45, 1032–7.

Digoxin + Ezetimibe

Ezetimibe does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, ezetimibe 10 mg daily for 7 days did not alter the pharmacokinetics of a single 500-microgram dose of digoxin. In addition, ezetimibe did not alter the ECG effects of digoxin.[1] No digoxin dose adjustment would be expected to be necessary if ezetimibe is also given.

1. Kosoglou T, Statkevick P, Johnson-Levonas AO, Paolini JF, Bergman AJ, Alton KB. Ezetimibe. A review of its metabolism, pharmacokinetics and drug interactions. *Clin Pharmacokinet* (2005) 44, 467–94.

Digoxin + Fenoldopam

Oral fenoldopam appears to cause a small reduction in plasma digoxin levels in most patients, but more marked changes may occur in a few individuals.

Clinical evidence, mechanism, importance and management

Ten patients with congestive heart failure receiving digoxin long-term (doses not stated) were additionally given *oral* fenoldopam 100 mg three times daily for 9 days. The mean AUC and steady-state plasma levels of digoxin were reduced by about 20%. In two patients, the steady-state plasma levels of digoxin fell by 48% (from 1.36 to 0.71 nanograms/mL), and by 68% (from 1.93 to 0.61 nanograms/mL), respectively. In a further patient, digoxin levels rose by 45% (from 1.03 to 1.49 nanograms/mL).[1] Most patients appear not to show marked changes in plasma digoxin levels, but a few individuals may possibly need some dose adjustment. Monitor concurrent use for both efficacy and digoxin adverse effects.

1. Strocchi E, Tartagni F, Malini PL, Valtancoli G, Ambrosioni E, Pasinelli F, Riva E, Fuccella LM. Interaction study of fenoldopam-digoxin in congestive heart failure. *Eur J Clin Pharmacol* (1989) 37, 395–7.

Digoxin + Flecainide

Digoxin levels are unaltered or only modestly increased by the use of flecainide.

Clinical evidence

The plasma digoxin levels of 10 patients with congestive heart failure were unchanged when they took flecainide 100 to 200 mg twice daily for 7 days. A similar lack of interaction was also seen in 4 patients who took both drugs over a 4-week period.[1]

In contrast, a study in 15 healthy subjects found that flecainide 200 mg twice daily increased the trough and peak plasma levels of digoxin 250 micrograms by 24% and 13%, respectively.[2] The changes observed in vital signs were not clinically significant. Based on the results of a single-dose study the steady-state digoxin levels were predicted to rise by about 15% during the use of flecainide 200 mg twice daily.[3]

Mechanism

Uncertain. It is suggested that any changes may be due to alterations in the volume of distribution.[3]

Importance and management

Documentation is limited but what is known suggests that either no interaction occurs, or any changes are small and unlikely to be clinically relevant in most patients. However, the UK manufacturers of flecainide recommend that digoxin plasma levels should be measured not less than 6 hours after any digoxin dose, before or after the administration of flecainide.[4] The US manufacturers suggest close monitoring of cardiac function on concurrent use.[5] The authors of one of the reports[2] suggest that patients with high drug levels, atrioventricular nodal dysfunction, or both, should be monitored during concurrent treatment.

Digoxin + Fondaparinux

No clinically significant interaction appears to occur between digoxin and fondaparinux.

Clinical evidence, mechanism, importance and management

A phase I randomised study in 24 healthy subjects found that the pharmacokinetics of oral digoxin 250 micrograms twice daily for one day then 250 micrograms daily for 6 days was unaffected by subcutaneous fondaparinux 10 mg daily. The pharmacokinetics of fondaparinux were not affected by digoxin. The combination was well tolerated and no clinically significant changes in vital signs and ECGs were observed.[1] No additional precautions therefore seem necessary on concurrent use.

1. Mant T, Fournié P, Ollier C, Donat F, Necciari J. Absence of interaction of fondaparinux sodium with digoxin in healthy volunteers. *Clin Pharmacokinet* (2002), 41 (Suppl 2), 39–45.

Digoxin + Ginkgo (*Ginkgo biloba*)

Ginkgo does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence

A study in 8 healthy subjects found that ginkgo biloba leaf extract 80 mg three times daily had no significant effects on the pharmacokinetics of a single 500-microgram dose of digoxin.[1]

Mechanism

Digoxin is a P-glycoprotein substrate and *in vitro* studies[2] suggest that ginkgo may inhibit the activity of this drug transporter protein, which could lead to increased digoxin levels. However, this effect was not seen clinically.

Importance and management

The clinical study suggests that ginkgo is unlikely to alter digoxin levels in clinical use. Therefore no dose adjustment would be expected to be necessary if patients taking digoxin also wish to take ginkgo.

Digoxin + Ginseng

***Panax ginseng* (Asian ginseng), *Panax quinquefolius* (American ginseng) and *Eleutherococcus senticosus* (Siberian ginseng) may interfere with the results of digoxin assays.**

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking digoxin for many years (serum levels normally in the range 0.9 to 2.2 nanograms/mL) was found, during a routine check, to have digoxin levels of 5.2 nanograms/mL, but without evidence of toxicity, bradycardia or any other ECG changes.[1] The levels remained high even when the digoxin was stopped. It turned out he had also been taking ***Eleutherococcus senticosus* (Siberian ginseng)** capsules. When the ginseng was stopped, the digoxin levels returned to the usual range, and digoxin was resumed. Later rechallenge with the ginseng caused a rise in his serum digoxin levels. No digoxin or digitoxin contamination was found in the capsules, and the authors of the report also rejected the idea that the eleutherosides (chemically related to cardiac glycosides) in ginseng might have been converted *in vivo* into digoxin, or that the renal elimination of digoxin might have been impaired, as the patient showed no signs of toxicity.

***Panax ginseng* (Asian ginseng)**, ***Panax quinquefolius* (American ginseng)** and ***Eleutherococcus senticosus* (Siberian ginseng)** have been found to interfere with some digoxin assays including fluorescence polarisation immunoassay (FPIA, Abbott Laboratories)[2-4] and microparticle enzyme immunoassay (MEIA, Abbott Laboratories).[2,3] The more specific monoclonal antibody-based **digoxin** immunoassay, Tina-quant (Roche), was unaffected by all the ginsengs,[3,4] and the Beckman (Synchron LX system) monoclonal assay was unaffected by ***Panax ginseng* (Asian ginseng)**.[4] It therefore seems possible that the ginsengs affected the accuracy of the digoxin assays so that they gave false results.

The interference in the digoxin measurements described in the assays was not as high as that reported in the elderly patient and there is some doubt as to whether the herbal medicine taken by the patient was actually *Eleutherococcus senticosus* (Siberian ginseng).[3,5] So, whether this is clinically important, and measurement of serum digoxin levels is actually affected, is uncertain. Nevertheless it may be sensible to ask about ginseng use when interpreting unexpected digoxin levels and consider using a more specific monoclonal immunoassay.

Digoxin + Grapefruit juice

Digoxin levels are generally unaltered or only modestly increased by grapefruit juice, but in some individuals significant changes may occur.

Clinical evidence

A crossover study in 12 healthy subjects found that when they were given either grapefruit juice 220 mL or water, 30 minutes before and 3.5, 7.5, and 11.5 hours after a single 500-microgram dose of digoxin (taken with 50 mL of grapefruit juice or water respectively), the digoxin AUC_{0-4} and AUC_{0-24} were increased by about 10%. The maximum plasma levels and renal clearance of digoxin were not significantly affected. However, in 2 subjects taking grapefruit juice, the ECGs recorded 90 minutes after digoxin was taken revealed an asymptomatic first-degree atrioventricular block. Digoxin levels in these subjects had increased by 50% to 2.4 nanograms/mL and 2.8 nanograms/mL, respectively.[1] Another study found that grapefruit juice decreased the rate but not the extent of absorption of digoxin and had no effect on its AUC or renal clearance, but there was significant inter-individual variability.[2]

Mechanism

The modest increases in digoxin levels may be due to increased intestinal absorption of digoxin, possibly due to inhibition of P-glycoprotein-mediated digoxin transport by grapefruit juice, although this mechanism has been questioned.[1] *In vitro*, pomelo (*Citrus grandis*) and grapefruit juices inhibited the transport of digoxin by P-glycoprotein.[3]

Importance and management

Although grapefruit juice appears to have little effect on the bioavailability of digoxin, it is possible that in some individuals the interaction could be of clinical significance.[2] Therefore, if a patient taking digoxin unexpectedly develops bradycardia or other adverse effects it may be prudent to ask about grapefruit juice intake, and consider this as a possible cause. More study is needed to identify which patients may be at risk of a clinically relevant interaction.

Digoxin + Guanadrel

Guanadrel did not affect the pharmacokinetics of a single dose of digoxin in one study.

Clinical evidence, mechanism, importance and management

In 13 healthy subjects, guanadrel 10 mg orally every 12 hours for 8 days did not affect the pharmacokinetics of a single intravenous dose of digoxin given on day 5. One subject experienced a 10-minute episode of asymptomatic second-degree heart block (Wenckebach) 3 hours after the dose of digoxin, but the reason for this effect was not clear.[1] There seem to be no reports of adverse interactions between digoxin and guanadrel.

Digoxin and related drugs + H_2-receptor antagonists

Small changes in digoxin levels, both rises and falls, have been seen in patients also given cimetidine. Ranitidine does not appear to interact with metildigoxin.

Clinical evidence, mechanism, importance and management

In a study in 11 patients with congestive heart failure, **cimetidine** 300 mg every 6 or 12 hours reduced the steady-state serum digoxin levels by 25% (from 2 to 1.5 nanograms/mL), but none of them had any ECG changes or signs that their condition had worsened.[1] In four other patients with stable congestive heart failure, there was no significant changes in the pharmacokinetics of digoxin 125 to 250 micrograms daily when they were given **cimetidine** 300 mg every 6 hours.[2] Three single-dose studies in a total of 19 healthy subjects, and 6 patients with duodenal ulcers[3] found that **cimetidine** 600 mg to 1.2 g daily had no significant effect on the absorption[4] or the pharmacokinetics[3,5] of digoxin. Another study found a small increase in digoxin levels in healthy subjects, but only a small statistically insignificant rise in the steady-state levels of 11 patients given **cimetidine** 400 mg four times daily.[6] Six patients with chronic congestive heart failure given **metildigoxin** had no changes in their serum digoxin levels when they were given **ranitidine** 150 mg twice daily for a week.[7]

No interaction of clinical importance with either of these H_2-receptor antagonists has been established and no special precautions would seem to be necessary if they are given with digoxin.

Digoxin and related drugs + HRT

Post hoc analysis of one study found an increased rate of cardiovascular adverse events in women taking HRT who were also taking digitalis.

Clinical evidence, mechanism, importance and management

Retrospective analysis of data from a large randomised, placebo-controlled study of HRT (conjugated estrogens/medroxyprogesterone 0.625/2.5 mg daily) in women with coronary heart disease was conducted to see if there were any subgroups of patients who responded differently. Use of digitalis was associated with a fivefold excess rate of cardiovascular events in the first year, when women receiving HRT, were compared with the control group. A lower 1.5-fold excess rate was seen over the whole duration of the study (average 4.1 years). Possible mechanisms could be a drug-drug interaction or a drug-disease effect (HRT with congestive heart failure).[1]

However, it is impossible to say whether this represents a true effect, because the number of positive sub-group analyses in this study was the same as the number predicted by chance alone. Confirmatory evidence is required.[1] See also 'Digoxin and related drugs + Medroxyprogesterone or Megestrol', p.1105 for a report suggesting high-dose medroxyprogesterone does not have a clinically relevant effect on digitoxin levels.

Digoxin + Kaolin-pectin

Digoxin levels can be reduced by kaolin-pectin.

Clinical evidence

The concurrent use of kaolin-pectin suspension and digoxin reduced the peak plasma digoxin levels of 7 patients by 36%, while the $AUC_{0\text{-}24}$ was reduced by 15%. Conversely, when two doses of kaolin-pectin were taken, the first 2 hours before digoxin and the other 2 hours after digoxin, no significant changes were seen.[1]

Two single-dose studies have found 42% and 62% reductions in the bioavailability of digoxin caused by kaolin-pectin.[2,3] Another study found an interaction with digoxin tablets but not with digoxin capsules.[4]

Mechanism

Not understood. The digoxin may possibly become adsorbed onto the kaolin so that less is available for absorption. Another possibility is that the kaolin reduces the motility of the gut, which normally increases mixing and brings the digoxin into contact with the absorbing surface.

Importance and management

Evidence from this studies is somewhat conflicting; however, steady-state studies reflect the every-day situation much more closely than single-dose studies, and the one cited above[1] indicates that the total reduction in digoxin absorption is small (15%). This is unlikely to be of clinical importance. However, if an interaction does occur the effects can seemingly be minimised by separating the doses by 2 hours.

4. Allen MD, Greenblatt DJ, Harmatz JS, Smith TW. Effect of magnesium aluminum hydroxide and kaolin-pectin on absorption of digoxin from tablets and capsules. *J Clin Pharmacol* (1981) 21, 26–30.

Digoxin + Kava

A standardised kava extract did not alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 20 healthy subjects given a single 500-microgram dose of digoxin before and on the last day of treatment with a standardised kava rhizome (*Piper methysticum*) extract 1227 mg three times daily for 14 days, found no changes in the pharmacokinetics of digoxin. The product used was standardised for kavalactone content.[1]

It was suggested that kava may alter digoxin pharmacokinetics by affecting P-glycoprotein, since kavalactones are modulators of P-glycoprotein *in vitro*. However, the clinical study showed that kava does not cause clinically relevant changes in digoxin pharmacokinetics. Therefore no changes in digoxin levels would be anticipated on concurrent use, the caveat being that, as with all herbal medicines, these results may not be applicable to all kava products.[1]

1. Gurley BJ, Swain A, Barone GW, Williams DK, Breen P, Yates CR, Stuart LB, Hubbard MA, Tong Y, Cheboyina S. Effect of goldenseal (*Hydrastis canadensis*) and kava kava (*Piper methysticum*) supplementation on digoxin pharmacokinetics in humans. *Drug Metab Dispos* (2007) 35, 240–5.

Digoxin and related drugs + Ketanserin

Ketanserin does not appear to affect the pharmacokinetics of either digoxin or digitoxin.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, ketanserin 40 mg twice daily did not cause any significant changes in the pharmacokinetics of single doses of either digoxin 1.25 mg or **digitoxin** 1 mg, and it was concluded that ketanserin is unlikely to alter serum concentrations of either of these drugs during clinical use.[1]

1. Ochs HR, Verburg-Ochs B, Höller M, Greenblatt DJ. Effect of ketanserin on the kinetics of digoxin and digitoxin. *J Cardiovasc Pharmacol* (1985) 7, 205–7.

Digoxin + Lanthanum

Lanthanum did not significantly affect the pharmacokinetics of digoxin in a single-dose study.

Clinical evidence, mechanism, importance and management

In a crossover study, 14 healthy subjects were given lanthanum 1 g for 3 doses on one day, followed by a fourth dose the next day. A single 500-microgram dose of digoxin was given 30 minutes after the fourth dose of lanthanum. The digoxin half-life was increased during concurrent use from 11.4 hours to 14.8 hours but this was not considered to be clinically significant. Other pharmacokinetic parameters were not affected.[1] Ideally further multiple-dose studies in patients are needed to confirm this lack of interaction, but the available evidence suggests that a clinically relevant interaction is unlikely.

1. Fiddler G. Fosrenol™ (lanthanum carbonate) does not affect the pharmacokinetics of concomitant treatment with digoxin. *J Am Soc Nephrol* (2002) 13, 749A.

Digoxin + Liquorice

An isolated case of digoxin toxicity has been reported in an elderly patient attributed to the use of a herbal laxative containing kanzo (liquorice).

Clinical evidence

An 84-year-old man taking digoxin 125 micrograms daily and furosemide complained of loss of appetite, fatigue and oedema of the lower extremities 5 days after starting to take a Chinese herbal laxative containing liquorice (kanzo) 400 mg and rhubarb (daio) 1.6 g three times daily. He was found to have a raised digoxin level of 2.9 nanograms/mL (previous level 1 nanogram/mL) with a pulse rate of 30 bpm, and a slightly low potassium level (2.9 mmol/L).[1]

Mechanism

The reason for the increase in digoxin levels is unclear. Digoxin inhibits the sodium-potassium ATP-ase pump, which is concerned with the transport of sodium and potassium ions across the membranes of the myocardial cells. Potassium loss caused by a combination of the liquorice, rhubarb and diuretics exacerbated the potassium loss from the myocardial cells, thereby enhancing the bradycardia, already caused by an elevated digoxin level. Hypokalaemia also promotes the binding of digoxin to myocardial cells. The patients pre-existing cardiovascular disease may have also predisposed the patient to enhanced digoxin effects.

Importance and management

Evidence appears to be limited to one case. It is likely that the effects of the elevated digoxin levels were exacerbated by the hypokalaemia possibly caused by the herbal laxative. The theoretical basis for an interaction between liquorice and digoxin is well established, but there are few actual cases. Any herbal preparation that can reduce potassium levels would be expected to increase the risk of digoxin toxicity. This is likely to be additive with other concurrent medications a patient may also be taking that can cause hypokalaemia, such as loop diuretics. It would be prudent to exercise caution in patients who are taking digitalis glycosides and who regularly use/abuse laxatives including liquorice and/or anthraquinone-containing substances such as rhubarb. However, note that if these laxatives are used as recommended (at a dose producing a comfortable soft-formed motion), then this interaction is probably unlikely to be important.

1. Harada T, Ohtaki E, Misu K, Sumiyoshi T, Hosoda S. Congestive heart failure caused by digitalis toxicity in an elderly man taking a licorice-containing Chinese herbal laxative. *Cardiology* (2002) 98, 218.

Digoxin + Lithium

No pharmacokinetic interaction occurs between digoxin and lithium but the addition of digoxin to lithium possibly has a detrimental short-term effect on the control of mania. An isolated report describes severe bradycardia in one patient given both drugs.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects taking lithium carbonate in doses to achieve mean steady-state serum levels of 0.76 mmol/L (range 0.4 to 1 mmol/L) found that the pharmacokinetics of a 750-microgram intravenous dose of digoxin were unchanged by lithium, and that there were no significant effects on sodium pump activity or electrolyte concentrations.[1] However an experimental 7-day study in patients with manic-depressive psychoses found that there was a greater improvement in those given lithium with placebo than those given lithium with digoxin. This may be a reflection of changes in Na-K ATP-ase.[2] An isolated report describes tremor, confusion and severe nodal bradycardia in a patient given both drugs. The bradycardia worsened (30 bpm) even after both drugs were stopped.[3] The clinical significance of all of these findings is uncertain. Note that one UK manufacturer of digoxin[4] lists lithium as a drug that may increase sensitivity to digoxin because it may cause hypokalaemia or intracellular potassium deficiency, but note that hypokalaemia does not appear to be a commonly accepted adverse effect of lithium.

Digoxin and related drugs + Macrolides

Clarithromycin markedly increases digoxin levels, and numerous cases of digoxin toxicity have been reported. Increases in digoxin levels also occur with telithromycin. Cases of rapid and marked two to fourfold increase in digoxin levels have also been reported for azithromycin, erythromycin, josamycin and roxithromycin. A similar case has been seen with digitoxin and azithromycin.

Clinical evidence

A. Digitoxin

A man with congestive heart failure taking digitoxin 70 micrograms daily for 5 days of each week, with enalapril and furosemide, was admitted to hospital with nausea and bradycardia of 26 bpm 4 days after starting a 3-day course of **azithromycin** (dose not stated). His serum digitoxin levels were found to be raised from his usual baseline range of 9.9 to 19 nanograms/mL up to 34 nanograms/mL. His renal function was normal. Another patient receiving intravenous digitoxin 250 micrograms daily had a marked rise from his steady-state digitoxin range of 11 to 15 nanograms/mL after being given **azithromycin** 500 mg daily for 3 days. The digitoxin was withdrawn one day later, but the levels climbed to a peak of 32 nanograms/mL after a further 3 days, and remained in the toxic range for a further 3 days.[1]

B. Digoxin

(a) Azithromycin

A 31-month-old boy with Down's syndrome and tetralogy of Fallot (a congenital heart defect resulting in reduced blood flow to the lungs) was discharged from hospital after repair of his heart defect. He was taking digoxin 60 micrograms twice daily, furosemide, and potassium chloride. Eight days later, when readmitted with symptoms of heart failure, intermittent fever and wheezing, he was given azithromycin (10 mg/kg on day one, then 5 mg/kg daily for 4 days). Three days later his steady-state serum digoxin levels had risen from 1.79 nanograms/mL to 2.37 nanograms/mL and he experienced anorexia, nausea, and second degree atrioventricular block. All the symptoms resolved when the digoxin was withdrawn. Digoxin was restarted at 50 micrograms twice daily after the azithromycin course was completed and steady-state digoxin levels of 1.42 nanograms/mL were noted.[2]

The manufacturers of azithromycin said that, as of October 2000, there were 230 cases of the concurrent use of azithromycin and digoxin on their database. Of these, 78 cases had adverse events indicating possible digoxin toxicity. However on review, 21 cases were clearly excluded. Of the remaining cases, only 13 provided digoxin levels, and of these, high serum digoxin concentrations were reported in 6, but generally insufficient data made interpretation difficult.[3] The manufacturers concluded that the possibility that a patient may experience an increase in digoxin levels while taking azithromycin cannot be entirely excluded.[3]

(b) Clarithromycin

A woman receiving warfarin, heparin, carbamazepine and digoxin was admitted to hospital with syncope, vomiting and an irregular heart rhythm shortly after starting clarithromycin 1 g daily. Her serum digoxin levels were found to be raised. The clarithromycin was decreased, the carbamazepine and digoxin stopped, and she was treated with digoxin-specific antibody fragments (*Digibind*) and intravenous fluids. Her serum digoxin levels fell again and the digitalis toxicity disappeared.[4]

In 1995, the manufacturers of clarithromycin had a few other cases on their records of raised digoxin levels in patients following treatment with clarithromycin[4] and there are many other case reports of this interaction in the literature,[5-19] including a case series of 6 patients with end stage renal disease.[20]

A subsequent randomised, placebo-controlled study in 12 healthy subjects confirmed that clarithromycin 250 mg twice daily for 3 days increased the AUC of a single 750-microgram oral dose of digoxin by 70%. The non-glomerular renal clearance of digoxin was reduced by 40%.[21] Intravenous digoxin was much less affected.[21,22] In two further studies clarithromycin 500 mg twice daily for 7 days increased the AUC of digoxin by 57% and 35%.[23,24] Note that these studies were designed to investigate the interaction of other drugs, and clarithromycin was being used as a positive control.

Two studies that prospectively measured digoxin levels in patients before and during the use of clarithromycin found an important increase in all patients: in one study digoxin levels were increased by 70%,[25] and in the other, digoxin levels were increased from a range of 1 to 1.6 nanograms/mL up to 2.3 to greater than 4 nanograms/mL.[26] In one of these studies, there was a significant correlation between the dose of clarithromycin and the increase in digoxin serum levels.[25]

A case-control study using data from healthcare databases in Ontario from 1994 to 2000 identified 1 051 patients who had been admitted to hospital with digoxin toxicity. Of these, 55 patients (5.2%) had been exposed to clarithromycin in the preceding 3 weeks, when compared with just 0.5% of controls, which represented about a tenfold increase in risk.[27]

(c) Erythromycin

An elderly woman with a prosthetic heart valve and left ventricular dysfunction, taking warfarin, furosemide, hydralazine, isosorbide dinitrate and digoxin, was given erythromycin. She took only four 250-mg doses. Four days later her serum digoxin levels were found to have risen to 2.6 nanograms/mL from a normal steady-state range of 1.4 to 1.7 nanograms/mL, and she had evidence of digitalis toxicity.[28] Another four similar cases have also been reported.[29-31]

A study in a man who was resistant to digoxin found that erythromycin 1 g daily increased the AUC of digoxin by 300%.[32] A neonate given oral digoxin 5 micrograms/kg daily developed digoxin toxicity 2 days after erythromycin (10 mg three times daily, then 17 mg three times daily) was given. Digoxin levels rose from 1.8 nanograms/mL to 16 nanograms/mL.[33]

(d) Josamycin

A case report describes a premature neonate receiving digoxin who had a 50% increase in digoxin levels (from 2 to 2.95 nanograms/mL), resulting in bradycardia, and sinoatrial block after being given josamycin for 4 days. This was treated with antidigitalis Fab fragments.[34]

(e) Rokitamycin

In a study in 10 subjects rokitamycin did not affect serum digoxin levels.[35]

(f) Roxithromycin

A 76-year-old woman taking digoxin and a number of other drugs (enalapril, isosorbide mononitrate, furosemide, diltiazem, glyceryl trinitrate, slow-release potassium, prednisolone, omeprazole, calcitriol) developed signs of digoxin toxicity (nausea, vomiting, first degree heart block) within 4 days of starting to take roxithromycin 150 mg twice daily. Her serum digoxin levels were raised about fourfold.[36]

(g) Telithromycin

A study in 26 healthy subjects given digoxin 500 micrograms twice daily on the first day followed by 250 micrograms twice daily found that telithromycin 800 mg daily increased the digoxin AUC by 37% and increased its maximum blood levels by 74%. Trough plasma levels were increased by 21% and remained within the therapeutic range. No signs of digoxin toxicity were observed on ECGs.[37]

A 58-year-old woman taking digoxin 250 micrograms daily developed syncope and malaise after a 5-day course of telithromycin 800 mg daily. Her digoxin levels were 55% higher than her normal baseline level, and there were ECG changes.[38]

Mechanism

It was originally thought that the interaction between the macrolides and digoxin was due to the effect of the antibacterials on gut flora. Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be the responsibility of the gut flora,[29] in particular *Eubacterium lentum*, which is anaerobic and Gram positive.[31,39] In the presence of antibacterials that inhibit this organism, much more digoxin becomes available for absorption, which results in a marked rise in serum levels. At the same time the inactive metabolites derived from the gut disappear.[29,40] However, it is worth noting that most classes of antibacterials do not appear to interact with digoxin despite inhibiting *E. lentum in vitro*,[39] see 'Digoxin and related drugs + Beta-lactam antibacterials', p.1088. In addition, more recent data showing that digoxin levels are affected by clarithromycin in all, or the majority, of patients or subjects throw doubt on this theory.

A more plausible explanation for the interaction between digoxin and clarithromycin, and probably also erythromycin, is that the antibacterials inhibit the intestinal[22,41] or renal[14,25] P-glycoprotein transport of digoxin, which would increase the oral bioavailability and reduce the non-glomerular renal clearance respectively. Both mechanisms may be important.[21] Further, the increased gastric emptying due to erythromycin may also increase the bioavailability of digoxin[42] or digitoxin.[39]

Importance and management

The pharmacokinetic interaction between oral digoxin and clarithromycin is established, and likely to occur in the majority of patients. Digoxin toxicity has been commonly reported. Monitor all patients well for signs of increased digoxin effects when clarithromycin is first given, reducing the digoxin dose as necessary. Telithromycin appears to interact similarly to clarithromycin, and similar advice applies.

Information about azithromycin and erythromycin is limited to a relatively small number of patients, and there is only one report of an interaction between digoxin and josamycin or digoxin and roxithromycin. Until more is known, it would be prudent to monitor all patients well for signs of increased digoxin effects when any of these macrolide antibacterials is first given, reducing the digoxin dose as necessary. In addition, remember that azithromycin has a long serum half-life (60 hours), which means that it can continue to interact for several days after it has been withdrawn. Rokitamycin appears not to interact.

Digoxin and related drugs + Medroxyprogesterone or Megestrol

Doses of medroxyprogesterone acetate or megestrol used for malignant disease do not appear to interact with digitoxin to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

Steady-state **digitoxin** levels were monitored in 3 patients before and after 5 weeks of treatment with oral medroxyprogesterone acetate 500 mg twice daily or megestrol 160 mg daily. Only small and clinically irrelevant changes in **digitoxin** levels and clearance were seen.[1]

For the possible effect of HRT including medroxyprogesterone on digitalis glycosides (unnamed), see 'Digoxin and related drugs + HRT', p.1102.

Digoxin + Methyldopa

Methyldopa does not appear to affect digoxin levels, but marked bradycardia has been seen in two elderly women given both drugs.

Clinical evidence

In 8 healthy subjects, methyldopa 250 mg daily had no effect on the steady-state serum levels of digoxin 250 micrograms daily.[1] However, a case report describes two elderly women with hypertension and left ventricular failure, who developed marked bradycardia when they were given digoxin with methyldopa 750 mg or 3.75 g daily but not when they were given digoxin alone. Average heart rates were 50 bpm and 48 bpm, respectively, while minimum heart rates were 32 bpm and 38 bpm, respectively. They were subsequently discharged taking digoxin and hydralazine with heart rates within the normal range.[2]

Mechanism

Uncertain. Both digoxin and methyldopa[3] can cause some bradycardia, but these effects seem to have been more than simply the sum of the individual drug effects on the autonomic nervous system.[2]

Importance and management

Information is limited but it would seem that concurrent use need not be avoided, but be aware that on rare occasions undesirable bradycardia has occurred.

Digoxin + Metoclopramide

Digoxin levels may be reduced by about one-third if metoclopramide is given with slowly dissolving forms of digoxin. No interaction is likely with digoxin in liquid form or in fast-dissolving preparations.

Clinical evidence

A study in 11 patients taking slowly dissolving digoxin tablets (*Orion*) found that metoclopramide 10 mg three times a day for 10 days reduced the serum digoxin levels by 36% (from 0.72 to 0.46 nanograms/mL).[1] The digoxin concentrations rose to their former levels when the metoclopramide was withdrawn.

Another study in healthy subjects found metoclopramide 10 mg three times daily caused a 19% reduction in the AUC of digoxin and a 27% reduction in peak serum digoxin levels (digoxin formulation not stated).[2] Yet another study in healthy subjects clearly showed that metoclopramide decreased the absorption of digoxin from tablets (*Lanoxin*) but not capsules (*Lanoxicaps*).[3]

Mechanism

It would seem[4-6] that the metoclopramide increases the motility of the gut to such an extent that full dissolution and absorption of some digoxin formulations does not occur.

Importance and management

Information about an interaction between digoxin and metoclopramide is very limited, but the interaction seems to be established. It is not likely to occur with solid form, fast-dissolving digoxin preparations (e.g. liquid-filled capsules) or digoxin in liquid form, but only with those preparations which are slowly dissolving (i.e. some tablet formulations). A reduction in digoxin levels of one-third could result in under-digitalisation. Be aware of this interaction if both drugs are given.

Digoxin + Mexiletine

Digoxin levels are not significantly altered by mexiletine.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, mexiletine 200 mg every 8 hours for 4 days slightly reduced the serum levels of digoxin 250 micrograms daily from 0.32 nanograms/mL to 0.27 nanograms/mL.[1] Two other studies in a total of 17 patients[2,3] confirmed that mexiletine does not significantly affect serum digoxin levels.

3. Day T, Hunt D. Interaction between mexiletine and digoxin. *Med J Aust* (1983) 2, 630.

Digoxin + Mizolastine

Mizolastine can cause a small but clinically irrelevant rise in digoxin levels.

Clinical evidence, mechanism, importance and management

A placebo-controlled, crossover study in 12 healthy subjects found that mizolastine 10 mg daily for a week caused a 17% increase in the maximum plasma levels of digoxin 250 micrograms daily. The digoxin AUC and half-life were unchanged and the haemodynamic parameters measured (blood pressure, ECG) were unaltered.[1] No special precautions would seem necessary during concurrent use.

1. Chaufour S, Le Coz F, Denolle T, Dubruc C, Cimarosti I, Deschamps C, Ulliac N, Delhotal-Landes B, Rosenweig P. Lack of effect of mizolastine on the safety and pharmacokinetics of digoxin administered orally in repeated doses to healthy volunteers. *Int J Clin Pharmacol Ther* (1998) 36, 286–91.

Digoxin and related drugs + Moclobemide

Moclobemide had no clinically relevant effect on the pharmacokinetics of beta-acetyldigoxin.

Clinical evidence, mechanism, importance and management

A study in 14 patients with decompensated heart failure, given an individualised dose of **beta-acetyldigoxin** for 2 weeks, found that moclobemide 100 mg three times daily given for 8 days caused a non-significant 14% reduction (from 0.99 to 0.85 nanograms/mL) in plasma **beta-acetyldigoxin** levels. No adverse effects attributable to an interaction were seen.[1] No special precautions appear to be required during the concurrent use of **acetyldigoxin** and moclobemide.

1. Amrein R, Güntert TW, Dingemanse J, Lorscheid T, Stabl M, Schmid-Burgk W. Interactions of moclobemide with concomitantly administered medication: evidence from pharmacological and clinical studies. *Psychopharmacology (Berl)* (1992) 106, S24–S31.

Digoxin + Montelukast

Montelukast does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study in 11 healthy subjects, montelukast 10 mg was given for 12 days with a single 500-microgram dose of digoxin on day 7. It was found that the pharmacokinetic profile of the digoxin was unchanged by montelukast.[1] No digoxin dose adjustments are needed if montelukast is used concurrently.

1. Depre M, Van Hecken A, Verbesselt R, Wynants K, De Lelepeire I, Freeman A, Holland S, Shahane A, Gertz B, De Schepper PJ. Effect of multiple doses of montelukast, a CysLT1 receptor agonist, on digoxin pharmacokinetics in healthy volunteers. *J Clin Pharmacol* (1999) 39, 941–4.

Digoxin + Moracizine

Moracizine does not significantly increase digoxin levels in patients with normal renal function. However, some adverse conduction effects have been seen.

Clinical evidence

Thirteen patients taking digoxin 125 to 250 micrograms daily had a non-significant rise in their serum digoxin levels of 10 to 15% when they were given moracizine 10 mg/kg daily in three divided doses for 2 weeks. Further, 9 patients who took digoxin and moracizine for one to 6 months had no significant changes in their serum digoxin levels.[1]

In a single-dose study in 9 healthy subjects, and in a study in patients receiving maintenance treatment with digoxin over a 13-day period, the pharmacokinetics of intravenous and oral digoxin were not affected by moracizine.[2,3] However, cardiac arrhythmias (AV junctional rhythm and heart block) were seen, which resolved when the moracizine was stopped.[3]

Mechanism

Not established. There does not appear to be a pharmacokinetic interaction between moracizine and digoxin. Concurrent use can cause a significant increase in the PR interval and QRS duration, which can result in AV block.[4]

Importance and management

Although no clinically important changes in digoxin levels appear to occur during the concurrent use of moracizine, the occurrence of arrhythmias in a few patients indicates that good monitoring is advisable. It has been pointed out that the additive effects of both drugs on intranodal and intraventricular conduction may be excessive in some patients with heart disease.[4] More study is needed.

Digoxin + Nateglinide or Repaglinide

The pharmacokinetics of nateglinide and digoxin are not altered by concurrent use. Repaglinide does not affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

(a) Nateglinide

A crossover study in 12 healthy subjects found that when a single 1-mg dose of digoxin was given with the first dose of nateglinide 120 mg three times daily for 2 days, there were no changes in the pharmacokinetics of either drug.[1]

(b) Repaglinide

A crossover, multiple-dose study in 14 healthy subjects found that repaglinide 2 mg three times daily before meals had no effect on the pharmacokinetics of digoxin 250 micrograms daily. Concurrent use was well tolerated.[2]

Digoxin + Nefazodone

Nefazodone causes a moderate increase in digoxin levels. Digoxin does not appear to affect the pharmacokinetics of nefazodone.

Clinical evidence, mechanism, importance and management

In a study, 18 healthy subjects were given digoxin 200 micrograms daily for 8 days, then nefazodone 200 mg twice daily for 8 days, and then both drugs together for 8 days. Nefazodone increased the AUC of digoxin by 15%, and increased the peak and trough plasma levels of digoxin by 29% and 27%, respectively. However, no clinically significant changes in ECG measurements occurred (PR, QRS and QT intervals), nor was the heart rate or any other vital sign altered. The pharmacokinetics of the nefazodone were unchanged.[1]

Evidence appears to be limited to this study, but as it was well conducted, an interaction is probably established. The increase in the AUC of digoxin is modest, and would not generally be expected to be clinically significant. This is supported by the finding of no change in adverse effects. No particular precautions would seem necessary on concurrent use.

Digoxin and related drugs + Neuromuscular blockers

Serious cardiac arrhythmias can develop in patients receiving digitalis glycosides who are given suxamethonium (succinylcholine) or pancuronium.

Clinical evidence

Eight out of 17 digitalised patients (anaesthetised with thiamylal and then maintained with nitrous oxide and oxygen) developed serious ventricular arrhythmias following the intravenous injection of **suxamethonium** (**succinylcholine**) 40 to 100 mg. Four out of the 8 patients reverted to their previous rhythm when they were given tubocurarine 15 to 30 mg, with one patient returning to a regular nodal rhythm from ventricular tachycardia.[1]

Of the other 9 patients, 3 had immediate and definite ST-T wave changes, and the remaining 6 had no demonstrable changes.[1] There are other reports of this interaction,[2-4] including one that describes sinus tachycardia and atrial flutter in 6 out of 18 patients taking digoxin after they were given **pancuronium**.[4]

Mechanism

Not understood. One possibility is that the suxamethonium (succinylcholine) may cause the rapid removal of potassium from the myocardial cells. Another idea is that it affects catecholamine-releasing cholinergic receptors.

Importance and management

Information regarding an interaction between the digitalis glycosides and the neuromuscular blockers is limited but the interaction with suxamethonium (succinylcholine) appears to be established. Suxamethonium should be used with great caution in patients taking digitalis glycosides. Similarly, caution would seem appropriate with pancuronium.

Digoxin and related drugs + NSAIDs

Indometacin can cause potentially toxic rises in digoxin levels particularly in neonates, while azapropazone, diclofenac, fenbufen and tiaprofenic acid raise levels to a lesser degree. Two studies found that ibuprofen raised serum digoxin levels, whereas another found no evidence of an interaction. Isoxicam, ketoprofen, lornoxicam, meloxicam, nimesulide, piroxicam, and rofecoxib do not appear to interact significantly with digoxin. In contrast, phenylbutazone appears to lower plasma digitalis glycoside levels.

Clinical evidence

A. Digitoxin

(a) Azapropazone

In 8 patients with arthritis, azapropazone 900 mg daily did not significantly alter the AUC of a single 500-microgram intravenous dose of digitoxin, but its mean half-life was increased by about 10%. Two of the patients had individual half-life increases of almost one-third.[1]

(b) Diclofenac

Digitoxin 100 micrograms had no effect on the plasma levels of diclofenac 50 mg twice daily in 8 subjects; digitoxin levels were not reported.[2]

(c) Phenylbutazone

In 6 patients, phenylbutazone 200 or 400 mg daily halved the plasma levels of digitoxin 100 micrograms daily, on two separate occasions. Digitoxin levels returned to their former values within roughly the same period of time after phenylbutazone was withdrawn.[3] A similar response has been described elsewhere in one patient.[4]

B. Digoxin

(a) Diclofenac

A study in 7 healthy subjects found that diclofenac 100 mg daily for 10 days increased the serum levels of digoxin by 29%.[5] Another study in 6 healthy subjects similarly found that diclofenac 50 mg three times daily raised the serum digoxin levels by about one-third.[6]

(b) Etoricoxib

A study in healthy subjects given digoxin found that the addition of etoricoxib 120 mg daily for 10 days did not alter the steady-state AUC of digoxin or its renal elimination, but the maximum serum digoxin levels were increased by about 33%.[7]

(c) Fenbufen

Fenbufen 900 mg daily was found to cause an insignificant rise in the serum levels of digoxin.[8]

(d) Ibuprofen

The serum digoxin levels of 12 patients were reported to have risen by about 60% after they were given at least 1.6 g of ibuprofen daily for a week. However, after a month the digoxin levels had returned to their former amount.[9] These findings may be unreliable because half of the patients were not satisfactorily compliant with treatment. Another study found that ibuprofen 1.2 g daily for 10 days raised the serum digoxin levels of 9 healthy subjects by 25%.[5] Yet another study found that ibuprofen 600 mg three times daily for 10 days had no effect on steady-state serum digoxin levels of 8 patients.[10]

(e) Indometacin

1. Neonates. A study in 11 premature neonates (gestational age 25 to 33 weeks) given digoxin found that when they were given indometacin (mean total dose of 320 micrograms/kg over 12 to 24 hours) for patent ductus arteriosus, their mean serum digoxin levels rose on average by 40%. The digoxin was stopped in 5 of them because serum levels were potentially toxic.[11] This confirms the observation of digitalis toxicity in 3 similarly treated premature neonates,[12] and of toxic serum digoxin levels in another neonate.[13] A further report describes very high digoxin levels (8.2 nanograms/mL) without symptoms of toxicity in a full-term neonate given indometacin.[14]

2. Adults. Indometacin 50 mg three times daily for 10 days increased steady-state digoxin levels of 10 patients by about 40% (from 0.57 to 0.8 nanograms/mL), with a range of 0 to 100%.[10] Indometacin 150 mg daily for 10 days increased the serum digoxin levels of 9 healthy subjects by 25%.[5] In yet another study, a 60% increase in digoxin levels was seen with indometacin 150 mg daily.[15] This contrasts with the results of single-dose studies in two groups of 6 healthy adult subjects[16,17] who were given a 4-hour infusion of digoxin. Both studies suggested that no interaction occurs with indometacin.

(f) Isoxicam

Isoxicam 200 mg daily did not affect the steady-state plasma levels of 12 healthy subjects taking **beta-acetyldigoxin**.[18] This confirms the findings of a previous study.[19]

(g) Ketoprofen

Ketoprofen 50 mg four times daily for 4 days had no effect on the serum digoxin levels of 12 patients.[20]

(h) Lornoxicam

In 12 healthy subjects, the concurrent use of lornoxicam 4 mg twice daily for 14 days and digoxin 250 micrograms daily had only a small effect on the pharmacokinetics of each drug. The apparent clearance of the digoxin was decreased by 14% while the maximum serum level of the lornoxicam was decreased by 21% and its elimination half-life increased by 36%.[21]

(i) Meloxicam

In 12 healthy subjects meloxicam 15 mg daily for 8 days had no effect on the pharmacokinetics of digoxin (given as **beta-acetyldigoxin**).[22]

(j) Nimesulide

Nimesulide 100 mg twice daily for 7 days had little effect on the pharmacokinetics of digoxin 250 micrograms daily in 9 patients with mild heart failure. No major change in their clinical condition occurred.[23]

(k) Phenylbutazone

Six healthy subjects had an a decrease of about 20% in their serum digoxin levels while taking phenylbutazone 200 mg three times daily for 4 days.[6] In contrast, one study found no alteration in the levels of digoxin when it was given with phenylbutazone 600 mg daily.[15]

(l) Piroxicam

In 10 patients taking digoxin for mild heart failure, piroxicam 10 or 20 mg daily for 15 days had no effect on the steady-state digoxin levels, nor were consistent effects seen on the pharmacokinetics of digoxin.[24] Piroxicam 20 mg daily for 10 days was found to have no effect on serum digoxin levels in 6 healthy subjects.[5]

(m) Rofecoxib

Rofecoxib 75 mg daily did not cause any significant changes in the plasma pharmacokinetics or renal elimination of a single 500-microgram dose of digoxin elixir.[25]

(n) Tiaprofenic acid

Tiaprofenic acid 200 mg three times daily for 10 days caused a non-significant 15% rise (from 0.97 to 1.12 nanograms/mL), in the serum digoxin levels of 12 healthy subjects.[26]

Mechanism

The reasons for the altered digoxin pharmacokinetics in some of the studies are not clear. However, in the studies in neonates, the elevated digoxin levels were clearly related to an indometacin-induced deterioration in renal function.[11,13,14] It should be noted that all NSAIDs have the potential to cause renal impairment.

It is suggested that phenylbutazone lowers digitoxin levels by increasing its rate of metabolism by the liver.[3]

Importance and management

The interaction between digoxin and **indometacin** seems established in neonates, but documentation is limited. It has been suggested that the digoxin dose should be halved if indometacin is given to premature or full-term infants and the serum digoxin levels and urinary output monitored. Also be alert for moderate increases in serum digoxin levels in adults if indometacin is given. In adults it may be sufficient to monitor pulse rate (for bradycardia) and take digoxin levels if an interaction is suspected.

The interaction between digoxin and **diclofenac** is less well established and its clinical importance is somewhat uncertain as the rises in digoxin levels were mostly modest. It would be prudent to monitor concurrent use (e.g. for bradycardia) and monitor digoxin levels as necessary. Adjust the digoxin dose accordingly.

The importance of the interaction with azapropazone, etoricoxib, fenbufen and tiaprofenic acid is not known. In most cases changes to doses are unlikely to be necessary, but remain aware of the potential for an interaction. No special precautions would appear to be necessary with isoxicam, ketoprofen, meloxicam, piroxicam, and rofecoxib. More study is needed in most cases, but especially with ibuprofen, where the evidence is conflicting (although note that the one study reporting a significant interaction was poor).

The interaction with **phenylbutazone** and digitoxin appears to be in direct contrast to that with the other NSAIDs, but documentation is limited. However, phenylbutazone has, unlike many of the other NSAIDs, been found to have clinically relevant effects on hepatic enzymes. The dose of digitoxin may possibly need to be increased to avoid under-digitalisation if phenylbutazone is added to established treatment. Monitor concurrent use well.

Digoxin + Orlistat

Orlistat does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, orlistat 120 mg three times daily for 6 days was found to have no effect on the pharmacokinetics of a single 400-microgram oral dose of digoxin (in soft gelatin capsules).[1] This suggests that an approximate 30% reduction in dietary fat absorption induced by orlistat should not change the efficacy of digoxin and that no special precautions will be needed in patients who are given both drugs.

1. Melia AT, Zhi J, Koss-Twardy SG, Min BH, Smith BL, Freundlich NL, Arora S, Passe SM. The influence of reduced dietary fat absorption induced by orlistat on the pharmacokinetics of digoxin in healthy volunteers. *J Clin Pharmacol* (1995) 35, 840–3.

Digoxin + Penicillamine

Digoxin levels can be reduced by penicillamine.

Clinical evidence

In 10 patients, penicillamine 1 g daily taken 2 hours after an oral dose of digoxin, reduced the serum digoxin levels measured 2, 4 and 6 hours later, by 13%, 20% and 39%, respectively. In 10 other patients similarly treated but given digoxin intravenously, the serum digoxin levels measured 4 and 6 hours later were reduced by 23% and 64%, respectively.[1] The same authors have also reported this interaction in children.[2]

Information seems to be limited to the reports cited, and the reason for its occurrence is unknown. Patients taking digoxin should be checked for signs of under-digitalisation if penicillamine is added.

Digoxin and related drugs + Pinaverium

Digoxin levels are not affected by pinaverium in patients taking either beta-acetyldigoxin or metildigoxin.

Clinical evidence, mechanism, importance and management

A study in 25 patients, taking either **beta-acetyldigoxin** or **metildigoxin** for congestive heart failure, found that pinaverium 50 mg three times daily for 12 days had no significant effect on their plasma digoxin levels.[1] Two other studies in patients taking either digoxin 125 to 250 micrograms daily or **digitoxin** 100 micrograms, daily or every other day, found that pinaverium bromide 50 mg three times daily did not affect cardiac glycoside blood levels.[2] No dose adjustments of the digitalis glycoside seem necessary on concurrent use.

Digoxin and related drugs + Pioglitazone or Rosiglitazone

Pioglitazone and rosiglitazone do not affect the pharmacokinetics of digoxin, but they may adversely affect cardiac function in patients with cardiac failure.

Clinical evidence

(a) Pioglitazone

In healthy subjects, pioglitazone 45 mg daily did not alter the steady-state pharmacokinetics of digoxin 250 micrograms daily.[1,2]

(b) Rosiglitazone

A study in healthy subjects found that rosiglitazone 8 mg daily for 14 days had no effect on the steady-state pharmacokinetics of digoxin 375 micrograms daily. Concurrent use was safe and well tolerated (aside from one patient who withdrew because of a rash).[3]

Mechanism

Pioglitazone and rosiglitazone can cause fluid retention, which may cause or exacerbate heart failure.

Importance and management

No pharmacokinetic interaction occurs. However, the US manufacturers advise caution with the use of pioglitazone or rosiglitazone in those with a history of heart failure because it may cause fluid retention, which could lead to a deterioration in cardiac function.[1,4] They state that starting these drugs in those with severe heart failure (NYHA class III or IV) is contraindicated, whereas the UK manufacturers contraindicate use in heart failure (NYHA class I to IV).[5,6] If digoxin or any other **digitalis glycoside** is being used to treat cardiac failure, the use of pioglitazone or rosiglitazone would not therefore be recommended. This is not a drug-drug interaction but a drug-disease interaction.

6. Avandia (Rosiglitazone maleate). GlaxoSmithKline UK. UK Summary of product characteristics, May 2009.

Digoxin + Probenecid

Probenecid has no clinically significant effect on digoxin levels.

Clinical evidence, mechanism, importance and management

A study in 2 healthy subjects taking digoxin 250 micrograms daily found that after taking *ColBenemid* (probenecid 500 mg with colchicine 500 micrograms) twice daily for 3 days, their plasma digoxin levels were slightly but not significantly raised (from 0.67 to 0.7 nanograms/mL, and from 0.6 to 0.67 nanograms/mL, respectively).[1] Another study in 6 healthy subjects found that probenecid 2 g daily for 8 days had no significant effect on the pharmacokinetics of digoxin.[2] No special precautions would seem necessary during concurrent use.

2. Hedman A, Angelin B, Arvidsson A, Dahlqvist R. No effect of probenecid on the renal and biliary clearances of digoxin in man. *Br J Clin Pharmacol* (1991) 32, 63–7.

Digoxin + Propafenone

Propafenone can increase digoxin levels by 30 to 90%, or even more in children.

Clinical evidence

In 5 patients, propafenone (increasing over 6 days to 300 mg every 8 hours) increased the mean steady-state serum levels of digoxin 125 to 250 micrograms daily by 83%. Three patients continued to take both drugs for 6 months, at which point the digoxin levels were 63% higher. No digitalis toxicity was seen.[1] In another study, propafenone 600 mg daily in divided doses increased the steady-state serum digoxin levels of 10 patients by 90% (from 0.97 to 1.54 nanograms/mL), and two of them developed symptoms of toxicity (nausea, vomiting).[2] An even greater increase was seen in 3 children, who had rises in their serum digoxin levels of 112 to 254% over 3 to 24 days when given propafenone 250 to 500 mg/m^2 daily.[3] The mean AUC of digoxin increased by 14% in 27 patients receiving propafenone 10 mg/kg daily in divided doses. However, there was great inter-individual variability, with 22 patients having an increase in AUC, and 5 a decrease in AUC. One patient experienced digoxin toxicity resulting in fatal ventricular fibrillation.[4]

Propafenone 450 mg daily increased the mean steady-state plasma digoxin levels of 12 healthy subjects by about 35% (from 0.58 to 0.78 nanograms/mL), and the cardiac effects were increased accordingly.[5] In a study in 6 subjects[6] given a single 1-mg intravenous dose of digoxin, propafenone 150 or 300 mg every 8 hours increased the AUC of digoxin by 28% and decreased the total clearance of digoxin by 22%. A similar study with oral digoxin found a 25% increase in the AUC of digoxin when healthy subjects were given propafenone.[7]

Mechanism

Not understood. One suggestion is that propafenone increases the bioavailability of the digoxin.[7] Another is that the volume of distribution and non-renal clearance of digoxin are changed by the propafenone.[6] Conversely, others reported that propafenone decreased the renal clearance of digoxin.[2,5] There is certainly some *in vitro* evidence that propafenone and its metabolite inhibit P-glycoprotein, which is concerned with digoxin secretion by the renal tubular cells.[8,9]

Importance and management

A very well established interaction of clinical importance. Monitor the effects of concurrent use and reduce the digoxin dose appropriately in order to avoid toxicity. Most patients appear to be affected and dose reductions in the range 15 to 70% were found necessary in one of the studies cited.[2] The data available suggest that the extent of the rise may possibly depend on the propafenone serum concentration rather than on its dose.[6,10]

Digoxin + Propantheline

Digoxin levels may be increased by at least one-third if propantheline is given with slow-dissolving forms of digoxin tablets. No clinically significant interaction is likely with digoxin given as a liquid or in soft-gelatin capsules or in the form of fast-dissolving tablets.

Clinical evidence

The serum digoxin levels of 9 out of 13 patients rose by 30% (from 1.02 to 1.33 nanograms/mL), when they took a slow-dissolving formulation of digoxin tablets (*Orion*) with propantheline 15 mg three times daily for 10 days. The serum levels stayed the same in 3 patients and fell slightly in one. An associated study in 4 healthy subjects given digoxin in liquid form found that serum digoxin levels were unaffected by propantheline.[1]

Another study by the same workers found that propantheline increased the digoxin serum levels of a slow-dissolving tablet formulation (*Orion*) by 40%, but had no effect on serum digoxin levels with a fast-dissolving tablet formulation (*Lanoxin*).[2] In a further study, propantheline increased the AUC of digoxin from *Lanoxin* tablets by 24%, compared with a non-significant increase of 13% with digoxin in the form of a solution in a capsule (*Lanoxicaps*).[3]

Mechanism

Propantheline is an antimuscarinic, which reduces gut motility. This allows the slow-dissolving formulations of digoxin more time to pass into solution so that more is available for absorption.

Importance and management

The interaction between digoxin and propantheline appears to be established, but it is only of importance if slow-dissolving digoxin formulations are used. No interaction is likely with liquid or liquid-filled capsule forms of digoxin. With slow-dissolving forms of digoxin tablets it may be necessary to reduce the digoxin dose.

Digoxin + Prostaglandins

Iloprost does not significantly alter digoxin pharmacokinetics. In one study epoprostenol caused a small decrease in digoxin clearance in the short-term.

Clinical evidence, mechanism, importance and management

In a study, 12 patients taking digoxin 250 micrograms daily were given a 6-hour intravenous infusion of **iloprost** 2 nanograms/kg per minute over a period of 20 days. The mean time to maximum digoxin levels was delayed by an hour, but overall the pharmacokinetics of the digoxin were unchanged.[1,2] No special precautions would seem to be necessary on concurrent use.

In 14 patients with congestive heart failure, the clearance of digoxin was reduced by an estimated 15% by **epoprostenol** given for 3 days, but this effect was no longer apparent by the end of 12 weeks of concurrent use. The clinical relevance of this awaits evaluation but it seems unlikely to be important. However, the authors of the report suggest that the possible short-term changes in patients with high trough-plasma digoxin levels and those prone to digoxin toxicity should be borne in mind when using the combination.[3]

Digoxin + Protease inhibitors

A woman had elevated digoxin levels and signs of toxicity after she was given ritonavir. Pharmacokinetic studies have shown that ritonavir and ritonavir-boosted saquinavir cause modest to marked increases in single-dose digoxin levels.

Clinical evidence

(a) Ritonavir

A 61-year-old HIV-positive woman taking lamivudine, indinavir, stavudine, pentamidine, with warfarin and digoxin 250 micrograms daily for atrial fibrillation, presented with increasing nausea and vomiting 3 days after starting to take ritonavir 200 mg twice daily. Digoxin levels about 5 hours and 27 hours after her last dose were 5.6 nanograms/mL and 2.1 nanograms/mL, respectively.[1]

A study in 12 healthy subjects found that ritonavir 300 mg twice daily for 11 days significantly increased the AUC and volume of distribution of a single 500-microgram intravenous dose of digoxin by 86% and 77%, respectively. Non-renal and renal digoxin clearance were decreased by 48% and 35%, respectively, and its half-life increased by 156%.[2] Another study found that ritonavir 200 mg twice daily for 15 days increased the AUC of a single 400-microgram oral dose of digoxin by 22%, with 9 of 12 subjects having an increase. Non-renal clearance, but not renal clearance, was reduced.[3]

(b) Saquinavir

In a crossover study in 16 healthy subjects, ritonavir-boosted saquinavir 100/1000 mg twice daily for 16 days increased the AUC and maximum levels of a single 500-microgram dose of digoxin by 49% and 27%, respectively.[4,5]

Mechanism

Raised digoxin levels are possibly due to inhibition of the P-glycoprotein-mediated renal transport of digoxin by ritonavir and saquinavir.[1-4]

Importance and management

A pharmacokinetic interaction between ritonavir and digoxin would appear to be established, although its extent is uncertain. The study with intravenous digoxin found a marked effect, whereas the study with oral digoxin found a much smaller effect. Nevertheless, given the case report

and the study with ritonavir-boosted saquinavir, it would seem prudent to closely monitor patients taking digoxin when ritonavir and/or saquinavir[4-6] is started or stopped, being alert for the need to adjust the digoxin dose. There do not appear to be any reports or studies of the interaction of digoxin with other protease inhibitors; however, most protease inhibitors are inhibitors and/or substrates for P-glycoprotein, so it would seem likely that they may all interact to a greater or lesser extent.

Digoxin and related drugs + Proton pump inhibitors

A small rise in digoxin levels may occur with lansoprazole, omeprazole, pantoprazole or rabeprazole, but this is not thought to be clinically significant. One case of digoxin toxicity has been reported with omeprazole.

Clinical evidence

(a) Omeprazole

In a study in healthy subjects, omeprazole 20 mg daily for 11 days caused only minor changes in the disposition of a single 1-mg oral dose of digoxin. On average the AUC was increased by 10%.[1] However, a 65-year-old woman had signs of digoxin toxicity 3 months after starting to take omeprazole 20 mg daily. She was found to have a digoxin level of 3.9 nanograms/mL (previous level 1.1 nanograms/mL) and ECG changes, which resolved after the administration of digoxin immune Fab. No changes in renal function were noted in this patient.[2]

(b) Pantoprazole

Beta-acetyldigoxin 200 micrograms twice daily was given to 18 healthy subjects, with and without pantoprazole 40 mg daily, for 5 days. The pantoprazole caused a 10% rise in the digoxin AUC and a 9% rise in the maximum digoxin serum levels, but both were considered to be clinically irrelevant. No changes in the digoxin-induced height reduction in the T-wave on the ECG occurred.[3]

(c) Rabeprazole

A preliminary report, giving few details, states that rabeprazole increased the minimum levels of digoxin by about 20%, and also increased its AUC and maximum level.[4] A study in 47 patients regularly taking digoxin and either **lansoprazole** or omeprazole found that changing the proton pump inhibitor to an equivalent dose of rabeprazole did not significantly change the mean serum digoxin level, although 12 of the patients had increases of more than 15%.[5] The US manufacturer of rabeprazole states it increases the AUC and maximum level of digoxin by 19%, and 29%, respectively.[6] However, these changes are thought to be within the normal variations of digoxin levels and so are not considered clinically significant.[7]

Mechanism

The increase in digoxin levels with omeprazole may be the result of higher gastric pH which results in less digoxin hydrolysis and an increase in digoxin absorption.[8] The manufacturers of lansoprazole predict that it may have similar effects.[9] Non-selective digoxin assay methods may not detect an interaction, whereas selective HPLC assay methods and ECG studies provide evidence that the bioavailability of digoxin may be increased by omeprazole.[8] An *in vitro* study found that omeprazole, pantoprazole and lansoprazole inhibit the P-glycoprotein-mediated intestinal transport of digoxin.[10]

Importance and management

Although some studies suggest small changes in digoxin pharmacokinetics may occur these changes are usually small and unlikely to be clinically significant. No special precautions would therefore seem to be necessary if proton pump inhibitors and digoxin are given concurrently. However, the UK manufacturer of lansoprazole recommends that plasma levels of digoxin should be monitored and dose adjustments made if necessary when starting or stopping lansoprazole.[11]

Digoxin and related drugs + Quinidine

In most patients the serum levels of digoxin are approximately doubled within five days of starting quinidine. Digitoxin levels are also increased but to a lesser extent and the interaction takes a longer period of time to develop.

Clinical evidence

(a) Digitoxin

Quinidine 750 mg daily increased the steady-state plasma digitoxin levels of 8 healthy subjects by 45% (from 13.6 to 19.7 nanograms/mL), over 32 days.[1] Another study found a 31% increase in serum digitoxin levels over 10 days,[2] whereas yet another found a 115% increase in plasma levels after 70 days of treatment with 360 mg quinidine three times daily.[3] A study in 5 healthy subjects found that quinidine reduced the total body clearance of digitoxin by 63%, resulting in raised serum digitoxin levels.[4]

(b) Digoxin

The observation that quinidine appeared to increase serum digoxin levels prompted a retrospective study of patient records, which revealed that 25 out of 27 patients taking digoxin had a rise in their serum digoxin levels from 1.4 nanograms/mL to 3.2 nanograms/mL when given quinidine. Of the patients who had a rise,16 developed typical signs of digoxin toxicity (nausea, vomiting, anorexia), which resolved in 10 of them when the digoxin dose was reduced or withdrawn, and in 5 when the quinidine was withdrawn.[5]

This is one of the first reports published in 1978 (two other groups independently reported it at a similar time[6,7]) that clearly describes this interaction, although hints of its existence can be found in papers published over the previous 50 years. Since then large numbers of research reports, both retrospective and prospective, and case studies have confirmed and established the incidence and magnitude of this interaction. It occurs in over 90% of patients and, on average, there is a 100% increase in serum digoxin levels, although there are pronounced inter-individual differences and the increase is somewhat dependent on the quinidine dose. There are numerous reports and reviews of this interaction, only a selection of which are listed here. Two reviews published in 1982 and 1983 contain valuable bibliographies.[8,9]

Mechanism

Quinidine reduces the renal excretion of digoxin by 40 to 50%, and it also appears to have some effects on non-renal clearance, which includes a reduction in digoxin excretion in the bile.[10] There is also evidence that

increases in the rate and extent of absorption of digoxin from the gut occur.[11] More recent studies show that the mechanism behind these effects on absorption and renal excretion is likely to be P-glycoprotein inhibition by quinidine.[12-14] Digoxin also appears to cause a small reduction in the renal clearance of quinidine.[15] Quinidine appears to increase digitoxin serum levels by reducing its non-renal clearance.

Importance and management

The interaction between digoxin and quinidine is very well-documented, well-established and of definite clinical importance. As serum digoxin levels are usually roughly doubled (up to fivefold increases have been seen[8]) and over 90% of patients are affected, digitalis toxicity will develop unless the dose of digoxin is reduced (approximately halved).[5,8,16,17] A suggested rule-of-thumb is that if serum digoxin levels are no greater than 0.9 nanograms/mL and potassium levels are within the reference range then the addition of quinidine is unlikely to cause toxic digoxin levels, whereas with levels of 1 nanogram/mL or more, toxic concentrations may develop.[18] Monitor the effects and readjust the dose as necessary. Significant effects occur within a day of taking the quinidine and reach a maximum after about 3 to 6 days (quicker or slower in some patients), but digoxin levels will only stabilise when the quinidine has reached steady-state and that depends on whether a loading dose of quinidine is given. The effects are to some extent dose-related but the correlation is not good: less than 400 to 500 mg of quinidine daily has minimal effects, and increasing doses up to 1.2 g has greater effects.[16,19] About 5 days are needed after withdrawing the quinidine before serum digoxin levels fall to their former levels. It has been recommended that patients with chronic renal failure should have their digoxin dose reduced by as much as two-thirds.[20-22] An appropriate upward readjustment will be necessary if the quinidine is subsequently withdrawn.

Far less is known about the interaction between digitoxin and quinidine but similar precautions should be taken. It develops much more slowly.

Digoxin + Quinine

The digoxin levels of some but not all patients may rise by more than 60% if they are given quinine, and there is a report of digoxin toxicity in an elderly patient during concurrent use.

Clinical evidence

After taking quinine 300 mg four times daily for a day the steady-state digoxin levels of 4 subjects taking digoxin 250 micrograms daily rose by 63%, from 0.49 to 0.8 nanograms/mL. After taking the quinine for a further 3 days the digoxin levels rose a further 11% (to 0.86 nanograms/mL). Digoxin renal clearance fell by 20%.[1]

Quinine sulfate 250 mg daily for 7 days increased the mean serum digoxin levels of 7 healthy subjects by 25%, from 0.64 to 0.8 nanograms/mL. When quinine sulfate 250 mg was given three times daily there was a further 8% rise. Considerable individual differences were seen; one subject had a 92% rise.[2] In contrast, 17 patients given quinine 750 mg daily had only a small and statistically insignificant rise in mean serum digoxin levels, from 0.8 to 0.91 nanograms/mL. Serum levels were virtually unaltered in 11 patients, decreased in two and markedly increased (amount not stated) in four.[3] Another study found that quinine reduced the total clearance of digoxin by 26%.[4]

An 76-year-old man with hypertension and atrial fibrillation taking digoxin 500 micrograms daily and quinine sulfate 750 mg daily as well as aspirin, candesartan and amlodipine was admitted after an episode of fainting, and an ECG detected AV block, a prolonged QTc interval of 570 milliseconds and torsade de pointes. Digoxin levels were found to be 5 nanograms/mL. The authors attributed the effect to digoxin toxicity caused by the presence of quinine.[5]

Mechanism

Not fully understood. A reduction in non-renal clearance is apparently largely responsible for the rise in serum digoxin levels with quinine.[2,4,6] This is possibly due to changes in digoxin metabolism or in its biliary excretion.[4,6]

Importance and management

An established interaction of clinical importance but only moderately documented. Monitor the effects of concurrent use (e.g. for bradycardia) and reduce the digoxin dose where necessary. Some patients may have a substantial increase in serum digoxin levels whereas others will have only a small or moderate rise. There appears to be only one case report of digoxin toxicity arising from this interaction.

Digoxin and related drugs + Quinolones

Levofloxacin, gemifloxacin, moxifloxacin and sparfloxacin do not affect the pharmacokinetics of digoxin. Similarly moxifloxacin does not interact with beta-acetyldigoxin. Gatifloxacin may cause small increases in digoxin levels, which are probably not clinically significant. The effects of garenoxacin are unclear.

Clinical evidence

(a) Garenoxacin

In a study designed to look at the effects of garenoxacin on gut flora, 16 healthy subjects were given digoxin 250 micrograms every 6 hours on day one, then 250 micrograms daily to day 14, with garenoxacin 600 mg daily on days 8 to 14. Garenoxacin did not decrease (but may actually increase) the numbers of *E. lentum* in faeces (see 'Digoxin and related drugs + Macrolides', p.1103, for an explanation of the possible significance of these findings). Thus an interaction due to the effect of garenoxacin on intestinal microflora is unlikely.[1]

(b) Gatifloxacin

The vital signs of 12 healthy subjects given gatifloxacin 400 mg daily for 7 days while taking digoxin 250 micrograms daily were not altered. The

AUC and steady-state levels of digoxin were increased by 19% and 12% respectively. Dose adjustments were not considered necessary.[2]

(c) Gemifloxacin

No clinically relevant pharmacokinetic changes were seen in a study in 14 healthy elderly subjects given gemifloxacin 320 mg daily for 7 days while taking digoxin (*Lenoxin*) 250 micrograms daily. No clinically important changes in vital signs or ECGs were found.[3]

(d) Levofloxacin

The pharmacokinetics of a single 400-microgram dose of digoxin (*Lanoxicaps*) were unchanged when 12 healthy subjects were given levofloxacin 500 mg twice daily for 6 days.[4]

(e) Moxifloxacin

In 14 healthy subjects, moxifloxacin 400 mg daily for 14 days did not cause any clinically relevant changes in the steady-state pharmacokinetics of digoxin 250 micrograms daily.[5] No pharmacokinetic changes were seen in another study in 12 healthy subjects given a single 600-microgram dose of **beta-acetyldigoxin** with moxifloxacin 400 mg daily for 2 days.[6]

(f) Sparfloxacin

In 24 healthy subjects, sparfloxacin, 400 mg as a loading dose, followed by 200 mg daily for 9 days did not affect the pharmacokinetics of digoxin (*Lanoxicaps*) 300 micrograms daily.[7]

Mechanism

Up to 10% of patients receiving oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be due to gut flora,[8] in particular *Eubacterium lentum*, which is anaerobic and Gram positive. However, there is some doubt about this as a probable mechanism and, despite *in vitro* susceptibility of *E. lentum* to a range of antibacterials including some quinolones there is currently no information to suggest that quinolones inhibit the gut flora-mediated metabolism of digoxin.[9] For further information on the possible significance of *E. lentum*, see *Mechanism* under 'Digoxin and related drugs + Macrolides', p.1103.

Importance and management

There appears to be no clinically significant interaction between digoxin and quinolones. Information about other digitalis glycosides and quinolones generally seems to be lacking. Bearing in mind their extensive use, this silence in the literature would suggest that no problems normally arise.

Digoxin and related drugs + Rauwolfia alkaloids

The concurrent use of digitalis glycosides and rauwolfia alkaloids is usually uneventful, but the incidence of arrhythmias appears to be increased, particularly in those with atrial fibrillation. Excessive bradycardia and syncope have also been described.

Clinical evidence

Three patients taking digoxin and either **reserpine** or whole root ***Rauwolfia serpentina*** developed arrhythmias, namely atrial tachycardia with 4:1 Wenckebach irregular block, ventricular bigeminy and tachycardia, and atrial fibrillation. A large number of other patients received both drugs without problems.[1]

The incidence of premature ventricular systoles was roughly doubled in patients taking digoxin and **rauwolfia** compared with a similar group taking **rauwolfia** alone.[2] **Reserpine** reduced the tolerated dose of **acetylstrophanthidin** in 15 patients with congestive heart failure; 8 out of 9 patients with atrial fibrillation developed ECG abnormalities, including complete heart block and ventricular ectopics, during acute digitalisation following **reserpine** use, compared with only one of 9 patients not taking **reserpine**.[3]

A case report describes a man taking digoxin 250 micrograms and 375 micrograms on alternate days and **reserpine** 25 micrograms daily, who developed sinus bradycardia and carotid sinus supersensitivity. He was hospitalised because of syncope, which resolved when the **reserpine** was withdrawn.[4]

Mechanism

Not understood. A possible explanation is that because the rauwolfia alkaloids deplete the neurotransmitter from the sympathetic nerve supply to the heart, the parasympathetic vagal supply (i.e. heart slowing) has full rein. Digitalis also reduces heart rate which in the presence of the rauwolfia becomes excessive. In this situation the rate could become so slow that ectopic foci, which would normally be swamped by a faster, more normal beat, begin to fire, leading to the development of arrhythmias. Syncope could also result from the combination of bradycardia and the hypotensive effects of reserpine.

Importance and management

Although the evidence suggests that not all patients taking digitalis glycosides and a rauwolfia alkaloid develop an interaction, some caution is advisable. One group of authors, despite having described the adverse reactions cited above,[1] conclude that time has proven the safety of the combination. However, they warn that arrhythmias must be anticipated. Particular risk of arrhythmias seems to occur in patients with atrial fibrillation, and in digitalised patients given reserpine parenterally, because of the sudden release of catecholamines that takes place.[4]

Digoxin and related drugs + Rifampicin (Rifampin)

Digitoxin levels can be halved by rifampicin. Digoxin levels are modestly reduced by rifampicin.

Clinical evidence

(a) Digitoxin

A comparative study in 21 patients with tuberculosis and 19 healthy subjects taking digitoxin 100 micrograms daily found that the serum digitoxin levels of the patients taking rifampicin were about half of the levels in healthy subjects not taking rifampicin (18.4 nanograms/mL compared with 39.1 nanograms/mL).[1] The half-life of digitoxin was reduced from 8.2 days to 4.5 days by the rifampicin. There are case reports confirming that rifampicin can markedly reduce serum digitoxin levels.[2,3]

(b) Digoxin

A woman, hospitalised for endocarditis, taking digoxin 250 to 375 micrograms daily, furosemide, aspirin, isosorbide dinitrate and potassium chloride, had a marked fall of about 80% in her serum digoxin level when she was given rifampicin 600 mg daily. The serum digoxin returned to its former level over the 2 weeks following rifampicin withdrawal.[4] She had only moderate renal impairment (serum creatinine 221 micromol/L).

Another report describes 2 patients undergoing renal dialysis whose digoxin dose needed to be doubled while they were taking rifampicin, and similarly reduced when the rifampicin was withdrawn.[5] This confirms an earlier report.[6]

A study in 8 healthy subjects found that the AUC and maximum plasma levels of a single 1-mg oral dose of digoxin were reduced by 30% and 52%, respectively, by rifampicin 600 mg daily for 10 days.[7] In two further studies rifampicin 300 mg twice daily for 7 days reduced the AUC of a single oral dose of digoxin by 16%, and reduced its maximum levels by about 25%.[8,9] Note that these studies were designed to investigate the interaction of other drugs, and rifampicin was being used as a positive control.

A 15% reduction in the AUC and maximum plasma levels of digoxin was seen when a single 1-mg intravenous dose of digoxin was given after pre-treatment with rifampicin 600 mg daily for 10 days.[7] Similarly, a study in 8 healthy subjects who were given a single 1-mg intravenous dose of digoxin after 14 days of treatment with rifampicin 600 mg daily found an increased excretion of digoxin into the bile, and a 27% reduction in the AUC of digoxin.[10]

There is a report of rifampicin 600 mg daily being used to increase the metabolism of digoxin (as well as propafenone and warfarin) in a case of a multiple drug overdose in a 16-year-old girl. Two hours after plasma exchange, the serum digoxin level was 3.45 nanograms/mL and this had fallen by 50% 26 hours after starting rifampicin. The usual digoxin half-life is reported to be 36 to 48 hours.[11]

Mechanism

The interaction between digitoxin and rifampicin is almost certainly due to the increase in digitoxin metabolism caused by rifampicin, which is a potent enzyme inducer.[1] Digoxin is largely excreted unchanged in the urine and the interaction with rifampicin appears to be mainly due to induction of P-glycoprotein, resulting in reduced digoxin absorption from the intestine,[7,10] and increased biliary excretion.[10]

Importance and management

The interaction between digitoxin and rifampicin is established and clinically important. Under-digitalisation may occur unless the digitoxin dose is increased appropriately. Good monitoring is obviously advisable.

The pharmacokinetic interaction with digoxin is also established, but rifampicin causes only a minor to modest reduction in digoxin levels, and the few case reports suggest that these changes are generally not clinically relevant. However, it would be prudent to monitor the concurrent use of these drugs, being alert for the need to increase the digoxin dose. It may be that renal impairment increases the extent of this interaction, as several of the cases cited involved patients with some degree of renal impairment.

There does not seem to be any information regarding the other rifamycins, **rifabutin** (a weak enzyme inducer) and **rifapentine** (a moderate enzyme inducer). However, the UK manufacturers and the CSM in the UK warn that rifabutin may possibly reduce the effects of a number of drugs, including digitalis (but not digoxin).[12,13]

Digoxin + Ropinirole

Ropinirole does not affect the pharmacokinetics of digoxin to a clinically significant extent.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 patients with Parkinson's disease were given ropinirole (initially 250 micrograms increasing to 2 mg three times daily) in addition to their usual treatment with digoxin 125 or 250 micrograms daily. Although ropinirole decreased the AUC of digoxin by 10%, and decreased its maximum plasma concentration by 25%, the digoxin minimum plasma concentration was not significantly altered. The authors therefore reasonably concluded that no digoxin dose adjustment would be needed on concurrent use.[1]

1. Taylor A, Beerahee A, Citerone D, Davy M, Fitzpatrick K, Lopez-Gil A, Stocchi F. The effect of steady-state ropinirole on plasma concentrations of digoxin in patients with Parkinson's disease. *Br J Clin Pharmacol* (1999) 47, 219–22.

Digoxin + Sevelamer

The pharmacokinetics of a single dose of digoxin were not affected by sevelamer in one study.

Clinical evidence, mechanism, importance and management

In a randomised study a single 1-mg oral dose of digoxin was given with or without sevelamer 2.4 g followed by a standard breakfast. Five further doses of sevelamer were given immediately before subsequent meals over the following 2 days. During this time, the pharmacokinetic profile of digoxin was not altered.[1]

Sevelamer is a non-absorbed phosphate-binding polymer with bile-acid binding properties, but it appears that it does not bind with digoxin. Ideally this finding requires confirmation in long-term studies, but the available evidence suggests that a clinically significant interaction with sevelamer is unlikely.

1. Burke S, Amin N, Incerti C, Plone M, Watson N. Sevelamer hydrochloride (Renagel®), a non-absorbed phosphate-binding polymer, does not interfere with digoxin or warfarin pharmacokinetics. *J Clin Pharmacol* (2001) 41, 193–8.

Digoxin + SSRIs

Citalopram, fluvoxamine, paroxetine, and sertraline appear not to affect the pharmacokinetics of digoxin. However, one case-control study found a small increased risk of digoxin toxicity after starting sertraline, paroxetine, fluoxetine or fluvoxamine, and two isolated reports describe increased serum digoxin levels attributed to the use of fluoxetine or paroxetine.

Clinical evidence

In a case-control study in 3 144 patients who had been admitted to hospital with digoxin toxicity, patients were significantly more likely than controls to have received a new prescription for **sertraline**, **fluoxetine**, **fluvoxamine**, or **paroxetine** in the 30 days before admission (adjusted odds ratios, 2.8 to 3). This was after adjusting for renal impairment and other interacting drugs. Nevertheless, this increased risk was not statistically significantly different to that in patients taking tricyclics (1.5) or benzodiazepines (2.1), which the authors considered have no known basis for an interaction.[1] Consider also 'Digoxin and related drugs + Benzodiazepines and related drugs', p.1086). In addition, the risk was small compared with the 12-fold increased risk found by the same authors in a similar study of clarithromycin (see 'Digoxin and related drugs + Macrolides', p.1103. Furthermore, there is little evidence of an interaction in other studies, although isolated case reports do describe toxicity. These are discussed in the individual sections below.

(a) Citalopram

A study in 11 healthy subjects found that citalopram 40 mg daily for 28 days did not have any significant effect on the pharmacokinetics of a single 1-mg dose of digoxin taken on day 21. No clinically significant ECG changes were observed.[2]

(b) Fluoxetine

An isolated report describes a 93-year-old woman with congestive heart failure who developed increased serum digoxin levels on two occasions when **fluoxetine** was added.[3]

(c) Fluvoxamine

After taking fluvoxamine 100 mg daily for 15 days, the pharmacokinetics of a single 1.25-mg intravenous dose of digoxin were unchanged in 8 healthy subjects.[4]

(d) Paroxetine

A study in healthy subjects found that paroxetine 30 mg daily had no effect on the pharmacokinetics of digoxin 250 micrograms daily. The pharmacokinetics of paroxetine were unaffected by digoxin.[5] A case report describes digoxin toxicity in a 68-year-old woman with atrial fibrillation and depression, which was attributed to the addition of paroxetine 20 mg daily. Her digoxin levels reached 5.2 nanograms/mL.[6]

(e) Sertraline

A placebo-controlled study in 19 healthy subjects found that sertraline, in an initial dose of 50 mg daily titrated to 200 mg daily, had no effect on the steady-state pharmacokinetics of digoxin, except for a decrease in time to maximum plasma levels.[7]

Mechanism

It has been suggested that paroxetine might inhibit P-glycoprotein leading to reduced renal excretion of digoxin.[6] This suggestion has been criticised by other authors who propose that the increase in levels seen in the case with paroxetine may be due to hospital-induced compliance or renal impairment.[8,9] Moreover, the case-control study found no evidence of a significantly different risk of digoxin toxicity between those SSRIs with greater P-glycoprotein inhibitory activity (sertraline and paroxetine) than those with less P-glycoprotein inhibitory activity (fluoxetine, fluvoxamine).[1]

Importance and management

The pharmacokinetic studies show that, in general, it is unlikely that SSRIs will affect the steady-state serum levels of digoxin. The excess risk seen in the case-control study was considered to be small and related to detection bias or confounding by indication,[1] although the findings do introduce a note of caution. Nevertheless, the fact that there are only isolated case reports of a possible interaction with digoxin for such a widely used class of drugs suggests that problems are rarely encountered. No special precautions would seem to be necessary.

Digoxin + St John's wort (*Hypericum perforatum*)

Digoxin toxicity occurred in a patient taking digoxin when he stopped taking St John's wort. There is good evidence that some preparations of St John's wort can reduce the levels of digoxin by about one-quarter to one-third.

Clinical evidence

An 80-year-old man taking long-term digoxin and St John's wort herbal tea (2 litres daily) developed symptoms of digoxin toxicity (nodal bradycardia of 36 bpm and bigeminy) when he stopped taking the herbal tea.[1]

In a study 13 healthy subjects were given digoxin for 5 days until steady-state had been achieved, and then St John's wort extract (*LI 160*, Lichtwer Pharma) 300 mg three times daily for a further 10 days. The AUC and trough level of digoxin decreased by 28% and 37%, respectively. When compared with a parallel group of 12 subjects taking digoxin and placebo, the St John's wort group had 26% lower maximum plasma digoxin levels, 33% lower trough digoxin levels and a 25% lower AUC.[2]

In another study, 8 healthy subjects pretreated with St John's wort 300 mg three times daily for 14 days were given a single 500-microgram dose of digoxin. St John's wort decreased the AUC_{0-7} of digoxin by 18%.[3]

Another study in 18 healthy subjects found that St John's wort 300 mg three times daily (Nature's Way, containing a daily dose of 24 mg of hyperforin) for 14 days reduced the maximum levels and AUC_{0-24} of a single 250-microgram dose of digoxin by 36% and 23%, respectively. These findings were comparable to rifampicin (an established P-glycoprotein inducer) 600 mg daily for 7 days. No significant adverse effects were reported.[4]

In a further randomised placebo-controlled study, 93 healthy subjects were given digoxin alone for 7 days and then with one of ten St John's wort preparations for 14 days. The extract used in the earlier study (*LI 160*, *Jarsin 300*, Lichtwer Pharma) 300 mg three time daily similarly reduced the digoxin AUC, peak and trough plasma levels by 25%, 37%, and 19%, respectively. Comparable results were found with hypericum powder containing similar amounts of hyperforin (about 21 mg daily), while hypericum powder with half the hyperforin content (about 10 mg daily) reduced the AUC, peak and trough plasma levels by about 18%, 21%, and 13%, respectively. Some St John's wort products, including tea, juice, oil extract, and powder with low-dose hyperforin (all 5 mg daily or less), did not significantly affect the pharmacokinetics of digoxin.[5] Similarly, a further study in 28 healthy subjects found no statistically significant change in digoxin pharmacokinetics when another low-hyperforin (about 3.5 mg daily) St John's wort extract (*Esbericum*) 120 mg was given twice daily for 11 days to patients who had received a digoxin loading dose of 750 micrograms daily for 2 days before starting St John's wort, and then received digoxin 250 micrograms daily each day during the study.[6]

Mechanism

St John's wort, and specifically hyperforin, a major active constituent, has been shown to increase the activity of the P-glycoprotein drug transporter protein in the intestines, which reduces the absorption of digoxin.[2,4,7,8]

Importance and management

An interaction between St John's wort and digoxin would appear to be established. The extent of the interaction may depend on the St John's wort preparation involved and dose used and seems to be correlated with the dose of hyperforin.[4-6,8] Reductions in serum digoxin levels of the size seen with *LI 160* could diminish the control of arrhythmias or heart failure. Digoxin serum levels should therefore be well monitored if St John's wort is either started or stopped and appropriate dose adjustments made if necessary. The recommendation of the CSM in the UK is that St John's wort should not be used by patients taking digoxin.[9]

Digoxin + Statins

Atorvastatin, fluvastatin and simvastatin cause small increases in the plasma levels of digoxin. Pravastatin and rosuvastatin appear to have no effect on digoxin pharmacokinetics.

Clinical evidence

(a) Atorvastatin

Digoxin 250 micrograms daily was given to 24 healthy subjects for 10 days, with atorvastatin 10 or 80 mg daily for a further 10 days. The mean steady-state plasma digoxin levels were unaffected by atorvastatin 10 mg, but atorvastatin 80 mg caused a 20% rise in maximum digoxin levels and a 15% rise in its AUC.[1]

(b) Fluvastatin

In a crossover study in 18 patients, fluvastatin 40 mg caused no significant changes in the pharmacokinetics of digoxin 100 to 375 micrograms daily.[2] Another similar study in patients found changes of up to 15% in maximum plasma digoxin levels and clearance.[3]

(c) Pravastatin

In 18 healthy subjects, pravastatin 20 mg daily for 9 days had no significant effect on the steady-state serum levels of digoxin 200 micrograms daily.[4]

(d) Rosuvastatin

In a randomised study, 18 healthy subjects were given rosuvastatin 40 mg daily or placebo for 12 days, with a single 500-microgram dose of digoxin on day 8. The absorption, renal excretion, AUC and maximum serum levels of digoxin were unaffected by rosuvastatin.[5]

(e) Simvastatin

Plasma digoxin levels can be slightly raised, by about 0.3 nanograms/mL, by simvastatin.[6]

Mechanism

The small changes seen in digoxin levels are probably due to the inhibitory effects of these statins on P-glycoprotein. Pravastatin does not appear to inhibit P-glycoprotein.[7]

Importance and management

The small changes seen in the digoxin levels with the statins seem unlikely to be clinically relevant in most patients.

Digoxin + Sucralfate

Sucralfate caused only a small reduction in the absorption of digoxin in one study, but an isolated report describes a marked reduction in one patient.

Clinical evidence

In a study in 12 healthy subjects, sucralfate 1 g four times daily for 2 days had no effect on most of the pharmacokinetic parameters of a single 750-microgram dose of digoxin; however, the AUC of digoxin was reduced by 19% and the amount of digoxin eliminated in the urine was reduced by 12%. Digoxin was also absorbed faster.[1] No interaction occurred when the digoxin was given 2 hours before the sucralfate.[1]

An elderly patient was admitted to hospital with pressure-like chest pain, shortness of breath and generalised fatigue. She was taking several drugs including digoxin 125 micrograms daily and sucralfate 2 g twice daily, but her digoxin levels were found to be subtherapeutic (about 0.1 nanogram/mL), even though the doses of digoxin and sucralfate were separated by 2 hours. She was given intravenous digoxin 250 micrograms for an episode of atrial flutter on the day of admission, with a further dose the next day. Sucralfate was discontinued on day 4 as she had not had any recent gastrointestinal symptoms and, on day 5 digoxin levels were within the therapeutic range (0.9 nanograms/mL). She continued to take oral digoxin 125 micrograms daily without sucralfate and levels remained at about the therapeutic range in the 2-week period after hospitalisation.[2]

Mechanism

Uncertain. One possibility is that the digoxin and sucralfate bind together in the gut, which reduces the digoxin absorption.

Importance and management

Information appears to be limited to the reports cited. The reduction in digoxin levels reported in the study is small and therefore normally unlikely to be clinically relevant, but the unexplained and isolated case suggests that clinicians should at least be aware of the possibility of an interaction.

Digoxin + Surfactant excipients

Non-ionic surfactants used as pharmaceutical excipients such as polyoxyl castor oil (*Cremophor*) may slightly enhance the absorption of digoxin.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 12 healthy subjects found that **polyoxyl castor oil** (***Cremophor RH40***) 600 mg three times daily increased the AUC_{0-5} and peak plasma levels of a single 500-microgram oral dose of digoxin by about 22%. The absorption of digoxin was delayed. The pharmacodynamic effects of digoxin were not affected by ***Cremophor***. It was suggested that ***Cremophor*** increases digoxin plasma levels by inhibiting intestinal P-glycoprotein, or that the ***Cremophor*** prolongs the dissolution of digoxin tablets resulting in delayed absorption from the intestines.[1] Whatever the reason, the effects found were modest, an their clinical relevance is not established.

Digoxin + Tegaserod

Tegaserod slightly reduces the AUC of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects given tegaserod 6 mg twice daily for 5 days found that the time to peak levels of a single 1-mg dose of digoxin, given on day 4, was reduced by 30 minutes, and the mean AUC and maximum plasma concentrations were slightly reduced by 12% and 15%, respectively.[1] These small changes are unlikely to be clinically relevant. Note that the manufacturer discontinued the marketing of tegaserod in the US be-

cause of a finding of an excess risk of serious cardiovascular ischaemic events.[2]

Digoxin + Tetracycline

Limited early evidence suggested that tetracycline may cause a rise in digoxin levels.

Clinical evidence

A patient taking digoxin tablets 500 micrograms daily was given tetracycline 500 mg every 6 hours for 5 days. His urinary excretion of digoxin metabolites fell sharply within 2 days, and his steady-state serum digoxin levels rose by 43%.[1] Another subject had a marked fall in the excretion of digoxin metabolites from the gut after taking tetracycline.[2] In a study, tetracycline prolonged the half-life of digoxin and increased its serum levels by about 70% (from 1.7 to 2.9 nanograms/mL).[3]

Mechanism

Uncertain. Up to 10% of patients taking oral digoxin excrete it in substantial amounts in the faeces and urine as inactive metabolites (digoxin reduction products or DRPs). This metabolism seems to be performed by the gut flora,[1] in particular *Eubacterium lentum*, which is anaerobic and Gram positive.[2,4] In the presence of some antibacterials, such as tetracycline, which can inhibit this organism, more digoxin becomes available for absorption, which results in a rise in serum levels. At the same time the inactive metabolites derived from the gut disappear.[2] However, this is not necessarily the full explanation, see also 'Digoxin and related drugs + Macrolides', p.1103.

Importance and management

The interaction between digoxin and tetracycline is not well established, the evidence is very limited, and its general clinical importance is uncertain. Bear this interaction in mind in case of an unexpected response to digoxin.

Digoxin and related drugs + Thyroid hormones and Antithyroid drugs

Thyrotoxic patients are relatively resistant to the effects of digitalis glycosides and may need reduced doses of these drugs as treatment with antithyroid drugs (carbimazole, thiamazole) progresses, whereas patients with hypothyroidism may need increased doses of digitalis glycosides as treatment with thyroid hormones progresses. Carbimazole has been shown to reduce levels of digoxin in healthy subjects.

Clinical evidence

(a) Carbimazole

The observation of relatively low plasma digoxin levels in a patient taking carbimazole prompted a further study in 10 healthy subjects. In 9 out of the 10 subjects, steady-state peak serum digoxin levels were reduced by 23% (from 1.72 to 1.33 nanograms/mL) by a single 60-mg dose of carbimazole, but in the other subject the serum digoxin levels were increased. Other pharmacokinetic parameters were unaffected.

Carbimazole abolished the systolic blood pressure decrease seen in the first 3 hours with digoxin, and also reduced the duration of the digoxin-induced diastolic blood pressure fall from 12 hours to 6 hours. The changes in heart rates, cardiac output and stroke volumes were not statistically significant, but inter-individual differences were large.[1-3]

(b) Thiamazole

A study in 12 patients with hyperthyroidism found that normalisation of serum T3 and thyroxine by thiamazole treatment did not produce significant changes in the pharmacokinetics of digoxin.[4]

Mechanism

One explanation for the changed response to digitalis with carbimazole is that there is a direct and altered response of the heart due to the raised or lowered thyroid hormone levels. Another is that changes in glomerular filtration rate associated with hypo- or hyperthyroidism result in increased or decreased serum digoxin, respectively.[5] Why carbimazole *reduced* serum digoxin levels in healthy subjects (normal thyroid status) is not known.

Importance and management

Evidence for an interaction between thyroid hormones or antithyroid drugs and digitalis glycosides is limited, but given the evidence here, and the way thyroid hormones or antithyroid drugs are known to affect other drugs, and interaction certainly seems possible. As thyroid status is returned to normal by the use of antithyroid drugs or thyroid hormones the dose of the digitalis glycosides may need to be adjusted appropriately. Hyperthyroid patients may need to have their digitalis dose gradually reduced as treatment proceeds (because initially they are relatively resistant to the effects of digitalis and start off needing higher doses). They are also relatively insensitive to the chronotropic effects of digitalis.[6,7] Hypothyroid patients on the other hand may need a gradually increasing dose (because initially they are relatively sensitive to digitalis).[5,6] In either of these situations it would be prudent to monitor serum digoxin levels and glomerular filtration rate as treatment continues. The modest reduction in digoxin levels caused by carbimazole in healthy subjects does not fit with the need to decrease digoxin doses when antithyroid drugs are used in patients. However, the situation in healthy subjects may not accurately reflect that in subjects with thyroid disease.

Digoxin + Ticlopidine

In 15 subjects ticlopidine 250 mg twice daily for 10 days reduced the peak serum levels and AUC of digoxin by about 10%.[1] This reduction is small and unlikely to be of clinical importance.

1. Vargas R, Reitman M, Teitelbaum P, Ryan JR, McMahon FG, Jain AK, Ryan M, Regel G. Study of the effect of ticlopidine on digoxin blood levels. *Clin Pharmacol Ther* (1988) 43, 176.

Digoxin + Tiludronate

Tiludronate does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that tiludronate, 600 mg daily for 2 days then 400 mg daily for the next 10 days, caused no significant changes in the pharmacokinetics of digoxin 250 micrograms daily.[1] No digoxin dose adjustments would appear to be needed on concurrent use.

1. Sanofi Winthrop. Data on file, June 1996.

Digoxin + Tolvaptan

Tolvaptan may modestly increase the levels of digoxin.

Clinical evidence, mechanism, importance and management

In a study in 14 healthy subjects, tolvaptan 60 mg daily for 5 days increased the steady-state AUC and maximum plasma concentration of digoxin by about 30% and 20%, respectively. There was no change in heart rate, blood pressure, ventricular rate or QTc interval, and no change in tolvaptan pharmacokinetics, when compared with a single dose given alone.[1] Digoxin is a substrate of the drug transporter protein P-glycoprotein, which is inhibited by tolvaptan.[2] Therefore concurrent use results in the modestly increased digoxin exposure seen in the study; however, this modest increase is probably of little clinical importance in most patients. The UK manufacturer advises that patients receiving both digoxin and tolvaptan should be monitored for excessive digoxin effects,[3] (e.g. bradycardia) which would seem prudent, particularly for those patients with digoxin levels already at the high end of the therapeutic range.

3. Samsca (Tolvaptan). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, August 2009.

Digoxin + Tramadol

Some UK manufacturers state that digoxin toxicity has occurred rarely during the concurrent use of digoxin and tramadol.[1,2] There appear to be no published reports of an interaction, and in the absence of any more information, it is difficult to judge the general relevance of these cases.

1. Zamadol (Tramadol hydrochloride). Meda Pharmaceuticals. UK Summary of product characteristics, August 2009.
2. Dromadol (Tramadol hydrochloride). Napp Pharmaceuticals Ltd. UK Summary of product characteristics, April 2008.

Digoxin + Trapidil

Trapidil does not alter digoxin levels, but may oppose some of its effects.

Clinical evidence, mechanism, importance and management

In 10 healthy subjects, trapidil 400 mg daily for 8 days had no effect on the steady-state serum levels of digoxin 375 micrograms daily. It was noted that the positive chronotropic effect of trapidil opposed the negative chronotropic effect of digoxin, which should be remembered when using both drugs, but overall no adverse effects that would prevent concurrent use were noted.[1]

1. Sziegoleit W, Weiss M, Fahr A, Scharfe S. Trapidil does not affect serum levels and cardiotonic action of digoxin in healthy humans. *Jpn Circ J* (1987) 51, 1305–9.

Digoxin + Trazodone

A rise in digoxin levels, accompanied by toxicity in one instance, has been seen when two patients taking digoxin were given trazodone.

Clinical evidence, mechanism, importance and management

An elderly woman taking digoxin 125 micrograms daily (and also taking quinidine, clonidine and triamterene with hydrochlorothiazide) complained of nausea and vomiting within about 2 weeks of starting to take trazodone (initially 50 mg, increasing to 300 mg daily over 11 days). Her serum digoxin levels had risen more than threefold (from 0.8 to 2.8 nanograms/mL). The digoxin was stopped and then restarted at half the original dose, which maintained therapeutic levels.[1] The patient had poor renal function, but this did not change significantly during this incident. Another case report also describes raised digoxin levels, apparently caused by trazodone.[2]

Direct information seems to be limited to these two reports, which is insufficient evidence to make any general recommendations; however, if a patient taking digoxin develops otherwise unexplained adverse effects, it may be prudent to consider trazodone as a possible cause.

1. Rauch PK, Jenike MA. Digoxin toxicity possibly precipitated by trazodone. *Psychosomatics* (1984) 25, 334–5.
2. Knapp JE. Mead Johnson Pharmaceutical Newsletter, 1983.

Digoxin + Trimethoprim

Digoxin levels can be modestly increased by about 22% by trimethoprim, although some individuals may show a much greater rise.

Clinical evidence

(a) Elderly patients

After taking trimethoprim 200 mg twice daily for 14 days the mean serum digoxin levels in 9 elderly patients (aged 62 to 92 years) had risen by an average of 22% (from 0.9 to 1.2 nanograms/mL). One patient had a 75% rise. A 34% increase in mean serum creatinine was also seen. When the trimethoprim was withdrawn, the serum digoxin levels returned to their previous value.[1,2]

(b) Young healthy adult subjects

Trimethoprim 200 mg twice daily for 10 days did not affect the total body clearance of a single 1-mg intravenous dose of digoxin in 6 young healthy subjects (aged 24 to 31 years). Renal clearance was reduced, but this was compensated for by an increase in extra-renal clearance.[2]

Mechanism

It is suggested that trimethoprim reduces the renal excretion of digoxin.[1,2] The paradoxical finding between the elderly patients and the young healthy subjects may be the age difference, probably as the elderly patients may not be able to accommodate an increase in extra-renal digoxin clearance.

Importance and management

Information seems to be limited to the information cited. Although the serum digoxin rise in the elderly was modest, it would seem prudent to monitor the effects because some individuals can apparently experience a marked rise. Reduce the digoxin dose if necessary. Trimethoprim is contained in **co-trimoxazole** but it is not known whether prophylactic doses of co-trimoxazole (160 mg trimethoprim a day, from 960 mg co-trimoxazole) will interact to a clinically significant extent. An interaction would seem likely with high-dose co-trimoxazole regimens and care with any co-trimoxazole regimen is needed in the elderly.

2. Petersen P, Kastrup J, Bartram R, Hansen JM. Digoxin-trimethoprim interaction. *Acta Med Scand* (1985) 217, 423–7.

Digoxin + Trimetazidine

Trimetazidine does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 13 healthy subjects, trimetazidine 20 mg twice daily for at least 14 days did not affect the pharmacokinetics of a single 500-microgram dose of digoxin.[1] These results suggest that the dose of digoxin is unlikely to need adjusting in patients who are also given trimetazidine.

1. Edeki TI, Johnston A, Campbell DB, Ings RMJ, Brownsill R, Genissel P, Turner P. An examination of the possible pharmacokinetic interaction of trimetazidine with theophylline, digoxin and antipyrine. *Br J Clin Pharmacol* (1989) 26, 657P.

Digoxin + Trospium

In a study in 40 healthy subjects, trospium 20 mg twice daily for 12 days did not affect the pharmacokinetics of a single 500-microgram dose of digoxin elixir given on day 7.[1]

1. Sandage B, Sabounjian L, Shipley J, Profy A, Lasseter K, Fox L, Harnett M. Predictive power of an in vitro system to assess drug interactions of an antimuscarinic medication: a comparison of in vitro and in vivo drug-drug interaction studies of trospium chloride with digoxin. *J Clin Pharmacol* (2006) 46, 776–84.

Digoxin + Urapidil

Urapidil does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, urapidil 60 mg twice daily on days 5 to 8 had no significant effects on the serum levels of digoxin 250 micrograms twice daily on day one, then 250 micrograms daily on days 2 to 8. Blood pressures and pulse rates were not significantly changed.[1] No special precautions seem necessary if both drugs are given.

1. Solleder P, Haerlin R, Wurst W, Klingmann I, Mosberg H. Effect of urapidil on steady-state serum digoxin concentration in healthy subjects. *Eur J Clin Pharmacol* (1989) 37, 193–4.

Digoxin + Ursodeoxycholic acid (Ursodiol)

Ursodeoxycholic acid modestly reduces the exposure to digoxin.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects, ursodeoxycholic acid 13 mg/kg daily for 19 days decreased the oral absorption and the AUC_{0-4} of a single 500-microgram dose of digoxin given on day 15 by 9% and 17%, respectively. The pharmacokinetics of a single intravenous dose of digoxin were not affected by ursodeoxycholic acid. It was suggested that the reduction in the absorption of oral digoxin may have occurred because ursodeoxycholic acid may induce P-glycoprotein, which is involved in the transport of digoxin.[1] Evidence for an interaction between digoxin and ursodeoxycholic acid appears to be limited to the study cited, but an interaction would appear to be established. However, the changes seen were small, and seem unlikely to be clinically relevant. Therefore, based on this study, no adjustment would seem to be necessary in the dose of digoxin, if ursodeoxycholic acid is also given.

1. Becquemont L, Glaeser H, Drescher S, Hitzl M, Simon N, Murdter TE, Heinkele G, Hofmann U, Schaefer C, Burk O, Verstuyft C, Eichelbaum M, Fromm MF. Effects of ursodeoxycholic acid on P-glycoprotein and cytochrome P450 3A4–dependent pharmacokinetics in humans. *Clin Pharmacol Ther* (2006) 79, 449–60.

Digoxin + Valaciclovir

Valaciclovir appears not to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a randomised study, 12 healthy subjects were given 1 g of oral valaciclovir alone, two 750-microgram doses of digoxin alone, valaciclovir 1 g after the second of two 750-microgram doses of digoxin given 12 hours apart, and finally valaciclovir 1 g three times daily for 8 days starting 12 hours before the first digoxin dose.[1] It was found that no clinically significant changes occurred in the pharmacokinetics of either drug and no ECG changes were seen. It was therefore concluded that no dose adjustments of either drug are needed if they are given concurrently.[1] Valaciclovir is a prodrug of **aciclovir**, it therefore also seems unlikely that an interaction will occur between **aciclovir** and digoxin.

1. Soul-Lawton JH, Weatherley BC, Posner J, Layton G, Peck RW. Lack of interaction between valaciclovir, the L-valyl ester of aciclovir and digoxin. *Br J Clin Pharmacol* (1998) 45, 87–9.

Digoxin + Valspodar

Valspodar increases the AUC of digoxin two to threefold.

Clinical evidence, mechanism, importance and management

In a study, 12 healthy subjects were given digoxin 1 mg on day one, followed by 125 micrograms daily for the next 10 days. Starting on day 7 they were also given a single 400-mg dose of valspodar, followed by valspodar 200 mg twice daily for the next 4 days. The steady-state digoxin AUC was increased by 76% after the first dose of valspodar, and by the end of valspodar dosing it had increased by 211%. This was apparently due to a 73% reduction in digoxin renal clearance and a 58% reduction in non-renal clearance, probably because of reduced tubular secretion, reduced biliary elimination, and increased intestinal absorption caused by P-glycoprotein inhibition. No symptoms of digitalis toxicity were seen and there were no changes in vital signs or ECG parameters.[1]

Information seems to be limited to this study in healthy subjects but it suggests that the digoxin dose should be reduced if valspodar is given. An initial 50% reduction has been suggested.

1. Kovarik JM, Rigaudy L, Guerret M, Gerbeau C, Rost K-L. Longitudinal assessment of a P-glycoprotein-mediated drug interaction of valspodar on digoxin. *Clin Pharmacol Ther* (1999) 66, 391–400.

Digoxin + Vancomycin

In one early study, vancomycin prolonged the half-life of digoxin and increased its serum levels from 1.6 nanograms/mL to 3 nanograms/mL. It was suggested that this effect might be as a result of reduced renal clearance.[1] This appears to be the only evidence of a possible interaction, and as such, no general recommendations can be made.

1. Halawa B. Interakcje digoksyny z cefradina (Sefril), tetracylina (Tetracyclinum), gentamycyna (Gentamycin) i wankomycyna (Vancocin). *Pol Tyg Lek* (1984) 39, 1717–20.

Digoxin + Vardenafil

Vardenafil does not appear to interact with digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 19 healthy subjects were given digoxin 375 micrograms daily for 28 days, with vardenafil 20 mg daily on alternate days from day 16 to day 28. The pharmacokinetics of digoxin were not significantly changed by vardenafil, and there was no alteration in vital signs, ECG readings and laboratory parameters (not stated). The incidence of mild to moderate headache rose slightly from 7 out of 19 with placebo to 13 out of 19 with digoxin.[1] There would appear to be no reason to monitor digoxin levels in patients given vardenafil.

1. Rohde G, Bauer R-J, Unger S, Ahr G, Wensing G. Vardenafil, a new selective PDE5 inhibitor, produces no interaction with digoxin. *Pharmacotherapy* (2001) 21, 1254.

Digoxin + Vasodilators

Dihydralazine, and sodium nitroprusside or hydralazine infusions, can reduce digoxin levels Isosorbide dinitrate did not alter digoxin pharmacokinetics in one study.

Clinical evidence, mechanism, importance and management

(a) Hydralazine or Sodium nitroprusside

An experimental study in 8 patients with congestive heart failure found that when they were given either sodium nitroprusside by infusion (7 to 425 micrograms/minute) or hydralazine by intravenous injection (5 mg every 10 to 20 minutes to a total dose of 10 to 60 mg) the total renal digoxin clearance was increased by about 50% by both drugs and the serum digoxin levels were decreased by 20% by the nitroprusside and 11% by the hydralazine.[1] Another study found that **dihydralazine** shortened the half-

life of digoxin and reduced its serum levels, but did not affect digoxin bioavailability.[2]

It is not known whether these changes would be sustained during long-term concurrent use, but the changes in the levels seen were relatively modest. A clinically important interaction seems unlikely, but ideally longer-term studies are needed to confirm this.

(b) Isosorbide dinitrate

In a crossover study in 8 patients with chronic heart failure, given digoxin 250 micrograms daily for 20 days with isosorbide dinitrate 10 mg three times daily for the last 10 days, there was no change in the mean steady-state concentration, AUC or half-life of digoxin.[3]

1. Cogan JJ, Humphreys MH, Carlson CJ, Benowitz NL, Rapaport E. Acute vasodilator therapy increases renal clearance of digoxin in patients with congestive heart failure. *Circulation* (1981) 64, 973–6.

3. Mahgoub AA, El-Medany AH, Abdulatif AS. A comparison between the effects of diltiazem and isosorbide dinitrate on digoxin pharmacodynamics and kinetics in the treatment of patients with chronic ischemic heart failure. *Saudi Med J* (2002) 23, 725–31.

Digoxin + Vitamin E substances

Alpha tocoferil acetate had no effect on digoxin pharmacokinetics, but vitamin E formulations with polyethylene glycol might.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, **alpha tocoferil acetate** 400 units twice daily for 15 days did not affect the pharmacokinetics of a single 500-microgram dose of digoxin given on day 15. This was in contrast to a formulation of vitamin E containing polyethylene glycol (**alpha tocoferil acid succinate**), which altered digoxin pharmacokinetics (amount not stated) without altering its ECG effects.

It was suggested that the effect of polyethylene glycol on digoxin was via P-glycoprotein inhibition,[1] see also 'Digoxin + Surfactant excipients', p.1116.

1. Chan L, Humma LM, Schriever CA, Fahsingbauer BS, Dominguez CP, Baum CL. Vitamin E formulation affects digoxin absorption by inhibiting P-glycoprotein (P-GP) in humans. *Clin Pharmacol Ther* (2004) 75, P95.

Digoxin + Zileuton

Zileuton does not appear to affect the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 12 healthy subjects were given zileuton 600 mg every 6 hours for 13 days, with digoxin 250 micrograms daily from days 1 to 11. Zileuton had no effect on the steady-state pharmacokinetics of digoxin, although the time to reach maximum plasma levels was reduced from 1.43 hours to 0.95 hours. Concurrent use was well tolerated.[1] This evidence suggests that no digoxin dose adjustment is necessary if zileuton is also given.

1. Awni WM, Hussein Z, Cavanaugh JH, Granneman GR, Dube LM. Assessment of the pharmacokinetic interaction between zileuton and digoxin in humans. *Clin Pharmacokinet* (1995) 29 (Suppl 2), 92–7.

26

Diuretics

The majority of the interactions of the diuretics appear to be pharmacodynamic in nature, that is, they appear to be due to the combined effects of the diuretic and the other interacting drug. Obvious examples of this would be hypotension caused by the use of a loop diuretic and a beta blocker, or hyperkalaemia caused by the use of an ACE inhibitor and a potassium-sparing diuretic. Some commonly accepted interactions appear to be sparsely documented, most probably because they are perceived to be a predictable effect of using two drugs with similar actions together. 'Table 26.1', (below) lists the major diuretic drug groups classified by their effect on potassium. Carbonic anhydrase inhibitors are included under potassium-depleting diuretics, but note that hypokalaemia caused by this type of drug is said to be transient and rarely clinically significant.

Eplerenone, a selective aldosterone antagonist similar to spironolactone, is metabolised by the cytochrome P450 isoenzyme CYP3A4 and is therefore affected by other drugs that are inhibitors or inducers of this enzyme.

The interactions covered in this section are mainly those in which the diuretic is affected. There are many other interactions throughout the publication where diuretics affect the actions of other drugs.

Table 26.1 Diuretics

Group	*Drugs*
Potassium-depleting diuretics	
Carbonic anhydrase inhibitors*	Acetazolamide, Diclofenamide (Dichlorphenamide)
Loop diuretics	Bumetanide, Etacrynic acid, Furosemide, Piretanide, Torasemide
Thiazides and related diuretics	Altizide, Bemetizide, Bendroflumethiazide, Benzthiazide, Butizide, Chlorothiazide, Chlortalidone, Clopamide, Cyclopenthiazide, Cyclothiazide, Epitizide, Hydrochlorothiazide, Hydroflumethiazide, Indapamide, Mefruside, Methyclothiazide, Metipamide, Metolazone, Teclothiazide, Trichlormethiazide, Xipamide
Potassium-sparing diuretics	
Aldosterone inhibitors	Eplerenone, Potassium canrenoate, Spironolactone
Other	Amiloride, Triamterene

*Note that hypokalaemia caused by this type of drug is said to be transient and rarely clinically significant

Acetazolamide + NSAIDs

A woman developed acute renal failure following retinal surgery, after the postoperative use of a total of 2 g of acetazolamide, 80 g of mannitol and 700 mg of ketoprofen over a 2-day period.[1] There appear to be no other similar case reports, and therefore the significance of this case is unclear. However, note that other interactions have been reported with related drugs. For instance, 'loop diuretics', (p.1125), are known to increase the risk of NSAID-induced acute renal failure, and a severe toxic reaction has been reported in patients receiving concurrent high-dose aspirin and acetazolamide, see 'Aspirin or other Salicylates + Carbonic anhydrase inhibitors', p.151.

1. Truc C, Rigal E, Pernot A, Vaudelin G, Boulétreau P. Anti-inflammatoires non stéroïdiens et diurétiques: une association à risque néphrotoxique. *Ann Fr Anesth Reanim* (2000) 19, 675–7.

Acetazolamide + Sodium bicarbonate

Acetazolamide is associated with the development of renal calculi (usually calcium phosphate) and it has been claimed that sodium bicarbonate, even on alternate days, potentiates the risk of calculus formation.[1] There seem to be no case reports describing an adverse interaction, and so the general significance of this suggested interaction is unclear.

1. Rubenstein MA, Bucy JG. Acetazolamide-induced renal calculi. *J Urol (Baltimore)* (1975) 114, 610–12.

Acetazolamide + Timolol

The use of acetazolamide tablets with timolol eye drops resulted in severe mixed acidosis in a patient with chronic obstructive pulmonary disease.

Clinical evidence, mechanism, importance and management

An elderly man with severe chronic obstructive pulmonary disease was given oral acetazolamide 750 mg daily and timolol maleate 0.5% eye drops, one drop in each eye twice daily, as premedication to reduce ocular hypertension before surgery for glaucoma. Five days later he developed progressively worsening dyspnoea and he was found to have a severe, mixed acidosis.[1] This seems to have been caused by the additive effects of acetazolamide, which blocked the excretion of hydrogen ions in the kidney, and the bronchoconstrictor effects of the timolol, which was absorbed in sufficient amounts to exacerbate the airway obstruction in this patient, and thereby reduced the respiration. This isolated case emphasises the potential risks of using beta blockers, even as non-systemic preparations, such as eye drops, in patients with obstructive pulmonary disease. The manufacturers of acetazolamide note that it should be used with caution in those with pulmonary obstruction or emphysema because of the increased risk of acidosis.[2,3] This is, in part, a drug-disease interaction.

Diuretics + Aliskiren

Aliskiren reduces the plasma levels of furosemide, but does not appear to affect the pharmacokinetics of hydrochlorothiazide. Aliskiren may cause hypotension in patients receiving high doses of diuretics and may possibly increase serum potassium levels in patients receiving potassium-sparing diuretics.

Clinical evidence, mechanism, importance and management

The AUC and maximum plasma level of **furosemide** were reduced by about 30% and 50%, respectively, by the concurrent use of aliskiren.[1,2] The manufacturers therefore say that the effects of **furosemide** may be reduced when aliskiren is started.[2]

In a study in healthy subjects aliskiren 300 mg daily did not significantly affect the pharmacokinetics of **hydrochlorothiazide** 25 mg daily. The AUC of aliskiren was not affected by **hydrochlorothiazide**, its steady state maximum plasma level was reduced by 22%; however, this was not considered to be clinically relevant. There was an increased incidence of dizziness in subjects receiving aliskiren and **hydrochlorothiazide**, when compared with either drug alone, but this might be expected with two effective antihypertensive drugs given to normotensive healthy subjects.[3] Studies in patients with mild-to-moderate hypertension, showed no difference in the rate of dizziness or the incidence of adverse effects with the combination of aliskiren and **hydrochlorothiazide**, when compared with monotherapy.[3,4]

The manufacturers of aliskiren note that in patients with marked volume- and/or salt-depletion, for example those receiving high doses of diuretics, symptomatic hypotension could occur after initiation of treatment with aliskiren. Close medical supervision is required in such patients.[1,2] Based on experience with the use of other substances that affect the renin-angiotensin system, the concurrent use of **potassium-sparing diuretics** and aliskiren may lead to increases in serum potassium and caution is advisable.[1]

Diuretics + Liquorice

A case report describes hypokalaemia in a patient who took hydrochlorothiazide and liquorice. This interaction seems possible with liquorice and any potassium-depleting diuretic (i.e. thiazides or loop diuretics).

Clinical evidence, mechanism, importance and management

A 41-year-old woman who presented with hypertension was unsuccessfully treated with atenolol and candesartan. After the addition of **hydrochlorothiazide**, she developed hypokalaemia with muscle cramps and weakness, which persisted for more than 4 weeks after the hydrochlorothiazide was discontinued. The patient had denied eating liquorice sweets, but was found to have been drinking at least 3 litres of liquorice tea daily.[1] Liquorice has mineralocorticoid-like actions, which may lower potassium levels. This effect may be additive with the effects of the potassium-depleting diuretics, which may result in clinically significant hypokalaemia. Evidence is extremely sparse. Consider this interaction in a case of otherwise unexplained hypokalaemia.

Eplerenone + Miscellaneous

Corticosteroids or tetracosactide may potentially reduce the antihypertensive effect of eplerenone, whereas alpha blockers, antipsychotics, amifostine, baclofen, and tricyclic antidepressants may increase its antihypertensive effects. Antacids, cisapride, and midazolam had no effect on eplerenone pharmacokinetics. Eplerenone had no important effect on cisapride, midazolam, warfarin or contraceptive steroid pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer notes that **aluminium**/**magnesium**-containing antacids had no effect on the pharmacokinetics of eplerenone.[1]

(b) Cisapride

A pharmacokinetic study found no interaction between cisapride (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.[1,2]

(c) Combined hormonal contraceptives

Eplerenone 100 mg daily was given to 24 healthy subjects on days 1 to 11 of a 28-day cycle of a combined hormonal contraceptive (**ethinylestradiol**/**norethisterone** 35 micrograms/1 mg). There was no change in the **ethinylestradiol** AUC, but there was a small 17% increase in the **norethisterone** AUC, which is unlikely to be clinically relevant.[3]

For comment that drospirenone may increase the risk of hyperkalaemia if given with eplerenone or other potassium-sparing diuretics, see 'Drospirenone-containing contraceptives or HRT + Potassium-sparing drugs', p.1197.

(d) Corticosteroids or Tetracosactide (Cosyntropin)

Corticosteroids or tetracosactide can cause fluid and sodium retention and coadministration with eplerenone may potentially reduce the antihypertensive effect.[2]

(e) Drugs that may cause postural hypotension

The manufacturer suggests that there is a risk of increased hypotensive effects and/or postural hypotension if eplerenone is given with **alpha blockers** (e.g. **alfuzosin**, **prazosin**), **tricyclic antidepressants**, **antipsychotics**, **amifostine** and **baclofen**.[2] Increased monitoring would seem prudent.

(f) Midazolam

A pharmacokinetic study has shown no pharmacokinetic interaction between midazolam (a cytochrome P450 isoenzyme CYP3A4 substrate) and eplerenone.[1,2]

(g) Warfarin

Eplerenone did not alter the pharmacokinetics of warfarin to a clinically significant extent.[1,2] However, in the UK the manufacturer still recommends caution when the warfarin dose is near the upper limit of the therapeutic range.[2]

Loop diuretics + Aspirin or other Salicylates

Aspirin may reduce the diuretic effect of bumetanide, furosemide, or piretanide, and the venodilation produced by furosemide. The combination of aspirin and furosemide may increase the risk of acute renal failure and salicylate toxicity. The risk of ototoxicity with high doses of salicylates may theoretically be increased by loop diuretics.

Clinical evidence

(a) Bumetanide

In 8 healthy subjects aspirin 640 mg four times daily reduced the 24-hour urinary output in response to bumetanide 1 mg by 18%.[1]

(b) Furosemide

A study in 11 patients with chronic heart failure found that both aspirin 75 mg daily and aspirin 300 mg daily for 14 days reduced the venodilatory effects produced by a single 20-mg intravenous dose of furosemide (as measured by the forearm venous capacitance).[2] Six patients with cirrhosis and ascites had a reduced diuretic response to intravenous furosemide 40 mg given after a single intravenous dose of **lysine aspirin** 450 mg.[3] A further study in 6 patients found that the combination of furosemide and aspirin temporarily reduced creatinine clearance in patients with chronic renal insufficiency.[4]

Studies in healthy subjects similarly found that intravenous aspirin or **lysine aspirin** blunted the diuresis[5,6] and sodium excretion[6] caused by intravenous furosemide, and appeared to increase potassium excretion;[6] the reduced diuretic effect seemed to correlate with an inhibition of proximal tubular secretion.[5] A similar reduction in sodium excretion was found in a study where healthy subjects were given aspirin and furosemide orally.[7]

In contrast, another study in healthy subjects found that oral aspirin 4 g daily did not influence the effects of oral furosemide 40 mg on renal sodium excretion or urinary creatinine excretion.[8]

A study in healthy subjects found that when aspirin 600 mg and furosemide 40 mg were given at the same time there was a significant reduction in the total excretion of salicylates, but when the drugs were given 30 minutes apart the total amount of salicylate excreted increased slightly.[7]

(c) Piretanide

A study in 4 healthy subjects found that intravenous **lysine aspirin** 1 g decreased the diuresis and sodium excretion caused by intravenous piretanide 12 mg.[6]

Mechanism

Uncertain. Aspirin may compete with furosemide for a common secretory mechanism in the proximal tubule.[5,7] In addition, aspirin may also inhibit renal prostaglandins, which appear to mediate the increased renal blood flow induced by loop diuretics in cirrhotics with ascites.[3] Consider also 'Loop diuretics + NSAIDs', p.1125.

Importance and management

The clinical significance of these interactions is unclear. The UK manufacturer of furosemide warns that aspirin may attenuate the action of furosemide and may cause acute renal failure in cases of pre-existing hypovolaemia or dehydration.[9] Note that the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven and there are concerns that it may attenuate the haemodynamic and survival benefits of other drugs. However, antiplatelet drugs are recommended in patients with underlying ischaemic heart disease,[10,11] but aspirin should be avoided in patients with recurrent hospital admissions for worsening heart failure.[10]

The manufacturers also warn that salicylate toxicity may occur if furosemide is given concurrently in patients receiving high doses of salicylates, as in rheumatic disease, because of competitive renal excretory sites.[4,9] High doses of salicylates can be ototoxic, particularly if the patient is dehydrated, and the risk of ototoxicity may theoretically be increased if salicylates are given with other ototoxic drugs, including loop diuretics such as bumetanide, **etacrynic acid** or furosemide.[12,13]

Loop diuretics + Epoprostenol

In a study modelling data from 23 patients with heart failure, an infusion of epoprostenol did not significantly alter the pharmacokinetics of furosemide.[1] Note that the combination of loop diuretics with epoprostenol may lead to an enhanced hypotensive effect.

Loop diuretics + Food

Some studies suggest that food modestly reduces the bioavailability and diuretic effects of furosemide, whereas others suggest that no significant effect occurs. Food does not appear to affect bumetanide or torasemide bioavailability.

Clinical evidence

(a) Solutions or standard tablets

Ten healthy subjects were given **furosemide** 40 mg with and without a standard breakfast. Food reduced the peak plasma levels and bioavailability of **furosemide**, by 55% and about 30%, respectively.[1] The results were almost identical when 5 of the subjects were given a heavy meal.[1] Furthermore, the diuresis over 10 hours was reduced by 21% (from 2072 to 1640 mL) and the diuresis over 24 hours was reduced by 15% (from 2668 to 2270 mL) when **furosemide** was taken with breakfast.[1]

A study in 10 patients with chronic respiratory failure also found that food decreased **furosemide** absorption and bioavailability; the mean 24-hour urinary recovery of unchanged drug was 11.5 mg and 9.41 mg, when the **furosemide** was given before and after food, respectively. In addition, when the data from these patients was compared with that from 11 healthy fasted subjects, the **furosemide** bioavailability was found to be lower, possibly due to enhanced glucuronidation and incomplete drug absorption. The diuretic effect was also lower in patients than healthy subjects; however, when **furosemide** was taken after food there was no significant change in the resulting diuresis, when compared with the fasting state.[2]

A comparative study in healthy subjects found that the absorption of both **bumetanide** 2 mg (9 subjects) and **furosemide** 40 mg (8 subjects), given as *solutions*, was delayed, and peak plasma levels were reduced, by a standard breakfast.[3] However, although food reduced the oral bioavailability of **furosemide** by about one-third, from 76% to 43%, the bioavailability of **bumetanide** was not significantly reduced (75% with food and 84% fasting). Food delayed the absorption but did not significantly alter the bioavailability of **furosemide** as tablets or solutions in two other studies.[4,5] In one of these studies, there was no difference in diuresis between fed and fasting subjects.[5]

A study in 14 healthy subjects given oral **torasemide** 10 mg found that administration with food decreased the absorption rate of **torasemide**, but did not affect the extent of absorption, when compared with the fasting state.[6]

(b) Sustained-release tablets

In a single-dose, crossover study in 28 subjects given two different controlled-release formulations of **furosemide** 60 mg, the absorption of one preparation (*Furix Retard*) was reduced by about 32% when it was given with breakfast, but the extent of absorption of the other formulation (*Lasix Retard*) was *increased* by about 18%. In the fasting phase of the study, *Furix Retard* had a higher extent and rate of absorption than *Lasix Retard*. However, the differences in diuresis and total natriuresis between the formulations, and between the fed and fasted state, were minor.[7] Another study suggested that **furosemide** extended-release tablets, which use an erosional matrix designed to retain the preparation in the stomach and deliver **furosemide** to the duodenum and upper jejunum over 6 hours, should be given in the fed state to ensure that the formulation remains in the stomach for long enough for absorption of **furosemide** to occur.[8]

Mechanism

Not understood.

Importance and management

Information about the effect of food on **furosemide** absorption is somewhat contradictory. Of the five studies using solutions or standard tablets, three found that the bioavailability of furosemide was modestly reduced by food (by about 30%) and the other two found no effect. Similarly, one study found a reduction in diuresis, whereas two others found no clinically relevant decrease in diuresis. It would also seem that the absorption of controlled-release formulations of furosemide may be modestly affected by food, but this may lead to increased absorption depending on the preparation.[7] The authors of this study noted that the amount of furosemide absorbed did not correlate with the extent of diuresis, and concluded that the urinary excretion profile of furosemide may be more important for producing diuresis than the amount of furosemide absorbed. Food does not appear to affect the bioavailability of **bumetanide** given as solution or **torasemide** tablets.

It would seem that furosemide, bumetanide and torasemide can be given to most patients without regard to meal times, although in some patients, such as those with heart failure or renal failure, reduced furosemide absorption may decrease urinary excretion of the drug and the diuretic threshold may not be achieved. In such patients giving furosemide without food might maximize the chance of achieving a diuretic response.[9]

Loop diuretics + H_2-receptor antagonists

Ranitidine and cimetidine may cause a moderate increase in the bioavailability of furosemide, but with no associated increase in diuretic effect. Cimetidine appears not to interact with torasemide.

Clinical evidence, mechanism, importance and management

(a) Furosemide

In a study in 6 healthy subjects, a single 400-mg dose of **cimetidine** increased the mean AUC of furosemide by one-third, although there was wide interpatient variation. However, there were no changes in the diuretic effects of furosemide or in the pharmacokinetics of cimetidine, and an associated study using multiple doses of **cimetidine** over 5 days found no pharmacokinetic or pharmacodynamic interaction.[1] A similar study in patients with hepatic cirrhosis also found that **cimetidine** does not interact with furosemide.[2]

Eighteen healthy subjects were given oral furosemide 40 mg one hour after intravenous **ranitidine** 50 mg or saline. The **ranitidine** increased the AUC of furosemide by 28% and increased the maximum serum levels by 37%.[3] The effects of furosemide could possibly be slightly increased by **ranitidine**, but the clinical importance of this is probably small. No special precautions seem necessary.

(b) Torasemide

In 11 healthy subjects **cimetidine** 300 mg four times daily for 3 days was found to have no effect on the pharmacokinetics of a single 10-mg oral dose of torasemide, nor were there any changes in the volume of urine or the excretion of sodium, potassium or chloride.[4]

Loop diuretics + NSAIDs

The antihypertensive and diuretic effects of the loop diuretics appear to be reduced by NSAIDs, including coxibs, although the extent of this interaction largely depends on individual NSAIDs. Diuretics increase the risk of NSAID-induced acute renal failure. The concurrent use of NSAIDs with loop diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation. Some NSAIDs may theoretically increase the risk of ototoxicity associated with loop diuretics.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses,[1,2] the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.[2] Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,[1] the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,[2] the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.[1] The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for **diuretics**. However, the differences between the groups were not significant.

A case-control study using the UK General Practice Research Database found that current NSAID use increased the risk of acute renal failure (relative risk 3.2 compared with no NSAID use) and this risk was further increased with concurrent **diuretic** use (relative risk 11.6).[3] Note that the risk of renal complications appear to be similar with coxibs as with non-specific NSAIDs.[4]

Individual clinical reports and clinical or pharmacological studies of the effects of specific NSAIDs on diuretics are outlined in the subsections below and in 'Table 26.2', (p.1126).

A. Bumetanide

(a) Celecoxib and other Coxibs

A patient taking celecoxib with bumetanide developed a moderately raised serum creatinine. Another patient taking an ACE inhibitor, spironolactone and bumetanide developed a severely raised serum creatinine, hyperkalaemia, and worsening of congestive heart failure shortly after starting celecoxib.[5] A similar case occurred in another patient taking bumetanide about 8 days after **rofecoxib** was started.[5]

(b) Indometacin

In two studies, a single 100-mg dose of indometacin was found to reduce the bumetanide-induced output of urine, sodium and chloride (but not potassium) by about 25%.[6-8] There are other reports confirming this interaction between bumetanide and indometacin, including a clinical study,[9] and a report of a patient who developed heart failure as a result of this interaction.[10]

(c) Sulindac

A study in 8 healthy subjects found that a single 300-mg dose of sulindac did not significantly reduce the diuretic response (measured by urinary volume, and urinary excretion of sodium, potassium, and chloride) to a single 1-mg dose of bumetanide.[11] However, another study in 9 healthy subjects found that pretreatment with sulindac 200 mg twice daily for 5 days reduced the diuretic effect of a single 1-mg dose of bumetanide (mean urine flow rate after 2 hours reduced by 21% and cumulative sodium excretion at 3 hours reduced by 22%).[12]

(d) Tolfenamic acid

A study in 8 healthy subjects found that tolfenamic acid 300 mg reduced the diuretic response (measured by urinary volume, and urinary excretion of sodium, potassium, and chloride) to a single 1-mg dose of bumetanide by 34% at 2 hours.[11]

B. Furosemide

A comparison of four NSAIDs with different chemical structures and different potencies for inhibiting urinary prostaglandin E_2 synthesis found that **flurbiprofen**, **indometacin**, **piroxicam** and **sulindac** were equipotent in reducing furosemide-stimulated sodium excretion and creatinine clearance.[13]

(a) Azapropazone

Ten healthy subjects had no change in their urinary excretion in response to furosemide 40 mg daily when they were also given azapropazone 600 mg twice daily. The furosemide did not antagonise the uricosuric effects of the azapropazone.[14]

(b) Celecoxib and other Coxibs

In a placebo-controlled study, 7 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after receiving celecoxib 200 mg twice daily for 5 doses. It was found that this short-term use of celecoxib did not reduce the natriuretic or diuretic effects of furosemide.[15]

Two patients with a history of chronic heart failure, taking furosemide 40 or 80 mg daily, developed acute renal failure when they started to take celecoxib 100 or 200 mg twice daily. Neither patient showed any sign of decompensated heart failure on admission (which can in itself cause renal failure) and both recovered on stopping the celecoxib and furosemide combination. One patient was also taking enalapril, and this was restarted with the furosemide without any changes in renal function.[16] The same authors also described two other patients taking furosemide who developed renal failure when they started to take **rofecoxib**.[16] Other cases have occurred in patients taking furosemide, often with ACE inhibitors, after they started **rofecoxib**.[5]

(c) Diclofenac

A study in patients with heart failure and cirrhosis found that diclofenac 150 mg daily reduced the furosemide-induced excretion of sodium by 38%, but the excretion of potassium was unaltered.[17]

(d) Diflunisal

A study in 12 healthy subjects found that diflunisal 500 mg twice daily reduced sodium excretion in response to furosemide by 59%, but potassium excretion remained unchanged.[18] In patients with heart failure and cirrhosis taking furosemide, diflunisal 500 to 700 mg daily decreased the sodium excretion by 36% and the potassium excretion by 47%.[17] However, another study in healthy subjects found no interaction between diflunisal and furosemide.[19]

(e) Flupirtine

A study in healthy subjects found that a single 200-mg dose of flupirtine did not affect the overall furosemide diuresis, but the diuretic effect was slightly delayed.[20]

(f) Flurbiprofen

A study in 7 healthy subjects found that the increase in renal osmolal clearance of a standard water load in response to furosemide 40 mg orally or 20 mg intravenously fell from 105% to 19% and from 140% to 70%, respectively, after flurbiprofen 100 mg was given.[21] A single-dose study in 10 healthy subjects found that flurbiprofen 100 mg reduced the urinary volume, and urinary excretion of sodium and potassium, in response to oral furosemide 80 mg by 10%, 9%, and 12%, respectively.[22,23]

(g) Ibuprofen

An elderly man with heart failure taking digoxin, isosorbide dinitrate and furosemide 80 mg daily, developed symptomatic congestive heart failure with ascites when given ibuprofen 400 mg three times daily. His serum urea and creatinine levels rose and no diuresis occurred, even when the furosemide dosage was doubled. Two days after withdrawing the ibuprofen, brisk diuresis took place, renal function returned to normal, and his condition improved steadily.[24] Another elderly patient similarly had a poor response to furosemide (also hydrochlorothiazide and later to metolazone as well) until she stopped taking ibuprofen 600 mg four times daily and at least two **aspirin** daily (for headache).[25] This was due to hyponatraemic hypovolaemia brought on by the drug combination.

Table 26.2 Summary of the interactions of diuretics and NSAIDs

NSAID	*Excretion of sodium*	*Excretion of potassium*	*Diuresis*	*Blood pressure*	*Other effects*
Bumetanide					
Celecoxib					Increased serum creatinine
Indometacin	Reduced by 25%		Reduced by 25%		Development of congestive heart failure in one case
Rofecoxib					Increased serum creatinine Worsening congestive heart failure
Sulindac	Reduced by 22%		Reduced by 21%		
Tolfenamic acid			Reduced by 34%		
Furosemide					
Azapropazone			Non-significant effect		
Celecoxib	Non-significant effect		Non-significant effect		Increased serum creatinine Acute renal failure developed in 2 cases
Diclofenac	Decreased by 38%		Non-significant effect		
Diflunisal	Decreased by 36 to 59%	No significant effect in healthy subjects Decreased by 47% in patients			
Flupirtine			Delayed		
Flurbiprofen	Decreased by 9%	Decreased by 12%	Decreased by 10%		
Ibuprofen			Decreased		Development of congestive heart failure in one case Decreased GFR
Indometacin	Decreased by 64 to 82%	Decreased by 49%	Decreased by 41 to 69%	Mean blood pressure increased by 13 mmHg	
Ketoprofen			Decreased		
Ketorolac	Decreased by 26%		Decreased by about 20%		
Lornoxicam	Decreased		Decreased		
Meloxicam			Non-significant effect		
Metamizole (Dipyrone)			Non-significant effect		
Mofebutazone	Non-significant effect	Non-significant effect	Non-significant effect		
Naproxen	Decreased		Decreased by 50%		GFR decreased
Nimesulide	Decreased		Slight decrease		
Piroxicam	Decreased		Decreased		
Rofecoxib					Development of acute renal failure
Sulindac	Decreased by 38 to 52%	Decreased by 8%	Decreased by 25 to 38%		
Tenoxicam	Non-significant effect			Non-significant effect	
Piretanide					
Indometacin	Decreased by 35%				
Naproxen		Decreased by 14%	Non-significant effect		
Piroxicam	Decreased				
Sulindac	Decreased at 0 to 4 hours, increased at 4 to 8 hours				
Torasemide					
Indometacin	Decreased				

Continued

Table 26.2 Summary of the interactions of diuretics and NSAIDs (continued)

NSAID	*Excretion of sodium*	*Excretion of potassium*	*Diuresis*	*Blood pressure*	*Other effects*
Altizide					
Rofecoxib					Congestive heart failure with weight gain occurred in one case
Bemetizide					
Indometacin	Decreased by 47%				
Bendroflumethiazide					
Ibuprofen				Small increase	Weight gain in 2 patients but overall the effect was non-significant
Indometacin				Increase of 16/9 mmHg	Weight gain
Sulindac				Decreased	
Chlortalidone					
Ibuprofen					Diabetic nephropathy reported in one case
Hydrochlorothiazide					
Diclofenac	Decreased	Non-significant effect		Non-significant effect	Weight gain
Ibuprofen				Small increase (systolic)	Weight gain
Indometacin		Increased		Transient increase of 6/3 mmHg Increase of 16/9 mmHg seen when amiloride also taken	Weight gain
Kebuzone				18 mmHg increase (systolic)	
Naproxen			Non-significant effect		Hyponatraemia reported in a patient also taking amiloride
Phenylbutazone				18 mmHg increase (systolic)	
Piroxicam				Slight increase (patients also taking amiloride)	
Rofecoxib	Decreased	Non-significant effect			
Sulindac	Decreased by 29% over 0 to 4 hours		Usually non-significant but a decrease of 35% over 0 to 4 hours has been reported	Non-significant effect Non-significant effect, or *enhanced* hypotensive effects reported when amiloride also taken	Acute renal failure reported in one case
Methyclothiazide					
Indometacin					Acute renal failure reported in one case
Metolazone					
Indometacin	Decreased by 34%	Decreased by 30%			
Sulindac	Decreased by 19%	Decreased by 16%			
Amiloride					
Indometacin					Case of hyperkalaemia in a patient also taking hydrochlorothiazide
Spironolactone					
Indometacin	Decreased by 54%				
Mefenamic acid			Decreased		
Triamterene					
Diclofenac					Acute renal failure reported in one case (trichlormethiazide also taken)

Continued

Table 26.2 Summary of the interactions of diuretics and NSAIDs (continued)

NSAID	*Excretion of sodium*	*Excretion of potassium*	*Diuresis*	*Blood pressure*	*Other effects*
Ibuprofen				Non-significant (hydrochlorothiazide also taken)	Acute renal failure reported in two cases and increased serum creatinine reported in one case (trichlormethiazide also taken in all cases)
Indometacin					Acute renal failure reported in six cases (hydrochlorothiazide also taken in one case) and increased serum creatinine reported in two cases

In a small, placebo-controlled, crossover study in 8 healthy subjects, ibuprofen 400 mg and 800 mg three times daily for 3 days significantly reduced the glomerular filtration rate and the diuresis produced by a single 20-mg intravenous dose of furosemide, but did not alter sodium excretion.[26]

Loop diuretics such as furosemide have been reported to occasionally cause hearing loss and NSAIDs including ibuprofen have also been reported to have ototoxic effects, which could theoretically be additive.[27]

(h) Indometacin

A study in 4 healthy subjects and 6 patients with essential hypertension found that furosemide 80 mg three times daily reduced the mean blood pressure by 13 mmHg, but when indometacin 50 mg four times daily was also given the blood pressures returned to virtually pretreatment levels. Moreover, the normal urinary sodium loss induced by the furosemide was significantly reduced.[28]

A study in healthy subjects and patients with congestive heart failure found that indometacin 100 mg reduced the furosemide-induced urinary output by 53% and also reduced the excretion of sodium, potassium, and chloride by 64%, 49%, and 62%, respectively, in the patients with congestive heart failure. The drug interaction was much less pronounced in the healthy subjects.[29] A study in 14 patients with ascites secondary to liver cirrhosis found that indometacin 50 mg every 6 hours for 2 doses significantly reduced the urinary volume and the natriuretic response to furosemide, by 69% and 82%, respectively, but produced only a small, non-significant reduction in creatinine clearance.[30] Another study found that indometacin reduced the urinary output in response to furosemide by 28% in healthy subjects and by 41% in elderly patients (three with mild-to-moderate heart failure).[31] There are other case reports and studies confirming the interaction between furosemide and indometacin.[26,32-38]

(i) Ketoprofen

A study in 12 healthy subjects given furosemide 40 mg daily found that ketoprofen 100 mg twice daily reduced the 6-hour urine output by 67 mL, and the 24-hour urine output by 651 mL on the first day of treatment. However no significant differences were seen after 5 days of treatment.[39]

(j) Ketorolac

Twelve healthy subjects were given oral ketorolac 30 mg four times daily, and then a single 30-mg intramuscular dose of ketorolac 30 minutes before a 40-mg intravenous dose of furosemide. No precise figures are given, but the maximum serum level of the furosemide, its diuretic effect, and the electrolyte loss were said to be significantly reduced by the ketorolac.[40] Another study in healthy elderly subjects found that when they were given oral ketorolac 120 mg, then, on the following day, intramuscular ketorolac 30 mg, followed 30 minutes later by furosemide 40 mg, the urinary output fell by 16% and the sodium output fell by 26% over the next 8 hours, when compared with furosemide alone.[41]

(k) Lornoxicam

A study in 12 healthy subjects found that lornoxicam 4 mg significantly antagonised the diuretic and natriuretic effects of furosemide, but this was not quantified.[42]

(l) Meloxicam

In a study in 12 healthy subjects meloxicam 15 mg daily for 3 days had no significant effect on the pharmacokinetics of furosemide 40 mg. The furosemide-induced diuresis was unchanged, and although the cumulative urinary electrolyte excretion was somewhat lower, this was not considered to be clinically significant.[43] A similar study in patients with heart failure taking an ACE inhibitor also found no clinically significant pharmacokinetic or pharmacodynamic interaction between furosemide and meloxicam.[44]

(m) Metamizole sodium (Dipyrone)

A study in 9 healthy subjects found that metamizole sodium 3 g daily for 3 days, reduced the clearance of intravenous furosemide 20 mg from 175 to 141 mL/minute but the diuretic effects of the furosemide were unchanged.[45]

(n) Mofebutazone

A study in 10 healthy subjects found that mofebutazone 600 mg had no effect on the diuretic effects of furosemide 40 mg. The urinary volume and excretion of sodium, potassium and chloride were unchanged.[46]

(o) Naproxen

Two elderly women with congestive heart failure did not respond to treatment with furosemide and digoxin until the naproxen they were taking was withdrawn.[24] A single-dose study in patients with heart failure found that the volume of urine excreted in response to furosemide was reduced about 50% by naproxen.[31] In a placebo-controlled study, 6 patients with cirrhosis and ascites were given a single 40-mg intravenous dose of furosemide before and after naproxen 500 mg twice daily for 5 doses. It was found that this short-term use of naproxen reduced the glomerular filtration rate and the natriuretic and diuretic effects of furosemide.[15]

Loop diuretics such as furosemide have been reported to occasionally cause hearing loss and NSAIDs including naproxen have also been reported to have ototoxic effects, which could theoretically be additive.[27,47]

(p) Nimesulide

A study in 8 healthy subjects found that nimesulide 200 mg twice daily attenuated the effects of furosemide 40 mg twice daily. Subjects who had initially lost weight when taking furosemide regained weight, diuresis was slightly reduced, cumulative sodium excretion was decreased and the glomerular filtration rate was transiently reduced.[48]

(q) Piroxicam

A 96-year-old woman with congestive heart failure did not adequately respond to furosemide until the dosage of piroxicam she was taking was reduced from 20 to 10 mg daily.[49]

In one study in 9 hypertensive patients with a creatinine clearance of less than 60 mL/minute, who were taking furosemide, piroxicam 20 mg daily for 3 days produced a significant reduction in the natriuretic and kaliuretic effects of an additional single 40-mg dose of furosemide. However, in 13 other patients, with a creatinine clearance of greater than 60 mL/minute, who were taking a thiazide diuretic, piroxicam did not alter the effects of a single 40-mg dose of furosemide. In a third group of 8 healthy subjects, the same dose of piroxicam reduced the natriuretic effects, but not the kaliuretic effects, of a single 40-mg dose of furosemide.[50]

(r) Sulindac

A study in 5 healthy subjects found that pretreatment with two 150-mg oral doses of sulindac reduced the urinary volume and urinary sodium following an intravenous dose of furosemide 80 mg by 25% and 38%, respectively. In patients with cirrhosis and ascites, two doses of sulindac 150 mg reduced the urinary volume, urinary sodium, and urinary potassium following an 80-mg intravenous dose of furosemide by 38%, 52%, and 8%, respectively.[51] In another placebo-controlled study in 15 healthy

women, sulindac 200 mg twice daily for 5 days produced a similar but slightly smaller reduction in the natriuretic effect of a single 40-mg intravenous dose of furosemide, than indometacin.[37]

(s) Tenoxicam

A study in 12 patients found that tenoxicam 20 to 40 mg daily had no significant effect on the urinary excretion of sodium or chloride due to furosemide 40 mg daily, and blood pressure, heart rate and body-weight also were not affected.[52]

C. Piretanide

(a) Indometacin

A comparative study[53] into the pharmacological mechanisms underlying the way that drugs interfere with the actions of loop diuretics found that indometacin 50 mg three times daily for 2 days reduced the peak fractional and cumulative excretion of sodium in response to a single 6-mg dose of piretanide. The clinical importance of this change was not studied.

(b) Naproxen

Pretreatment of healthy subjects with naproxen 500 mg decreased the fractional potassium clearance produced by piretanide 6 mg by 14%, but no attenuation of the diuretic response was seen. Estimation of piretanide urinary clearance was not possible as naproxen interfered with the analysis.[54]

(c) Piroxicam

A comparative study into the pharmacological mechanisms underlying the way that drugs interfere with the actions of loop diuretics found that piroxicam 20 mg twice daily for 2 days did not significantly affect the peak fractional excretion of sodium in response to a single 6-mg dose of piretanide, but the cumulative excretion of sodium over 5 and 24 hours was reduced.[53]

(d) Sulindac

Pretreatment of healthy subjects with sulindac 200 mg decreased the fractional urinary flow rate produced by piretanide 6 mg by 15% and attenuated the natriuretic effect of piretanide over 0 to 4 hours. However, natriuresis was increased over the 4 to 8-hour period of the study.[54]

D. Torasemide

A study in healthy subjects suggested that indometacin did not affect the diuretic and natriuretic effects of torasemide,[55] but on the basis of a later study, the same workers suggested that pathological factors in patients may allow an interaction similar to that between furosemide and indometacin to occur. Indometacin was found to reduce the natriuretic actions of torasemide when the subjects were given a low sodium diet, but did not affect the natriuretic actions when they received a normal diet. The sodium balance, therefore, appeared to be a determinant of the interaction between NSAIDs and loop diuretics.[56]

Mechanism

Uncertain and complex. It is likely that a number of different mechanisms come into play. NSAIDs cause fluid and salt retention, which would be expected to antagonise the effects produced by diuretics. The sodium retentive properties of NSAIDs appear to be most noticeable in patients who already have a predisposition to sodium retention, such as those with heart disease, liver disease etc.[57,58] A reduction in glomerular filtration rate is sometimes observed with NSAIDs and this may reduce the natriuretic efficacy of loop diuretics particularly in states of renal underperfusion such as congestive heart failure, volume depletion, and liver cirrhosis.[59]

One probable mechanism involves the synthesis of renal prostaglandins, particularly prostaglandin E_2 and prostacyclin, which inhibit the reabsorption of sodium and help to maintain renal blood flow and glomerular filtration rates in the face of disease or circulatory stress, such as occurs when the loop diuretics cause sodium excretion.[60] If this synthesis is blocked by NSAIDs, then renal blood flow, natriuresis and diuresis will be reduced.[59,61]

NSAIDs can also decrease renin release, leading to reduced aldosterone secretion, which results in reduced potassium secretion in the distal nephron. Patients with renal impairment or patients who are receiving other drugs that decrease potassium secretion, for example 'ACE inhibitors', (p.32), are at increased risk of hyperkalaemia.[58] It appears that coxibs also affect renal prostaglandins and renin release and are likely to interact similarly to non-selective NSAIDs.[58,62]

In addition, NSAIDs may alter the access of some diuretics to their tubular site of action by competing for transport in the proximal tubule.[59,63]

Importance and management

NSAIDs, including coxibs, can cause renal impairment, particularly in patients with hypovolaemia or dehydration and in whom prostaglandins are playing an important role in maintaining renal function. Such patients include those taking diuretics, the elderly and those with concurrent conditions such as congestive heart failure and ascites. Hence the combination of diuretics and NSAIDs may increase the nephrotoxicity of NSAIDs.[36,64-68]

Loop diuretics such as **etacrynic acid**,[69] furosemide,[27] or piretanide[70] can exhibit ototoxic properties particularly if given in high doses and in renal impairment.[27] The risk of ototoxicity may theoretically be increased if these diuretics are given with other ototoxic drugs such as some NSAIDs, including ibuprofen and naproxen.[27,47]

The antihypertensive and diuretic effects of the loop diuretics are reduced by NSAIDs. This interaction is very well documented between furosemide and indometacin, and of clinical importance, whereas less is known about the interactions with other NSAIDs. Nevertheless, the interaction should be anticipated with all of them. The use of an alternative non-NSAID analgesic should always be considered, if possible. However, in cases where concurrent use cannot be avoided, the loop diuretic dosage may need to be raised (according to clinical response), but the effects on renal function and electrolytes, as well as efficacy, should be closely monitored. Patients at greatest risk of an adverse interaction include the elderly and patients with cirrhosis, cardiac failure and/or renal impairment, and NSAIDs should usually be used with caution in these patient groups regardless of the concurrent use of diuretics. Note that a retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common NSAIDs taken by this cohort of patients were diclofenac, ibuprofen, indometacin and naproxen.[57] Furthermore, the European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association both recommend avoiding NSAID use, if possible, in patients with congestive heart failure.[71,72]

Much less is known about the interactions of NSAIDs with **bumetanide**, and even less about **piretanide**, **torasemide**, and **etacrynic acid**, but the evidence suggests that they probably interact in the same way as furosemide. It would therefore seem prudent to be alert for a potential reduction in effect if an NSAID is given.

Loop diuretics + Probenecid

Probenecid decreases the renal clearance of furosemide and bumetanide, but it appears not to significantly alter their overall diuretic effect. Probenecid reduces the natriuretic effect of piretanide, although the clinical relevance of this is uncertain.

Clinical evidence

(a) Bumetanide

Probenecid 1 g did not affect the natriuretic or diuretic response of 8 healthy subjects to 500 micrograms or 1 mg of intravenous bumetanide.[1] Another study reported a fall in natriuresis and a reduction in the clearance of bumetanide when probenecid was given, but this was of minimal clinical importance.[2]

(b) Furosemide

The concurrent use of furosemide and probenecid has been closely studied to determine the renal pharmacological mechanisms of loop diuretics. One study in patients given furosemide 40 mg daily found that the addition of probenecid 500 mg twice daily for 3 days reduced their urinary excretion of sodium by about 36% (from 56.3 to 35.9 mmol daily).[3] Other studies have found that probenecid causes a fall,[4] a rise,[5] and no change[6,7] in diuresis in response to furosemide, and causes a reduction of 35 to 80% in the renal clearance of furosemide.[4,6-9] One study found that probenecid 1 g increased the half-life of furosemide by 70% and decreased its oral clearance by 65%.[8] Similar results were found in another study.[10]

(c) Piretanide

A comparative study[11] into the pharmacological mechanisms underlying the way drugs interfere with the actions of loop diuretics found that probenecid 1 g reduced the peak fractional excretion of sodium produced by a 6-mg dose of oral piretanide by 65%. Another study confirmed that probenecid reduces the natriuretic effects of piretanide.[12] The clinical importance of these changes was not studied.

Mechanism

Loop diuretics are secreted from the blood into the urine through the organic acid transport pathway. Other organic acids such as probenecid can alter loop diuretic secretion by competing for transport in the proximal tubule.[13]

Importance and management

Probenecid appears to reduce the renal clearance of furosemide and bumetanide, but the effect on diuresis does not usually appear to be clinically significant. Nevertheless, one manufacturer of furosemide warns that probenecid may reduce its effects.[14] Probenecid does reduce the natriuretic effects of piretanide, and although the clinical effects of this have not been studied, it may be prudent to be alert for a decreased response to piretanide if probenecid is also given. There appears to be no direct evidence regarding **torasemide**, but one manufacturer[15] warns that its effects may be reduced by probenecid. It may be prudent to be alert for this if both drugs are given.

Loop diuretics; Furosemide + Bile-acid binding resins

Colestyramine and colestipol markedly reduce the absorption and diuretic effects of furosemide.

Clinical evidence

In 6 healthy subjects **colestyramine** 8 g reduced the absorption of a single 40-mg dose of furosemide by 95%. The 4-hour diuretic response was reduced by 77% (urinary output reduced from 1510 to 350 mL). Similarly, **colestipol** 10 g reduced the absorption of furosemide by 80% and reduced the 4-hour diuretic response by 58% (urinary output reduced from 1510 to 630 mL).[1]

Mechanism

Both colestyramine and colestipol are anionic exchange resins, which can bind with furosemide in the gut, thereby reducing its absorption and its effects.

Importance and management

An established interaction, although direct evidence seems to be limited to this study. The absorption of furosemide is relatively rapid; therefore giving it 2 to 3 hours before either the colestyramine or colestipol should be an effective way of overcoming this interaction. This needs confirmation. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Loop diuretics; Furosemide + Cloral hydrate and related drugs

Intravenous furosemide, given after cloral hydrate, occasionally causes sweating, hot flushes, a variable blood pressure, and tachycardia. Dichloralphenazone and cloral betaine may interact similarly.

Clinical evidence

Six patients in a coronary care unit, given an intravenous bolus of 40 to 120 mg of furosemide and who had received cloral hydrate during the previous 24 hours, developed sweating, hot flushes, variable blood pressure, and tachycardia. The reaction was immediate and lasted for about 15 minutes. No special treatment was given. Furosemide had caused no problems when given before the cloral hydrate was started.[1]

A retrospective study of hospital records revealed that, out of 43 patients who had received both cloral hydrate and furosemide, one patient developed this reaction and 2 others may have done so.[2] The interaction has also been described in an 8-year-old boy.[3]

Mechanism

Not understood. One suggestion is that furosemide displaces trichloroacetic acid (the metabolite of cloral hydrate) from its protein binding sites, which in its turn displaces levothyroxine or alters the serum pH so that the levels of free levothyroxine rise leading to a hypermetabolic state.[1]

Importance and management

An established interaction, but information is limited to three reports. The incidence is uncertain but probably low. Concurrent use need not be avoided, but it would be prudent to give intravenous furosemide cautiously if cloral hydrate has been given recently. It seems possible that drugs that release cloral hydrate when metabolised (e.g. **dichloralphenazone**, **cloral betaine**) might interact similarly. There is no evidence that furosemide given orally or cloral hydrate given to patients already taking furosemide causes this reaction.[2]

Loop diuretics; Furosemide + Germanium

An isolated case report describes a man who became resistant to furosemide after he took germanium.

Clinical evidence, mechanism, importance and management

A 63-year-old man was hospitalised for hypertension and oedema 10 days after adding ginseng containing germanium to his usual treatment with cyclophosphamide and furosemide. He gained almost 13 kg in weight. After treatment with intravenous furosemide he was discharged and again took ginseng with germanium. This time he gained 12 kg in weight over 14 days, despite an increase in the dose of furosemide from 80 mg twice daily to 240 mg twice daily. The weight gain and oedema again resolved when the ginseng and germanium was withdrawn and intravenous furosemide was given. The authors suggest that germanium was responsible for this interaction.[1]

This is an isolated report, and its general significance is unclear. However, note that it has been said that the use of germanium should be discouraged due to its potential to cause renal toxicity.[2]

2. Sweetman SC, ed. Martindale: The complete drug reference. 36th ed. London: Pharmaceutical Press; 2009. p. 2311.

Loop diuretics; Furosemide + Paracetamol (Acetaminophen)

In 10 healthy women paracetamol 1 g four times daily for 2 days was found to have no effect on the diuresis or natriuresis in response to 20 mg of intravenous furosemide.[1]

1. Martin U, Prescott LF. The interaction of paracetamol with frusemide. *Br J Clin Pharmacol* (1994) 37, 464–7.

Loop diuretics; Furosemide + Phenytoin

The diuretic effects of furosemide can be reduced by as much as 50% by phenytoin.

Clinical evidence

A group of epileptic patients were noted to have higher than expected dependent oedema, with an apparently reduced response to diuretics: this prompted further study. In 30 patients taking **phenytoin** 200 to 400 mg

daily with phenobarbital 60 to 180 mg daily the maximal diuresis in response to furosemide 20 or 40 mg occurred after 3 to 4 hours instead of the usual 2 hours. The total diuresis was reduced by 32% for the 20-mg dose, 49% for the 40-mg dose and 50% when intravenous furosemide 20 mg was given. Some of the patients were also taking carbamazepine, pheneturide, ethosuximide, diazepam or chlordiazepoxide.[1]

Another study in 5 healthy subjects given **phenytoin** 100 mg three times daily for 10 days found that the maximum serum levels of furosemide 20 mg, given orally or intravenously, were reduced by 50%.[2]

Mechanism

Not understood. One suggestion is that the phenytoin causes changes in the jejunal sodium pump activity, which reduces the absorption of the furosemide,[2] but this is not the whole story because an interaction also occurs when furosemide is given intravenously.[1] Other suggestions, based on *in vitro* or *animal* evidence, are that the phenytoin generates a 'liquid membrane,' which blocks the transport of the furosemide to its active site,[3] or that phenytoin antagonises the diuretic effect of furosemide by interfering with the renal tubular sodium pump mechanism.[4]

Importance and management

Information is limited but the interaction is established. A reduced diuretic response should be expected in the presence of phenytoin. A dosage increase may be needed.

Loop diuretics; Furosemide + Sevelamer

Sevelamer abolished the diuretic effect of furosemide in a haemodialysis patient.

Clinical evidence, mechanism, importance and management

A haemodialysis patient taking furosemide 250 mg twice daily found that her urine output reduced from 950 mL/day to zero when she started taking sevelamer 800 mg at breakfast and lunchtime, and 1.6 g with dinner. Urine output returned to the previous level within 24 hours of stopping the sevelamer. This effect also occurred on rechallenge. The dose times were adjusted so that she took furosemide 500 mg in the morning and sevelamer 1.6 g at lunch and dinner, and her urine output was unaffected and remained stable.[1]

The authors suggest that furosemide became bound to sevelamer in the gut, and this prevented its absorption.

This appears to be the only case report of an interaction between these drugs so far; however, it is worth bearing this case in mind should a similar situation arise in other patients. Note that the manufacturers of sevelamer[2,3] suggest that, when giving any other oral drug for which a reduction in the bioavailability could have a clinically significant effect on safety or efficacy, the drug should be given at least 1 hour before or 3 hours after sevelamer.

Loop diuretics; Furosemide + Sucralfate

The manufacturer notes that when sucralfate was given with furosemide the absorption of furosemide from the intestine was decreased and therefore its effects were reduced.[1] They advise that oral furosemide and sucralfate must not be taken within 2 hours of each other.[1,2] However, a study in *animals* had shown that the amount of furosemide excreted in the urine was not affected by concurrent oral administration of sucralfate, and the excretion of sodium and potassium in response to furosemide was not altered.[3]

Potassium-sparing diuretics + H_2-receptor antagonists

Although the H_2-receptor antagonists appear to cause minor changes in the pharmacokinetics of amiloride and triamterene, none of these have been shown to be of clinical significance.

Clinical evidence, mechanism, importance and management

(a) Amiloride

A study in 8 healthy subjects given amiloride 5 mg daily found that **cimetidine** 400 mg twice daily for 12 days reduced the renal clearance of amiloride by 17% and reduced its urinary excretion from 65% to 53%. Amiloride also reduced the excretion of **cimetidine** from 43% to 32%, and the AUC was reduced by 14%.[1] No changes in the diuretic effects (urinary volume, sodium or potassium excretion) occurred. It seems that each drug reduces the gastrointestinal absorption of the other drug by as yet unidentified mechanisms. The overall plasma levels of the amiloride remain unchanged because the reduced absorption is offset by a reduction in its renal excretion. These mutual interactions do not seem to be clinically significant.

(b) Triamterene

A study in 6 healthy subjects given triamterene 100 mg daily for 4 days found that **cimetidine** 400 mg twice daily increased the AUC of triamterene by 22%, reduced its metabolism (hydroxylation) by 32%, and reduced its renal clearance by 28%. There also appeared to be a reduction in the absorption of triamterene. However, the loss of sodium in the urine was not significantly changed, and the potassium-sparing effects of triamterene were not altered.[2] Because the diuretic effects of triamterene are minimally changed, this interaction is unlikely to be clinically important.[2]

In 8 healthy subjects, **ranitidine** 150 mg twice daily for 4 days roughly halved the absorption (as measured by renal clearance) of triamterene 100 mg daily. Its metabolism was also reduced, with the total effect being a 21% reduction in the AUC. As a result of the reduced plasma triamterene levels, the urinary sodium loss was reduced to some extent but potassium excretion remained unchanged.[3] Overall the diuretic effects of triamterene were only mildly affected. Another study found that a 22% reduction in the AUC of triamterene is unlikely to result in a significant change in its diuretic effects.[2] No clinically significant interaction is therefore anticipated.

Potassium-sparing diuretics + NSAIDs

The concurrent use of triamterene (with or without a thiazide) and an NSAID has, in several cases, rapidly led to acute renal failure. NSAIDs may possibly antagonise the antihypertensive and/or diuretic effects of potassium-sparing diuretics and may also increase the risk of hyperkalaemia. There may be an increased risk of gastrointestinal events with spironolactone and NSAIDs.

Clinical evidence

A retrospective analysis of records of patients taking diuretics (thiazides, loop and/or potassium-sparing) and NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use,

although the relative risk (1.4) with potassium-sparing diuretics was less than that when combined with a thiazide (2.9). The most common NSAIDs taken by this cohort of patients were **diclofenac**, **ibuprofen**, **indometacin** and **naproxen**.[1] The combination of NSAIDs, for example indometacin, with potassium-sparing diuretics has been associated with severe hyperkalaemia, particularly in patients with impaired renal function.[2-5] NSAIDs can reduce the diuretic, natriuretic and antihypertensive effects of diuretics in some patients.[2-5] Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients treated with antihypertensives, including diuretics, and the findings of these are summarised in 'Table 23.2', (p.1027). Individual clinical reports and clinical or pharmacological studies of the effects of specific NSAIDs on diuretics are outlined in the subsections below and in 'Table 26.2', (p.1126).

A. Amiloride

A 78-year-old woman, who had been receiving **indometacin** 100 mg twice daily as suppositories and furosemide 40 mg every other day, experienced progressive weakness after furosemide was discontinued and amiloride/hydrochlorothiazide 5/50 mg daily was prescribed. She was found to have severe hyperkalaemia (serum potassium 6.8 mmol/L), which resolved after the drugs were discontinued. On rechallenge neither **indometacin** nor amiloride/hydrochlorothiazide, given alone, significantly changed her serum potassium levels, but giving indometacin with amiloride subsequently resulted in hyperkalaemia.[6] For further mention of interactions between amiloride/hydrochlorothiazide and indometacin or other NSAIDs, see 'Thiazide diuretics + NSAIDs', p.1138.

B. Spironolactone

(a) Indometacin

A study in healthy subjects found that indometacin 150 mg daily reduced the natriuretic effect of spironolactone 300 mg daily by 54%.[7]

(b) Mefenamic acid

The UK manufacturer of spironolactone reports that mefenamic acid has been shown to attenuate the diuretic effect of spironolactone.[8]

(c) Rofecoxib

For a report of heart failure in an elderly woman taking spironolactone, altizide and other drugs, when rofecoxib was added to her treatment, see 'Thiazide diuretics + NSAIDs', p.1138.

(d) Unspecified NSAIDs

A retrospective, population based case-control study suggested that the current use of spironolactone was associated with a 2.7-fold increased risk of a gastrointestinal event. This association was stronger as the dosage increased and was more pronounced when spironolactone was combined with ulcerogenic drugs including NSAIDs. Increasing the dosage of other diuretics including **amiloride** or loop diuretics was not associated with upper gastrointestinal bleeding.[9] The study has been criticised because of, among other things, the use of unmatched controls,[10,11] although another retrospective study found that, with long-term treatment, spironolactone was associated with gastritis in 2% of patients.[12] The manufacturer also mentions gastric bleeding, ulceration and gastritis as adverse reactions that have been reported with spironolactone.[2]

C. Triamterene

(a) Diclofenac

A patient receiving triamterene 100 mg and **trichlormethiazide** 2 mg daily was given intramuscular diclofenac 75 mg before admission to hospital with breast pain. On admission serum creatinine was 91 micromol/L and after 2 days it had increased to 248 micromol/L, but it returned to normal over 2 weeks. The subsequent use of oral diclofenac produced no adverse effects. The observed deterioration in renal function was attributed to an interaction between triamterene and diclofenac.[13]

(b) Diflunisal

Diflunisal had no effects on the pharmacokinetics of triamterene in healthy subjects, but the plasma AUC of an active metabolite, *p*-hydroxytriamterene was increased by more than fourfold.[14]

(c) Ibuprofen

A 37-year-old black man who had regularly taken ibuprofen 800 mg one to three times daily and hydrochlorothiazide/triamterene 50/75 mg daily, developed acute renal failure after strenuous exercise. A renal biopsy showed acute tubular necrosis. The patient had taken the ibuprofen and diuretics 2 hours before exercise and it was suggested that peak anti-prostaglandin effects of the ibuprofen probably coincided with maximal exercise-induced renal vasoconstriction. Other factors such as diuretic use, hypertension and hypertensive nephrosclerosis may also have predisposed the patient to ischaemic tubular damage.[15] See also *Indometacin*, below.

(d) Indometacin

A study in 4 healthy subjects found that indometacin 150 mg daily given with triamterene 200 mg daily over a 3-day period reduced the creatinine clearance in 2 subjects by 62% and 72%, respectively. Renal function returned to normal after a month. Indometacin alone caused an average 10% fall in creatinine clearance, but triamterene alone caused no consistent change in renal function. No adverse reactions were seen in 18 other subjects treated in the same way with indometacin and furosemide, hydrochlorothiazide or spironolactone.[16,17]

A patient with systemic lupus erythematosus and membranous glomerulopathy who was taking triamterene/hydrochlorothiazide 50/25 mg daily developed raised serum creatinine after taking **ibuprofen** 600 mg daily for 35 days. One day after changing to a high dose of indometacin (50 mg three times daily by mouth and 100 mg at night as a suppository) the patient developed acute renal failure with oliguria and slight hypertension.[18] Five patients are reported to have rapidly developed acute renal failure after receiving indometacin and triamterene, either concurrently or sequentially.[19-22]

Mechanism

Uncertain. One suggestion is that triamterene causes renal ischaemia, for which the kidney compensates by increasing prostaglandin production, thereby preserving renal blood flow. Indometacin opposes this by inhibiting prostaglandin synthesis, so that the damaging effects of triamterene on the kidney continue unchecked. Increases in pharmacologically active metabolites of triamterene may occur due to competition for renal excretory pathways but the clinical significance of this is uncertain. As renal production of prostaglandins helps to maintain renal blood flow and renal vasodilatation during volume depletion, other NSAIDs might also be expected to affect this compensatory mechanism when diuretics are used.

Prostaglandins may also contribute to the natriuretic effects of spironolactone. The NSAIDs may reduce the diuretic effects of spironolactone by blocking prostaglandin synthesis.

Importance and management

Information is limited to these reports, but the increased risk of renal impairment with indometacin and triamterene is established, although the incidence is uncertain. Since acute renal failure can apparently develop unpredictably and very rapidly it would seem prudent to use triamterene and indometacin cautiously, or avoid the combination altogether. The manufacturer of triamterene[23] and the authors of the report with diclofenac[13] suggest caution with the use of any NSAID with triamterene. Strenuous exercise can reduce renal blood flow, and the author of the case report with ibuprofen notes that although renal failure secondary to this is rare, patients taking medication that reduces renal blood flow are more at risk of this complication.[15] The manufacturers of amiloride[4] and **eplerenone**[24] also warn about the possibility of acute renal failure in patients also taking NSAIDs and recommend that these patients should be adequately hydrated and have their renal function monitored.[24]

The European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association guidelines on the management of chronic heart failure both recommend that NSAIDs, including coxibs, should be avoided, if possible, with aldosterone antagonists (such as **eplerenone** or spironolactone), as this increases the risk of developing hyperkalaemia and renal failure.[25,26]

Potassium-sparing diuretics + Potassium compounds

The concurrent use of spironolactone or triamterene and potassium supplements can result in severe and even life-threatening hyperkalaemia. Amiloride and eplerenone are expected to interact similarly. Potassium-containing salt substitutes can be as hazardous as potassium supplements.

Clinical evidence

In a retrospective analysis of hospitalised patients who had received **spironolactone**, hyperkalaemia had developed in 5.7% of patients taking **spironolactone** alone and in 15.4% of those also taking a **potassium chloride** supplement. The incidence was 42% in those with severe azotaemia (a high blood level of urea or nitrogen compounds) given **spironolactone** and **potassium chloride**.[1] A retrospective survey of another group of 25 patients taking **spironolactone** and oral **potassium chloride** supplements found that half of them had developed hyperkalaemia.[2]

A patient developed severe hyperkalaemia and cardiotoxicity as a result of taking **spironolactone** and a **potassium supplement**.[3] Three patients taking furosemide and **spironolactone** became hyperkalaemic[4,5] because they took **potassium-containing salt substitutes** (*No Salt* in one case[4]): two developed cardiac arrhythmias.[5] In another case, the pacemaker of a patient failed because of hyperkalaemia caused by the concurrent use of **triamterene** with hydrochlorothiazide (*Dyazide*) and **potassium chloride** (*Slow-K*).[6]

Mechanism

The effects of the potassium-sparing diuretics and potassium compounds are additive, which can result in hyperkalaemia.

Importance and management

The interaction with spironolactone is established and of clinical importance. A case has also been reported with triamterene, and **amiloride** and **eplerenone** would be expected to behave similarly. Avoid potassium compounds in patients taking potassium-sparing diuretics except in cases of marked potassium depletion, where the effects can be closely monitored. Warn patients about the risks of salt substitutes containing potassium, which may increase the potassium intake by 50 to 60 mmol daily.[5] The signs and symptoms of hyperkalaemia include muscular weakness, fatigue, paraesthesia, flaccid paralysis of the extremities, bradycardia, shock and ECG abnormalities, which may develop slowly and insidiously. Note that the manufacturers of eplerenone contraindicate the concurrent use of potassium supplements,[7,8] but in the US, this contraindication is only in patients given eplerenone for hypertension.

Potassium-sparing diuretics + Total parenteral nutrition

Metabolic acidosis developed in two patients receiving total parenteral nutrition associated with the concurrent use of triamterene or amiloride. The cases were complicated by a number of pathological and other factors, but it was suggested that the major reason for the acidosis was because the diuretics prevented the kidneys from responding normally to the acid load. The authors of the report advise caution during concurrent use.[1]

Potassium-sparing/Thiazide diuretics + Trimethoprim

Excessively low sodium levels have been seen in a few patients taking hydrochlorothiazide with amiloride or triamterene when they were given trimethoprim or co-trimoxazole. Trimethoprim may cause hyperkalaemia and this may be additive with the effects of potassium-sparing diuretics, including the aldosterone antagonists.

Clinical evidence

A 75-year-old woman with multiple medical conditions taking methyldopa, levothyroxine and **co-amilozide** (**hydrochlorothiazide** with **amiloride**) developed nausea and anorexia, and was found to have hyponatraemia (sodium 107 mmol/L), within 4 days of starting to take trimethoprim 200 mg twice daily. The problem resolved when the diuretics and trimethoprim were stopped. When rechallenged 4 months later with trimethoprim, hyponatraemia did not occur, but it developed rapidly when **co-amilozide** was also restarted.[1] The authors of this report have seen several other patients who developed hyponatraemia within 4 to 12 days of starting trimethoprim or co-trimoxazole, all of whom were elderly and all but one of whom were taking a diuretic [unnamed].[1]

Another report describes hyponatraemia in two other patients after co-trimoxazole was added to treatment with **co-amilozide** or **co-triamterzide** (**hydrochlorothiazide** with **triamterene**).[2]

Mechanism

Not established. Thiazide diuretics combined with potassium-sparing diuretics are said to be particularly liable to cause hyponatraemia.[3] Trimethoprim can also cause hyponatraemia and/or hyperkalaemia,[4,5] by blocking amiloride-sensitive sodium channels in the collecting duct (this produces a similar effect to that of a potassium-sparing diuretic). It seems likely that these adverse effects can be additive with the effects of other drugs.

Importance and management

Information is very limited but it would seem prudent to be on the alert for any signs of hyponatraemia (nausea, anorexia, etc.) in any patient taking potassium-sparing diuretics with thiazides and trimethoprim. Although there appears to have been no specific case reports of hyperkalaemia in patients taking trimethoprim with potassium-sparing diuretics (including the **aldosterone antagonists** eplerenone and spironolactone), in theory the risk of hyperkalaemia would be increased by concurrent use. It may therefore be prudent to also monitor potassium levels.

Potassium-sparing diuretics; Eplerenone + CYP3A4 inducers

St John's wort slightly decreases the AUC of eplerenone. The manufacturers of eplerenone recommend the avoidance of St John's wort and other stronger inducers of CYP3A4, such as rifampicin (rifampin), because of the possible risk of decreased eplerenone efficacy.

Clinical evidence, mechanism, importance and management

St John's wort (*Hypericum perforatum*) caused a small 30% decrease in the AUC of a single 100-mg dose of eplerenone.[1,2] Eplerenone is metabolised by the cytochrome P450 isoenzyme CYP3A4, and therefore inducers of this isoenzyme, such as **St John's wort**, would be expected to decrease its levels. In the UK, the manufacturer predicts that a more pronounced decrease in the AUC of eplerenone might occur with stronger CYP3A4 inducers, such as **rifampicin** (**rifampin**).[1] Because of the possibility of decreased efficacy, they do not recommend the concurrent use of potent CYP3A4 inducers with eplerenone, and they specifically name **carbamazepine**, **phenytoin**, **phenobarbital**, **rifampicin**, and **St John's wort**.[1] However, it is unlikely that the decrease seen with **St John's wort** is clinically relevant. Further study of the other potential interactions is needed to demonstrate their clinical significance.

Potassium-sparing diuretics; Eplerenone + CYP3A4 inhibitors

Ketoconazole markedly increases the bioavailability of eplerenone. The manufacturers of eplerenone contraindicate the concurrent use of ketoconazole, and other potent inhibitors of CYP3A4. Mild to moderate inhibitors of CYP3A4 (including diltiazem, fluconazole, saquinavir and verapamil) increase the AUC of eplerenone by up to almost threefold. Grapefruit juice had a small but unimportant effect on the AUC of eplerenone.

Clinical evidence

(a) Azoles

Ketoconazole 200 mg twice daily for 7 days increased the AUC of a single 100-mg dose of eplerenone 5.4-fold in 18 healthy subjects.[1,2] The manufacturers predict that **itraconazole** will have a similar effect to **ketoconazole**.[1,3] **Fluconazole** 200 mg daily for 7 days increased the AUC of eplerenone 2.2-fold in 18 healthy subjects.[2]

(b) Calcium-channel blockers

In 24 healthy subjects the steady-state AUC of eplerenone 100 mg daily was increased by about twofold by **verapamil** 240 mg daily for 7 days.[2] **Diltiazem** has caused similar increases in the AUC of eplerenone.[3]

(c) Grapefruit juice

Grapefruit juice caused only a small 25% increase in the AUC of eplerenone 100 mg.[1]

(d) Macrolides

In 24 healthy subjects **erythromycin** 500 mg twice daily increased the steady-state AUC of eplerenone 100 mg daily by 2.9-fold.[2] The manufacturers predict that **clarithromycin**,[1,3] **telithromycin**,[3] and **troleandomycin**[1] will have a greater effect. Eplerenone reduced the AUC of **erythromycin** by 14%, which was not considered clinically relevant.[2]

(e) Protease inhibitors

In 24 healthy subjects **saquinavir** 1.2 g three times daily increased the steady-state AUC of eplerenone 100 mg daily by 2.1-fold.[2] The manufacturers predict that **ritonavir** and **nelfinavir** will have a greater effect.[1,3] Eplerenone reduced the maximum level of **saquinavir** by 30%, and the AUC by 21%,[2] but the clinical relevance of this has not been assessed.

Mechanism

Eplerenone metabolism is primarily mediated by the cytochrome P450 isoenzyme CYP3A4, and therefore inhibitors of this isoenzyme will increase its bioavailability.

Importance and management

These pharmacokinetic interactions are established. Although the clinical relevance has not been assessed, it is known that the risk of hyperkalaemia with eplerenone is related to its dose.[3] Because the increase in the AUC of eplerenone with ketoconazole is so great, the manufacturers contraindicate this combination.[1,3] They also contraindicate the concurrent use of other potent inhibitors of CYP3A4, and they list clarithromycin, itraconazole, **nefazodone**, nelfinavir, ritonavir,[1,3] telithromycin[3] and troleandomycin.[1]

In the UK, the manufacturer recommends that the dose of eplerenone should not exceed 25 mg daily in patients taking mild to moderate CYP3A4 inhibitors such as **amiodarone**, diltiazem, erythromycin, fluconazole, saquinavir and verapamil.[3] In the US, the manufacturer recommends that the starting dose of eplerenone for hypertension should be reduced to 25 mg daily for patients taking these drugs.[1] This seems a sensible precaution. However, note that erythromycin sometimes appears to be as potent an inhibitor of CYP3A4 as clarithromycin (and certainly seems to be more potent than the other moderate CYP3A4 inhibitors listed above),[2] and so additional caution (e.g. increased monitoring of potassium levels) is probably warranted with this combination.

Potassium-sparing diuretics; Spironolactone + Aspirin

Although aspirin reduces the spironolactone-induced loss of sodium in the urine it does not appear to alter the antihypertensive effects of spironolactone.

Clinical evidence

(a) Effects on blood pressure

Five patients with low-renin essential hypertension, well-controlled for 4 months or more with spironolactone 100 to 300 mg daily, took part in a crossover study. Aspirin 2.4 to 4.8 g daily given over 6-week periods had no effect on blood pressure, serum electrolytes, body-weight, blood-urea-nitrogen or plasma renin activity.[1]

(b) Effects on natriuresis

A study in 10 healthy subjects given single 25-, 50- and 100-mg doses of spironolactone, found that a single 600-mg dose of aspirin reduced the urinary excretion of sodium in response to spironolactone.[2] In a further study in 7 of these subjects, the effectiveness of the spironolactone was reduced by 70%, and the overnight sodium excretion was reduced by one-third when they were given spironolactone 25 mg four times daily for one week followed by a single 600-mg dose of aspirin.[2] Reductions in sodium ex-

cretion are described in other studies of this interaction.[3,4] In one of these, the sodium excretion brought about by spironolactone was completely abolished when aspirin was given 90 minutes after the spironolactone, but when the drugs were given in the reverse order the inhibition of sodium excretion, which was caused by aspirin, was not completely reversed by spironolactone.[4]

In another study in 7 patients with ascites due to liver cirrhosis, pretreatment with two doses of aspirin 900 mg reduced the natriuretic effect of spironolactone 300 mg daily by 33%. However, there was no significant change in urinary output.[5]

(c) Gynaecomastia

For mention of an isolated report of gynaecomastia occurring in a patient taking spironolactone when a compound analgesic preparation containing aspirin was added to his treatment, see 'Potassium-sparing diuretics; Spironolactone + Dextropropoxyphene (Propoxyphene)', below.

Mechanism

Uncertain. There is evidence that the active secretion of canrenone (the active metabolite of spironolactone) is blocked by aspirin, but the significance of this is not entirely clear.[3]

Importance and management

An adequately but not extensively documented interaction. Despite the results of the studies showing a reduced natriuretic effect, the small study in hypertensive patients shows that the effects of spironolactone on reducing blood pressure might not be affected by anti-inflammatory doses of aspirin. In general, concurrent use need not be avoided, but if the diuretic response to spironolactone is less than expected consider this interaction as a cause.

None of these studies looked at the effects of low-dose aspirin on spironolactone. Nevertheless, it is likely that the proven protective cardiovascular benefits of low-dose aspirin in patients with hypertension and/or coronary artery disease would usually outweigh the possible reduction in the efficacy of spironolactone. However, note that the European Society of Cardiology (ESC) and American College of Cardiology/American Heart Association (ACC/AHA) heart failure guidelines say that the prophylactic use of aspirin in patients with heart failure has not been proven unless the patient has underlying ischaemic heart disease[6,7] and should be avoided in patients with recurrent hospital admissions for worsening heart failure.[7] Consider also 'Potassium-sparing diuretics + NSAIDs', p.1132, for a discussion of the interactions of spironolactone with NSAIDs.

Potassium-sparing diuretics; Spironolactone + Colestyramine

A few case reports have described hyperchloraemic metabolic acidosis, which was associated with the use of colestyramine and spironolactone.

Clinical evidence

Four case reports describe the development of hyperchloraemic metabolic acidosis in patients with liver cirrhosis taking colestyramine (up to about 25 g daily), who were also taking spironolactone 75 mg or 100 mg daily.[1-4] One patient developed significant hyperkalaemia (potassium 8 mmol/L),[4] and 2 patients developed mild renal impairment.[1,3] One patient had recently recovered from a respiratory tract infection, which the authors suggested may have contributed to the acidosis.[1] Acidosis resolved when the colestyramine was stopped.

Mechanism

Bicarbonate has been shown to compete *in vitro* with bile acids for binding sites on the colestyramine resin.[1,3] The chloride ions in the colestyramine resin may cause an anion exchange of not only the bile salts, as is the intention, but also bicarbonate in the small bowel. This removal of bicarbonate from the body can predispose to the development of a hyperchloraemic metabolic acidosis and hyperkalaemia. This might be exacerbated by the bicarbonate-losing and hyperkalaemic effects of spironolactone.[1-4]

Importance and management

In healthy subjects with normal renal function, acidosis does not usually occur, as the kidneys can correct it by increasing the excretion of chloride and production of bicarbonate.[1-4] However, in patients with renal impairment, volume depletion (e.g. secondary to diuretics) or concurrent conditions that predispose to acidosis (such as a respiratory tract infection), this interaction may be significant. It has been suggested that electrolytes should be closely monitored when patients who are at risk of an interaction are taking colestyramine and spironolactone,[1] although note that the interaction appears to be rare.

Potassium-sparing diuretics; Spironolactone + Dextropropoxyphene (Propoxyphene)

A single case report describes the development of gynaecomastia and a rash when a man taking spironolactone was given a compound analgesic preparation containing dextropropoxyphene.

Clinical evidence, mechanism, importance and management

A patient who had been taking spironolactone uneventfully for 4 years developed swollen, tender breasts and a rash on his chest and neck a fortnight after starting to take *Darvon Compound* (dextropropoxyphene, **aspirin**, **phenacetin** and **caffeine**). The problem disappeared when both drugs were withdrawn but the rash reappeared when the *Darvon Compound* alone was given and disappeared when it was withdrawn. No problems occurred when the spironolactone was given alone, but both the rash and the gynaecomastia recurred when the *Darvon Compound* was again added.[1] The reasons for this reaction are not understood. Gynaecomastia is a known adverse effect of spironolactone (incidence 1.2%), but the authors considered it unlikely that it should spontaneously develop after so many years of treatment. Consequently they attribute the reaction to an interaction with *Darvon Compound*, but say they cannot be sure which of the components is responsible. This is an isolated case, and would therefore not be expected to be of general relevance.

Potassium-sparing diuretics; Spironolactone + Food

Food may increase the plasma levels of spironolactone, but this did not alter its antihypertensive efficacy in one long-term study.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects food increased the AUC of canrenone (the major active metabolite of spironolactone) by about 30% after a single 100-mg dose of spironolactone, when compared with the fasted state.[1] However, a 60-day study by the same research group later found that the steady-state canrenone levels did not differ when spironolactone 100 mg daily was taken at least 30 minutes before eating, compared with immediately after eating. Furthermore, in a crossover study in 10 hypertensive patients, the antihypertensive efficacy of spironolactone was not altered by food. It was suggested that the difference is due to a more specific drug assay in the second study.[2] Other authors have also found that, in healthy subjects, food increased the AUC of a single dose of spironolactone by 71%, and also increased the AUC of three of its metabolites (including canrenone) by 32%, but they did not assess whether this altered the hypotensive effect.[3] It appears from the long-term study, that food does not alter the antihypertensive efficacy of spironolactone. It has been recommended that spironolactone be taken with food to try and reduce the gastric irritant effects of the drug.[2]

Thiazide diuretics + Bile-acid binding resins

The absorption of hydrochlorothiazide can be reduced by more than one-third if colestipol is given concurrently. Chlorothiazide appears to interact similarly. Colestyramine also reduces the absorption of hydrochlorothiazide by more than two-thirds.

Clinical evidence

In 6 healthy subjects the plasma levels of **hydrochlorothiazide** were reduced by about two-thirds by **colestyramine** 8 g, taken 2 minutes before and 6 and 12 hours after a single 75-mg oral dose of **hydrochlorothiazide**. Total urinary excretion of **hydrochlorothiazide** fell by 83%. In a parallel study with **colestipol** 10 g, the blood levels of **hydrochlorothiazide** fell by about 14% and the total urinary excretion fell by 31%.[1] A further study found that giving the **colestyramine** 4 hours after the **hydrochlorothiazide** reduced the effects of the interaction but **hydrochlorothiazide** absorption was still reduced by one-third.[2] In another study **colestipol**, given simultaneously or one hour after **chlorothiazide**, reduced the urinary excretion of **chlorothiazide** by 58% and 54%, respectively.[3]

Mechanism

Hydrochlorothiazide becomes bound to these non-absorbable anionic exchange resins within the gut, and less is available for absorption.

Importance and management

Established interactions of clinical importance. The best dosing schedule would appear to be to give hydrochlorothiazide 4 hours before colestyramine to minimise mixing in the gut. Even so, a one-third reduction in hydrochlorothiazide absorption occurs[2] and the possibility of this interaction should be considered in patients taking colestyramine or colestipol who have a reduced response to this diuretic. The optimum time-interval with colestipol has not been investigated but it would be reasonable to take similar precautions. Note that it is normally recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine and 1 hour before or 4 hours after colestipol.

Thiazide diuretics + Calcium and/or Vitamin D

Hypercalcaemia and possibly metabolic alkalosis can develop in patients who are given fairly high doses of vitamin D and/or moderately large amounts of calcium if they are also given a thiazide diuretic, which can reduce the urinary excretion of calcium. The oral vitamin D analogue, paricalcitol, is predicted to interact similarly. One case of hypercalcaemia has been reported in a patient using a high-strength topical tacalcitol with a thiazide diuretic.

Clinical evidence

(a) Calcium and vitamin D

An elderly woman taking **hydrochlorothiazide** 25 mg and triamterene 50 mg daily became confused, disorientated and dehydrated 6 months after starting to take vitamin D_2 50 000 units and calcium 1.5 g daily (as calcium carbonate) for osteoporosis. Her serum calcium level had risen to about 3.5 mmol/L (normal range about 2 to 2.6 mmol/L).[1]

A young woman with osteoporosis taking 3 mg of vitamin D_2 and calcium 2 g daily (as lactate) became hypercalcaemic 3 days after starting to take **chlorothiazide** 500 mg every 6 hours.[2]

(b) Calcium carbonate

A 47-year-old man was admitted to hospital complaining of dizziness and general weakness, which had begun 2 months previously. He was taking **chlorothiazide** 500 mg daily for hypertension, 'thyroid' 120 mg daily for hypothyroidism and calcium carbonate 7.5 to 10 g daily for heartburn. On examination he was found to have metabolic alkalosis with respiratory compensation, a total serum calcium concentration of 3.4 mmol/L (range given as 2.15 to 2.6 mmol/L) and an abnormal ECG. He was diagnosed as having the milk-alkali syndrome. Recovery was rapid when the thiazide and calcium carbonate were withdrawn and a sodium chloride infusion, furosemide and oral phosphates were given.[3]

An elderly woman with normal renal function taking **hydrochlorothiazide** 50 mg daily developed hypercalcaemia about 3 weeks after increasing her dose of calcium carbonate from 2.5 g daily to 7.5 g daily.[4] Another case describes hypercalcaemic alkalosis in an 87-year-old woman who had been prescribed **hydrochlorothiazide** with amiloride, but was also regularly self-medicating with a calcium-containing antacid (calcium/magnesium carbonate).[5]

In all three cases the thiazide diuretic was thought to be implicated as the levels of calcium ingestion, although moderately high, were in the region of the normally recommended doses.

(c) Oral vitamin D

In a group of 12 patients treated for hypoparathyroidism with vitamin D (**dihydrotachysterol** or **ergocalciferol**), 5 patients became hypercalcaemic when they took **bendroflumethiazide** or **methyclothiazide**.[6] A significant rise in plasma calcium levels occurred in 7 patients given vitamin D and **methyclothiazide** or **chlorothiazide**, and hypercalcaemia developed in 3 of them.[7] A study in 12 children taking **calcitriol** (31 nanograms/kg daily) found that the addition of **hydrochlorothiazide** (1 to 2 micrograms/kg daily) reduced the urinary excretion of calcium caused by the calcitriol.[8] Another study in 7 patients with vitamin D-induced calciuria found that the addition of **hydrochlorothiazide** and amiloride reduced the urinary excretion of calcium due to the **calcitriol** to a greater extent than **hydrochlorothiazide** alone. Moreover, the addition of amiloride helped to prevent adverse effects associated with the use of **hydrochlorothiazide**, such as hypokalaemia and alkalosis.[9]

(d) Topical vitamin D analogues

A case of asymptomatic hypercalcaemia has been reported in a patient taking **trichlormethiazide** 6 mg daily and using 10 g of a high-strength topical **tacalcitol** ointment (20 micrograms/g) daily for psoriasis as part of a clinical study. His calcium level reached a peak of 3.55 mmol/L 28 days after starting the tacalcitol ointment and it fell back to within the normal range within 7 days of stopping the ointment.[10]

Mechanism

The thiazide diuretics can cause calcium retention by reducing its urinary excretion. This, added to the increased intake of calcium, resulted in excessive calcium levels. Alkalosis (the milk-alkali syndrome, associated with hypercalcaemia, alkalosis, and renal impairment) may also occur in some individuals because the thiazide limits the excretion of bicarbonate. Note that loop diuretics such as furosemide increase the urinary excretion of calcium.

Importance and management

An established interaction. The incidence is unknown but the reports cited[6,7] suggest that it can be considerable if the intake of vitamin D and calcium are high. Concurrent use need not be avoided; thiazides have been used clinically to aid in the treatment of hypocalcaemia, by reducing urinary calcium excretion,[11] and to reduce vitamin-D induced hypercalciuria,[8,9] but the serum calcium levels should be regularly monitored to ensure that they do not become excessive. Patients should be warned about the ingestion of very large amounts of calcium carbonate (readily available without prescription) if they are taking thiazide diuretics. The manufacturer of **paricalcitol** suggests that a similar interaction is possible;[12] however, calcium levels should be routinely monitored in patients taking this drug, and so further precautions are unlikely to be necessary in those taking thiazides.

The case of hypercalcaemia with the use of a topical vitamin D analogue is rare and the strength of the preparation of tacalcitol used was fivefold higher than the current licensed preparation of 4 micrograms/g (*Curatoderm*). However, severe hypercalcaemia may develop when ointments containing **tacalcitol**, **calcipotriol** or **maxacalcitol** are abundantly applied to patients with psoriasis since the drugs can be easily absorbed through the skin lesions,[13] and it would seem reasonable to assume that this effect may be exacerbated by the concurrent use of thiazides. It may therefore be worth bearing this interaction in mind if a topical vitamin D analogue and a thiazide are given.

Thiazide diuretics + NSAIDs

There is evidence that most NSAIDs can increase blood pressure in patients taking antihypertensives, including diuretics, although some studies have not found the increase to be clinically relevant. The concurrent use of NSAIDs with thiazide diuretics may exacerbate congestive heart failure and increase the risk of hospitalisation. Diuretics may increase the risk of NSAID-induced acute renal failure.

Clinical evidence

Various large epidemiological studies and meta-analyses of clinical studies have been conducted to assess the effect of NSAIDs on blood pressure in patients taking **antihypertensives**, and the findings of these are summarised in 'Table 23.2', (p.1027). In these studies, NSAIDs were not always associated with an increase in blood pressure, and the maximum increase was 6.2 mmHg. The effect has been shown for both coxibs and non-selective NSAIDs. In two meta-analyses,[1,2] the effects were evaluated by NSAID. The confidence intervals for all the NSAIDs overlapped, showing that there was no statistically significant difference between the NSAIDs, with the exception of the comparison between **indometacin** and **sulindac** in one analysis.[2] Nevertheless, an attempt was made at ranking the NSAIDs based on the means. In one analysis,[1] the effect was greatest for **piroxicam**, **indometacin**, and **ibuprofen**, intermediate for **naproxen**, and least for **sulindac** and **flurbiprofen**. In the other meta-analysis,[2] the effect was greatest for **indometacin** and **naproxen**, intermediate for **piroxicam**, and least for **ibuprofen** and **sulindac**. An attempt was also made to evaluate the effect by **antihypertensive** in one analysis.[1] The mean effect was greatest for beta blockers, intermediate for vasodilators (includes ACE inhibitors and calcium-channel blockers), and least for **diuretics**. However, the differences between the groups were not significant.

A retrospective analysis of records of patients taking **diuretics** (thiazides, loop and/or potassium-sparing) with NSAIDs found a twofold increase in the risk of hospitalisation for congestive heart failure on concurrent use. The most common NSAIDs taken by this cohort of patients were **diclofenac**, **ibuprofen**, **indometacin** and **naproxen**. The **diuretics** most often used were thiazides combined with potassium-sparing drugs and this therapy showed a significantly higher risk than the other diuretic therapies.[3]

A case-control study using the UK General Practice Research Database found that current NSAID use increased the risk of acute renal failure (relative risk 3.2 compared with no NSAID use) and this risk was further increased with concurrent **diuretic** use (relative risk 11.6).[4] Note that the risk of renal complications appear to be similar with coxibs as with non-specific NSAIDs.[5]

Individual clinical reports and clinical or pharmacological studies of the effects of specific NSAIDs on diuretics are outlined in the subsections below and in 'Table 26.2', (p.1126).

A. Altizide

An 80-year-old woman who had been successfully treated with altizide, **spironolactone**, bisoprolol and aspirin for 5 years experienced symptoms of progressive breathlessness, weight gain and nocturnal orthopnoea about 4 days after starting to take **rofecoxib** for arthritis. About 10 days later, she was admitted to hospital with heart failure and started to recover over the next 2 to 5 days following discontinuation of the **rofecoxib** and replacement of the beta blocker and diuretics with furosemide.[5] Note that rofecoxib has generally been withdrawn because of reports of cardiovascular adverse effects.

B. Bemetizide

In a study in healthy subjects **indometacin** 100 mg was found to reduce the urinary excretion of sodium and chloride caused by bemetizide by 47% and 44%, respectively.[6]

C. Bendroflumethiazide

(a) Ibuprofen

In a randomised, placebo-controlled study, 7 hypertensive patients taking bendroflumethiazide 5 to 10 mg daily were also given ibuprofen 400 mg four times daily for 2 weeks. Although some small increases in blood pressure occurred, the diastolic blood pressure of all patients remained below 90 mmHg throughout the ibuprofen phase. Overall no statistically significant weight gain was noted, although 2 patients gained more than 2 kg.[7]

(b) Indometacin

A controlled study in 7 hypertensive patients taking bendroflumethiazide 5 to 10 mg daily found that indometacin 100 mg daily for 3 weeks raised their blood pressure by 13/9 mmHg when lying and by 16/9 mmHg when standing. Body-weight increased by 1.1 kg.[8] Indometacin also attenuated the hypotensive effect of bendroflumethiazide in another study.[9]

(c) Sulindac

A brief report suggested that sulindac *enhanced* the hypotensive effects of bendroflumethiazide in 5 hypertensive patients.[9]

D. Chlortalidone

A 61-year-old man with a history of mild diabetes and hypertension who was taking chlortalidone 25 mg daily developed diabetic nephropathy after starting **ibuprofen**.[10]

E. Hydrochlorothiazide

(a) Coxibs

A study in healthy subjects found that a single 25-mg oral dose of **rofecoxib** reduced the natriuretic effect of hydrochlorothiazide 25 mg, but potassium excretion was unaltered.[11]

(b) Diclofenac

Diclofenac 25 mg three times daily was given to 8 patients with essential hypertension who were taking hydrochlorothiazide. Blood pressure was not significantly altered after the addition of diclofenac, but a weight gain of about 1 to 2 kg was noted, which was thought to have been caused by

the sodium retaining effects of diclofenac.[12] In another study in hypertensive black women, diclofenac 75 mg twice daily for one month did not alter the antihypertensive effect of the combination of hydrochlorothiazide 25 mg daily and lisinopril 10 to 40 mg daily.[13] A further study, in healthy subjects, found that diclofenac 50 mg reduced the natriuretic effect of hydrochlorothiazide, but potassium excretion was unchanged.[11]

(c) Diflunisal

Diflunisal 375 mg twice daily caused the plasma levels of hydrochlorothiazide to rise by 25 to 30%, but this does not appear to be clinically significant.[14] Diflunisal also has uricosuric activity, which may counteract the uric acid retention that occurs with hydrochlorothiazide.

(d) Ibuprofen

In two studies in patients taking hydrochlorothiazide, ibuprofen 400 or 600 mg three times daily for 4 weeks caused a small rise in systolic but not in diastolic blood pressure.[12,15] However, a weight gain of about 1 to 2 kg was noted in one of the studies.[12] Another study found that ibuprofen 400 mg three times daily had no effect on blood pressure controlled by **triamterene** with hydrochlorothiazide, although one patient had a marked reduction in renal function.[16] Ibuprofen 800 mg four times daily for a week had little effect on blood pressure controlled with hydrochlorothiazide in yet another study.[17] In two further studies, ibuprofen 800 mg three times daily for one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily[18] or lisinopril 10 to 40 mg daily.[13]

An 88-year-old patient taking multiple drugs developed severe hyponatraemia when hydrochlorothiazide was combined with **furosemide** and ibuprofen. The authors comment that the use of thiazides is sometimes overlooked when other drugs that may affect serum sodium, such as NSAIDs, are prescribed.[19]

For a report of acute renal failure after strenuous exercise in a patient taking ibuprofen and hydrochlorothiazide with triamterene, see 'Potassium-sparing diuretics + NSAIDs', p.1132.

(e) Indometacin

A controlled study in 7 patients with hypertension taking **amiloride** 5 to 10 mg with hydrochlorothiazide 50 to 100 mg, found that indometacin 100 mg daily for 3 weeks raised their blood pressure by 13/9 mmHg when lying and by 16/9 mmHg when standing. Body-weight increased by 1.1 kg.[8] A later study in patients taking hydrochlorothiazide found a 6/3 mmHg blood pressure rise after they took indometacin for 2 weeks, but this had gone after 4 weeks.[20] A blood pressure rise of only 5/1 mmHg was seen in another study in hypertensive patients taking hydrochlorothiazide with indometacin 100 mg daily.[21] Indometacin also attenuated the hypotensive effect of hydrochlorothiazide (given with **amiloride**) in another study.[9]

In other studies indometacin had no effect on blood pressure in healthy subjects,[22] no effect on the sodium excretion caused by hydrochlorothiazide,[23] and did not affect the pharmacokinetics of hydrochlorothiazide.[22,23] However, in one of these studies indometacin did attenuate the hydrochlorothiazide-induced decreases in body-weight and plasma potassium levels.[22]

For a report of hyperkalaemia in a patient taking indometacin and hydrochlorothiazide with amiloride and a report of acute renal failure in a patient taking indometacin and hydrochlorothiazide with triamterene, see 'Potassium-sparing diuretics + NSAIDs', p.1132.

(f) Kebuzone

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given kebuzone 750 mg daily. This rise represents about a 35% reduction in the antihypertensive effect of hydrochlorothiazide.[24]

(g) Naproxen

One study found that naproxen had no clinically relevant interaction with hydrochlorothiazide alone.[20] Naproxen had a similar lack of influence on the diuretic response to hydrochlorothiazide in another study in healthy subjects.[25] In a further study, in hypertensive patients, naproxen attenuated the antihypertensive efficacy of hydrochlorothiazide taken with **amiloride** and timolol, but how much of the attenuation was due to an interaction with the diuretic was unclear.[26]

A case report describes severe hyponatraemia resulting from the use of hydrochlorothiazide/**amiloride** and naproxen.[27]

(h) Phenylbutazone

A mean systolic blood pressure rise of 18 mmHg (from 171 to 189 mmHg) occurred in 15 patients taking hydrochlorothiazide 50 mg daily, when they were given phenylbutazone 750 mg daily. This rise represents about a 35% reduction in the antihypertensive effect of hydrochlorothiazide.[24]

(i) Piroxicam

One study found that piroxicam attenuated the antihypertensive efficacy of hydrochlorothiazide taken with **amiloride** and timolol, but how much of the attenuation is due to an interaction with the diuretic is unclear.[26]

(j) Sulindac

One study in healthy subjects found that pretreatment with sulindac 200 mg decreased the fractional urinary flow rate, produced by hydrochlorothiazide 100 mg alone, by 35% and attenuated the natriuretic effect of hydrochlorothiazide, over 0 to 4 hours, by 29%. However, beyond 4 hours, sulindac pretreatment did not affect these renal responses to hydrochlorothiazide.[25] Sulindac does not usually appear to reduce either the hypotensive or diuretic effects of hydrochlorothiazide,[12,20,21] and may even slightly *enhance* the antihypertensive effects of hydrochlorothiazide/**amiloride** with[26] or without,[9] timolol. Another study found that sulindac did not alter the antihypertensive efficacy of hydrochlorothiazide/**amiloride** given with beta blockers.[28] Similarly, sulindac 200 mg twice daily for one month did not alter the antihypertensive effect of the combinations of hydrochlorothiazide 25 mg daily with fosinopril 10 to 40 mg daily,[18] or lisinopril 10 to 40 mg daily.[13]

An 81-year-old woman who was taking hydrochlorothiazide, digoxin, methyldopa and potassium was admitted to hospital with pseudogout and was prescribed sulindac 400 mg followed by 200 mg twice daily for 2 days. She received 800 mg of sulindac within the first 22 hours and developed renal impairment over the next 4 days. The sulindac was discontinued and her renal function improved.[10]

F. Methyclothiazide

A 68-year-old woman with long-standing hypertension and diabetes who was receiving methyclothiazide, insulin, quinidine and nitrates was admitted to hospital with pericarditis. Renal impairment developed within 4 days of starting **indometacin** 25 mg three times daily and improved on discontinuation of the indometacin.[10]

G. Metolazone

(a) Indometacin

Indometacin was found to reduce the urinary sodium excretion in response to metolazone by 34% in 6 healthy subjects.[29] The excretion of total potassium fell by 30%.

(b) Sulindac

Sulindac was found to reduce the urinary sodium excretion in response to metolazone by 19% in 6 healthy subjects.[29] The excretion of total potassium fell by 16%.

H. Trichlormethiazide

For a report of raised serum creatinine levels when a patient receiving triamterene and trichlormethiazide was given diclofenac, see 'Potassium-sparing diuretics + NSAIDs', p.1132.

I. Unspecified

In a randomised study, **ibuprofen** 400 mg every 8 hours caused a mean increase in blood pressure of about 5 to 7 mmHg in 12 hypertensive patients taking thiazides with beta blockers or centrally-acting antihypertensives.[30]

Mechanism

Not understood. NSAIDs, including coxibs, can affect renal function and cause salt and water retention, which antagonises the effects of diuretics.[31] Prostaglandins have a role to play in renal function and drugs such as the NSAIDs, which inhibit prostaglandin synthesis, would therefore be expected to have some effect on the actions of diuretics, whose venodilatory effects also depend on the activity of the prostaglandins. See 'Loop diuretics + NSAIDs', p.1125.

The attenuation of the antihypertensive effect of thiazides by NSAIDs has not been uniformly observed; for example sulindac has been found to enhance the antihypertensive effect in some, but not all, studies, and ibuprofen and indometacin have been found to have variable effects.[32] It has been suggested that, in some cases, differences in the metabolism of NSAIDs may possibly affect renal prostaglandins, for example sulindac may have less effect because its active metabolite is highly protein bound

and does not appear in the urine in appreciable amounts,[9,26] but currently there appears to be insufficient data to distinguish between the NSAIDs. NSAIDs suppress diuretic-stimulated renin secretion and dietary salt intake may also alter the effect by varying endogenous renin activity.[32] A study in *rats* suggested that indometacin may oppose the effects of the thiazides by reducing chloride delivery to the site of thiazide action in the distal tubule.[33]

Importance and management

Overall, the evidence suggests that some patients taking thiazide diuretics can have a rise in blood pressure, and sometimes associated weight gain,[32] when given NSAIDs, but this may not always be clinically relevant. Furthermore the concurrent use of NSAIDs and diuretics may increase the risks of acute renal failure. Some consider that the use of NSAIDs should be kept to a minimum in patients taking antihypertensives.[34] The effects may be greater in the elderly and in those with blood pressures that are relatively high, as well as in those with salt imbalance such as in cardiac failure or liver disease.[31,34] However, others consider that the clinical importance of an interaction between NSAIDs and antihypertensives is less than has previously been suggested.[35] While their findings do not rule out a 2/1 mmHg increase in blood pressure with NSAIDs in treated hypertensives, they suggest that if patients in primary care have inadequate control of blood pressure, other reasons may be more likely than any effect of concurrent NSAIDs.[35] There is insufficient data at present to clearly differentiate between NSAIDs, although there is some evidence that the effects of indometacin are greatest and sulindac least. Further study is needed.

The thiazide-related diuretic metolazone may be used in conjunction with a loop diuretic in patients with congestive heart failure. In this context it is worth noting that the European Society of Cardiology (ESC) Task Force and the joint American College of Cardiology/American Heart Association both recommend avoiding NSAID use, if possible, in patients with congestive heart failure.[36,37]

For the effects of NSAIDs on other antihypertensive drug classes see 'ACE inhibitors', (p.32), 'beta blockers', (p.997), 'calcium-channel blockers', (p.1027) and 'loop diuretics', (p.1125).

Thiazide diuretics; Chlorothiazide + Fluoxetine

Fluoxetine 30 mg daily for 8 days did not affect the pharmacokinetics of a single dose of chlorothiazide 500 mg.[1] No dose adjustments would seem necessary on concurrent use.

1. Lemberger L, Bergstrom RF, Wolen RL, Farid NA, Enas GG, Aronoff GR. Fluoxetine: clinical pharmacology and physiologic disposition. *J Clin Psychiatry* (1985) 46, 14–19.

Thiazide diuretics; Hydrochlorothiazide + Phenytoin

A study in 7 healthy subjects found that pretreatment with phenytoin 100 mg three times daily for 6 days did not influence the pharmacokinetics of a single 75-mg oral dose of hydrochlorothiazide.[1]

1. Keller E, Sulzer U, Brennes M, Schollmeyer P, Hoppe-Seyler G. Disposition of hydrochlorothiazide (Hct) during phenytoin (Ph) treatment. *Klin Wochenschr* (1981) 59, 1223–4.

Thiazide diuretics; Hydrochlorothiazide + Propantheline

Propantheline can slightly increase the absorption of hydrochlorothiazide.

Clinical evidence, mechanism, importance and management

In 6 healthy fasting subjects the absorption of hydrochlorothiazide 75 mg was delayed and increased (AUC increased by 23% and urinary recovery increased by 36%) by propantheline 60 mg. It was suggested that this occurs because propantheline causes a slower delivery of the hydrochlorothiazide to its areas of absorption.[1] This small increase is unlikely to be clinically important.

Gastrointestinal drugs

The various gastrointestinal drug groups covered in this section are listed in 'Table 27.1', (below). Many of the interactions of these drugs occur by causing alterations in the absorption of other drugs. The section 'Drug absorption interactions', (p.3), discusses how these interactions occur and contains more detailed information on some of the mechanisms of interaction covered in this section.

Interactions of H_2-receptor antagonists

Cimetidine is a non-specific inhibitor of the cytochrome P450 isoenzyme-mediated hepatic metabolism of many drugs, and can therefore increase their plasma levels and/or bioavailability. These interactions are most likely to be clinically significant for drugs with a narrow therapeutic index. Famotidine, nizatidine and ranitidine do not inhibit cytochrome P450 to a clinically relevant extent and are therefore less likely than cimetidine to be involved in interactions that occur by this mechanism. However, it should be noted that the absorption of some drugs may be affected by the changes in gastric pH, which can be produced by any of the H_2-receptor antagonists. Furthermore, drug interactions may also occur because there is competition for renal tubular secretion: cimetidine, famotidine and ranitidine have all been implicated in this type of interaction.

This section is concerned with interactions that result in a change to the effect of the H_2-receptor antagonist. Interactions where H_2-receptor antagonists are affecting another drug are discussed in the section relevant to that drug.

Interactions of proton pump inhibitors

The cytochrome P450 isoenzyme CYP2C19 is the main route of metabolism of esomeprazole, lansoprazole, omeprazole, pantoprazole, and to a lesser extent rabeprazole. This isoenzyme is subject to genetic polymorphism,[1] (see 'Genetic factors in drug metabolism', (p.4), for a further explanation of polymorphism). The poor metaboliser phenotype for CYP2C19 is found in approximately 1 to 6% of Caucasians, 1 to 7.5% of Blacks and 12 to 23% of Oriental and Indian Asians.[2]

Most patients are extensive CYP2C19 metabolisers, and their major route for the metabolism of these proton pump inhibitors will be through this isoenzyme. As a consequence,[2] the levels of proton pump inhibitors in these patients are likely to be affected by drugs that inhibit or induce CYP2C19, such as 'fluvoxamine', (p.1161). Patients of the extensive metaboliser phenotype have also been shown in some studies to have a poorer clinical outcome, when compared with poor metabolisers e.g. in the eradication of *H. pylori,* as they tend to have lower therapeutic levels of proton pump inhibitors.[2-4]

Poor metabolisers, who lack CYP2C19 metabolising capacity, use alternative pathways to metabolise proton pump inhibitors, and this is mainly CYP3A4. Because poor metabolisers are more dependent on CYP3A4 for metabolism of the proton pump inhibitors the levels of proton pump inhibitors may be more significantly raised in these patients, when compared with extensive metabolisers, when they are given CYP3A4 inhibitors, such as 'clarithromycin' , (p.1160), or 'ketoconazole', (p.246).

Omeprazole and esomeprazole are also inhibitors of CYP2C19, and therefore they may increase the levels of drugs that are metabolised by this isoenzyme, such as diazepam.[1,2] Other CYP2C19 substrates are listed in 'Table 1.3', (p.6).

In vitro study suggests that some proton pump inhibitors, including omeprazole, lansoprazole and pantoprazole may possibly be P-glycoprotein substrates and inhibitors and this may be a factor in some of their interactions.[5] An example of this is the increase in lansoprazole levels caused by the P-glycoprotein inhibitor 'clarithromycin', (p.1160).

Table 27.1 Gastrointestinal drugs

Group	*Drugs*
5-Aminosalicylates	Balsalazide, Mesalazine, Olsalazine, Sulfasalazine
Antidiarrhoeals	Loperamide
Antimuscarinics	Pirenzepine
Bismuth compounds	Bismuth salicylate, Bismuth subcitrate potassium, Bismuth subnitrate, Tripotassium dicitratobismuthate
H_2-receptor antagonists	Cimetidine, Famotidine, Nizatidine, Ranitidine, Roxatidine
Mucosal protectants	Carbenoxolone, Liquorice, Sucralfate
Prokinetic drugs	Cisapride, Mosapride
Proton pump inhibitors	Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, Rabeprazole

Alosetron + SSRIs

Fluvoxamine markedly increases alosetron levels. Alosetron had no clinically significant effect on fluoxetine pharmacokinetics in healthy subjects.

Clinical evidence, mechanism, importance and management

Note that isolated possible cases of serotonin syndrome have been reported when with other 5-HT_3-receptor antagonists were given with SSRIs, see 'SSRIs + 5-HT_3-receptor antagonists', p.1485.

(a) Fluoxetine

An open study in 12 healthy subjects found that alosetron 1 mg twice daily for 15 days had no clinically significant effect on the pharmacokinetics of a single 20-mg dose of fluoxetine. There was a median 3-hour delay in the time to reach peak levels of both *S*- and *R*-fluoxetine, but this was thought unlikely to be clinically relevant for a drug that requires several weeks to achieve its full therapeutic effect.[1]

(b) Fluvoxamine

The manufacturer of alosetron notes that fluvoxamine (50 mg increased to 200 mg daily for 16 days) increased the AUC of alosetron about sixfold and prolonged its half-life about threefold when a single 1-mg dose of alosetron was given on day 16. This was attributed to the potent inhibitory effect of fluvoxamine on the cytochrome P450 isoenzyme CYP1A2, by which alosetron is metabolised. These marked increases are likely to be clinically important, and the manufacturer contraindicates concurrent use of alosetron with fluvoxamine.[2]

Aluminium hydroxide + Ascorbic acid (Vitamin C) or Citrates

Patients with renal failure given aluminium compounds and oral citrates can develop a potentially fatal encephalopathy due to a very marked rise in blood-aluminium levels. A similar increase in aluminium levels may also occur in patients with normal renal function. There is also some evidence that aluminium compounds and ascorbic acid (vitamin C) may interact similarly.

Clinical evidence

(a) Ascorbic acid

A study in 13 healthy subjects given aluminium hydroxide 900 mg three times daily found that ascorbic acid (vitamin C) 2 g daily increased the urinary excretion of aluminium threefold.[1] Ascorbic acid significantly increases the concentration of aluminium in the liver, brain, and bones of *rats* given aluminium hydroxide.[2]

(b) Citrates

Cases of an interaction between aluminium hydroxide and oral citrates have been reported, some of which resulted in fatalities. Four patients with advanced chronic renal impairment taking aluminium hydroxide and citrate (**Shohl's**) solution died due to hyperaluminaemia.[3] When these cases were compared with another 34 renal patients, it was found that they had taken more aluminium hydroxide, more citrate, and were older. In the group as a whole, increased serum aluminium levels were correlated with increased citrate intake.[4] In a study, five healthy subjects were given aluminium hydroxide with or without citrate solution: aluminium levels were 11 micrograms/L at baseline, rising to 44 micrograms/L when aluminium hydroxide was given, and rising to 98 micrograms/L when citrate was added. Aluminium clearance also dramatically increased in the presence of citrate.[4] Another report describes this interaction in 2 patients with renal impairment, and in a possible further 6 patients, all of whom died.[5] In a further single-dose study in 6 patients with end-stage renal disease, sodium citrate with citric acid 30 mL markedly increased the AUC of aluminium (from a 30-mL dose of aluminium hydroxide gel) by 4.6-fold.[6] A number of other studies in healthy subjects have confirmed that citrate markedly increases aluminium absorption, see *Mechanism*, below.

A haemodialysis patient given **effervescent co-codamol** had a tenfold increase in serum aluminium levels. This was attributed to sodium citrate in the formulation which is used to produce the effervescence.[7]

Mechanism

Studies in healthy subjects clearly demonstrate that citrate markedly increases the absorption of aluminium from the gut.[4,8,9] The absorption is increased threefold if taken with **lemon juice**,[10] eight to tenfold if taken with **orange juice**,[11,12] and five to 50-fold if taken with citrate,[4,8,9,11] but the reason is not understood. It could be that a highly soluble aluminium citrate complex is formed.[5,8]

Importance and management

The interaction between aluminium and citrates in patients with renal impairment is established and clinically important as it is potentially fatal. Concurrent use should be strictly avoided. Remember too that some effervescent and dispersible tablets (including many proprietary non-prescription analgesics, indigestion and hangover remedies such as *Alka-Seltzer*) contain citric acid or citrates,[7,13] and they may also occur in soft drinks.[13] Haemodialysis patients should be strongly warned about these.

The interaction between aluminium and ascorbic acid is not yet well established, but the information available so far suggests that this combination should also be avoided by patients with renal impairment. It is not clear whether orange juice is also unsafe but the available evidence suggests that concurrent administration is probably best avoided.

The importance of the interaction between aluminium and citrates in subjects with normal renal function is by no means clear, because it is still not known whether increased aluminium absorption results in aluminium accumulation over the long-term in those with normal renal function.[12] Some authors have recommended that food or drinks containing citric acid (citrus fruits and fruit juices) should not be taken at the same time as aluminium-containing medicines, but that their ingestion should be separated by 2 to 3 hours.[12] However, one study in healthy subjects reported significantly raised aluminium levels when a citric acid solution and an aluminium hydroxide antacid were taken 2 hours apart.[14] Further study is needed in subjects with normal renal function to establish the clinical significance of a possible interaction.

It is worth noting that formulations of a wide range of drugs (including many non-prescription preparations) contain citrates as the effervescing or dispersing agent.

Antacids + Milk

Hypercalcaemia, alkalosis and renal impairment (milk-alkali syndrome) can develop in patients taking antacids with calcium-containing substances, including dairy products.

Clinical evidence

A man presented with nausea, vomiting, constipation, polyuria and polydipsia, which was diagnosed as milk-alkali syndrome, due to daily treatment with 6 tablets of *Caved-S* and 3.5 pints of milk, for dyspepsia related to a peptic ulcer.[1] This dose of *Caved-S* meant he was taking 600 mg of **aluminium hydroxide**, 1.2 g of **magnesium carbonate**, 600 mg of **sodium bicarbonate** and 2.28 g of **deglycyrrhizinised liquorice** daily.[1] Another case report describes a 42-year-old man who presented with confusion, agitation, involuntary movements of his limbs, severe dehydration, and metabolic and respiratory alkalosis. He had taken large amounts of a **calcium**/**magnesium carbonate**-containing antacid preparation (*Rennies)* and had also consumed at least 3 litres of diary products each day for upper abdominal complaints. Milk-alkali syndrome was diagnosed and he was successfully treated with isotonic saline and potassium.[2] A pregnant woman developed vomiting, drowsiness, abdominal pain and acute pancreatitis after excessive antacid use. She had been taking up to 10 tablets of *Rennies* antacid (**calcium**/**magnesium carbonate**), containing about 3 g of elemental calcium with up to 3 glasses of milk each day.[3]

In a study in 125 patients with non end-stage renal disease, milk-alkali syndrome was found to be the cause of hypercalcaemia in 11 (8.8%) of the patients: 9 had severe hypercalcaemia (serum calcium greater than 3.5 mmol/L).[4] Two cases have also been reported in patients taking standard doses of **calcium carbonate** who also had other risk factors for developing severe hypercalcaemia and milk-alkali syndrome (such as concurrent medications, acute renal impairment, volume depletion).[5] Several other cases have been reported in recent years involving excessive use of non-prescription **calcium carbonate**,[6-8] one of which was in a pregnant woman.[7]

Mechanism

High intake and absorption of calcium can suppress the parathyroid hormone, which leads to bicarbonate retention by the kidneys, leading to metabolic and respiratory alkalosis. The alkalosis also causes reduced excretion of calcium by the kidneys. Hypermagnesaemia may also have a part to play.

Importance and management

The milk-alkali syndrome was a common adverse effect of antacid use when it was the primary treatment of peptic ulcer disease, but it has become very uncommon with the advent of H_2-receptor antagonists and proton pump inhibitors. However, the above cases illustrate that while taking antacids, even well within the recommended dosage range, as in the first case, it is still possible to develop a serious and potentially life-threatening reaction if the intake of calcium is high. This should be borne in mind in patients who take medications containing calcium, such as antacids or supplements for the prophylaxis of osteoporosis, and also consume large quantities of dairy products in their diet. Note that many calcium-containing antacids are freely available without prescription. Chronic milk-alkali syndrome can lead to the formation of calcification and kidney damage, which may be irreversible. The quantity of calcium ingested does not appear to be directly correlated to either the development or severity of milk-alkali syndrome, which has been reported with an intake of between 4 g to 60 g of calcium carbonate.[3] However, a safe maximum calcium intake of 1.2 to 1.5 g of elemental calcium (3 to 3.75 g of calcium carbonate) has been suggested.[3]

Aprepitant + CYP2C9 substrates

Aprepitant is an inducer of the cytochrome P450 isoenzyme CYP2C9, and slightly reduces the plasma levels of substrates of this isoenzyme such as 'warfarin', (p.432), and 'tolbutamide' (p.588). The manufacturers therefore recommend caution when aprepitant is given with other drugs that are known to be metabolised by CYP2C9, because of the possibility that their plasma levels may be reduced.[1,2] They specifically mention phenytoin. However, phenytoin is also an inducer of CYP3A4 and the manufacturers predict that it will decrease the levels of aprepitant, and might reduce its efficacy, see 'Aprepitant + CYP3A4 inducers', below.[1,2] Consequently, the UK manufacturer advises avoiding the concurrent use of phenytoin.[1] Other CYP2C9 substrates are listed in 'Table 1.3', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, July 2009.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, July 2009.

Aprepitant + CYP3A4 inducers

Rifampicin markedly reduced the AUC of aprepitant, and reduced efficacy would be expected. The concurrent use of aprepitant and other potent inducers of CYP3A4 should be avoided.

Clinical evidence, mechanism, importance and management

The manufacturers note that when a single 375-mg dose of aprepitant was given on day 9 of a 14-day regimen of **rifampicin** 600 mg daily, the AUC of aprepitant was decreased by about 91%, and the half-life decreased by about 68%.[1,2]

Rifampicin is an inducer of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore decreases aprepitant levels

Although not assessed, this marked reduction in aprepitant levels could result in reduced efficacy. In the UK, the manufacturer recommends that concurrent use of aprepitant and potent inducers of CYP3A4, such as **rifampicin**, be avoided.[1] They also name **phenytoin** (see also 'Aprepitant + CYP2C9 substrates', above), **carbamazepine**, and **phenobarbital**, and also recommend that concurrent use of **St John's wort** is avoided.[1] **Primidone** is metabolised to phenobarbital and is therefore likely to interact similarly. Other inducers of CYP3A4 are listed in 'Table 1.4', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, July 2009.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, July 2009.

Aprepitant + CYP3A4 inhibitors

Ketoconazole markedly increases aprepitant levels. Other potent inhibitors of CYP3A4 are predicted to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturers note that when a single 125-mg dose of aprepitant was given on day 5 of a 10-day course of **ketoconazole** 400 mg daily, the AUC of aprepitant was increased by about fivefold, and the half-life by about threefold.[1,2]

Ketoconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4, by which aprepitant is metabolised. Concurrent use therefore raises aprepitant levels.

Although the effect of these increases has not been assessed, such marked increases in levels could increase adverse effects. The manufacturers recommend caution when aprepitant is given with **ketoconazole** and other drugs that are potent inhibitors of CYP3A4. They specifically name **protease inhibitors** (the US manufacturer names **nelfinavir** and **ritonavir**), **clarithromycin**, **itraconazole**, **nefazodone**,[1,2] **troleandomycin**,[2] **telithromycin**, **posaconazole**, and **voriconazole.**[1].

For the effect of **diltiazem** (a moderate CYP3A4 inhibitor), see 'Calci-

um-channel blockers + Aprepitant', p.1026. Other inhibitors of CYP3A4 are listed in 'Table 1.4', (p.6).

1. Emend (Aprepitant). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, July 2009.
2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, July 2009.

Aprepitant + CYP3A4 substrates

Aprepitant can increase the levels of CYP3A4 substrates in the short-term, then reduce them within 2 weeks. Concurrent use of aprepitant with pimozide, terfenadine, astemizole or cisapride is contraindicated.

Clinical evidence, mechanism, importance and management

In the first few days of use, aprepitant 125 mg on day 1 followed by 80 mg daily for 4 days markedly increased levels of midazolam, a probe drug substrate for the cytochrome P450 isoenzyme CYP3A4. Then, within 2 weeks, a reduction in levels was seen, see 'Benzodiazepines + Aprepitant', p.840. This effect was not seen with a dose regimen of 40 mg on day 1 followed by 25 mg daily for 4 days. Aprepitant is therefore both a dose-dependent inhibitor and an inducer of CYP3A4.

Because of this, aprepitant is expected to increase drug levels of other CYP3A4 substrates by up to about threefold, and the manufacturer recommends caution.[1,2] They specifically recommend caution with **ergot derivatives**.[1] Moreover, the manufacturers specifically contraindicate the concurrent use of aprepitant with **pimozide**, **terfenadine**, **astemizole** or **cisapride**, because of the risk of life-threatening torsade de pointes arrhythmias with increased levels.

For a list of CYP3A4 substrates, see 'Table 1.4', (p.6). Within 2 weeks of aprepitant therapy, a reduced level of CYP3A4 substrates might occur, and caution is also advised during this time.

For recommendations regarding antineoplastics that are CYP3A4 substrates, see 'Antineoplastics + Aprepitant', p.701.

Bismuth compounds + Food

Food may reduce the absorption of bismuth.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects given **tripotassium dicitratobismuthate** (containing approximately 216 mg bismuth) 2 hours before a standard breakfast, peak plasma levels of bismuth were found to be on average 64 micrograms/L around 30 minutes later; one subject had bismuth level of 232 micrograms/L and ten others had a level greater than 50 micrograms/L. However, when the same bismuth compound was taken immediately after a standard breakfast, the bismuth levels were found to be lower (an average of 10.9 micrograms/mL, one subject levels were 120 micrograms/mL). In contrast, basic **bismuth carbonate** (equivalent to 160 mg bismuth) produced very low systemic levels of bismuth (no patient had a level greater than 2.7 micrograms/L) and food did not significantly affect its absorption.[1] The manufacturers recommend that **tripotassium dicitratobismuthate** (*De-Noltab*, containing 120 mg of bismuth per tablet, usual dose of up to 4 tablets daily) should be taken half an hour before each of the three main meals of the day and 2 hours after the last meal of the day or taken twice daily, half an hour before both breakfast and the evening meal.[2]

The manufacturers of *Pylorid* (**ranitidine bismuth citrate**) noted that food causes a decrease in bismuth absorption which is not of clinical relevance, but because of limited data that suggest increased ulcer healing when *Pylorid* is given with food, they noted that it should preferably be taken with food.[3]

Food reduced the bioavailability of a single tablet containing a combination of **bismuth subcitrate potassium**, metronidazole and tetracycline in one study. However, the efficacy of this combined preparation for eradication of *Helicobacter pylori* does not seem to be affected (eradication rates reported at nearly 90%) and the authors suggest that this prolonged local exposure in the stomach may be beneficial.[4] Again the manufacturers note that reduced absorption is not considered clinically significant and they recommend that *Pylera* (**bismuth subcitrate potassium**) should be given after meals and at bedtime.[5]

5. Pylera (Bismuth subcitrate potassium, metronidazole, and tetracycline hydrochloride). Axcan Pharma Inc. US Prescribing information, February 2007.

Bismuth compounds + H_2-receptor antagonists

Ranitidine possibly causes an increase in the absorption of bismuth from tripotassium dicitratobismuthate, but not bismuth salicylate or bismuth subnitrate. Any increase is considered unlikely to be clinically relevant with recommended short courses for *H. pylori* eradication. Other H_2-receptor antagonists would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects the AUC of a single 240-mg dose of **tripotassium dicitratobismuthate** (TDB, *De Noltabs*), was increased fourfold by two 300-mg doses of ranitidine (taken the night before and 2 hours before the bismuth compound). The maximum serum levels were approximately doubled. The same regimen of ranitidine had no significant effect on the absorption of bismuth from **bismuth salicylate** (*Pepto-Bismol*) or **bismuth subnitrate** (*Roter* tablets).[1]

The authors suggest that the reduction in gastric acidity maintains TDB in its colloidal form, which is more likely to be absorbed, and that this may result in increased bismuth toxicity.[1] Other H_2-receptor antagonists, and other drugs that reduce gastric acidity would be expected to interact similarly (see also 'Bismuth compounds + Proton pump inhibitors', below).

However, the manufacturers of TDB say that the toxic range of bismuth is arbitrary and a small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case.[2] Note that a complex of ranitidine with bismuth and citrate (**ranitidine bismuth citrate**) is available in many countries and is a recommended constituent in one of the triple therapy regimens for *H. pylori* eradication. As with all bismuth compounds, it is recommended that this is used only for limited periods: a maximum of 16 weeks (two 8-week courses or four 4-week courses) in a 12-month period.[3]

Bismuth compounds + Proton pump inhibitors

Omeprazole markedly increases the absorption and bioavailability of bismuth. Other proton pump inhibitors are expected to interact similarly. However, this is probably unlikely to be clinically relevant.

Clinical evidence

In a randomised study, 34 healthy subjects were given a triple therapy capsule *Helizide* (containing **bismuth subcitrate potassium** 140 mg, metronidazole 125 mg, and tetracycline 125 mg) at a dose of three capsules four times daily, with or without omeprazole 20 mg twice daily for 6 days. Omeprazole increased the maximum plasma levels and AUC of bismuth by about threefold. However, the maximum plasma level achieved was 25.5 micrograms/L, which was still well below 50 micrograms/L, a level reported to be highly unlikely to cause toxicity.[1] The authors also state that in clinical studies in which *Helizide* was given with omeprazole for

10 days to several hundred patients,[2] no patient showed signs of encephalopathy, a notable toxic adverse effect of bismuth.[1]

In an earlier single-dose study in 6 healthy subjects, a single 240-mg dose of **tripotassium dicitratobismuthate** was taken 1 hour after the last dose of a 1-week course of omeprazole 40 mg daily. Omeprazole increased the AUC of bismuth fourfold, and increased the maximum plasma levels from 36.7 to 86.7 micrograms/L, which the authors pointed out approaches the considered 'toxic range' for bismuth (100 micrograms/L and above).[3]

Mechanism

The solubility and absorption of some bismuth compounds are known to be increased by decreased acidity of the stomach.[1] See also 'Bismuth compounds + H_2-receptor antagonists', p.1145).

Importance and management

The authors of the single-dose study recommended that the dosage of tripotassium dicitratobismuthate should be halved when given with omeprazole because of the possibility of systemic bismuth toxicity.[3] However, an increased risk of toxicity has not been seen in subsequent studies using bismuth subcitrate potassium for up to 10 days.[1,2] The manufacturers of tripotassium dicitratobismuthate say that the toxic range of bismuth is arbitrary and the small increase in absorption is not clinically relevant, except perhaps in patients with renal failure, in whom this bismuth compound should be avoided in any case.[4] No clinically significant effect would be expected if combined treatment is limited to the recommended 2-week regimen for resistant *Helicobacter pylori* infection. As this interaction is due to changes in gastric pH other proton pump inhibitors would be expected to interact similarly.

Carbenoxolone + Antacids

There is some evidence that antacids may possibly reduce the bioavailability of carbenoxolone liquid.

Clinical evidence, mechanism, importance and management

The bioavailability of carbenoxolone in a liquid formulation was found to be approximately half that of carbenoxolone in granular and capsule formulations when each preparation was given with an **aluminium/magnesium hydroxide** antacid.[1] The extent to which antacids might reduce the ulcer-healing effects of carbenoxolone liquid seems not to have been assessed, but consider the possibility of a reduction in its efficacy if an antacid is also given.

1. Crema F, Parini J, Visconti M, Perucca E. Effetto degli antiacidi sulla biodisponibilità del carbenoxolone. *Farmaco (Prat)* (1987) 42, 357–64.

Carbenoxolone + Antihypertensives

Carbenoxolone causes fluid retention and raises blood pressure in some patients. This may be expected to oppose the effects of antihypertensive drugs. The potassium-depleting effects of carbenoxolone and diuretics such as the thiazides or loop diuretics can be additive. Both spironolactone and amiloride can oppose the ulcer-healing effects of carbenoxolone.

Clinical evidence, mechanism, importance and management

(a) Antihypertensives, general

Carbenoxolone can raise blood pressure. Five out of 10 patients taking carbenoxolone 300 mg daily, and 2 out of 10 patients taking carbenoxolone 150 mg daily, had a rise in their diastolic blood pressure of 20 mmHg or more.[1] Other reports[2-8] confirm that fluid retention and hypertension occur in those taking carbenoxolone, with the reported incidence of hypertension varying from as low as 4%[8] to as high as 50%,[7] and fluid retention occurring in 0%[2] to 46% of patients.[7] The reason for the blood pressure rise is that carbenoxolone has mineralocorticoid-like activity and therefore causes sodium and water retention. There appear to be few direct reports of adverse interactions between antihypertensives and carbenoxolone. Patients taking carbenoxolone should have regular checks on their weight and blood pressure, and carbenoxolone should be used with caution, if at all, in those with cardiac disease such as hypertension or congestive heart failure (see also, Diuretics, below).

(b) Diuretics

Spironolactone[3] (an aldosterone antagonist) and **amiloride**[9] are best avoided with carbenoxolone because they oppose its ulcer-healing effects, but there is a case report of the successful use of **spironolactone** in a patient with carbenoxolone-associated hypertension and hypokalaemia.[10] **Thiazide diuretics** have been used to control the oedema and hypertension caused by carbenoxolone. However, if these or other potassium-depleting diuretics (see 'Table 26.1', (p.1121)) are used it should be remembered that the potassium-losing effects of the carbenoxolone and the diuretic may be additive, and therefore a potassium supplement may be needed to prevent hypokalaemia. For example, rhabdomyolysis and acute tubular necrosis associated with severe hypokalaemia occurred in a patient given carbenoxolone and **chlortalidone**, without a potassium supplement.[11] Laryngospasm and stridor have been reported in a patient secondary to hypokalaemia and alkalosis caused by long-term use of **furosemide** and a carbenoxolone-containing antacid (*Pyrogastrone*).[12] Possible alternatives to carbenoxolone are the H_2-receptor antagonists, or the proton pump inhibitors, which do not appear to interact with antihypertensives.

Carbenoxolone + Phenytoin

A single 100-mg dose of phenytoin had no significant effect on the half-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects.[1] This limited evidence would seem to suggest that there is no reason for avoiding the concurrent use of these two drugs.

1. Thornton PC, Papouchado M, Reed PI. Carbenoxolone interactions in man - preliminary report. *Scand J Gastroenterol* (1980) 15 (Suppl 65), 35–9.

Carbenoxolone + Sulfonylureas

Chlorpropamide appears to reduce the serum levels of carbenoxolone. Tolbutamide does not appear to have any significant effect on the pharmacokinetics of carbenoxolone.

Clinical evidence, mechanism, importance and management

A single 500-mg dose of **tolbutamide** had no significant effect on the half-life of a single 100-mg dose of carbenoxolone in 4 healthy subjects, whereas a single 250-mg dose of **chlorpropamide** delayed the absorption

of carbenoxolone and reduced its plasma levels in 6 patients taking carbenoxolone 100 mg three times daily.[1] The clinical importance of this latter interaction is uncertain.

1. Thornton PC, Papouchado M, Reed PI. Carbenoxolone interactions in man - preliminary report. *Scand J Gastroenterol* (1980) 15 (Suppl 65), 35–9.

Cisapride + Miscellaneous

In many countries cisapride has been withdrawn from the market, or is only available for restricted use because of its potential to cause torsade de pointes arrhythmias, especially when cisapride serum levels are elevated.[1] This can lead to cardiac arrest and sudden death. The interactions of cisapride and their importance and management are summarised in 'Table 27.2', (p.1148).

1. Ahmad SR, Wolfe SM. Cisapride and torsades de pointes. *Lancet* (1995) 345, 508.

Enteral feeds + Aluminium compounds and/or Sucralfate

Aluminium-containing antacids and sucralfate can interact with high-protein liquid enteral feeds to produce an obstructive plug.

Clinical evidence

(a) Aluminium-containing antacids

Three patients, who were being fed with a liquid high-protein nutrient (*Fresubin liquid*) through an enteral tube, developed an obstructing protein-aluminium-complex oesophageal plug when intermittently given an aluminium/magnesium hydroxide antacid (*Alucol-Gel*).[1] Another report also describes blockage of a nasogastric tube in a patient given aluminium hydroxide (*Aludrox*) and *Nutrison*.[2]

(b) Sucralfate alone or with aluminium-containing antacids

A number of reports describe the development of hard putty-like or creamy precipitations and encrustations that have blocked the oesophagus or stomach of patients given sucralfate with enteral feeds (*Ensure Plus*,[3] *Fresubin plus F*,[4] *Glucerna*,[5] *Jevity*,[5] or *Osmolite*[6]). Another patient developed this precipitate when given *Isocal* and sucralfate with aluminium/magnesium hydroxide.[7] Similarly, a patient receiving *Pulmocare* nasogastric feed, sucralfate and aluminium hydroxide gel also developed an oesophageal bezoar, which was analysed and found to contain components of both the drugs and the enteral feed.[8]

Data from the French Pharmacovigilance system database found 16 adults and 5 newborn babies who developed bezoars while taking sucralfate; nasogastric feeding was identified as a risk factor.[9]

Mechanism

It seems that a bezoar (a relatively insoluble complex) forms between the protein in the enteral feeds, and the aluminium from the antacids or sucralfate (sucralfate is about 18% aluminium). It thickens when the pH falls.[3]

Importance and management

An established and clinically important interaction that can result in the blockage of enteral or nasogastric tubes. The authors of one report say that high molecular protein solutions should not be mixed with antacids or followed by antacids, and if an antacid is needed, it should be given some time after the nutrients and the tube should be vigorously flushed beforehand.[1] The authors of another report say that they feed for 18 hours daily and then give the sucralfate overnight without problems.[2] The manufacturers recommend separating the administration of sucralfate suspension and enteral feeds given by nasogastric tube by one hour.[10]

H_2-receptor antagonists + Antacids

The absorption of cimetidine, famotidine, nizatidine, and ranitidine may possibly be reduced to some extent by antacids, but it seems doubtful if this significantly reduces their effects. Roxatidine absorption appears not to be affected by antacids. Cimetidine appears not to interfere with the effectiveness of *Gaviscon* (sodium alginate compound).

Clinical evidence

(a) Cimetidine

When 12 healthy subjects were given oral cimetidine 300 mg four times daily for 5 doses, with and without 30 mL of *Mylanta II* (**aluminium/magnesium hydroxide** mixture), the absorption of cimetidine was unaffected.[1] No interaction was found with cimetidine in single-dose studies using **aluminium phosphate**[2,3] or **aluminium/magnesium hydroxide**[4,5] antacids.

In contrast, a number of other single-dose studies indicated that antacids reduce the absorption of cimetidine. The AUCs of 200- to 800-mg doses of cimetidine were reduced by an average of 19 to 34% by 10 to 45 mL doses of a variety of **aluminium/magnesium**-containing antacids.[6-10] When the antacids were given 1 to 3 hours after cimetidine 'marginal' or insignificant reductions occurred in the AUCs.[7,11,12]

Gaviscon (**sodium alginate/antacid**) is an anti-reflux preparation that needs a small amount of gastric acid to be present in order for the alginic acid 'raft' to form. A study in 12 healthy subjects designed to find out if an H_2-receptor antagonist would alter the effectiveness of *Liquid Gaviscon* found that cimetidine 400 mg four times daily for 7 days caused some slight changes in gastric emptying, but the distribution of the *Gaviscon* in the fundus of the stomach was not altered.[13]

The pharmacokinetics of a 200-mg dose of cimetidine were not significantly changed by [**simeticone**] 2.25 g in 11 healthy subjects.[14]

(b) Famotidine

Mylanta II (**aluminium/magnesium hydroxide** mixture) 30 mL reduced the AUC and peak plasma levels of famotidine by about one-third when both drugs were taken simultaneously, but no significant interaction occurred when the antacid was taken 2 hours after famotidine.[15] Another study found that the maximum plasma levels of famotidine were reduced by about 25% by *Mylanta II* in 17 healthy subjects.[16] *Mylanta Double Strength* (**aluminium/magnesium hydroxide** with **simeticone**) was found to reduce the absorption of famotidine by 19%, a difference that was considered unimportant.[10] Two chewable tablets of *Mylanta II* were found to have no effect on the pharmacokinetics or pharmacodynamics of famotidine 10 or 20 mg in 18 healthy subjects.[17]

(c) Nizatidine

Mylanta Double Strength (**aluminium/magnesium hydroxide** with **simeticone**) reduced the absorption of nizatidine by 12%, which was considered clinically insignificant.[10] In a study in 11 healthy subjects a single 30-mL dose of *Gelusil* (**aluminium/magnesium hydroxide** with **simeticone**) reduced the mean AUC and maximum serum levels of nizatidine (given simultaneously) by 13% and 17%, respectively.[18] Another study found that the pharmacokinetics of nizatidine were not affected by an **aluminium/magnesium hydroxide** antacid (*Maalox)* although an increase in the time to peak effect of nizatidine was seen.[19]

(d) Ranitidine

In 6 healthy subjects, *Mylanta II* (**aluminium/magnesium hydroxide** mixture) 30 mL reduced the peak plasma levels and AUC of a single 150-mg dose of ranitidine by about one-third.[20] *Mylanta Double Strength* (**aluminium/magnesium hydroxide** with **simeticone**) reduced the absorption of ranitidine by 26%, which was not thought to be clinically significant.[10] Another study found that **aluminium/magnesium**-containing antacids reduced the

Table 27.2 Summary of the interactions of cisapride

Interacting drugs	*Reported effects*	*Action*	*Refs*
Alcohol	Cisapride increases gastric emptying and can modestly increase serum alcohol levels. A modest 22% increase in the AUC of cisapride seen in one study.	Unlikely to be significant, however the sedative effects might be accelerated. Unknown significance; monitor patient for sedation.	1-5
Antacids Aluminium [hydr]oxide and magnesium hydroxide	No effect on cisapride absorption seen.	None.	6
Antiepileptics e.g. Phenytoin	Increase in gastrointestinal motility caused by cisapride may affect the rate and/or extent of absorption, which may be important for some drugs with a narrow therapeutic index, such as some antiepileptics. However, no available case reports to suggest this is a problem, and one case reporting no interaction.	Uncertain. Monitor antiepileptic drug levels as usual practice. Advise the patient to report any increase in adverse effects.	1, 7
Antimuscarinics e.g. Disopyramide	Cisapride increases gastric emptying but antimuscarinics slow gastric emptying. **Disopyramide** absorption and serum levels were increased by cisapride in one study.	The clinical outcome is uncertain but caution is warranted if increased levels of the other drug likely to be significant e.g. **Disopyramide** is contraindicated as it can prolong the QT interval.	8
Butyrophenones e.g. Bromperidol, Haloperidol	Increased psychotic symptoms and bromperidol levels occurred in one case report. No significant pharmacokinetic interaction between cisapride and either bromperidol or haloperidol in a study in schizophrenic patients, but possible worsening of psychotic symptoms seen when cisapride was given with haloperidol.	Significance uncertain, but probably small.	9, 10
Ciclosporin	An increase in AUC and serum levels of ciclosporin has been reported.	Monitor ciclosporin levels more frequently.	11
CYP3A4 inhibitors: **Macrolides** e.g. Clarithromycin, Erythromycin **Azole antifungals** e.g. Ketoconazole **Protease inhibitors** **Nefazodone** **Diltiazem** **Cimetidine** **See also Table 1.4, p.6**	Increased levels of cisapride result in an increase in the risk of QT prolongation and life-threatening ventricular arrhythmias e.g. *torsade de pointes*.	Avoid.	1, 12-22
Diazepam	Accelerated absorption of diazepam reported. Transient increase in sedation possible.	Monitor the patient and advise that sedation may occur more quickly.	1, 23
Digoxin	Small reduction in the AUC and serum levels of digoxin seen in one study.	Unlikely to be clinically significant.	24
Diltiazem	A case of syncope and prolonged QT interval reported – see also CYP3A4 inhibitors above.	See CYP3A4 inhibitors above.	25
Drugs that prolong the QT interval	Increased risk of QT prolongation and life-threatening ventricular arrythmias.	Avoid. Should not be used with other drugs that prolong the QT interval.	1, 16
Esomeprazole	An increase in AUC and elimination half-life of cisapride reported, but no increase in serum levels. No QT-prolonging effects seen.	Unlikely to be clinically significant.	1, 26
Fluoxetine	No effect on the QT interval seen.	None.	27
Grapefruit juice	Significant increases in cisapride levels seen but high inter-subject variability occurred. No QT interval changes were seen.	May be of more significance in patients taking higher doses of cisapride or also taking other interacting drugs. Avoid concurrent use if possible.	28-30
H_2-receptor antagonists e.g. Cimetidine, ranitidine	Increase in cisapride levels and reduction in cimetidine and ranitidine bioavailability seen.	Unlikely to be clinically significant. For cimetidine, see also CYP3A4 inhibitors, above.	1, 31-35
Morphine	An increase in peak morphine serum levels was seen but with no increase in the adverse effects of morphine.	Uncertain but be aware in case of increased morphine adverse effects.	36
Nifedipine	An increase in nifedipine levels with increased nifedipine effects seen, probably due to increased absorption.	Monitor patient and adjust the nifedipine dose accordingly.	37
Pantoprazole	Small reduction in cisapride levels and no QT interval effects seen.	None.	38

Continued

Table 27.2 Summary of the interactions of cisapride (continued)

Interacting drugs	*Reported effects*	*Action*	*Refs*
Paracetamol	No significant effect on the pharmacokinetics of paracetamol was found in one study but another small study found that the metabolism of paracetamol was reduced.	Unlikely to be clinically significant.	39, 40
Propranolol	No change in levels or effect of propranolol.	None.	41
Red wine	Minor changes in cisapride levels seen in one single-dose study.	Significance is unclear.	30
Simvastatin	Slightly increased cisapride levels and reduced simvastatin levels.	Unlikely to be generally significant although it may be prudent to check that simvastatin remains effective.	42
Warfarin and related anticoagulants	**Warfarin**: A small but insignificant increase in INR was seen in healthy subjects, but one case report describes a large rise in INR. **Acenocoumarol**: Increased anticoagulant effect reported, which resolved when cisapride stopped. **Phenoprocoumon**: No significant change in anticoagulant effects.	It seems prudent to monitor patients taking anticoagulants who are given cisapride until their INR is stable.	1, 43-46

absorption of ranitidine by up to almost 60%.[9] Yet another study showed that **aluminium phosphate** reduced the bioavailability of ranitidine by 30%.[21] In contrast, one study found no significant changes in the pharmacokinetics of ranitidine given with an **aluminium/magnesium hydroxide** antacid (*Maalox*).[19]

(e) Roxatidine

In a crossover study, 24 healthy subjects were given roxatidine 150 mg with 10 mL of *Maalox* (**aluminium/magnesium hydroxide**) four times daily. The pharmacokinetics of roxatidine were unchanged, apart from a clinically insignificant increase in its half-life.[22]

Mechanism

Not fully understood. Changes in gastric pH caused by the antacid, and retarded gastric motility have been suggested as potential mechanisms. An *in vitro* study showed no absorption interaction occurred between cimetidine and antacids.[5]

Importance and management

A modest reduction in the bioavailability of cimetidine, famotidine, nizatidine and ranitidine can occur with some antacids although this appears to be more likely when larger doses of antacids are used. None of these interactions are well established and evidence that the effects of the H_2-receptor antagonists are reduced seems to be lacking. If the antacids are given 1 to 2 hours before or after the H_2-receptor antagonist (if fasting), or 1 hour after (if the H_2-receptor antagonist is taken with food), no reduction in absorption should occur.[7,15,16,23]

Given the evidence available it seems unlikely that a clinically significant interaction will occur between any H_2-receptor antagonist and standard doses of an antacid.

H_2-receptor antagonists + Metoclopramide

Metoclopramide reduces the bioavailability of cimetidine. Ranitidine may increase the bioavailability and half-life of metoclopramide.

Clinical evidence

(a) Cimetidine

In a study in healthy subjects, a 14-mg dose of a liquid formulation of metoclopramide (given a two 7-mg doses, 10 minutes before and 30 minutes after cimetidine) reduced the bioavailability of **cimetidine** by 22%, although this result did not reach statistical significance.[1] In another study in healthy subjects, the AUC of a single 200-mg dose of **cimetidine** was reduced by about 30% by a single 20-mg dose of metoclopramide.[2] Another study found that **cimetidine** bioavailability was not significantly affected when it was given 2 hours before metoclopramide.[3]

(b) Ranitidine

In a single-dose study in healthy subjects given ranitidine 300 mg and metoclopramide 10 mg, the time to maximum serum levels of ranitidine was reduced from 2.3 to 1.4 hours by metoclopramide. The AUC and maximum serum level of ranitidine were not significantly decreased.[4] In a study in healthy subjects, ranitidine 150 mg twice daily for 5 days increased the AUC of a single 20-mg dose of metoclopramide by about 13% and increased its half-life from 5.6 to 6.7 hours.[5]

Mechanism, importance and management

Reduced gastrointestinal transit time produced by metoclopramide may have led to the reduction in cimetidine bioavailability.[2] Similarly, the shortened time to maximum ranitidine levels may be due to accelerated gastric emptying.[4] However, the clinical effects of these results do not ap-

pear to be significant, particularly as there appears to be a lack of reports of H_2-receptor antagonist treatment failure when metoclopramide has also been taken.

The increase in the bioavailability of metoclopramide seen in the study with ranitidine is unlikely to be significant.

H_2-receptor antagonists + Probenecid

Probenecid markedly decreases the renal clearance of famotidine and modestly reduces the renal clearance of cimetidine. However, these effects are not expected to result in adverse clinical effects.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 6 healthy subjects were given probenecid 500 mg every 6 hours for 13 doses, with a single 300-mg intravenous dose of **cimetidine** 3 hours after the last probenecid dose. Probenecid reduced the renal clearance of **cimetidine** by 22%, without affecting its overall clearance.[1] Probenecid 1.5 g increased the AUC of a single 20-mg dose of **famotidine** in 8 healthy subjects by 81%, and reduced the renal tubular clearance by 89%.[2] It has been suggested that probenecid inhibits the renal secretion of **cimetidine** and famotidine, thereby reducing their renal clearance. This is consistent with the way that probenecid affects some other drugs. The effects of **famotidine** would be expected to be increased, but dose-related toxicity arising from this interaction seems unlikely. The effects of **cimetidine** are unlikely to be significantly altered. There would therefore seem to be no reason for avoiding concurrent use. Other H_2-receptor antagonists are also renally excreted and therefore they may behave similarly.

2. Inotsume N, Nishimura M, Nakano M, Fujiyama S, Sato T. The inhibitory effect of probenecid on renal excretion of famotidine in young, healthy volunteers. *J Clin Pharmacol* (1990) 30, 50–56.

H_2-receptor antagonists + Rifampicin (Rifampin)

No clinically significant interaction appears to occur between rifampicin and cimetidine or ranitidine.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

In a study, 12 patients given daily doses of rifampicin 8 mg/kg, isoniazid 8 mg/kg and ethambutol 25 mg/kg for at least 14 days, and 13 untreated control subjects were given a single 300-mg dose of intravenous cimetidine. In the patients receiving antimycobacterials, the non-renal clearance of cimetidine was increased by 52% but the total clearance and volume of distribution were unchanged. This reduction in renal clearance may have been associated with age-related impairment of renal function (although the study did exclude patients with a glomerular filtration rate of less than 60 mL/minute), but it was suggested that the increased non-renal clearance may have been due to enzyme induction of cimetidine metabolism.[1] As total clearance was unchanged this interaction seems unlikely to be clinically significant.

(b) Ranitidine

In a controlled study, 112 patients with pulmonary tuberculosis were treated in 2 groups, one with a daily regimen of rifampicin 10 mg/kg, isoniazid 300 mg and ethambutol 20 mg/kg and ranitidine 150 mg twice daily, and the other with the same antimycobacterials but without ranitidine. The pharmacokinetics of rifampicin (as measured by the total and unchanged urinary excretion) were not affected by ranitidine. No changes occurred in the incidence of adverse hepatic reactions, while gastrointestinal reactions were reduced.[2] There would seem to be no reason for avoiding the use of ranitidine, or any other H_2-receptor antagonists, in patients taking rifampicin.

1. Keller E, Schollmeyer P, Brandenstein U, Hoppe-Seyler G. Increased nonrenal clearance of cimetidine during antituberculous therapy. *Int J Clin Pharmacol Ther Toxicol* (1984) 22, 307–11.
2. Purohit SD, Johri SC, Gupta PR, Mehta YR, Bhatnagar M. Ranitidine-rifampicin interaction. *J Assoc Physicians India* (1992) 40, 308–10.

H_2-receptor antagonists + Sucralfate

Most *in vitro* and human studies have found that sucralfate does not affect the absorption of either cimetidine,[1-3] ranitidine,[4] or roxatidine,[5] but two studies found 22 to 29% reductions in ranitidine bioavailability due to the concurrent use of sucralfate,[6,7] which would not be expected to be clinically significant. There is no clear reason for avoiding concurrent use.

H_2-receptor antagonists + Tobacco or Nicotine

Smoking may reduce the plasma levels of cimetidine and ranitidine, but does not appear to alter the effects of famotidine. Cimetidine, and to a lesser extent ranitidine, reduce the clearance of nicotine in non-smokers, but there is some evidence to suggest that cimetidine has no effect on nicotine clearance in smokers.

Clinical evidence

(a) Nicotine

Cimetidine 600 mg twice daily for one day, given before nicotine (1 microgram/kg per minute given intravenously for 30 minutes), reduced the nicotine clearance in 6 healthy non-smokers by 27 to 30%. **Ranitidine** 300 mg twice daily, taken for one day, reduced the clearance of nicotine by about 7 to 10%.[1] See also tobacco, below.

(b) Tobacco

In one study, tobacco smokers were given single oral doses of either **ranitidine** 150 mg or **cimetidine** 200 mg on two separate days. On one of the days they were allowed to smoke as normal and on the other they were not allowed to smoke. Peak levels for both drugs occurred sooner and were higher on the smoking day than on the non-smoking day. However, the plasma levels of the H_2-receptor antagonists, after peak levels were achieved, were lower. No effect was seen when intravenous **cimetidine** or **ranitidine** were given.[2]

A study in heavy smokers (more than 20 cigarettes per day for at least 1 year) given cimetidine 400 mg three times daily for 2 weeks found no reduction in the clearance of **nicotine** or in the number of cigarettes smoked, when compared with placebo.[3]

There was no difference in the pharmacokinetics and gastric acid-lowering effect of **famotidine** between 12 healthy smokers and 8 non-smokers.[4]

Mechanism, importance and management

The authors of one of the above studies[3] noted that tobacco smoking induces nicotine metabolism. This may at least partially explain the lack of effect of cimetidine on nicotine clearance seen in their previous study in non-smokers.[1] On balance cimetidine and other H_2-receptor antagonists probably have little effect on nicotine replacement therapy or tobacco smoking.

The healing of duodenal ulcers in patients taking H_2-receptor antagonists

such as cimetidine,[5,6] famotidine,[7] **nizatidine**[8] and ranitidine[6,7] is slower, and ulcer recurrence is more common, in smokers than in non-smokers. It is quite possible that this is due to smoking being a risk factor for the occurrence of duodenal ulcers[5,7-9] rather than a significant interaction between smoking and H_2-receptor antagonists.

H_2-receptor antagonists; Cimetidine + Phenobarbital

Phenobarbital modestly reduces the AUC of cimetidine, although this is probably not clinically relevant.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects, phenobarbital 100 mg daily for 3 weeks reduced the AUC of a single 400-mg oral dose of cimetidine by 15%, and the time during which the plasma concentrations of the cimetidine exceeded 0.5 micrograms/mL (regarded as therapeutically desirable) was reduced by 11%.[1]

Phenobarbital apparently stimulates the enzymes in the gut wall so that the metabolism of the cimetidine is increased. Thus the amount of cimetidine absorbed and released into the circulation is reduced.

Direct information is very limited, but the effect of phenobarbital on cimetidine levels is small and unlikely to be clinically important. No special precautions seem to be necessary.

1. Somogyi A, Thielscher S, Gugler R. Influence of phenobarbital treatment on cimetidine kinetics. *Eur J Clin Pharmacol* (1981) 19, 343–7.

H_2-receptor antagonists; Cimetidine + Propantheline

Propantheline reduces the bioavailability of cimetidine.

Clinical evidence, mechanism, importance and management

In a single-dose study in healthy subjects, propantheline 30 mg reduced the AUC and peak plasma levels of cimetidine 200 mg by about 22% and 33%, respectively. It was suggested that the reduced bioavailability of cimetidine possibly due to delayed gastric emptying, decreased gastrointestinal motility, and reduced mixing of intestinal contents caused by the propantheline.[1] The clinical significance of this single dose study is unclear. However, there do not appear to be any clinical reports of treatment failure when both drugs have been used concurrently.

1. Kanto J, Allonen H, Jalonen H, Mäntylä R. The effect of metoclopramide and propantheline on the gastrointestinal absorption of cimetidine. *Br J Clin Pharmacol* (1981) 11, 629–31.

$5\text{-}HT_3$-receptor antagonists + Aprepitant

Aprepitant appears to have no clinically relevant effect on the pharmacokinetics of dolasetron, granisetron, ondansetron or palonosetron.

Clinical evidence and mechanism

(a) Dolasetron

In a study in 12 healthy subjects, aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of a single 100-mg oral dose of dolasetron given on day one, regardless of CYP2D6 metaboliser type.[1]

(b) Granisetron

In a study in healthy subjects, aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of oral granisetron 2 mg given on day one.[2]

(c) Ondansetron

In a study in healthy subjects, aprepitant 375 mg on day one, then 250 mg on days 2 to 5 caused a minor 15% increase in the AUC of intravenous ondansetron 32 mg given on day one.[2]

(d) Palonosetron

Aprepitant 125 mg on day one, then 80 mg on days 2 and 3 had no effect on the pharmacokinetics of a single 250-microgram intravenous dose of palonosetron given to healthy subjects on day one.[3]

Importance and management

No important pharmacokinetic interaction appears to occur between the $5\text{-}HT_3$-receptor antagonists and aprepitant. Therefore, no dosage adjustment is required when aprepitant is given with dolasetron, granisetron, ondansetron, or palonosetron.

3. Shah AK, Hunt TL, Gallagher SC, Cullen MT. Pharmacokinetics of palonosetron in combination with aprepitant in healthy volunteers. *Curr Med Res Opin* (2005) 21, 595–601.

$5\text{-}HT_3$-receptor antagonists + Cimetidine

Cimetidine has no clinically significant effect on the pharmacokinetics of dolasetron or granisetron.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

A study in 18 healthy subjects given dolasetron 200 mg daily found that cimetidine 300 mg four times daily for 7 days increased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 24% and 15%, respectively, probably due to the inhibitory effect of cimetidine on the cytochrome P450-mediated metabolism of dolasetron. As 400-mg oral doses of dolasetron have been shown to be well tolerated (the usual oral dose is up to 200 mg) these changes were not considered to be clinically significant.[1] Therefore no dolasetron dosage adjustments appear to be necessary if cimetidine and dolasetron are used concurrently.

(b) Granisetron

In a study[2] in 12 healthy subjects, pretreatment with cimetidine 200 mg four times daily for 8 days had no effect on the pharmacokinetics of a single 40-microgram/kg intravenous dose of granisetron given on day 8. Therefore, no granisetron dose adjustments are likely to be necessary if cimetidine is given.

$5\text{-}HT_3$-receptor antagonists + Drugs that prolong the QT interval

The $5\text{-}HT_3$-receptor antagonists dolasetron, granisetron, ondansetron, tropisetron have been reported to cause minor

increases in the QTc interval. Palonosetron has no clinically significant effect on the QT interval.

Clinical evidence, mechanism, importance and management

The 5-HT_3-receptor antagonists are now known to cause small increases (generally not exceeding 15 milliseconds) in the QTc interval.[1] It has been concluded that this class effect is too small to be of clinical relevance,[1,2] and that there is insufficient evidence to differentiate the 5-HT_3-receptor antagonists by this effect.[3] In a more recent well-controlled study in 221 healthy subjects, intravenous **palonosetron** 250 micrograms, 750 micrograms and 2.25 mg had no significant effect on the QT interval, when compared with that of moxifloxacin as a positive control.[4] Nevertheless, the manufacturers issue differing guidance about concurrent use with other QT prolonging drugs as follows:

- **Dolasetron**: the UK manufacturer contraindicates[5] the concurrent use of dolasetron and **class I** or **class III antiarrhythmics**, and recommends caution with other drugs that prolong ECG intervals in patients at risk. The US manufacturer advises caution with all drugs that may prolong the QT interval. They include **diuretics**, with the potential for causing electrolyte abnormalities.[6]
- **Granisetron**: neither the UK nor the US manufacturers mention QT prolongation.[7,8]
- **Ondansetron**: the UK manufacturer recommends caution in patients treated with **antiarrhythmics** or **beta blockers**,[9] whereas the US manufacturer does not issue any cautions regarding QT-prolongation.[10]
- **Palonosetron**: the UK manufacturer recommends caution with other drugs that increase the QT interval.[11] The US manufacturer previously advised caution with drugs that prolong the QT interval, specifically mentioning **antiarrhythmics** and **diuretics** with the potential for causing electrolyte abnormalities.[12] However, on the basis of the new data mentioned above, this warning has now been deleted.[4]
- **Tropisetron**: the UK manufacturer recommends care when it is used with other drugs that are likely to prolong the QT interval, and specifically mentions **antiarrhythmics** and **beta blockers**.[13]

For further information about drug interactions involving the QT interval see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

5-HT_3-receptor antagonists + Enzyme inducers

Rifampicin (rifampin) causes a minor reduction in dolasetron levels and a modest reduction in ondansetron levels, and may affect granisetron and tropisetron similarly, but does not appear to alter palonosetron levels. Phenobarbital causes a minor reduction in the levels of granisetron.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

In a study in 17 healthy subjects given dolasetron 200 mg daily, **rifampicin** (**rifampin**) 600 mg daily for 7 days decreased the AUC and maximum plasma level of the active metabolite of dolasetron, hydrodolasetron, by 28% and 17%, respectively, probably due to induction of hydrodolasetron metabolism by **rifampicin**.[1] These changes were not considered to be clinically significant and therefore no dosage adjustments appear necessary if **rifampicin** and dolasetron are used concurrently.

(b) Granisetron

The US manufacturer notes that, in a pharmacokinetic study, **phenobarbital** increased the clearance of granisetron by 25%. They say that the relevance of this change is unknown,[2] but such a modest change is unlikely to be clinically important.

(c) Ondansetron

In a study in 10 healthy subjects, pretreatment with **rifampicin** 600 mg once daily for 5 days markedly decreased the AUC of a single 8-mg dose of oral ondansetron by 65% and intravenous ondansetron by 48%. This is most likely due to the induction of CYP3A4-mediated metabolism of ondansetron by **rifampicin**. The authors concluded that ondansetron may not be as effective if given to patients taking **rifampicin**.[3] Nevertheless, the US manufacturer says that, although the potent CYP3A4 inducers **phenytoin**, **carbamazepine**, and **rifampicin** increased ondansetron clearance, on the basis of available data, no ondansetron dose adjustment is recommended for patients taking these drugs.[4]

(d) Palonosetron

The UK manufacturer notes that, in a population pharmacokinetic analysis, **dexamethasone** and **rifampicin** had no effect on palonosetron clearance.[5] Therefore, no palonosetron dose adjustment is likely to be necessary when given with these drugs.

(e) Tropisetron

The manufacturer states that drugs known to induce hepatic enzymes might lower tropisetron plasma concentrations. However, they say that such changes are unlikely to be of practical importance with the recommended dosage regimen.[6]

5-HT_3-receptor antagonists + Food or Antacids

Food does not affect the absorption of dolasetron. Food slightly increases the bioavailability of ondansetron, but an antacid was found to have no effect.

Clinical evidence, mechanism, importance and management

(a) Dolasetron

In a single-dose study, 23 healthy subjects were given 200 mg of dolasetron orally either alone, or following a **high-fat breakfast** (containing fat 55 g, protein 33 g and carbohydrate 58 g). Although there was a slight delay in absorption, dosing with a meal and dosing without a meal were considered to be bioequivalent. Therefore, dolasetron may be given without regard to meals.[1]

(b) Ondansetron

When 12 healthy subjects were given an 8 mg ondansetron tablet 5 minutes after a **meal**, its bioavailability was only slightly increased (AUC raised by 17%). The concurrent use of an **aluminium**/**magnesium hydroxide** antacid (*Maalox*) had no effect on the bioavailability of ondansetron.[2] Therefore, no precautions appear to be needed when ondansetron is given with an antacid, and it may be taken without regard to meals.

2. Bozigian HP, Pritchard JF, Gooding AE, Pakes GE. Ondansetron absorption in adults: effect of dosage form, food, and antacids. *J Pharm Sci* (1994) 83, 1011–13.

5-HT$_3$-receptor antagonists; Dolasetron + Miscellaneous

Atenolol modestly reduced the clearance of the active metabolite of dolasetron, but verapamil had no effect. One patient taking verapamil and given dolasetron experienced heart block.

Clinical evidence, mechanism, importance and management

(a) Atenolol

The US manufacturer[1] notes that atenolol reduced the clearance of the active metabolite of dolasetron, hydrodolasetron, by 27%. This change is not likely to be clinically significant.

(b) Verapamil

The US manufacturer notes that, in one case, a 61-year-old woman taking verapamil developed complete heart block following the use of dolasetron,[1] although this was not proven to be as a result of an interaction. In other patients taking verapamil, the clearance of hydrodolasetron (the active metabolite of dolasetron) was unchanged.[1]

1. Anzemet Tablets (Dolasetron mesylate). Sanofi-Aventis US LCC. US Prescribing information, August 2008.

5-HT$_3$-receptor antagonists; Palonosetron + Metoclopramide

Metoclopramide 10 mg four times daily did not alter the pharmacokinetics of a single 750-microgram intravenous dose of palonosetron in healthy subjects.[1] Therefore, no dosage adjustment appears to be necessary with concurrent use of metoclopramide and palonosetron.

1. Aloxi (Palonosetron hydrochloride). MGI Pharma Inc. US Prescribing information, February 2008.

Domperidone + CYP3A4 inhibitors

Ketoconazole and erythromycin, both inhibitors of CYP3A4, increase the plasma levels of domperidone about threefold. Additive QT prolongation may also occur on the concurrent use of domperidone and ketoconazole or erythromycin.

Clinical evidence

(a) Erythromycin

In a study, healthy subjects were given domperidone 10 mg four times daily and erythromycin 500 mg three times daily, alone and in combination. The maximum plasma level and AUC of domperidone were increased about threefold by erythromycin. In this study, domperidone and erythromycin alone were found to increase the QTc interval by 2.5 milliseconds and 4.9 milliseconds, respectively, whereas the mean increase in the QTc interval on concurrent use was 9.9 milliseconds, which was greater than the additive effect of each drug alone.[1]

(b) Ketoconazole

In a study, healthy subjects took domperidone 10 mg four times daily and ketoconazole 200 mg twice daily, alone and in combination. The maximum plasma level and AUC of domperidone were increased about threefold by ketoconazole. In this study, domperidone and ketoconazole alone were found to increase the QTc interval by 1.6 milliseconds and 3.8 milliseconds, respectively, whereas the mean increase in the QTc interval on concurrent use was 9.8 milliseconds, which was greater than the additive effect of each drug alone.[1]

Mechanism

Domperidone is metabolised by the cytochrome P450 isoenzyme CYP3A4, which is inhibited by drugs such as erythromycin and ketoconazole. Concurrent use therefore increases domperidone levels, which increases its modest effects on the QT interval. Giving erythromycin or ketoconazole with.domperidone therefore has more than additive effects on the QT interval.

Importance and management

Evidence for an interaction between domperidone and erythromycin or ketoconazole is limited. The manufacturer advises that the concurrent use of domperidone with other drugs that are potent inhibitors of CYP3A4 and that also prolong the QT interval should be avoided. They specifically name erythromycin,[1,2] ketoconazole[1,2] and **ritonavir**.[2] This seems to be a very cautious approach, but may be prudent because alternatives to these combinations would usually be available. The increase in the QT interval due to increased exposure to domperidone caused by CYP3A4 inhibition alone would probably not be clinically relevant, but when added to the increase seen with erythromycin or ketoconazole alone (which at less than 5 milliseconds would not normally be considered to be clinically important, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290), the increase is possibly of some concern.

2. Domperidone (Domperidone maleate). Wockhardt UK Ltd. UK Summary of product characteristics, January 2008.

Loperamide + Colestyramine

An isolated report, supported by an *in vitro* study, indicates that the effects of loperamide can be reduced by colestyramine.

Clinical evidence, mechanism, importance and management

A man who had undergone extensive surgery to the gut, with the creation of an ileostomy, needed treatment for excessive fluid loss. His fluid loss was observed to be 'substantially less' when he took loperamide 2 mg every 6 hours alone, than when he took loperamide in combination with colestyramine 2 g every 4 hours.[1] The probable reason for this effect is that the colestyramine binds to loperamide in the gut, thereby reducing its activity. An *in vitro* study using 50 mL of simulated gastric fluid found that 64% of a 5.5-mg dose of loperamide was bound by 4 g of colestyramine.[1] Direct information is limited to this report, but what occurred is consistent with the way colestyramine interacts with other drugs. It has been suggested that administration of the two drugs should be separated as far as possible to prevent mixing in the gut, or that the loperamide dosage should be increased.[1] It is generally recommended that other drugs should be given 1 hour before or 4 to 6 hours after colestyramine.

1. Ti TY, Giles HG, Sellers EM. Probable interaction of loperamide and cholestyramine. *Can Med Assoc J* (1978) 119, 607–8.

Loperamide + Co-trimoxazole

Co-trimoxazole increases plasma levels of loperamide but this is not expected to be clinically significant.

Clinical evidence, mechanism, importance and management

Co-trimoxazole 960 mg twice daily was given to healthy subjects for 24 hours before and then 48 hours after they took a single 4-mg dose of loperamide (12 subjects) or loperamide oxide (a prodrug of loperamide, 10 subjects). Co-trimoxazole increased the loperamide AUC by 89% and doubled its maximum plasma levels. The loperamide oxide AUC was raised by 54% and its maximum plasma levels were raised by 41%. It is thought that co-trimoxazole inhibits the metabolism of loperamide, possibly by reducing its first pass metabolism.[1] However, despite these rises, because loperamide has a very wide margin of safety, it is thought unlikely that any dosage changes are needed.

1. Kamali F, Huang ML. Increased systemic availability of loperamide after oral administration of loperamide and loperamide oxide with cotrimoxazole. *Br J Clin Pharmacol* (1996) 41, 125–8.

Loperamide + Gemfibrozil and/or Itraconazole

Gemfibrozil and itraconazole alone or in combination significantly increase the bioavailability of loperamide.

Clinical evidence

In a placebo-controlled, crossover study, 12 healthy subjects were given a single 4-mg dose of loperamide on day 4 of taking either itraconazole 200 mg then 100 mg twice daily, gemfibrozil 600 mg twice daily, or both drugs together, each for 5 days. Itraconazole alone increased the AUC and peak levels of loperamide by 3.8-fold and 2.9-fold, respectively, and increased its half-life from 11.9 to 18.7 hours. Gemfibrozil alone increased the AUC and peak levels of loperamide by 2.2-fold and 1.6-fold, respectively, and increased its half-life from 11.9 to 16.7 hours. Itraconazole plus gemfibrozil synergistically increased the AUC and peak levels of loperamide by 12.6-fold and 4.2-fold, respectively, and increased its half-life from 11.9 to 36.9 hours.

Despite the large increases in loperamide bioavailability produced by gemfibrozil and/or itraconazole, no changes in drowsiness or psychomotor test results for loperamide were reported during concurrent treatment.

Mechanism

Loperamide is thought to be metabolised by both the cytochrome P450 isoenzymes CYP3A4 and CYP2C8, and is also a substrate for P-glycoprotein. Therefore the large increases in loperamide levels are thought to be due to CYP2C8 inhibition by gemfibrozil and CYP3A4 inhibition by itraconazole.[1] Loperamide is thought to lack CNS effects because it is a substrate for P-glycoprotein, which transports drugs out of the cells at the blood-brain barrier, thereby restricting CNS penetration.

Importance and management

The concurrent use of loperamide with gemfibrozil and/or itraconazole does not appear to produce clinically significant adverse effects, and therefore no special precautions would appear to be necessary. Consider also 'Loperamide + Protease inhibitors', p.1155.

1. Niemi M, Tornio A, Pasanen MK, Fredrikson H, Neuvonen PJ, Backman JT. Itraconazole, gemfibrozil and their combination markedly raise the plasma concentrations of loperamide. *Eur J Clin Pharmacol* (2006) 62, 463–72.

Loperamide + Protease inhibitors

Loperamide reduces the bioavailability of saquinavir by about 50%. Ritonavir increases the plasma level of loperamide without increasing its CNS adverse effects, and saquinavir similarly increases the bioavailability of loperamide. Tipranavir alone, and in combination with ritonavir, reduces the bioavailability and plasma levels of loperamide and its metabolites.

Clinical evidence

(a) Ritonavir

In a double-blind study, 12 healthy subjects were given a single 600-mg dose of ritonavir with either loperamide 16 mg or placebo. The loperamide AUC and maximum plasma level were increased threefold and 17%, respectively, by ritonavir, but no additional CNS adverse effects were seen.[1] For the effects of ritonavir given as a pharmacokinetic booster, see *Tipranavir*, below.

(b) Saquinavir

In a double-blind, placebo-controlled study, 12 healthy subjects were given single doses of either saquinavir 600 mg, loperamide 16 mg, or both drugs together. Loperamide reduced the AUC of saquinavir by about 54%. The maximum plasma level of saquinavir was also reduced by loperamide although this was not statistically significant. Saquinavir increased the AUC of loperamide by 40% and also produced a non-significant increase in the maximum level of loperamide.[2]

(c) Tipranavir

A study in 20 healthy subjects looked at the pharmacokinetics and pharmacodynamics of a single 16-mg dose of loperamide taken with either tipranavir 750 mg twice daily, ritonavir 200 mg twice daily or both drugs together. (Note that this dose of tipranavir is higher than the usual ritonavir-boosted dose of 500 mg twice daily.) Tipranavir alone *reduced* the maximum level and AUC of loperamide by 58% and 63%, respectively, whereas ritonavir *increased* these parameters by 83% and 121%, respectively. The combination of tipranavir and ritonavir, as is usual clinical practice, resulted in a net reduction in the maximum level and AUC of loperamide by 61% and 51%, respectively, similar to the effect seen with tipranavir alone. The maximum level and AUC of the metabolites of loperamide were also reduced. There were no clinically significant loperamide adverse effects on respiration or pupil contractility with either ritonavir or tipranavir alone, or in combination.[3]

Mechanism

Loperamide is primarily metabolised by the cytochrome P450 isoenzyme CYP3A4, and is thought to lack CNS effects because it is a substrate for P-glycoprotein, which transports drugs out of the cells at the blood-brain barrier, thereby restricting CNS penetration.[3] The increase in loperamide levels with ritonavir alone is thought to be due to ritonavir inhibiting its metabolism by CYP3A4. The lack of an increase in loperamide CNS effects suggests that ritonavir alone does not inhibit P-glycoprotein.[1,3]

Saquinavir probably inhibits the CYP3A4-mediated metabolism of loperamide. Loperamide reduces gastrointestinal motility and therefore may affect the absorption of some drugs. It is thought that this therapeutic action may have reduced the absorption of saquinavir leading to the reduction in its bioavailability.[2]

The reduction in loperamide levels with tipranavir alone or tipranavir with ritonavir is thought to be due to induction of gastrointestinal P-glycoprotein by tipranavir, resulting in a decrease in the systemic bioavailability of loperamide.[3] However, another study suggested that the increase in loperamide levels seen with concurrent saquinavir may be due to inhibition of CYP3A4.[2]

Importance and management

The reduced levels of saquinavir seen in the single-dose study suggest that loperamide may reduce the antiviral efficacy of saquinavir. Although the evidence is limited to this study and only a single, low-dose of unboosted saquinavir was given, it may be prudent to monitor patients taking loperamide with saquinavir to ensure that the antiviral efficacy of saquinavir is maintained. Whether loperamide would cause as large a reduction in saquinavir levels with higher doses of ritonavir-boosted saquinavir (as is usual practice) is unclear. Further study is needed. Pharmacokinetic information about other protease inhibitors appears to be lacking. However, one efficacy study reported that the viral load and CD4 count were maintained in patients treated with loperamide for **nelfinavir**-induced diarrhoea.[4]

Despite the increases in loperamide plasma levels seen in both studies with ritonavir alone, a lack of central opioid effects with loperamide (such as pupillary constriction, respiratory depression and also analgesic effects) was demonstrated. This suggests that loperamide is potentially a safe antidiarrhoeal to give with ritonavir during episodes of protease inhibitor-induced diarrhoea.[1] The increases in loperamide bioavailability seen with the single-dose saquinavir study above are also not thought to be clinically significant, although the dose of saquinavir used in this study were much smaller than that commonly used in HIV treatment regimens.[2] It would appear from the results of these studies that use of ritonavir-boosted saquinavir (as is common) with loperamide is also unlikely to lead to a clinically relevant increase in loperamide adverse effects.

The clinical relevance of the decrease in loperamide bioavailability with tipranavir alone or tipranavir with ritonavir is unknown.

Loperamide + Quinidine

Quinidine increases penetration of loperamide into the brain resulting in respiratory depression.

Clinical evidence

In a study in 8 healthy subjects, a single 600-mg dose of quinidine increased the AUC of loperamide and its metabolite by 148% and 94%, respectively. Loperamide alone did not produce respiratory depression, but when given with quinidine, respiratory depression occurred, as measured by the ventilatory response of the subjects to increasing carbon dioxide concentrations.[1]

Mechanism, importance and management

Loperamide is mainly metabolised by the cytochrome P450 isoenzyme CYP3A4, and is thought to lack CNS effects because it is a substrate for P-glycoprotein, which transports drugs out of the cells at the blood-brain barrier, thereby restricting CNS penetration. The central opioid adverse effects of loperamide that occurred in the study appear to be due to central P-glycoprotein inhibition by quinidine, resulting in increased loperamide penetration into the brain, and respiratory depression.[1]

Although information is limited, it would seem prudent to be alert for the CNS adverse effects of loperamide if quinidine is given. If adverse effects are troublesome consider reducing the dose of loperamide.

Mesalazine (Mesalamine) + Laxatives

On theoretical grounds, formulations designed to release mesalazine in response to the higher pH in the colon should not be given with lactulose, lactitol or other preparations that lower the colonic pH. However, studies suggest that both ispaghula and lactulose do not affect the bioavailability of mesalazine.

Clinical evidence and mechanism

Asacol is a preparation of mesalazine coated with an acrylic based resin (*Eudragit S*) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon.[1] The pH in the colon can be lowered by lactulose and lactitol, which are metabolised by gut bacteria to a number of acids (e.g. acetic, butyric, propionic, and lactic acid).[2] In healthy subjects, lactulose 30 to 80 g daily has been found to cause slight falls in colonic pH;[2,3] from about 6 to 5 in the right colon and from 7 to 6.7 in the left colon. Lactitol 40 to 180 g daily can cause similar falls in pH.[2] Ispaghula can also lower colonic pH (from 6.5 to 5.8 in the right colon, and from 7.3 to 6.6 in the left colon).[4] However, a study in patients given mesalazine found that despite this colonic acidification by ispaghula husk (*Fybogel*), the release of mesalazine appeared not to be affected, as 24-hour faecal and urinary excretion of mesalazine metabolites were unchanged.[5] Similarly, another study in 14 healthy subjects given delayed-release mesalazine (*Asacol*) 400 mg three times daily found that lactulose (15 mL increased to 30 mL twice daily) did not affect urinary or faecal excretion of mesalazine and its metabolites.[6]

Importance and management

Although on theoretical grounds ispaghula husk and lactulose might be expected to reduce the effects of mesalazine, from the above studies no interaction of clinical importance seems to occur, and there have been no reports as yet that a clinically important interaction occurs with either ispaghula husk, lactulose or lactitol. However, the UK manufacturers of *Asacol* recommend avoiding concurrent use of preparations that can lower the pH of the gut as they may reduce the efficacy of mesalazine.[1] Also note that this interaction is not mentioned by the US manufacturers of *Asacol*.[7] Furthermore, *Salofalk* is another preparation of mesalazine with a pH-dependent enteric coating.[8] This preparation disintegrates above pH 6, but no warning regarding drugs that affect the pH in the lower part of the gut is given.

Mesalazine (Mesalamine) + Proton pump inhibitors

Omeprazole does not affect the release of mesalazine from a delayed-release preparation (*Asacol*).

Clinical evidence, mechanism, importance and management

Asacol is a preparation of mesalazine coated with an acrylic based resin (*Eudragit S*) that disintegrates above pH 7 and thereby releases the mesalazine into the terminal ileum and colon. The release is rapid at pH values of 7 and above, but it can also occur between pH 6 and 7. Since the proton pump inhibitors can raise the pH in the stomach to 6 and above, the potential exists for the premature release of mesalazine from *Asacol*. However, a study in 6 healthy subjects given *Asacol* 400 mg three times daily for 3 weeks found that when they were also given **omeprazole** 20 mg daily during the second week, and **omeprazole** 40 mg daily during the third week, the steady-state pharmacokinetics of the mesalazine remained unchanged.[1] Had mesalazine been released earlier, the absorption characteristics would have changed. There would therefore appear to be no reason for avoiding the concurrent use of *Asacol* and **omeprazole** in doses of up to 40 mg daily. On the basis of this study, it seems likely that other proton pump inhibitors will behave similarly at equivalent doses.

Methylnaltrexone + Miscellaneous

Cimetidine does not have a clinically relevant effect on the pharmacokinetics of methylnaltrexone. Methylnaltrexone does not alter the pharmacokinetics of dextromethorphan.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

The manufacturer notes that, in a study in 18 healthy subjects, multiple 400-mg doses of cimetidine did not cause any clinically relevant changes in the pharmacokinetics of a single dose of methylnaltrexone. There was a 42% reduction in the renal clearance of methylnaltrexone, and a small 11% reduction in its total clearance, with no clinically relevant change in either the AUC or maximum plasma levels of methylnaltrexone.[1] The reduction in methylnaltrexone renal clearance is thought to be due to inhibition of organic cation transporters by cimetidine.[1] No dose adjustment of methylnaltrexone would be expected to be needed if cimetidine is also given.

(b) Dextromethorphan

The manufacturer briefly reports that, in a study in healthy male subjects, the metabolism of dextromethorphan was unaffected by a subcutaneous 300-microgram/kg dose of methylnaltrexone bromide.[1,2] This study was conducted because, *in vitro* methylnaltrexone was a weak inhibitor of the cytochrome P450 isoenzyme CYP2D6. Dextromethorphan is a substrate of CYP2D6, and the study suggests that methylnaltrexone causes no clinically relevant inhibition of this isoenzyme. Methylnaltrexone would not be expected to alter the pharmacokinetics of other CYP2D6 substrates.

2. Relistor (Methylnaltrexone bromide). Wyeth Pharmaceuticals Inc. US Prescribing information, June 2009.

Metoclopramide + Prochlorperazine

A single case report describes tongue swelling and respiratory obstruction in a patient given prochlorperazine and then metoclopramide.

Clinical evidence, mechanism, importance and management

A 19-year-old woman experienced progressive swelling of the tongue, partial upper-airways obstruction and a sensation of choking over a period of 12 hours after she was given intramuscular doses of metoclopramide to a total of 30 mg. She had received a 12.5-mg intramuscular dose of prochlorperazine for nausea 24 hours earlier. On examination her tongue was strikingly blue, but within 15 minutes of receiving benzatropine 2 mg it returned to its normal size and colour. The respiratory distress also disappeared.[1] The authors of the report suggested that the dystonic adverse effects of both drugs were additive, leading to the effects seen.[1] However, it should be noted that oedema of the tongue has also been described with metoclopramide alone.[2] Young patients, especially women, are particularly susceptible to the adverse effects of metoclopramide, and this patient received the standard total daily dose over just 12 hours, so an interaction is by no means established.

2. Robinson OPW. Metoclopramide—side effects and safety. *Postgrad Med J* (1973) 49 (Suppl July), 77–80.

Mosapride + Erythromycin

Erythromycin increases the plasma levels and prolongs the half-life of mosapride, but adverse cardiac effects appear to be unlikely.

Clinical evidence, mechanism, importance and management

In a study, 10 healthy subjects were given mosapride 5 mg three times daily for 14 days, with erythromycin stearate 300 mg four times daily on the last 7 days. Erythromycin increased the peak plasma levels of mosapride by 1.6-fold and increased its half-life from 1.6 to 2.4 hours. It was suggested that these pharmacokinetic changes occurred because erythromycin inhibited the metabolism of mosapride by the cytochrome P450 isoenzyme CYP3A4. This is similar to the effects seen with concurrent use of erythromycin and 'cisapride', (p.1147). However, unlike cisapride, the increases in mosapride levels seen in this study did not produce adverse changes in the ECG, including the QT interval.[1] It may be prudent to monitor concurrent use for an increase in mosapride adverse effects, and adjust the dose accordingly.

Pirenzepine + Antacids

***Mylanta* reduces the bioavailability of pirenzepine by about 30%. Another antacid, *Trigastril*, modestly *increases* the bioavailability of pirenzepine, but these changes are probably of little clinical importance.**

Clinical evidence, mechanism, importance and management

In a study in 20 healthy subjects, the AUC of a single 50-mg dose of pirenzepine was reduced by about 30% by 30 mL of *Mylanta* (**aluminium/magnesium hydroxide** and **simeticone**). The antacid reduced the peak plasma levels of pirenzepine by about 45%.[1] Another study in 10 healthy subjects found that the AUC of a single 50-mg dose of pirenzepine was *increased* by almost 25% by 10 mL of an antacid (*Trigastril,* **aluminium/magnesium hydroxide**, **calcium carbonate**).[2] In practical terms these modest changes in bioavailability are probably too small to matter.

1. Matzek KM, MacGregor TR, Keirns JJ, Vinocur M. Effect of food and antacids on the oral absorption of pirenzepine in man. *Int J Pharmaceutics* (1986) 28, 151–5.
2. Vergin H, Herrlinger C, Gugler R. Effect of an aluminium-hydroxide containing antacid on the oral bioavailability of pirenzepine. *Arzneimittelforschung* (1989) 39, 520–3.

Pirenzepine + Cimetidine

The pharmacokinetics of pirenzepine and cimetidine are not affected when both drugs are given together, but pirenzepine increases the cimetidine-induced reduction in gastric acid secretion, which is an apparently advantageous interaction.[1]

1. Jamali F, Mahachai V, Reilly PA, Thomson ABR. Lack of pharmacokinetic interaction between cimetidine and pirenzepine. *Clin Pharmacol Ther* (1985) 38, 325–30.

Pirenzepine + Food

Food reduces the bioavailability of pirenzepine by about 30%, but this is probably of little clinical importance.

Clinical evidence, mechanism, importance and management

The AUC of a single 50-mg dose of pirenzepine was reduced by about 30% in 20 healthy subjects when pirenzepine was taken half-an-hour before food, or with food. Peak plasma levels were reduced by about 30% and 45%, respectively. The time to achieve peak levels was also reduced.[1] In practical terms this modest change in bioavailability is probably too small to matter. The authors of this report suggest taking pirenzepine with food because compliance is better if associated with a convenient daily ritual.[1]

1. Matzek KM, MacGregor TR, Keirns JJ, Vinocur M. Effect of food and antacids on the oral absorption of pirenzepine in man. *Int J Pharmaceutics* (1986) 28, 151–5.

Proton pump inhibitors + Antacids

***Maalox* does not appear to alter the pharmacokinetics of omeprazole, pantoprazole or rabeprazole. Antacids may cause a slight reduction in the bioavailability of lansoprazole but this is probably not clinically relevant. There is no interaction between sodium alginate and omeprazole.**

Clinical evidence, mechanism, importance and management

(a) Lansoprazole

In a study in 12 healthy subjects a single 30-mL dose of *Maalox* (**aluminium/magnesium hydroxide**) slightly reduced the AUC of a 30-mg dose of lansoprazole by 13% (not statistically significant), and reduced the maximum plasma level by 27%. However, no changes were seen when the lansoprazole was given 1 hour after the antacid.[1] Note that in this study, the bioavailability of lansoprazole was highly variable between subjects (the AUC varied by a factor of 6). In another study, **magaldrate** had no effect on the AUC of lansoprazole, but slightly reduced its maximum level by 28%; however, this change was not considered clinically relevant.[2] Nevertheless, the manufacturer recommends that antacids should not be taken within one hour of lansoprazole,[3] but on the basis of the evidence given above, this seems to be an overcautious recommendation.

(b) Omeprazole

Two single-dose studies have shown that *Maalox* suspension (**aluminium/magnesium hydroxide**) did not affect the absorption or disposition of omeprazole from an enteric-coated formulation.[4,5] Similar findings were reported for *Maalox* suspension in another single-dose study, although in contrast, this study found that *Maalox granules* reduced the AUC of omeprazole enteric-coated tablets by 74%% and significantly reduced its plasma levels.[6]

A randomised, crossover study in healthy subjects given omeprazole capsules 20 mg daily for 3 days, with two *Gaviscon* tablets (aluminium hydroxide, **magnesium trisilicate** and **sodium alginate**) on day 3, found that omeprazole did not significantly affect the alginate raft formation or the length of time the raft stayed in the stomach.[7] In another study in healthy subjects, concurrent use of *Gaviscon Advance* (**sodium alginate**) 10 mL four times daily and omeprazole (*Losec MUPS)* 20 mg daily for 3 days did not affect the pharmacokinetics of omeprazole, although it was noted that *Gaviscon Advance*, unlike *Gaviscon,* does not contain any ant-

acid.[8] No special precautions appear to be necessary if omeprazole is given with these antacids.

(c) Pantoprazole

Pantoprazole 40 mg daily was given to 24 healthy subjects with and without 10 mL of *Maalox* (**aluminium/magnesium hydroxide**). The AUC, maximum serum levels, and the half-life of pantoprazole were unchanged by the antacid.[9] No special precautions would seem to be necessary if pantoprazole is given with **aluminium/magnesium hydroxide**-containing antacids.

(d) Rabeprazole

In a single-dose study, 12 healthy subjects were, on separate occasions, given 20 mg of rabeprazole with, without, and 1-hour after a dose of an **aluminium/magnesium hydroxide** antacid (*Maalox*).[10] The antacid had no effect on the pharmacokinetics of rabeprazole, so no special precautions would seem necessary on concurrent use.

Proton pump inhibitors + Calcium-channel blockers

The clearance of both nifedipine and omeprazole is modestly reduced by their concurrent use, but these changes seem unlikely to be of clinical importance. Pantoprazole does not affect the pharmacokinetics of nifedipine. Verapamil does not appear to affect the pharmacokinetics of rabeprazole to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Omeprazole

In a study in 10 healthy subjects, omeprazole 20 mg daily for 7 days reduced the clearance of **nifedipine** by 21%. In the same subjects, the clearance of a 40-mg intravenous dose of omeprazole was reduced by 14% by **nifedipine** 10 mg three times daily for 5 days.[1] In a related study, the same group of workers found that omeprazole 20 mg daily for 8 days increased the AUC of a single 10-mg dose of **nifedipine** by 26%, but blood pressure and heart rate were unchanged.[2] None of these changes are large and they seem not to be of clinical importance.

(b) Pantoprazole

In a randomised, crossover study, 24 healthy subjects were given pantoprazole 40 mg daily for 10 days, with sustained-release **nifedipine** 20 mg twice daily from day 6 to 10. The pharmacokinetics of the **nifedipine** were unchanged by the pantoprazole.[3] No special precautions would seem to be necessary if pantoprazole and **nifedipine** are given concurrently.

(c) Rabeprazole

A study in 19 healthy subjects found that **verapamil** 120 mg twice daily for 6 days did not significantly affect the pharmacokinetics of a single 20-mg dose of rabeprazole, although the levels of the inactive thioether metabolite were increased approximately twofold.

The main metabolic pathway of rabeprazole is non-enzymatic reduction to a thioether metabolite, with the cytochrome P450 isoenzymes CYP3A4 and CYP2C19 involved only to a minor extent. The results of this study indicate that verapamil does not appear to affect the minor metabolism of rabeprazole by CYP3A4, although it may affect the metabolic disposal of the inactive metabolite rabeprazole thioether.[4] In this study, subjects lacking or deficient in CYP2C19 had higher levels of rabeprazole than subjects with normal levels of CYP2C19, but this had no effect on the interaction with verapamil.

No special precautions seem likely to be necessary if rabeprazole is given with verapamil.

Proton pump inhibitors + Food

Food modestly reduces the bioavailability of lansoprazole and esomeprazole, but not omeprazole, pantoprazole, or rabeprazole. Foods such as apple sauce, apple or orange juice, and yoghurt do not seem to significantly affect the bioavailability of the contents of esomeprazole, lansoprazole or omeprazole capsules.

Clinical evidence, mechanism, importance and management

(a) Esomeprazole

In a crossover study in fasting healthy subjects, the bioavailability of the contents of an esomeprazole capsule mixed with one tablespoonful of **apple sauce** were similar to those of an intact esomeprazole capsule taken with water. **Apple sauce** was chosen because it is acidic and would therefore be unlikely to affect the enteric coat of the esomeprazole granules from the capsule.[1] An *in vitro* study found that esomeprazole enteric-coated granules from an opened capsule were stable when mixed with 100 mL tap water, **yoghurt**, **orange juice** or **apple juice**.[2] The authors suggest that it is likely that esomeprazole could be mixed with these **juices** or other **soft acidic foods** in patients who cannot swallow a capsule.[1,2] Nevertheless, for patients unable to swallow, the UK manufacturers recommend only dispersing esomeprazole *tablets* in **non-carbonated water** to avoid dissolving the enteric coating. They also note that food delays and decreases the absorption of esomeprazole *tablets*, but that this has little effect on gastric acidity.[3] The US manufacturers say that because the AUC of esomeprazole can be reduced by 43 to 53% by food, esomeprazole *capsules* and *oral suspension* should be taken at least one hour before meals.[4]

(b) Lansoprazole

A study found that food (a **standard meal**) reduced lansoprazole bioavailability by 27%.[5] Another study found a 50% reduction in lansoprazole bioavailability with food (a **standard breakfast**).[6] The authors of both these studies therefore recommended that lansoprazole should not be given with food.[5,6] The maximum plasma levels and AUC of lansoprazole are reduced by 50 to 70% when it is given 30 minutes after food. No significant effect was found when lansoprazole was given before meals.[7] The manufacturers recommend that, to achieve optimal efficacy, lansoprazole should be given in the morning at least 30 minutes before food.[7,8] However, in crossover studies in fasting healthy subjects, the bioavailability of enteric-coated granules (removed from a capsule of lansoprazole 30 mg) mixed with either **orange juice**, **tomato juice**, or with one tablespoonful of **strained pear**, **yoghurt**, **cottage cheese**, or ***Ensure* pudding** was comparable to that of an intact capsule given with water.[9,10] These studies suggest that for patients who are unable to swallow or who have difficulty swallowing, mixing the capsule contents with these specific juices or soft foods is acceptable. The US manufacturers also say that the intact contents of the *delayed-release capsules* may be mixed in with a small volume (60 mL) of **apple sauce**, ***Ensure* pudding**, **cottage cheese**, or **yoghurt**. However, the *soluble tablets* may only be dispersed in **water**, and, if given via a nasogastric tube, the tube should be flushed with water before and after administration. The *suspension* may only be mixed with **water** and must not be given through a nasogastric tube.[7]

(c) Omeprazole

In a study in healthy subjects, giving omeprazole with **breakfast** delayed its absorption, but did not affect the total amount absorbed.[11] Similarly, in another study in healthy subjects, a **standardised breakfast** did not affect the bioavailability or maximum plasma level of omeprazole (given as enteric-coated tablets), when compared with the fasting state, or when taken immediately before a meal, although the time to reach the maximum plasma level was increased.[12] Omeprazole may therefore be taken without regard to the timing of meals. For patients unable to swallow, the manufacturers recommend mixing the intact contents of the opened capsule with **non-carbonated water**, **apple**, **orange** or **pineapple juice**, **yoghurt**[13] or **apple sauce**.[13,14]

(d) Pantoprazole

The manufacturers state that food has no effect on the bioavailability of pantoprazole.[15,16] The US manufacturer recommends that the tablet is swallowed whole with water, with or without food.[15] The UK manufacturer advises taking pantoprazole before a meal, although because food has no effect on the bioavailability of pantoprazole, this is not essential.[16] The oral suspension should be taken 30 minutes before food and should only be mixed with **apple juice** or **apple sauce**.[15]

(e) Rabeprazole

A study in healthy subjects found that, although a **standard breakfast** delayed the absorption of rabeprazole, its AUC and maximum plasma level were not significantly affected.[17] The US manufacturers also report that a **high-fat meal** may delay the absorption of rabeprazole without altering its AUC and maximum serum levels.[18] Therefore the manufacturers say that rabeprazole may be taken with or without food.[18,19] The UK manufacturers note that, although food has no effect on the activity of rabeprazole, for once daily regimens they recommend taking it in the morning, before breakfast, to aid compliance.[19]

Proton pump inhibitors + Ginkgo (*Ginkgo biloba*)

Ginkgo induces the metabolism of omeprazole, and this might result in reduced efficacy. Other proton pump inhibitors are likely to be similarly affected.

Clinical evidence and mechanism

In one study, 18 healthy Chinese subjects were given a single 40-mg dose of omeprazole before and after a 12-day course of a standardised extract of ginkgo 140 mg twice daily. The subjects were divided into three groups: homozygous extensive CYP2C19 metabolisers (6 subjects), heterozygous extensive CYP2C19 metabolisers (5) and poor CYP2C19 metabolisers (7). The AUC of omeprazole was modestly decreased by 42%, 27% and 40%, respectively, and the plasma levels of the inactive metabolite, hydroxyomeprazole, were increased by 38%, 100%, and 232% in the three groups, respectively. Renal clearance of hydroxyomeprazole was also reduced by ginkgo. It was concluded that ginkgo increases the metabolism (hydroxylation) of omeprazole by inducing the cytochrome P450 isoenzyme CYP2C19.[1]

Importance and management

This appears to be the only study examining the effects of ginkgo on proton pump inhibitors. However, the reduction seen in the AUC of omeprazole (about 40%) suggest that there is a possibility that omeprazole will be less effective in patients taking ginkgo. As all proton pump inhibitors are metabolised by CYP2C19 to varying extents, it is likely that the effects of ginkgo seen in these studies will be similar with other proton pump inhibitors, although note that rabeprazole is much less dependent on this route of metabolism than other proton pump inhibitors.

There is insufficient evidence to generally recommend that ginkgo should be avoided in patients taking proton pump inhibitors. However, the potential reduction in the efficacy of the proton pump inhibitor should be borne in mind, particular where the consequences may be serious, such as in patients with healing ulcers.

Proton pump inhibitors + Grapefruit juice

Grapefruit juice has little effect on the AUC of lansoprazole or omeprazole, but modestly reduces the formation of their sulfone metabolites, which is unlikely to be clinically relevant.

Clinical evidence

(a) Lansoprazole

In a randomised, crossover study 21 healthy subjects were given a single 60-mg dose of lansoprazole with either 200 mL of water or freshly-squeezed grapefruit juice. The AUC of lansoprazole was slightly increased by 18%, and the formation of the sulfone metabolite was reduced by the grapefruit juice. Metabolism to the hydroxyl metabolite was not significantly affected.[1]

(b) Omeprazole

In a single-dose study in 12 healthy subjects, grapefruit juice 300 mL had no significant effect on the AUC or half-life of omeprazole 20 mg: the results were similar in both CYP2C19 metaboliser phenotypes, as indicated by plasma levels of hydroxyomeprazole. However, there was a 20% reduction in AUC of omeprazole sulfone.[2]

Mechanism

From the studies above[1,2] it appears that grapefruit juice may have a minor inhibitory effect on the intestinal metabolism of omeprazole and lansoprazole by the cytochrome P450 isoenzyme CYP3A4 (which results in the sulfone metabolites). Grapefruit juice does not affect the metabolism (hydroxylation) of the proton pump inhibitors by CYP2C19.

Importance and management

The small changes in lansoprazole and omeprazole pharmacokinetics are not clinically relevant, so it appears that they may be taken with grapefruit juice. See also ‘Proton pump inhibitors + Food’, p.1158, for the finding

that other fruit juices had no effect on esomeprazole, lansoprazole or omeprazole bioavailability.

Proton pump inhibitors + Iron compounds

Omeprazole may impair the absorption of oral iron preparations and vegetable sources of iron.

Clinical evidence, mechanism, importance and management

Two cases of iron deficiency in patients also taking long-term **omeprazole** have been reported. In both cases the authors report that other causes of the anaemia, such as occult gastrointestinal bleeding, were ruled out by clinical and laboratory tests. The patients were taken off **omeprazole** for 2 months and continued to take the same dose of **ferrous sulfate**, with a noted improvement in both the haemoglobin and mean corpuscular volume (MCV). It was considered that hypochlorhydria induced by **omeprazole** may have impaired the absorption of oral iron preparations.[1] In another study in 7 patients with hereditary haemochromatosis, the use of either **omeprazole** 20 mg or **lansoprazole** 30 mg daily for 7 days suppressed the absorption of non-haem iron (iron of vegetable source) from a test meal.[2] The significance of this to routine clinical practice is unclear as many other factors and disease states can affect oral iron absorption. However bear these reports in mind should a patient taking a proton pump inhibitor fail to respond to oral iron therapy. Further study is needed.

Proton pump inhibitors + Macrolides

Clarithromycin approximately doubles the serum levels of esomeprazole, lansoprazole and omeprazole, but has no significant effect on pantoprazole or rabeprazole. Lansoprazole and omeprazole may cause small rise in the serum levels of clarithromycin or its metabolite.
Limited evidence indicates that erythromycin raises serum omeprazole levels, without significantly altering its effects. Lansoprazole and omeprazole do not appear to affect the pharmacokinetics of roxithromycin.

Clinical evidence

(a) Clarithromycin

See also 'Proton pump inhibitors + Penicillins', p.1161, which describes case reports of glossitis, stomatitis and a black tongue when lansoprazole was given with antibacterial regimens including clarithromycin.

1. Esomeprazole. In a study in 18 healthy subjects the AUC, maximum serum levels and half-life of esomeprazole 40 mg once daily were increased by 70%, 18% and 35%, respectively, when clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 7 days were also taken. When the study was repeated in 19 healthy subjects with esomeprazole 20 mg, the AUC, maximum serum levels and half-life of esomeprazole were increased by 127%, 39% and 50%, respectively. All subjects were of the CYP2C19 extensive metaboliser phenotype. Similar increases in esomeprazole levels (e.g. AUC doubled) were seen in a further 6 subjects who were of the CYP2C19 poor metaboliser phenotype. In these studies, esomeprazole did not alter clarithromycin levels.[1]

2. Lansoprazole. The AUC of a single 60-mg dose of lansoprazole was raised 1.55-fold to 1.8-fold by clarithromycin 500 mg twice daily for 6 days in both extensive and poor metabolisers of CYP2C19.[2] In another study in healthy subjects, the AUC of lansoprazole 30 mg twice daily was increased by just 25% by clarithromycin 500 mg twice daily and amoxicillin 1 g twice daily for 4 days. The AUC of the hydroxyl metabolite of clarithromycin was also increased by about 25%.[3] Another study in healthy subjects found that clarithromycin 200 mg or 400 mg twice daily for 7 days increased the maximum plasma levels of lansoprazole by around 80% and 145%, respectively.[4]

3. Omeprazole. When 11 healthy subjects taking omeprazole 40 mg daily were also given clarithromycin 500 mg every 8 hours for 5 days, the maximum plasma levels of omeprazole rose by 30% and its $AUC_{0\text{-}24}$ rose by 89%, but the effect of omeprazole on gastric pH was unchanged. The clarithromycin maximum plasma level rose by 11% and the $AUC_{0\text{-}8}$ was increased by 15%.[5] In a similar study, approximately twofold increases in the AUC of omeprazole were reported.[6] In another study in 8 subjects (all extensive metabolisers of CYP2C19), clarithromycin 500 mg twice daily for 7 days caused a similar twofold increase in the AUC of omeprazole 20 mg twice daily but did not affect the AUC of **pantoprazole** 40 mg twice daily. The levels of clarithromycin were not affected by either proton pump inhibitor.[7]

4. Rabeprazole. A study in 19 healthy subjects (14 extensive metabolisers; 5 poor metabolisers), found that, irrespective of CYP2C19 phenotype, clarithromycin 400 mg twice daily for 6 days did not significantly affect the pharmacokinetics of a single 20-mg dose of rabeprazole, although levels of the inactive thioether were increased.[8]

(b) Erythromycin

A study was undertaken in a patient to confirm the *in vitro* findings that erythromycin inhibits the metabolism of **omeprazole**. After taking 500 mg of erythromycin base and **omeprazole** 20 mg daily for 8 weeks, it was found that the AUC of **omeprazole** was increased by almost fourfold, and the metabolite of **omeprazole** was undetectable. These raised **omeprazole** levels might have been expected to increase its effectiveness, but in this patient the time during which gastric pH was less than 4 *decreased* by 22%.[9]

(c) Roxithromycin

A study of roxithromycin 300 mg twice daily, given with **omeprazole** 20 mg twice daily or with **lansoprazole** 30 mg twice daily for 6 days, found that neither proton pump inhibitor significantly affected the pharmacokinetics of roxithromycin.[10]

Mechanism

Clarithromycin appears to inhibit the metabolism of esomeprazole,[1] lansoprazole[2,4] and omeprazole[5,6] by the cytochrome P450 isoenzyme CYP3A4, one of the enzymes involved in their metabolism. Pantoprazole is metabolised by CYP2C19 only and was therefore not affected by the inhibition of CYP3A4. The main metabolic pathway of rabeprazole is non-enzymatic reduction to a thioether metabolite, with CYP3A4 and CYP2C19 involved only to a minor extent, so that rabeprazole is less affected than other proton pump inhibitors by CYP2C19 polymorphism.[8,11] See 'Gastrointestinal drugs', (p.1142), for an overview of the metabolism of proton pump inhibitors and the role of CYP2C19 polymorphism. Erythromycin interacts similarly, whereas roxithromycin has only weak effects on CYP3A4. A study also reports that increased levels of lansoprazole in the presence of clarithromycin may, in part, be due to inhibition of P-glycoprotein.[2]

Importance and management

The pharmacokinetic interactions between clarithromycin and omeprazole, esomeprazole and lansoprazole are established. However, none of the changes reported represents an adverse interaction, but they may help to explain why concurrent use is valuable in the eradication of *Helicobacter pylori*. Erythromycin is likely to interact similarly, whereas roxithromycin does not. No clinically significant interaction appears to occur between rabeprazole or pantoprazole and clarithromycin.

Proton pump inhibitors + Penicillins

Esomeprazole, lansoprazole and omeprazole do not alter the pharmacokinetics of amoxicillin, and omeprazole does not alter bacampicillin bioavailability. Isolated reports describe glossitis, stomatitis and/or black tongue in a small number of patients given lansoprazole and antibacterials, which included amoxicillin, clarithromycin and metronidazole.

Clinical evidence and mechanism

(a) Pharmacokinetic interactions

A study in 12 healthy subjects found no significant changes in the pharmacokinetics of **amoxicillin** 1 g twice daily when it was given with **lansoprazole** 30 mg twice daily and clarithromycin 500 mg twice daily for 4 days.[1] Other randomised, crossover studies in a total of 36 healthy subjects also found no changes in the bioavailability or half-life of **amoxicillin** 1 g twice daily when it was given with clarithromycin 500 mg twice daily and **esomeprazole**, either 20 mg twice daily or 40 mg once daily for 7 days.[2]

In other studies **omeprazole** caused a few small changes in the pharmacokinetics of **bacampicillin** and **amoxicillin**, but their bioavailabilities were not reduced,[3-5] and the use of **amoxicillin** with **omeprazole** had a synergistic effect on *Helicobacter pylori* eradication.[4] Similarly, in another study, **omeprazole** 40 mg twice daily for 5 days did not affect the pharmacokinetics of **amoxicillin** 750 mg twice daily for 5 days, although the mean serum level of **omeprazole** was 12% lower and intragastric pH was slightly lower with the combination, than with **omeprazole** alone. This was felt to be partly due to suppression of *H. pylori*.[6] In a placebo-controlled study in 12 patients with non-ulcer dyspepsia, serum levels of a single dose of **amoxicillin** were not affected by pre-treatment with **omeprazole** for one week. Gastric mucosa levels of **amoxicillin** were similarly unaffected by **omeprazole**.[7]

(b) Stomatitis and similar adverse effects

Six cases of glossitis, stomatitis and/or black tongue were reported to the Sicilian Regional Pharmacovigilance Centre in patients taking **lansoprazole**, when combined with antibacterials used to treat *H. pylori* infections. All 6 patients had been given daily doses of **lansoprazole** 60 mg with clarithromycin 1 g and either metronidazole 1 g (3 patients) or **amoxicillin** 2 g (3 patients) for one week, after which the antibacterials were stopped. The **lansoprazole** was continued at 30 mg daily for periods of up to 3 weeks. The glossitis (1 patient), black tongue (3 patients) and stomatitis (2 patients) developed between days 2 and 19 of the courses of treatment.[8] In one small randomised study, nine cases of glossitis occurred when **lansoprazole** was given with **amoxicillin** but none occurred with **lansoprazole** alone.[9]

Importance and management

The incidence of glossitis, stomatitis and black tongue reported with lansoprazole and antibacterials appears to be rare. No new cases appear to have been published since these reports, even though these drug combinations are commonly used for the eradication of *H. pylori*. Just why these drugs cause these adverse effects, and whether they are due to just one drug or to an interaction is not understood. Note that the CSM in the UK have received reports of stomatitis, glossitis and a black, hairy tongue or discoloration with each of the reported drugs individually, but these are rare effects.[10]

The pharmacokinetics of amoxicillin do not appear to be affected by the concurrent use of esomeprazole, lansoprazole and omeprazole, and omeprazole was not affected by amoxicillin.

Proton pump inhibitors + SSRIs

Fluvoxamine markedly inhibits the metabolism of the proton pump inhibitors lansoprazole, omeprazole and rabeprazole in those of the CYP2C19 extensive metaboliser phenotype, producing levels comparable to those in poor metabolisers. Theoretically other proton pump inhibitors may be similarly affected. Omeprazole may increase escitalopram levels; esomeprazole and citalopram may also interact in this way.

Clinical evidence

(a) Escitalopram

In a study in healthy subjects,[1] **omeprazole** 30 mg daily for 6 days caused a 50% increase in the serum levels of a single 20-mg dose of escitalopram given on day 5.

(b) Fluvoxamine

Several studies in healthy subjects have investigated the effects of fluvoxamine (a CYP2C19 inhibitor) on the metabolism of proton pump inhibitors. In these studies, fluvoxamine 25 mg twice daily for 6 days had significant effects on the pharmacokinetics of three different proton pump inhibitors in patients who were of the extensive CYP2C19 metaboliser phenotype (the most common phenotype) as follows:

- **Lansoprazole**: Fluvoxamine increased the AUC and elimination half-life of a single 40-mg dose of lansoprazole by 3.8-fold and 3-fold, respectively.[2]
- **Omeprazole**: Fluvoxamine increased the AUC, half-life and maximum plasma concentration of a single 40-mg dose of omeprazole by 6-fold, 2.6-fold and 3.7-fold, respectively.[3]
- **Rabeprazole**: Fluvoxamine increased the AUC, elimination half-life and maximum plasma concentration of a single 20-mg dose of rabeprazole by 2.8-fold, 2.4-fold and 2-fold, respectively.[4]

These pharmacokinetic changes essentially had the effect of turning the extensive metabolisers into poor metabolisers.[2-4] In contrast, in patients who were of the CYP2C19 poor metabolisers phenotype, fluvoxamine did not have any significant effect on the pharmacokinetics of either of these three proton pump inhibitors.[2-4]

In an earlier study 12 healthy subjects (7 extensive metabolisers and 5 poor metabolisers of CYP2C19) were given fluvoxamine 10 to 50 mg daily for 7 days, with a single 20-mg dose of **omeprazole** on day 7. The AUC of **omeprazole** was increased by nearly threefold by fluvoxamine 10 to 20 mg and by over fourfold by fluvoxamine 25 to 50 mg (all subjects combined).[5]

Mechanism

All proton pump inhibitors are primarily metabolised by the cytochrome P450 isoenzyme CYP2C19, which is subject to genetic polymorphism,

see 'Gastrointestinal drugs', (p.1142). As fluvoxamine inhibits CYP2C19, it can increase the levels of proton pump inhibitors in patients who are extensive CYP2C19 metabolisers, but does not significantly affect the metabolism of proton pump inhibitors in patients who are poor metabolisers. Omeprazole and esomeprazole are also inhibitors of CYP2C19, and therefore may raise the levels of the SSRIs citalopram and escitalopram, which are metabolised by this route.

Importance and management

The interaction of **fluvoxamine** with proton pump inhibitors appears to be established. However, the increased levels of these proton pump inhibitors seen in extensive metabolisers taking fluvoxamine are similar to those seen in poor metabolisers not taking fluvoxamine, and are unlikely to lead to an increase in adverse effects because of the wide therapeutic margin of proton pump inhibitors.

Some studies have shown that CYP2C19 genotype is a factor in the success of proton pump inhibitor-based eradication regimens, as poor metabolisers of CYP2C19 appear to have higher *H. pylori* eradication rates with these regimens than extensive metabolisers.[6,7] Therefore, treatment of *H. pylori* is likely to be more successful in patients who are extensive metabolisers and are also taking an inhibitor of CYP2C19 such as fluvoxamine (see 'Table 1.3', (p.6), for further examples of CYP2C19 inhibitors). However, the addition of fluvoxamine to improve proton pump inhibitor-based eradication regimens is not clinically appropriate because of the risk of fluvoxamine adverse effects.

Omeprazole causes only a moderate increase in **escitalopram** levels; however, the manufacturer[8] suggests that caution is warranted and a dose adjustment of the escitalopram may be needed. The manufacturer of **esomeprazole**[9] predicts that it may raise the levels of citalopram (and therefore probably escitalopram).

Proton pump inhibitors + St John's wort (*Hypericum perforatum*)

St John's wort induces the metabolism of omeprazole, and this might result in reduced efficacy. Other proton pump inhibitors are likely to be similarly affected.

Clinical evidence and mechanism

In a crossover study, 12 healthy subjects (6 of the extensive CYP2C19 metaboliser phenotype and 6 of the poor CYP2C19 metaboliser phenotype) were given St John's wort 300 mg three times daily or placebo for 14 days, followed by a single 20-mg dose of omeprazole on day 15. St John's wort modestly decreased the AUC of omeprazole in all subjects (by 49% in extensive metabolisers and 41% in poor metabolisers), and also increased the plasma levels of hydroxyomeprazole by 35% in those who were extensive metabolisers. It also markedly increased the levels of the inactive CYP3A4 sulfone metabolite of omeprazole in both extensive and poor metabolisers (by 148% and 132%, respectively). It was concluded that St John's wort increases the metabolism of omeprazole by inducing both CYP2C19 and CYP3A4.[1]

Importance and management

This appears to be the only study examining the effects of St John's wort on proton pump inhibitors. However, the reduction seen in the AUC of omeprazole (about 40%) suggest that there is a possibility that omeprazole will be less effective in patients taking St John's wort. As all proton pump inhibitors are metabolised by CYP2C19 to varying extents, it is likely that the effects of St John's wort seen in these studies will be similar with other proton pump inhibitors, although note that rabeprazole is much less dependent on this route of metabolism than other proton pump inhibitors.

There is insufficient evidence to suggest that St John's wort should be avoided in patients taking proton pump inhibitors. However, the potential reduction in the efficacy of the proton pump inhibitor should be borne in mind, particular where the consequences may be serious, such as in patients with healing ulcers.

Proton pump inhibitors + Ticlopidine

Ticlopidine markedly decreases the clearance and increases the bioavailability of omeprazole in some patients.

Clinical evidence

In a study, 6 healthy subjects (all CYP2C19 extensive metabolisers, that is, those with normal levels of this isoenzyme) were given ticlopidine 100 mg three times daily with a single 40-mg dose of **omeprazole** on day 7. Ticlopidine increased the $AUC_{0\text{-}8}$ of **omeprazole** by about 76%, and reduced its clearance in 5 out of the 6 subjects.[1] In another study, 18 healthy subjects (6 of whom were CYP2C19 poor metabolisers, that is, those lacking or deficient in this isoenzyme) were given ticlopidine 200 mg daily with **omeprazole** 20 mg taken on day 8. Ticlopidine markedly increased the AUC of **omeprazole** in the 12 subjects that were CYP2C19 extensive metabolisers by about five- to sixfold, but did not alter **omeprazole** levels in the poor metaboliser group. The AUC of omeprazole in the extensive metabolisers given ticlopidine was similar to that in poor metabolisers (with or without ticlopidine). No adverse effects due to either **omeprazole** or ticlopidine were reported.[2]

Mechanism

Omeprazole is principally metabolised by the cytochrome P450 isoenzyme CYP2C19 to 5-hydroxyomeprazole, and ticlopidine is an inhibitor of this isoenzyme. People of CYP2C19 poor metaboliser phenotype have higher levels of omeprazole than extensive metabolisers, and ticlopidine effectively changes extensive metabolisers to poor metabolisers. Other proton pump inhibitors that are metabolised by CYP2C19, see 'Gastrointestinal drugs', (p.1142), would be expected to be similarly affected.

Importance and management

An interaction between omeprazole and ticlopidine is established; however, the increase in omeprazole levels reported with ticlopidine is unlikely to be of general relevance as omeprazole has a wide safety margin. No additional precautions, or an omeprazole dose reduction, appear to be necessary.

Proton pump inhibitors; Omeprazole + Artemisinin

Artemisinin modestly increases the metabolism of omeprazole, but the clinical significance of this is unclear.

Clinical evidence, mechanism, importance and management

A study in 9 healthy subjects found that artemisinin 250 mg twice daily for 7 days reduced the AUC of a single 20-mg dose of omeprazole by 35%. The pharmacokinetics of the omeprazole metabolites were unchanged, but the ratio of hydroxyomeprazole to omeprazole increased 2.2-fold in those of an extensive CYP2C19 metabolisers phenotype (see 'metabolism of proton pump inhibitors', (p.1142)). This suggests that artemisinin affects the pharmacokinetics of omeprazole by inducing its metabolism by the cytochrome P450 isoenzyme CYP2C19, although other isoenzymes may also be involved. A single 250-mg dose of artemisinin had no effect on the pharmacokinetics of omeprazole, which supports the proposed mechanism of enzyme induction.[1] A subsequent study in 8 healthy subjects who were of the extensive CYP2C19 metaboliser phenotype similarly found that artemisinin 500 mg daily for 7 days decreased the AUC of both the *S*- and *R*-enantiomers of a single 20-mg dose of omeprazole to the same extent, and increased the oral clearance of both enantiomers by about threefold.[2] The clinical significance of this interaction is unclear.

Proton pump inhibitors; Omeprazole + Disulfiram

An isolated case describes a catatonic reaction in a patient given omeprazole and disulfiram.

Clinical evidence, mechanism, importance and management

A patient who had been taking omeprazole 40 mg daily for 7 months was also given disulfiram 500 mg daily. Six days later he gradually developed confusion, which progressed to a catatonic state, with muscle rigidity and trismus (spasm of the muscles used to chew food), after 15 days. Both drugs were withdrawn and he gradually recovered. Some months later while taking disulfiram 250 mg daily, he again developed confusion, disorientation and nightmares within 72 hours of starting to take omeprazole 40 mg each morning. Again he recovered when both drugs were stopped.[1] The reason for this reaction is not understood, but the authors of the report suggest that omeprazole may have allowed the accumulation of one of the metabolites of disulfiram, carbon disulfide, which could have been responsible for the toxic effects.[1]

This is the first and only report of a possible interaction between omeprazole and disulfiram. Other patients given both drugs are said not to have shown adverse effects.[2] The general importance of this adverse interaction is therefore uncertain, but it seems likely to be small.

2. Astra Pharmaceuticals Ltd. Personal communication, May 1991.

Proton pump inhibitors; Omeprazole + Metronidazole

Omeprazole has no clinically significant effect on the pharmacokinetics of oral or intravenous metronidazole.

Clinical evidence, mechanism, importance and management

In 14 healthy subjects the plasma pharmacokinetics of a single oral dose of metronidazole were unaffected by 5 days pre-treatment with **omeprazole** 20 mg twice daily.[1] Similar results were found in another study with oral and intravenous metronidazole, but when the gastric juice was further studied it was found that the transfer of metronidazole into the gastric juice following an intravenous dose dropped from 15.5 to 2.6% in the presence of **omeprazole**.[2] The significance of these findings is unclear, but the clinical relevance seems small.

See also 'Proton pump inhibitors + Penicillins', p.1161, for case reports of glossitis, stomatitis and a black tongue with lansoprazole and antibacterial regimens including metronidazole.

2. Jessa MJ, Goddard AF, Barrett DA, Shaw PN, Spiller RC. The effect of omeprazole on the pharmacokinetics of metronidazole and hydroxymetronidazole in human plasma. saliva and gastric juice. *Br J Clin Pharmacol* (1997) 44, 245–53.

Proton pump inhibitors; Omeprazole + Mosapride

In a study, 9 healthy subjects were given a single 20-mg dose of omeprazole alone or 1 hour before a single 5-mg dose of mosapride. The peak levels and AUC of omeprazole were increased by 45% and 65%, respectively, when given with mosapride.[1] The clinical significance of this interaction is unclear, but as omeprazole is a generally safe and well tolerated drug, no particular adverse effects would be expected.

1. Takeuchi Y, Watanabe H, Imawari M. Mosapride citrate, a serotonin HT4 selective agonist, benifitially [sic] affects pharmacokinetics of proton pump inhibitor. *Gastroenterology* (2005) 128, (Suppl 2) A-531.

Proton pump inhibitors; Omeprazole + Ranitidine

In a study in 14 healthy subjects, omeprazole 40 mg (as two 20-mg capsules containing gastro-resistant pellets) were given either alone or after ranitidine 150 mg twice daily for 5 days. The AUC and peak plasma levels of omeprazole were increased by 20% and 10%, respectively, after pre-treatment with ranitidine.[1] These changes are small and therefore unlikely to be clinically relevant.

Proton pump inhibitors; Omeprazole + Tegaserod

Omeprazole may delay gastric emptying; this may be prevented by tegaserod.

Clinical evidence, mechanism, importance and management

In a study in 39 healthy male subjects, gastric emptying was assessed before and after treatment with omeprazole 20 mg twice daily, given with either tegaserod 6 mg three times daily or placebo for 14 days. Omeprazole alone significantly increased the half-life for gastric emptying and gastric retention time at 60 and 120 minutes after a test meal. Tegaserod largely prevented the development of delayed gastric emptying with omeprazole.[1] No significant adverse effects were reported in this study,[1] and it would appear that concurrent use of omeprazole with tegaserod may be beneficial.

Sulfasalazine + Antibacterials

Ampicillin moderately reduces, and rifampicin (with ethambutol) markedly reduces, the colonic release of 5-aminosalicylic acid (the active drug) from sulfasalazine. Metronidazole appears not to interact adversely with sulfasalazine.

Clinical evidence

(a) Ampicillin

In a study in 5 healthy subjects the conversion and release of the active metabolite of sulfasalazine, 5-aminosalicylic acid, was reduced by one-third when a single 2-g dose of sulfasalazine was given after a 5-day course of ampicillin 250 mg four times daily.[1]

(b) Metronidazole

A study in 10 patients (7 with Crohn's disease and 5 with ulcerative colitis) taking long-term sulfasalazine 2 to 4 g daily found that no statistically significant changes in serum sulfapyridine levels occurred while they were also taking metronidazole 400 mg twice daily for 8 to 14 days.[2] A study in 6 patients also found that sulfasalazine 1 g twice daily had no significant effect on the pharmacokinetics of metronidazole 250 mg twice daily, when both drugs were given concurrently for 6 days.[3]

(c) Rifampicin (Rifampin)

A crossover study in 11 patients with Crohn's disease receiving long-term treatment with sulfasalazine found that rifampicin 10 mg/kg daily and ethambutol 15 mg/kg daily reduced the plasma levels of both 5-aminosalicylic acid and sulfapyridine by about 60%.[4] A similar study in patients taking sulfasalazine 1.5 g to 4 g daily found that the plasma sulfapyridine levels were reduced by 57% when patients were taking rifampicin 10 mg/kg and ethambutol 15 mg/kg daily, when compared with placebo. They also noted an increase in the erythrocyte sedimentation rate (ESR) during antibacterial treatment.[5]

Mechanism

The azo link of sulfasalazine is split by anaerobic bacteria in the colon to release sulfapyridine and 5-aminosalicylic acid, the latter being the active metabolite that acts locally in the treatment of inflammatory bowel disease. Antibacterials that decimate the gut flora can apparently reduce this conversion and this is reflected in lower plasma levels.[4,5]

Importance and management

Information is limited, but the interactions between sulfasalazine and ampicillin or rifampicin (with ethambutol) appear to be established. The extent to which these antibacterials actually reduce the effectiveness of sulfasalazine in the treatment of Crohn's disease or ulcerative colitis seems not to have been assessed, but the studies do not suggest that the outcome is worse in patients given antibacterials while taking sulfasalazine. Metronidazole does not appear to interact. Information about other antibacterials appears to be lacking, but **neomycin**, which also affects the activity of the gut microflora, has been seen to interact similarly in *animal* studies.[6]

Sulfasalazine + Cimetidine

Cimetidine does not interact with sulfasalazine.

Clinical evidence, mechanism, importance and management

In a study, 5 patients with rheumatoid arthritis were given sulfasalazine alone, and another 9 patients were given cimetidine 400 mg three times daily for 18 weeks as well as their usual sulfasalazine. On comparing the two groups, it was found that cimetidine did not affect the plasma or urinary levels of sulfasalazine and there were no changes in blood cell counts or haemoglobin levels. It was therefore concluded that no clinically important interaction occurs between these two drugs.[1]

1. Pirmohamed M, Coleman MD, Galvani D, Bucknall RC, Breckenridge AM, Park BK. Lack of interaction between sulphasalazine and cimetidine in patients with rheumatoid arthritis. *Br J Rheumatol* (1993) 32, 222–6.

Sulfasalazine + Colestyramine

***Animal* studies show that colestyramine can bind with sulfasalazine in the gut, thereby reducing its activity, but it is not known if this also occurs in clinical use.**

Clinical evidence, mechanism, importance and management

A study in *rats* found that colestyramine binds with sulfasalazine so that the azo-bond is protected against attack by the bacteria within the gut. As a result the active 5-aminosalicylic acid is not released and the faecal excretion of intact sulfasalazine increases 30-fold.[1] It seems possible that this interaction could also occur in humans, but confirmation of this is lacking. Separating the drug dosages to prevent their admixture in the gut has proved effective with other drugs that bind with colestyramine. Standard advice is to avoid other drugs for one hour before, and 4 to 6 hours after taking colestyramine.

1. Pieniaszek HJ, Bates TR. Cholestyramine-induced inhibition of salicylazosulfapyridine (sulfasalazine) metabolism by rat intestinal microflora. *J Pharmacol Exp Ther* (1976) 198, 240–5.

Sulfasalazine + Iron compounds

Sulfasalazine and iron appear to bind together in the gut, but whether this reduces the therapeutic response to either drug is uncertain.

Clinical evidence, mechanism, importance and management

Ferrous sulfate 400 mg (containing iron 80 mg) reduced the peak serum levels of a single 50-mg/kg dose of sulfasalazine by 40% in 5 healthy subjects. The reasons for this interaction are not known, but it seems likely that sulfasalazine chelates with the iron in the gut and thereby interferes with its absorption.[1] The extent to which this suggested chelation affects the ability of the intestinal bacteria to split sulfasalazine and release its locally active metabolite, 5-aminosalicylic acid, seems not to have been studied. Therefore the effect of this interaction on the clinical response to sulfasalazine is unclear.

1. Das KM, Eastwood MA. Effect of iron and calcium on salicylazosulphapyridine metabolism. *Scott Med J* (1973) 18, 45–50.

Sulfasalazine + Zileuton

No pharmacokinetic interaction appears to occur between sulfasalazine and zileuton.

Clinical evidence, mechanism, importance and management

In a randomised, double-blind study, 14 healthy subjects were given sulfasalazine 1 g every 12 hours for 8 days, with zileuton 800 mg or a placebo every 12 hours on days 3 to 8. It was found that the pharmacokinetics of the sulfasalazine and its metabolites (sulfapyridine and *N*-acetylsulfapyridine) were not significantly changed. The study did not directly look at the pharmacokinetics of the zileuton but, when compared with a previous study, its pharmacokinetics appeared unchanged.[1] There would seem to be no reason for special precautions if both drugs are used.

Hormonal contraceptives and Sex hormones

The hormonal contraceptives are of two main types: the **combined hormonal contraceptives** containing both an oestrogen and a progestogen available as tablets, a patch or vaginal ring; and the **progestogen-only contraceptives**, which are available as tablets (sometimes called 'mini' pills), parenteral preparations (implants, depot injections) and intrauterine devices.

The oestrogen most commonly used in combined hormonal contraceptives is ethinylestradiol, in a usual daily dose of 20 micrograms (low-dose) or 30 or 35 micrograms (standard dose), although higher doses of ethinylestradiol may be used with liver enzyme-inducing drugs such as rifampicin (rifampin). Mestranol (a pro-drug of ethinylestradiol) is used only rarely (daily dose 50 micrograms, equivalent to about 35 micrograms of ethinylestradiol). A combined hormonal contraceptive containing the natural oestrogen, estradiol valerate, is also available, in doses of 1 to 3 mg daily.

The progestogens used in both oral combined and progestogen-only contraceptives are commonly those derived from 19-nortestosterone and can be subdivided into first generation (e.g. etynodiol diacetate, lynestrenol, norethisterone), second generation (levonorgestrel, norgestrel) and third generation (e.g. desogestrel, drospirenone, gestodene, norgestimate). Note that drospirenone is an analogue of spironolactone and also has antiandrogenic and antimineralocorticoid effects. A patch containing ethinylestradiol and norelgestromin (the active metabolite of norgestimate) and a vaginal ring containing ethinylestradiol and etonogestrel (the active metabolite of desogestrel) are also available. The progestogens used in parenteral progestogen-only contraceptives are either 19-nortestosterone derivatives (e.g. etonogestrel, norethisterone) or derived from progesterone (e.g. medroxyprogesterone acetate). Those in intrauterine devices are 19-nortestosterone derivatives (e.g. levonorgestrel).

Combined hormonal contraceptives are most usually taken cyclically for 21 days, followed by a period of 7 days during which withdrawal bleeding occurs. Some of them include 7 inert tablets to be taken at this time so that the daily routine of taking a tablet is not broken. The daily doses of both the oestrogen and progestogen can be the same (monophasic preparations), or the dose of the progestogen can vary (biphasic or triphasic). Sometimes the dose of oestrogen is also varied (sequential). The combined hormonal contraceptive patch is applied weekly for 3 weeks followed by a patch-free week. The vaginal ring is inserted for 3 weeks, followed by a one-week break before inserting a new ring. The oestrogenic and progestogenic components of these contraceptives act together to consistently suppress ovulation.

The oral progestogen-only contraceptives are taken continuously; the implants, injections or intra-uterine devices slowly release the progestogen over an extended period of time. They vary in their ability to inhibit ovulation, and not all reliably inhibit ovulation in all cycles; they probably act mainly by increasing the viscosity of the cervical mucus so that the movement of the sperm is retarded. They may also cause changes in the endometrium, which inhibit successful implantation.

Interactions

(a) Combined hormonal contraceptives

1. Altered metabolism. Almost all of the information on interactions of the hormonal contraceptives involve the oral combined hormonal contraceptives. Most of the clinically important interactions with these contraceptives involve increased metabolism. The major route for hepatic metabolism of ethinylestradiol is hydroxylation (about 30% of a dose) principally by the cytochrome P450 isoenzyme CYP3A4 and also by CYP2C9. Progestogens are also substrates for CYP3A4. Ethinylestradiol and its metabolites also undergo conjugation by sulfation and glucuronidation (via UGT1A1). Thus, enzyme inducers can increase the clearance of the contraceptive steroids and possibly increase breakthrough bleeding and decrease contraceptive efficacy (see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177). The drugs that have been shown to induce the metabolism of hormonal contraceptives are listed in 'Table 28.1', (below). Intuitively, low-dose combined hormonal contraceptives might be expected to be more susceptible to drug interactions than standard-dose or high-dose preparations, but evidence to support this is scant. Conversely, inhibitors of CYP3A4 (such as some 'azoles', (p.1176)) or inhibitors of conjugation enzymes (such as some 'coxibs', (p.1181)) reduce the clearance of contraceptive steroids, and, although there is no good evidence for this, may increase the incidence of adverse effects such as nausea, breast tenderness, headaches, and potentially more serious complications such as thromboembolic events.

Table 28.1 Enzyme-inducing drugs shown to increase the metabolism of hormonal contraceptives and/or reduce their effects on the suppression of ovulation

Group	*Drugs*
Antibacterials	Rifabutin, Rifampicin (Rifampin)
Antiepileptics	Barbiturates (e.g. phenobarbital, primidone), Carbamazepine, Oxcarbazepine, Phenytoin, Rufinamide, Topiramate
Antiretrovirals	Nelfinavir, Nevirapine, Ritonavir, Ritonavir-boosted protease inhibitors
Other drugs	Aprepitant, Bosentan, Modafinil, St John's wort (*Hypericum perforatum*)

2. Enterohepatic recirculation. Some of the conjugated metabolites of ethinylestradiol undergo enterohepatic recirculation, and certain antibacterials are postulated to reduce this by inhibiting gut flora, thereby possibly decreasing contraceptive efficacy, although this is unproven (see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170).

3. Interaction studies. In drug interaction studies, in addition to assessing the effect on the pharmacokinetics of the contraceptive steroids, ovulation parameters are also often assessed to confirm the absence of ovulation. When evaluating drug interactions with combined hormonal contraceptives, it is important to bear in mind that they are most usually given cyclically, and that levels of the contraceptive steroids increase to steady state between about day 10 and 21 and decrease to zero in the seven-day drug free interval. In reducing contraceptive steroid levels, enzyme-inducing drugs may therefore increase the length of the pill-free interval, as well as reducing the levels at steady state. If an interacting drug is to be used continuously, such as rifampicin (rifampin) for tuberculosis, it needs to be taken with the contraceptive for at least one full cycle to assess the full effect of the drug on ovulation.

4. Other drugs affected. Increasing information is accumulating to show that hormonal contraceptives can cause clinically relevant pharmacokinetic interactions with other drugs. Ethinylestradiol appears to be a minor to modest inhibitor of the cytochrome P450 isoenzyme CYP1A2 (see 'tizanidine', (p.1572)) and an inducer of glucuronidation (see 'lamotrigine', (p.1183)), and might also have some inhibitory effect on CYP2C19

(see 'proton pump inhibitors', (p.1200)). Because of the cyclical administration of combined hormonal contraceptives, these interactions with other drugs will be cyclical (greatest at steady state, and least on the last day of the pill free interval), as has been demonstrated with 'lamotrigine', (p.1183), and this complicates their management.

(b) Progestogen-only contraceptives

There is very little direct information about interactions with the progestogen-only contraceptives (oral, parenteral, and intrauterine). It is unwise to uncritically assume that interactions known to occur with the combined hormonal contraceptives also occur with these contraceptives. However, it seems probable that an increased risk of failure with the oral and parenteral progestogen-only contraceptives is likely with drugs that cause enzyme induction (listed in 'Table 28.1', (p.1165)), which results in an increased clearance of the progestogen, with an accompanying loss of efficacy. The progestogen-releasing intrauterine system is thought to have a primarily local effect, and may not be affected by enzyme-inducers (see 'Progestogen-only contraceptives + Enzyme inducers', p.1206). However, much more study is needed to clarify the situation.

(c) Emergency hormonal contraceptives

It is not known whether interacting drugs are likely to affect the emergency hormonal contraceptives, although it is common practice that women taking enzyme-inducing drugs (see 'Table 28.1', (p.1165)) are given an increased dose to accommodate the increased rate of metabolism by the liver (see 'Emergency hormonal contraceptives + Enzyme inducers', p.1198).

The efficacy of progestogen-only emergency hormonal contraceptives is not affected by antibacterials that do not induce liver enzymes (see 'Emergency hormonal contraceptives + Antibacterials', p.1198).

(d) Hormone replacement therapy (HRT)

The preparations used for HRT contain oestrogens, either alone or combined with progestogens. They differ from the hormonal contraceptives as the most commonly used oestrogens in HRT are natural oestrogens such as estradiol and conjugated oestrogens, and their doses are generally lower than equivalent doses of ethinylestradiol used in combined hormonal contraceptives. There are only a few reports of interactions with HRT preparations, but generally they are expected to behave very much like the combined oral contraceptives.

(e) Other preparations

Cyproterone acetate combined with ethinylestradiol (co-cyprindiol) is intended for use in women with androgen-dependent skin conditions, but it also acts as an oral contraceptive and is therefore predicted to interact like conventional oestrogen-containing oral contraceptives (see 'Co-cyprindiol (Cyproterone with Ethinylestradiol) + Miscellaneous', p.1167).

4. Zhang H, Cui D, Wang B, Han Y-H, Balimane P, Yang Z, Sinz M, Rodrigues AD. Pharmacokinetic drug interactions involving 17α-ethinylestradiol: a new look at an old drug. *Clin Pharmacokinet* (2007) 46, 133–57.

Co-cyprindiol (Cyproterone with Ethinylestradiol) + Miscellaneous

Co-cyprindiol is expected to interact with enzyme inducers in a similar manner to the oral combined hormonal contraceptives, and therefore the risk of contraceptive failure is increased. Like oral combined hormonal contraceptives, there may be rare cases of contraceptive failure with many of the antibacterials. There is some evidence that co-cyprindiol also interacts with minocycline to increase facial pigmentation.

Clinical evidence, mechanism, importance and management

Co-cyprindiol is a mixture of the anti-androgenic progestogen, cyproterone acetate 2 mg, with ethinylestradiol 35 micrograms. It is used for the treatment of acne and moderately severe hirsutism in women who may also wish to use it as an oral hormonal contraceptive.

(a) Antibacterials

Because of the possibility that the use of non-liver enzyme inducing antibacterials that reduce gut bacteria may rarely reduce the contraceptive efficacy of oral combined hormonal contraceptives such as co-cyprindiol, some authorities advise additional precautions (see the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) guidance under 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). Usually these precautions (additional barrier methods) are considered unnecessary after 3 weeks of concurrent use. However, the manufacturer of co-cyprindiol says that when **tetracyclines** are being taken it is advisable to use additional non-hormonal methods of contraception (except the rhythm or temperature methods) as an extremely high degree of contraceptive protection must be provided with co-cyprindiol due to the theoretical risk of cyproterone causing feminisation of a male foetus. However, they also note that oral **tetracyclines** have not actually been shown to reduce the contraceptive efficacy of co-cyprindiol. In addition co-cyprindiol may also possibly interact with **minocycline** to accentuate facial pigmentation (see 'Tetracyclines; Minocycline + Ethinylestradiol', p.393).

(b) Enzyme-inducing drugs

The contraceptive efficacy of co-cyprindiol is expected to be reduced by the same enzyme inducers (see 'Table 28.1', (p.1165)) that interact with conventional oral combined hormonal contraceptives.[1] The precautions described in this section for these contraceptives with the various drugs listed in 'Table 28.1', (p.1165), should therefore be followed, see 'Combined hormonal contraceptives + Barbiturates or Phenytoin', p.1177. Note that the efficacy of co-cyprindiol in the treatment of acne and hirsutism might also be expected to be reduced by these drugs.

(c) Other combined hormonal contraceptives

The manufacturer states that oral combined hormonal contraceptives (and presumably the combined hormonal contraceptive patch or vaginal ring) must not be taken with co-cyprindiol.[1] To do this would be analogous to doubling the ethinylestradiol dose with consequent increased risk of adverse effects. In addition, some of the progestogens in combined hormonal contraceptives have weak androgenic effects, which could oppose the benefits of cyproterone.

1. Dianette (Cyproterone with ethinylestradiol). Bayer plc. UK Summary of product characteristics, May 2008.

Combined hormonal contraceptives + Alosetron

Alosetron did not alter the pharmacokinetics or the suppression of ovulation in women given an oral combined hormonal contraceptive.

Clinical evidence, mechanism, importance and management

In a crossover study in 18 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** 20 micrograms with **levonorgestrel** 100 micrograms), alosetron 1 mg twice daily (given alone for 7 days beginning on day 22 of one cycle and with the contraceptive from day one until day 21 of the next cycle) had no effect on the AUC of **ethinylestradiol** or **levonorgestrel**. In addition, there was no change in progesterone, FSH and LH levels, and no evidence of ovulation based on follicle size.[1] This study suggests that alosetron is unlikely to alter the efficacy of oral combined hormonal contraceptives.

Combined hormonal contraceptives + Antacids

Despite *in vitro* evidence that some antacids might reduce the availability of norethisterone acetate, evidence from healthy women indicates that no pharmacokinetic interaction occurs between antacids and oral combined hormonal contraceptives containing norethisterone or levonorgestrel.

Clinical evidence, mechanism, importance and management

An *in vitro* study found that a 1% suspension of **magnesium trisilicate** in water adsorbed about 80% of **mestranol** and 50% of **norethisterone**, but minimal amounts of **ethinylestradiol**.[1,2] Similarly, another *in vitro* study reported reduced dissolution of **norethisterone acetate** from combined hormonal contraceptive tablets in the presence of **magnesium trisilicate**, **kaolin mixture**, and **aluminium hydroxide**.[3]

In contrast, a single-dose study in 12 healthy women given an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms and either **norethisterone acetate** 1 mg or **levonorgestrel** 150 micrograms) with **magnesium trisilicate** 500 mg and **aluminium hydroxide** 250 mg, found that the AUC and peak levels of all three steroids were unchanged.[4] This is in line with common experience. There do not appear to be any reports of contraceptive failure with antacids and **norethisterone acetate** or **mestranol**-containing oral combined hormonal contraceptives. No special precautions seem to be necessary.

Combined hormonal contraceptives + Anthelmintics

The use of praziquantel or metrifonate does not appear to alter the pharmacokinetics of oral combined hormonal contraceptives.

Clinical evidence, mechanism, importance and management

A study in 25 women with early active schistosomiasis (*S. haematobium* or *S. mansoni*) without signs of liver disease and 6 healthy women found that neither the disease itself nor the concurrent use of antischistosomal drugs (a single 40-mg/kg dose of **praziquantel**, or **metrifonate** in three doses of 10 mg/kg at fortnightly intervals) had any effect on the plasma levels of steroids from an oral combined hormonal contraceptive (**ethinylestradiol** 50 micrograms with **levonorgestrel** 500 micrograms).[1] Moreover, in other studies there was no evidence that women with early active schistosomiasis without signs of liver disease[2] or with liver fibrosis with normal liver function[3] were at any greater risk of hepatic impairment while taking oral combined hormonal contraceptives. No special precautions would therefore appear necessary in women with schistosomiasis taking oral hormonal contraceptives and **praziquantel** or **metrifonate**. Note that oral hormonal contraceptives are usually considered contraindicated in schistosomiasis with liver involvement when there is cirrhosis, especially if this is severe (decompensated).

Combined hormonal contraceptives + Antibacterials; Cephalosporins

A few anecdotal cases of oral combined hormonal contraceptive failure have been reported with cefalexin, cefalexin with clindamycin, and unspecified cephalosporins. The interaction (if such it is) appears to be very rare indeed.

Clinical evidence

Two pregnancies were attributed to the use of cephalosporins (unspecified) and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials).[1] One case of contraceptive failure has been attributed to **cefalexin**,[2] and one to **cefalexin** used with clindamycin.[3] One case of contraceptive failure (resulting in an ectopic pregnancy) has been attributed to the use of **cefalexin** 3 g daily for 2 weeks with an oral combined hormonal contraceptive (**ethinylestradiol** 30 micrograms with **levonorgestrel** 150 micrograms).[4]

In a case-control study, 356 women who had received oral hormonal contraceptives and antibacterials (said to be cephalosporins, penicillins, tetracyclines) were identified over a 5-year period in three dermatological practices. The contraceptive failure rate in these women (1.6% per year; 2 pregnancies occurred in women taking a cephalosporin and 3 in women taking minocycline) was indistinguishable from the failure rate seen in control patients taking oral hormonal contraceptives and no antibacterials (1% per year). All these five cases occurred after taking the antibacterial for at least 3 months.[5]

Mechanism

Suppression of intestinal bacteria, which results in reduced enterohepatic recirculation of ethinylestradiol and a fall in serum levels, is the suggested explanation for any interaction (see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170).

Importance and management

The reports that are summarised here are all that have been identified in the literature on the interaction between the combined hormonal contraceptives and cephalosporins. These interactions are not adequately established and the whole issue remains very controversial. Bearing in mind the extremely wide use of both groups of drugs, any increased incidence of contraceptive failure above that normally seen is clearly very low indeed. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. Because of the possibility of an interaction, and for simplicity and on pragmatic grounds, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that patients taking any antibacterial (that does not induce liver enzymes) should use a second form of non-hormonal contraception, such as condoms, while taking a short course of less than 3 weeks of the antibacterial, and also for 7 days after it has been stopped,[6] which would apply to cephalosporins. They apply this advice to both the oral and patch form of the combined hormonal contraceptive,[6] and, therefore it should also be applied to the vaginal ring. In contrast, the WHO does not recommend any additional precautions while taking antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[7] For further comment and advice see also 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170.

Combined hormonal contraceptives + Antibacterials; Macrolides

Controlled studies have not shown the macrolides clarithromycin, dirithromycin, roxithromycin and telithromycin to have any effect on contraceptive steroid levels and/or suppression of ovulation in women given combined hormonal contraceptives. In one controlled study, erythromycin modestly *increased* contraceptive steroid levels (estradiol and dienogest), but isolated anecdotal cases of failure of oral hormonal contraceptives have previously been reported with erythromycin. An isolated case of contraceptive failure has also been reported with spiramycin.

Clinical evidence

(a) Clarithromycin

Ten women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel** or **desogestrel**) showed a very slight but not statistically significant rise in serum **ethinylestradiol** levels while taking clarithromycin 250 mg twice daily for 7 days. No changes in **levonorgestrel** levels occurred, but levels of the active metabolite of **desogestrel** were increased. Ovulation did not occur (progesterone levels remained suppressed, and FSH and LH levels were reduced). These hormonal changes suggest that clarithromycin may even *increase* the efficacy of oral combined hormonal contraceptives.[1]

(b) Dirithromycin

Fifteen women taking an oral triphasic combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**) were given dirithromycin 500 mg daily for 14 days starting on day 21 of the cycle. A small but statistically significant decrease of 7.6% occurred in the mean **ethinylestradiol** AUC, but no woman ovulated (as assessed by ultrasound and ovarian hormone levels).[2]

(c) Erythromycin

Isolated cases of contraceptive failure have been attributed to erythromycin, and two pregnancies were attributed to the use of erythromycin and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (61 cases were attributed to other antibacterials).[3] Another survey of oral hormonal contraceptive failure identified one failure due to erythromycin (48 of 209 pill failures were attributed to antibacterials),[4] and break-through bleeding due to erythromycin has also been described in 2 cases.[5] Conversely, in two studies of contraceptive failures in dermatology patients, no pregnancies were identified in a total of 74 women taking erythromycin and an oral hormonal contraceptive.[6,7]

In one controlled study in postmenopausal women given an oral combined hormonal contraceptive (**estradiol** 2 mg with **dienogest** 3 mg) for 14 days, erythromycin 500 mg three times daily for 7 days increased the steady-state AUC of **estradiol** by 33% and that of **dienogest** by 63%.[8,9]

(d) Roxithromycin

While taking roxithromycin 150 mg twice daily, the anti-ovulatory effects of an oral triphasic combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) remained unchanged during one cycle in 21 healthy women. Efficacy was measured by monitoring ovulation, which was assessed by ultrasound and progesterone levels.[10]

(e) Spiramycin

One case of contraceptive failure has been attributed to the concurrent use of spiramycin.[11]

(f) Telithromycin

In 38 healthy women taking an oral triphasic combined hormonal contraceptive, telithromycin 800 mg daily for 10 days had no effect on the pharmacokinetics of **ethinylestradiol**, but increased the plasma levels of **levonorgestrel**. None of the women ovulated, as assessed by progesterone levels.[12]

Mechanism

The macrolides such as erythromycin might possibly be expected to suppress the bacteria responsible for the enterohepatic recycling of ethinylestradiol, but good evidence that this is clinically important is scant

(see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). Erythromycin, and to a varying extent the other macrolides discussed here, also inhibit the cytochrome P450 isoenzyme CYP3A4, which is responsible for the metabolism of the contraceptive steroids. Therefore they might be expected to increase rather than reduce contraceptive efficacy. This might be expected to offset any possible reduced enterohepatic recycling.

Importance and management

Information about erythromycin is very limited, but the fact that there are only isolated reports of pregnancies with this drug, coupled with its known enzyme-inhibiting properties (demonstrated with estradiol and dienogest), suggest that it is unlikely to cause contraceptive failure. Information on the other macrolides seems to be limited to the studies cited, on the basis of which no interaction appears to be likely with clarithromycin, roxithromycin or telithromycin. Dirithromycin also appears unlikely to cause oral hormonal contraceptive failure. No cases of contraceptive failure with these macrolides appear to have been reported. If one accepts the theory that there is an as yet unidentifiable tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then additional contraceptive precautions should be taken. However, if one tends to the theory that the anecdotal cases of contraceptive failure with non-enzyme inducing antibacterials are indistinguishable from the normal accepted failure rate, no special precautions are necessary.

In 1999, the UK Family Planning Association considered that it was almost certain that erythromycin did not interact with oral combined hormonal contraceptives.[13] However, for simplicity and on pragmatic grounds, in 2005, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit advised that additional contraceptives, such as condoms, should be used for short courses of all non-enzyme inducing antibacterials, see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170, for more detailed information. They applied this to both the oral and the patch form of the combined hormonal contraceptive,[14] and, therefore it should also be applied to the vaginal ring. In contrast, the WHO does not recommend any additional precautions while taking any antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring,[15] which seems a more logical approach for the macrolides given the data available.

For a discussion of the adverse hepatic interaction between oral hormonal contraceptives and the macrolide troleandomycin, see 'Combined hormonal contraceptives or HRT + Antibacterials; Troleandomycin', p.1174.

Combined hormonal contraceptives + Antibacterials; Metronidazole

Isolated cases of oral combined hormonal contraceptive failure have been reported with metronidazole. The interaction (if such it is) appears to be very rare indeed. In a controlled study, metronidazole did not affect contraceptive steroid levels.

Clinical evidence, mechanism, importance and management

In 10 women taking an oral combined hormonal contraceptive, metronidazole 400 mg three times daily for 6 to 8 days had no effect on the AUC of **ethinylestradiol** and **norethisterone**. However, 2 of the 10 women had a rise in plasma progesterone levels suggesting that ovulation may have occurred. One of a further 15 women taking metronidazole and an oral combined hormonal contraceptive also appeared to ovulate. Of the 3 women who ovulated one also ovulated during a cycle while not taking metronidazole.[1] Another similar study in 10 women found that none ovulated while taking metronidazole and an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**).[2]

Only 3 reports of pregnancies were identified in women who took metronidazole and an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984.[3] A survey of oral hormonal contraceptive failure identified one failure due to metronidazole (48 of a total of 209 cases were attributed to antibacterials),[4] and a follow-up study identified one further case.[5] Another survey[6] found one contraceptive failure in a woman taking metronidazole, and she was also taking **doxycycline** (see 'Combined hormonal contraceptives + Antibacterials; Tetracyclines', p.1173). It is possible that these cases represent chance associations.

The interaction between metronidazole and oral combined hormonal contraceptives is not established, and the whole issue of any interaction with non-enzyme inducing antibacterials remains controversial. Bearing in mind the extremely wide use of both metronidazole and oral combined hormonal contraceptives, any increased incidence of contraceptive failure above that seen in general usage is clearly very low indeed. Nevertheless, for simplicity and on pragmatic grounds the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit has recommended that an additional form of contraception, such as condoms, should be used for short courses of all non-enzyme inducing antibacterials,[7] which would include metronidazole. They apply this to both the oral and the patch form of the combined contraceptive and, therefore it should also be applied to the vaginal ring. In contrast, the WHO does not recommend any additional precautions while taking antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[8] For further comment and advice see also 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170.

Combined hormonal contraceptives + Antibacterials; Miscellaneous

One or two cases of contraceptive failure have been reported in patients given oral combined hormonal contraceptives and chloramphenicol, clindamycin (used with cefalexin), dapsone, fusidic acid, isoniazid, nifurtoinol and nitrofurantoin. These isolated cases are anecdotal and unconfirmed, and the interaction (if

such it is) appears to be very rare indeed. The combination of aminosalicylic acid, isoniazid and streptomycin does not appear to affect contraceptive activity.

Clinical evidence, mechanism, importance and management

One woman taking an oral combined hormonal contraceptive was briefly reported to have developed breakthrough bleeding and to have become pregnant while taking **chloramphenicol**.[1,2] One or two cases of contraceptive failure have been briefly attributed to **clindamycin** (used with cefalexin),[3] **dapsone**,[3] **fusidic acid**,[4] **isoniazid**,[3,5] **nifurtoinol**[6] and **nitrofurantoin**.[3,6] Breakthrough bleeding, due to **clindamycin** in one case and **chloramphenicol** in another case, have also been reported.[7] Conversely, no evidence of ovulation or of changes in plasma **ethinylestradiol** and **norethisterone** levels were seen in a study of 8 women taking an oral combined hormonal contraceptive with **aminosalicylic acid**, **isoniazid** and **streptomycin**.[8]

The interactions between the oral hormonal contraceptives and antibacterials summarised here are all that have been identified in the literature involving the drugs cited. These interactions are not established, and given the few anecdotal cases with each drug, could just be coincidental. With **isoniazid** in particular, there is evidence that the drug does not cause contraceptive failure when used in combination with other antimycobacterials (without rifampicin). On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. For simplicity and on pragmatic grounds, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use an additional form of contraception, such as condoms, while taking a short course of any antibacterial that does not induce liver enzymes, and for 7 days after the antibacterial has been stopped.[9] For further details of this advice see 'Combined hormonal contraceptives + Antibacterials; Penicillins', below. They applied this advice to both the oral and patch form of the combined hormonal contraceptives,[9] and, therefore it should also be applied to the vaginal ring. In contrast, the WHO does not recommend any additional precautions while taking any antibiotics (excluding rifampicin (rifampin)) with combined hormonal contraceptives, given orally, as the patch, or as the vaginal ring.[10]

Combined hormonal contraceptives + Antibacterials; Penicillins

The failure of oral combined hormonal contraceptives has been attributed to ampicillin, amoxicillin, flucloxacillin, oxacillin, phenoxymethylpenicillin, pivampicillin and talampicillin. However, the interaction (if such it is), appears to be very rare. Controlled studies have not shown any effect of ampicillin or amoxicillin on contraceptive steroid levels and the suppression of ovulation in women given these contraceptives.

Clinical evidence

(a) Oral hormonal contraceptives

1. Case reports. A case report describes 3 women taking an oral hormonal contraceptive who became pregnant when given **ampicillin**.[1] One woman had two unwanted pregnancies while taking an oral combined hormonal contraceptive (**ethinylestradiol** with **norethisterone**). On both occasions conception occurred when she was taking **ampicillin** for tonsillitis.[2] Another woman taking **ethinylestradiol** with **norethisterone** for 5 years with no history of breakthrough bleeding, lost a quantity of blood similar to a normal period loss within a day of starting to take **ampicillin** (exact dose unknown). There was no evidence of diarrhoea or vomiting in either case.[2] Two other case reports attributed contraceptive failure to **oxacillin**,[3] and to an intramuscular injection of **benethamine penicillin**, **procaine penicillin** and **benzylpenicillin**.[4]

The use of a penicillin (unspecified) was implicated in 32 pregnancies in women taking an oral hormonal contraceptive (unspecified) in the adverse reactions register of the CSM in the UK for the years 1968 to 1984 (a further 31 cases were attributed to other antibacterials).[5] In an earlier review, the penicillins in 15 cases of contraceptive failure were named as **ampicillin** (alone or with fusidic acid, tetracycline or **flucloxacillin**), **amoxicillin**, **talampicillin**, **phenoxymethylpenicillin** (one also with oxytetracycline) and 'penicillin'.[6] A survey of contraceptive failure described failures due to **amoxicillin** (16 cases), **flucloxacillin**, **phenoxymethylpenicillin**, **pivampicillin** (5 cases) and **amoxicillin** with **phenoxymethylpenicillin** (1 case),[7] and a follow-up survey identified 9 further cases involving **amoxicillin** and one with 'penicillin'.[8] Another similar survey described a total of 17 cases with **amoxicillin** and 5 cases with 'penicillin',[9] and a follow-up survey identified 8 further cases with **amoxicillin** and one case with 'penicillin'.[10]

2. Controlled studies. Three controlled studies have provided evidence that **ampicillin** does not alter the plasma levels of contraceptive steroids or reduce their anti-ovulatory effects.[11-13] In the first study, **ampicillin** 250 mg four times daily for 16 days was given to women taking **ethinylestradiol** with **etynodiol**. No women ovulated, as assessed by FSH, LH and progesterone levels. Two women had breakthrough bleeding while receiving **ampicillin**, and one had spotting while receiving placebo.[11] In another study in 7 patients and 6 healthy women, **ampicillin** 500 mg three times daily for 8 days had no significant effect on the plasma levels of **ethinylestradiol** or **levonorgestrel**. However, one woman had a large fall in **ethinylestradiol** levels. Despite this, none of the women ovulated, as assessed by progesterone levels.[12] The third study in 6 women found that **ampicillin** 1 g twice daily had no effect on the plasma levels of **ethinylestradiol** and **norethisterone**, and ovulation did not occur.[13]

(b) Vaginal ring

In a crossover study in 16 healthy women using the *NuvaRing* vaginal contraceptive ring, a 10-day course of **amoxicillin** 875 mg twice daily started on day one of a cycle did not alter the pharmacokinetics of **etonogestrel** or **ethinylestradiol**.[14]

Mechanism

Not understood. The oestrogen component of the contraceptive undergoes enterohepatic recirculation (i.e. it is repeatedly secreted in the bile as sulfate and glucuronide conjugates, which are hydrolysed by the gut bacteria before reabsorption). One idea is that if these bacteria are suppressed by the use of an antibacterial, the steroid conjugates are not hydrolysed and are therefore only poorly reabsorbed, resulting in lower than normal concentrations of circulating oestrogen in some women. This may result in inadequate suppression of ovulation.[6] However, although the penicillins reduce *urinary* oestriol secretion in pregnant women,[15-19] no marked changes in *serum* ethinylestradiol levels have been found in controlled studies in women taking an oral hormonal contraceptive with ampicillin or many other antibacterials (see 'tetracyclines', (p.1173), 'macrolides', (p.1168), 'quinolones', (p.1171)). It may be that the enterohepatic recirculation of ethinylestradiol is not clinically important: note that women with an ileostomy have normal serum contraceptive steroid levels.[20] Alternatively, it may be that the proportion of women for whom enterohepatic recirculation is important is extremely small.[20] Note that the progestogens do not take part in enterohepatic recirculation in their active forms, so the progestogenic component of the contraceptive would remain effective.

Importance and management

The interaction between combined hormonal contraceptives and penicillins is inadequately established and controversial. Almost all of the evidence is anecdotal with no controls. The total number of failures is extremely small when viewed against the number of women worldwide using combined hormonal contraceptives, so most women are apparently not at risk. If one tends to the theory that the anecdotal cases of contraceptive failure with broad-spectrum antibacterials are indistinguishable from the normal accepted failure rate, no special precautions are necessary. On the other hand, the personal and ethical consequences of an unwanted pregnancy can be very serious. If one accepts the theory that there is an as yet unidentifiable tiny group of women for whom enterohepatic recirculation of ethinylestradiol is important, then additional contraceptive precautions should be taken.

For simplicity, and on pragmatic grounds, the UK Faculty of Family Planning and Reproductive Health Care (FFPRHC) Clinical Effectiveness Unit recommends that women taking combined hormonal contraceptives should routinely use a second form of contraception, such as condoms, while taking a short course of less than 3 weeks of any antibacterial (non-enzyme inducing),[21] and for 7 days after the antibacterial has been stopped,[21] and this would include the penicillins. In addition, the FFPRHC recommends that if fewer than 7 active pills are left in the pack after the antibacterial has been stopped, the new packet should be started without a pill-free break, omitting any of the inactive tablets. For women using the combined contraceptive patch, if the 7 days after the antibacterial has been stopped runs into the usual 7 day patch-free period, a new patch should be applied when it is due to be changed and the patch-free week delayed by 7 days.[21] For women using the vaginal ring, if antibacterial (except amoxicillin, see *Amoxicillin and the need for additional precautions*, below) use runs beyond the 3 weeks of a ring-cycle, the next ring should be inserted immediately, without having the usual ring-free interval.[22] The FFPRHC also says that after 3 weeks of antibacterial treatment the gut flora becomes resistant to the antibacterial. Therefore women taking a long-term antibacterial that does not induce liver enzymes (for example, for acne), no longer need additional contraceptive protection after the initial 3 weeks of concurrent use. However, if the antibacterial is changed or another antibacterial is started, additional contraceptive cover is required. Women who have already been taking long-term antibacterials that do not induce liver enzymes, who start a combined hormonal contraceptive, do not require additional contraception, unless the antibacterial is changed.[21]

However, others have contended that these sorts of instructions may confuse patients, and complicate pill taking, and could have the opposite effect of increasing the failure rate of hormonal contraceptives.[23] Note that the WHO does not recommend any additional precautions while taking any antibacterials (excluding rifampicin (rifampin)) with combined hormonal contraceptives given orally, as the patch, or as the vaginal ring.[24]

Amoxicillin and the need for additional precautions. The UK manufacturer of the combined hormonal vaginal ring excludes amoxicillin from the advice applied to other antibacterials on the basis of the one study showing an absence of a pharmacokinetic interaction.[22] On the basis of a similar pharmacokinetic study, the FFPRHC have exempted tetracycline from the need for additional precautions with the combined hormonal contraceptive patch (see 'Combined hormonal contraceptives + Antibacterials; Tetracyclines', p.1173). If this type of study is sufficient evidence to exclude the need for additional precautions, then no additional precautions are probably required with ampicillin and oral combined hormonal contraceptives and many other antibacterials for which there are similar or better controlled studies.

Combined hormonal contraceptives + Antibacterials; Quinolones

In controlled studies, ciprofloxacin, moxifloxacin and ofloxacin did not alter the pharmacokinetics of the contraceptive steroids or the suppression of ovulation in women taking oral combined hormonal contraceptives. No cases of contraceptive failure appear to have been reported with the quinolones. The plasma levels of moxifloxacin may be slightly reduced by oral combined hormonal contraceptives.

Clinical evidence

(a) Ciprofloxacin

No ovulation (as assessed by LH, FSH and estradiol levels) occurred in 10 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **desogestrel**, **gestodene** or **levonorgestrel**) with ciprofloxacin 500 mg twice daily for 7 days (started on the first day of contraceptive intake). No breakthrough bleeding occurred.[1] Another study in 24 healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **desogestrel**) found that ciprofloxacin 500 mg twice daily for 10 days had no effect on the pharmacokinetics of **ethinylestradiol**. In addition, no subject ovulated, as assessed by progesterone and estradiol levels. However, 2 of the subjects were potentially ovulatory while taking a placebo instead of ciprofloxacin, as detected by an ultrasound of ovarian activity. A further 4 subjects taking ciprofloxacin and 2 taking placebo had lesser indications of ovarian activity.[2]

(b) Moxifloxacin

A placebo-controlled, crossover study in 29 young healthy women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**) found that moxifloxacin 400 mg daily on cycle days 1 to 7 had no clinically relevant effect on the pharmacokinetics of either contraceptive steroid. The hormonal parameters measured (estradiol, progesterone, LH, FSH) were also unchanged by the presence of the quinolone, indicating that ovulation continued to be suppressed.[3] In another non-randomised study looking at the effects of oral combined hormonal contraceptives (unspecified) on the pharmacokinetics of a single 400-mg dose of moxifloxacin, the total oral clearance of moxifloxacin was 20% greater and its AUC and maximum plasma concentrations were 15% lower in 15 women taking oral combined hormonal contraceptives, when compared with 15 women using non-hormonal methods of contraception.[4]

(c) Ofloxacin

Ofloxacin had no effect on the suppression of ovulation in 19 women taking an oral combined hormonal contraceptive (**ethinylestradiol** with **levonorgestrel**). In this placebo-controlled, crossover study, two courses of ofloxacin 200 mg twice daily for 7 days were given on days one to 7 of two consecutive contraceptive cycles. Ovulation was assessed by ultra-

sound of the ovaries, and by measuring FSH, estradiol and progesterone levels. Four of the women had signs of ovarian activity in both the placebo and ofloxacin cycles.[5]

Mechanism

The fluoroquinolones are likely to reduce gut bacteria, and so might be expected to interrupt the enterohepatic recirculation of ethinylestradiol,[1,6] but the evidence that this is clinically important is scant (for a more detailed discussion of this mechanism see 'Combined hormonal contraceptives + Antibacterials; Penicillins', p.1170). It was suggested that ethinylestradiol might slightly decrease levels of some quinolones by inducing conjugation.[4]

Importance and management
