Omeprazole is an inhibitor of the cytochrome P450 isoenzyme CYP2C19, by which moclobemide is extensively metabolised. Activity of this enzyme is genetically determined, see 'Genetic factors in drug metabolism', (p.4), for more information. Moclobemide is also an inhibitor of CYP2C19, which is the major pathway by which omeprazole is metabolised. Inhibition of this pathway means that metabolism of omeprazole in extensive metabolisers, who normally metabolise omeprazole to 5-hydroxyomeprazole by CYP2C19, will become more dependent on other pathways. Omeprazole sulfone is produced when omeprazole is metabolised by CYP3A4, and hence in extensive metabolisers given moclobemide its levels rise.

Importance and management

The pharmacokinetic interaction is established, but its clinical relevance is unclear. Both drugs are relatively safe, and therefore increased levels are generally likely to be well tolerated. However, if the adverse effects of either drug become troublesome consider an interaction as a possible cause. Note that the effect of moclobemide on omeprazole may be of more significance if drugs that inhibit CYP3A4 are also given, as both pathways of metabolism will be blocked.

Phenelzine + Cloral hydrate

A case of fatal hyperpyrexia and another case of serious hypertension have been linked to interactions between cloral hydrate and phenelzine, but in both cases there are other plausible explanations for the reactions seen.

Clinical evidence, mechanism, importance and management

A woman taking **phenelzine** 15 mg three times daily was found in bed deeply comatose with marked muscular rigidity, twitching down one side and a temperature of 41°C. She died without regaining consciousness. A postmortem failed to establish the cause of death, but it subsequently came to light that she had started drinking whisky, and she had access to cloral hydrate, of which she may have taken a fatal dose.[1] Another patient, taking **phenelzine** 15 mg three times daily, and cloral hydrate to aid sleep, developed an excruciating headache followed by nausea, photophobia and a substantial rise in blood pressure.[2] This latter reaction is similar to the 'cheese reaction', see 'tyramine-rich foods', (p.1395), but at the time the authors of the report were unaware of this type of reaction so that they failed to find out if any tyramine-rich foods had been eaten on the day of the attack.[2]

There is no clear evidence that either of these adverse reactions was due to an interaction between **phenelzine** and cloral hydrate, and there do not

seem to be any other reports to suggest that an interaction between these drugs is likely.

Phenelzine + Erythromycin

An isolated case report describes severe hypotension and fainting in a woman taking phenelzine, which occurred shortly after she started a course of erythromycin.

Clinical evidence, mechanism, importance and management

A woman taking phenelzine 15 mg daily experienced three syncopal episodes 4 days after starting to take erythromycin 250 mg four times daily for pneumonia. When admitted to hospital her supine systolic blood pressure was only 70 mmHg. When she sat up, it was unrecordable. Although she was not dehydrated, she was given 4 litres of sodium chloride 0.9%, without any effect on her blood pressure. Within 24 hours of stopping the phenelzine her blood pressure had returned to normal.[1] The reasons for this severe hypotensive reaction are not known, but it was suggested that the erythromycin may have caused rapid gastric emptying, which resulted in a very rapid absorption of the phenelzine (described by the author as rapid dumping into the blood stream), which resulted in the adverse effect of hypotension.[1] This seems to be the first and only report of this interaction, and so its general importance is uncertain. It seems likely to be small.

1. Bernstein AE. Drug interaction. *Hosp Community Psychiatry* (1990) 41, 806–7.

Phenelzine + Sulfafurazole (Sulfisoxazole)

An isolated report describes a patient taking phenelzine who developed weakness and ataxia after also taking sulfafurazole.

Clinical evidence, mechanism, importance and management

A woman who had been taking phenelzine 15 mg three times daily for about 3 weeks complained of weakness, ataxia, vertigo, tinnitus, muscle pains, and paraesthesia within 7 days of starting to take sulfafurazole 1 g four times daily. These adverse effects continued until the 10-day sulfonamide course was completed, and did not occur again in the following 8 weeks.[1] The reasons for this reaction are not understood, but as these adverse effects are a combination of the adverse effects of both drugs, it seems possible that a mutual interaction (perhaps saturation of the acetylating mechanisms in the liver) was responsible. This appears to be an isolated report and its general significance is unknown.

Nutritional agents, Supplements and Vitamins

This section covers the interactions where there is documented evidence that a drug alters the efficacy of nutritional agents, dietary supplements and vitamins. Information on the effects of these substances on other drugs is covered in the relevant section for that drug.

Agalsidase + Miscellaneous

Agalsidase alfa and agalsidase beta are unlikely to interact with other drugs by mechanisms involving cytochrome P450.[1] The UK manufacturers suggest that agalsidase alfa and agalsidase beta should not be given with amiodarone, chloroquine, gentamicin [and therefore probably any aminoglycoside], or monobenzone due to a theoretical risk of inhibition of intra-cellular alpha-galactosidase activity.[1,2] This would be expected to reduce the efficacy of agalsidase.

2. Fabrazyme (Agalsidase beta). Genzyme Therapeutics. UK Summary of product characteristics, February 2008.

Amygdalin + Ascorbic acid (Vitamin C)

Vitamin C may enhance the hydrolysis of amygdalin resulting in toxic levels of cyanide.

Clinical evidence

A patient with bladder cancer, who was taking several vitamin preparations, including high-dose vitamin C, and other complementary medicines in addition to her prescribed medicines, became unwell and complained of dizziness 2.5 hours after the first dose of amygdalin 3 g. She then developed tachycardia, seizures and severe lactic acidosis, and required intubation and ventilation. Cyanide poisoning was diagnosed and she recovered after being given activated charcoal and intravenous hydroxocobalamin 5 g over 30 minutes.[1]

Mechanism

There appear to be no reports of serious cyanide toxicity with doses of amygdalin up to 6 g daily. Hydrolysis of amygdalin can produce up to 6% hydrogen cyanide so a dose of 3 g could possibly produce up to 180 mg of cyanide, which is above the estimated potentially lethal dose of 50 to 100 mg. Amygdalin is hydrolysed in the presence of beta-glucosidases, which are not usually present in the upper gastrointestinal tract to any extent. However, hydrolysis of amygdalin in the gut is enhanced by ascorbic acid and it was considered likely that the high doses of vitamin C (more than 3 g daily) taken by the patient resulted in sufficient hydrolysis of amygdalin to produce toxic levels of cyanide.[1] In addition, body stores of cysteine, which facilitate cyanide detoxification, are depleted by vitamin C.[1,2]

Importance and management

Although this appears to be the only clinical report of this interaction, cyanide poisoning associated with amygdalin has been reported. It would therefore seem prudent to avoid the concurrent use of vitamin C. **Laetrile**, which is a product consisting mainly of amygdalin, would be expected to interact similarly with vitamin C.

Ascorbic acid (Vitamin C) + Salicylates

Aspirin might reduce the absorption of ascorbic acid by about one-third. Serum salicylate levels do not appear to be affected by ascorbic acid.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, the rise in plasma ascorbic acid levels over 3 hours was about one-third lower when a single 500-mg dose of ascorbic acid was given with **aspirin** 900 mg, when compared with ascorbic acid alone, and the urinary excretion of ascorbic acid was about 50% lower.[1] In another well-controlled study in healthy subjects, levels of ascorbic acid in the gastric mucosa, plasma and urine on day 7 were not significantly different when ascorbic acid 480 mg three times daily was given with **aspirin** 800 mg three times daily, when compared with ascorbic acid alone. However, aspirin 800 mg three times daily, given without ascorbic acid supplementation, reduced ascorbic acid levels.[2] There is some pharmacodynamic evidence that, in healthy subjects, ascorbic acid attenuates gastric mucosal lesions seen with **aspirin**.[3]

Another study, in 9 healthy subjects, found that ascorbic acid 1 g three times daily did not significantly affect the serum salicylate levels in response to **choline salicylate**.[4]

The clinical importance of the possible decrease in ascorbic acid levels is uncertain. It has been suggested that the normal physiological requirement of 30 to 60 mg of ascorbic acid daily may need to be increased to 100 to 200 mg daily in the presence of long-term **aspirin** therapy.[1]

Betacarotene + Colchicine

The desired effect of betacarotene supplementation may be reduced in those taking colchicine.

Clinical evidence

Divided doses of colchicine 1.9 mg to 3.9 mg daily reduced the serum levels of betacarotene 10 000 units daily (about 6 mg) in 5 obese subjects. Levels returned to normal when colchicine was stopped.[1] However, in another study, long-term use of colchicine 1 mg to 2 mg daily for 3 years had no effect on the serum levels of diet-derived carotene in 12 patients with familial Mediterranean fever.[2]

Mechanism

The mechanism is unclear. Colchicine causes reversible malabsorption in the gastrointestinal tract by disturbing epithelial cell function and inhibiting cell proliferation. It also lowered the serum levels of cholesterol in the first study. All these factors could have an effect on the absorption of betacarotene, which largely takes place in the gastrointestinal mucosa and whose distribution is dependent on the presence of lipoproteins.

Importance and management

The evidence for a possible interaction between betacarotene and colchicine is limited to two relatively old studies. While supplemental betacarotene absorption appears to be reduced, betacarotene ingested as part of the normal diet appears to be unaffected. Based on these two findings, and the fact that there is large interindividual variation in betacarotene absorption, it is difficult to recommend a clinical course of action other than to be aware that the desired effect of betacarotene supplementation may be reduced in those taking colchicine.

Betacarotene + Proton pump inhibitors

The desired effect of betacarotene supplementation may be reduced in those taking proton pump inhibitors.

Clinical evidence

In a study in 10 healthy subjects the AUC of a single 120-mg dose of betacarotene was halved by pretreatment with **omeprazole** 20 mg twice daily for 7 days.[1]

Mechanism

The exact mechanism is unclear. Betacarotene is absorbed in the small intestine by a simple passive-diffusion process. It has been suggested that omeprazole may retard this diffusion,[1] and that delayed gastric emptying may also contribute.[2]

Importance and management

Evidence for an interaction between betacarotene and omeprazole is limited, and as there is large interindividual variability in betacarotene absorption, the true bioavailability of the carotenoid can vary greatly even before omeprazole is taken. Coupled with the fact that betacarotene is a normal part of the healthy diet, it is very difficult to assess the true clinical importance of this interaction. Be aware that the desired effect of betacarotene supplements may be reduced or abolished by the concurrent use of omeprazole. If the suggested mechanism is correct, other proton pump inhibitors are likely to affect betacarotene absorption similarly.

Calcium compounds + Proton pump inhibitors

A study in elderly women found that omeprazole reduced the absorption of calcium from a single dose of calcium carbonate under fasting conditions. However, in another study, omeprazole did not affect the absorption of calcium from a test meal that included milk and cheese. Other proton pump inhibitors may have similar effects.

Clinical evidence

In a double-blind study, 18 elderly women (mean age 76 years) were given a multivitamin preparation containing vitamin D 400 units daily and either omeprazole 20 mg daily or placebo for 7 days and then again with calcium carbonate (elemental calcium 500 mg) after an overnight fast. Calcium supplements had been withheld for one week before the study. The fractional absorption of the single calcium carbonate dose was decreased by about 60% by omeprazole (from 9.1% with placebo to 3.5% with omeprazole).[1]

In contrast, in another study, higher 40-mg doses of omeprazole did not affect the absorption of calcium from food (535 mg from a test meal including milk and cheese).[2]

Mechanism

In vitro, calcium carbonate disintegration and dissolution is pH dependent, decreasing from 96% at pH 1 to 23% at pH 6.1.[3] Therefore increases in pH due to omeprazole could reduce calcium absorption. However, calcium absorption is dependent on other factors such as food, calcium dose and subject age. Calcium absorption in women decreases with increasing age.[4]

Importance and management

The study in elderly women found reduced calcium absorption in the presence of omeprazole. Other proton pump inhibitors might be expected to act similarly, as the mechanism appears to relate to gastric pH. However, another study found that omeprazole did not affect calcium absorption from food. Therefore factors that may influence calcium absorption other than gastric pH, including patient age, calcium dose, and food must also be considered when assessing the possibility of an interaction. More study is needed to assess the clinical relevance of this potential interaction.

Cannabis + Disulfiram

Two isolated case reports describe hypomanic-like reactions when patients taking disulfiram used cannabis, whereas no unusual interaction with the combination was seen in other subjects.

Clinical evidence, mechanism, importance and management

A man with a 10-year history of drug abuse (alcohol, amfetamines, cocaine, cannabis) taking disulfiram 250 mg daily, experienced a hypomanic-like reaction (euphoria, hyperactivity, insomnia, irritability) on two occasions, associated with the concurrent use of cannabis. The patient said that he felt as though he had been taking amfetamine.[1] One other similar case has been reported.[2] The reason for this reaction is not understood.

In a randomised study in alcohol-dependent subjects who had previously used cannabis, no unusual interaction effects were found in a group of 11 subjects receiving disulfiram and smoking cannabis twice weekly for 4 weeks.[3] Therefore the interaction described in the two case reports would not appear to be of general significance.

Cannabis + Nicotine

The effects of transdermal nicotine and cannabis smoking on increasing the heart rate are additive, and nicotine increased the stimulant effect of cannabis. Combined use might increase the addictive potential of both drugs.

Clinical evidence

In a study in 20 healthy subjects who smoked either a low-dose or high-dose cannabis cigarette 4 hours after the application of a placebo or a 21 mg nicotine patch, nicotine enhanced the maximum increase in heart rate seen with cannabis. The increase in heart rate for nicotine alone was between 10 and 15 bpm, for cannabis alone 32 and 42 bpm, for women and men, respectively, and for the combination, 45 and 58 bpm, respectively. In addition, the duration of tachycardia after smoking the low-dose cannabis was prolonged by 30 minutes by nicotine, but was not changed after the high-dose cannabis. Nicotine increased the subjective stimulant effects of cannabis, but the reported duration of effects of cannabis were shortened by nicotine. Plasma levels of nicotine and Δ^9-tetrahydrocannabinol (THC) did not differ on concurrent use. The cannabis cigarettes were standardised to 1.99% THC (low dose) and 3.51% THC (high dose).[1]

Mechanism

Unknown. The additive effect on heart rate may be due to sympathetic activity of both drugs, and might also involve cannabinoid receptors.[1]

Importance and management

Cannabis is often smoked with tobacco. The findings of the clinical study show that transdermal nicotine has additive effects with cannabis on heart rate, and increased the stimulant effect of cannabis. The clinical significance of these findings is uncertain.

Evening primrose oil + Phenothiazines

Although seizures have occurred in a few schizophrenics taking phenothiazines and evening primrose oil, no adverse effects were seen in others, and there appears to be no firm evidence that evening primrose oil should be avoided by those at risk of seizures.

Clinical evidence

Twenty-three patients were enrolled in a placebo-controlled study of evening primrose oil in schizophrenia. During the treatment phase, patients were given 8 capsules of *Efamol* in addition to their normal medication. Seizures developed in 3 patients, one during treatment with placebo. The other two patients were taking evening primrose oil, one was receiving **fluphenazine decanoate** 50 mg once every 2 weeks and the other **fluphenazine decanoate** 25 mg once every 2 weeks with **thioridazine**, which was later changed to **chlorpromazine**.[1] In another study, 3 long-stay hospitalised schizophrenics were taking evening primrose oil. Their schizophrenia became much worse and all 3 patients showed EEG evidence of temporal lobe epilepsy.[2]

In contrast, no seizures or epileptiform events were reported in a crossover study of 48 patients (most of them schizophrenics) taking **phenothiazines** when they were given evening primrose oil for 4 months.[3] Concurrent use was also apparently uneventful in another study in schizophrenic patients.[4]

Mechanism

Not understood. One suggestion is that evening primrose oil possibly increases the well-recognised epileptogenic effects of the phenothiazines, rather than having an epileptogenic action of its own.[1] Another idea is that it might unmask temporal lobe epilepsy.[1,2]

Importance and management

The interaction between phenothiazines and evening primrose oil is not well established, nor is its incidence known, but clearly some caution is appropriate during concurrent use, because seizures may develop in a few individuals. There seems to be no way of identifying the patients at particular risk. The extent to which the underlying disease condition might affect what happens is also unclear.

No interaction between antiepileptics and evening primrose oil has been established and the reports cited above[1,2] appear to be the sole basis for the suggestion that evening primrose oil should be avoided by epileptics. No seizures appear to have been reported in patients taking evening primrose oil in the absence of phenothiazines. One review,[5] analysing these two reports, goes as far as suggesting that formularies should now remove seizures or epilepsy as an adverse effect of evening primrose oil because the evidence for the seizures clearly point to the phenothiazines taken. Moreover, the manufacturers of *Epogam*, an evening primrose oil preparation, claim that it is known to have improved the control of epilepsy in patients previously uncontrolled with conventional antiepileptic drugs, and other patients are said to have had no problems during concurrent treatment.[6]

Folic acid + Antacids or H_2-receptor antagonists

Aluminium/magnesium hydroxide-containing antacids, cimetidine and ranitidine probably do not have a clinically relevant effect on the absorption of folic acid.

Clinical evidence, mechanism, importance and management

In a well-controlled study in healthy subjects, taking two 30 mL doses of an **aluminium/magnesium hydroxide** antacid (*Mylanta II*) one hour and three hours after a single 200-microgram dose of folic acid caused a small 15% reduction in folic acid absorption (from about 51% to 43%). Two doses of **cimetidine** 300 mg (5 hours before and simultaneously with the folic acid), caused a reduction of about 8% in folic acid absorption, and two doses of **ranitidine** 150 mg (the night before and 5 hours before the folic acid) caused about a 6% decrease (not statistically significant).[1]

Drugs that increase the gastrointestinal pH might reduce folic acid absorption since the optimal pH for active intestinal transport of folic acid is about 6. It is possible that in the pH range of physiological significance, folate binds to aluminium hydroxide.

The reduction in folate absorption in this study was small and unlikely to be clinically relevant. It is possible that an individual taking **aluminium antacids** long-term and with marginal dietary folate might become folate deficient.

As neither **cimetidine** nor **ranitidine** caused a significant reduction in the absorption of folic acid, it is unlikely that other H_2-receptor antagonists would interact, although there is no published data to confirm this.

1. Russell RM, Golner BB, Krasinski SD, Sadowski JA, Suter PM, Braun CL. Effect of antacid and H_2 receptor antagonists on the intestinal absorption of folic acid. *J Lab Clin Med* (1988) 112, 458–63.

Folic acid + Sulfasalazine

Sulfasalazine can reduce the absorption of folic acid.

Clinical evidence, mechanism, importance and management

The absorption of folic acid was reduced by about one-third (from 65% to 44.5%) in patients with ulcerative and granulomatous colitis, when compared with healthy subjects, and even further reduced (down to 32%) when sulfasalazine was taken.[1] Another study confirmed that serum folate levels are lower in patients with ulcerative colitis taking sulfasalazine, and that the mechanism was an impairment of folate absorption brought about by sulfasalazine.[2] Sulfasalazine is also known to interfere with folate metabolism.

It is well established that sulfasalazine is, rarely, associated with blood dyscrasias due to folate deficiency and also other haematological toxicities, and consequently regular blood counts are recommended to detect this. The effects of folate deficiency (e.g. macrocytosis, pancytopenia) can be normalised by giving folic acid or folinic acid.

2. Halsted CH, Gandhi G, Tamura T. Sulfasalazine inhibits the absorption of folates in ulcerative colitis. *N Engl J Med* (1981) 305, 1513–17.

Iron compounds + Antacids

The absorption of iron and the expected haematological response to iron can be reduced by the concurrent use of antacids.

Clinical evidence

(a) Iron compounds

A study in healthy subjects who were mildly iron-deficient (due to blood donation or menstruation) found that about 5 mL of *Mylanta II* (**aluminium/magnesium hydroxide** with simeticone) had little effect on the absorption of 10 or 20 mg of **ferrous sulfate** at 2 hours. However, **sodium bicarbonate** 1 g almost halved the absorption of **ferrous sulfate**.[1] Another study in healthy iron-replete subjects found that an antacid containing **aluminium/magnesium hydroxide** and **magnesium carbonate** reduced the absorption of **ferrous sulfate** and **ferrous fumarate** (both containing 100 mg of ferrous iron) by 37% and 31%, respectively.[2] Poor absorption of iron during the use of **sodium bicarbonate** and **aluminium hydroxide** has been described elsewhere.[3,4] One study did not find that the absorption of **ferrous sulfate** (iron 10 mg/kg) was affected by doses of **magnesium hydroxide** (5 mg for every 1 mg of iron) when the doses were given 30 minutes apart.[5] However, it has been suggested that, in this study, iron absorption was not measured for a sufficient period to fully rule out a reduction in absorption.[6]

Oral iron did not produce the expected rise in haemoglobin levels in patients taking non-absorbable alkalis such as **magnesium trisilicate**, and therefore a study was undertaken in 9 patients. Each patient was given 5 mg of isotopically labelled **ferrous sulfate** after a 35-g dose of **magnesium trisilicate**. The **magnesium** reduced the absorption of iron by an average of 70 to 88%, the reduction being small in some patients. However, in one individual iron absorption was reduced from 67% to 5%.[7]

(b) Iron polymaltose

In a study in patients with iron-deficiency anaemia, erythrocyte uptake of iron did not differ when oral iron polymaltose (equivalent to 100 mg of iron) was given alone or with **aluminium hydroxide** 600 mg (10 mL *Am-*

phojel). Iron polymaltose is a complex of ferric hydroxide with isomaltose.[8]

Mechanism

Uncertain. One suggestion is that magnesium sulfate changes ferrous sulfate into less easily absorbed salts, or increases its polymerisation.[7] Carbonates possibly cause the formation of poorly soluble iron complexes.[3] Aluminium hydroxide is believed to precipitate iron as the hydroxide and ferric ions can become intercalated into the aluminium hydroxide crystal lattice,[9] leaving less available for absorption.

Importance and management

Information is limited and difficult to assess because of the many variables (e.g. different dosages ranging from very small to those mimicking overdose, and a mix of subjects and patients). However, a reasonable 'blanket precaution' to achieve maximal absorption would be to separate the administration of iron preparations and antacids as much as possible to avoid admixture in the gut. This may not prove to be necessary with some preparations. For example, iron polymaltose does not appear to be affected by aluminium hydroxide.

Consider also 'Iron compounds + Calcium compounds', p.1405, for the effects of calcium compounds, some of which may be used as antacids.

Iron compounds + Beverages

Reduced iron absorption has been reported with beverages high in polyphenolics such as cocoa, coffee, tea, pennyroyal tea and peppermint tea. Chamomile tea, green tea and rooibos tea do not appear to significantly affect iron absorption.

Clinical evidence

(a) Chamomile

A study in 13 healthy subjects found that chamomile tea (an infusion of *Matricaria chamomilla*) sweetened with panela (an unrefined cane sugar sweetener containing fructose) did not affect the absorption of iron from an iron-fortified bread, when compared with the absorption of iron from the bread alone. The tannin content of the chamomile tea was reported to be 24.5 mg in 100 mL.[1]

(b) Cocoa

In a study in 10 healthy subjects[2] a 275 mL serving of cocoa beverage reduced the absorption of radiolabelled iron from a 50 g bread roll by about 70%. In this study, the inhibitory effect of cocoa beverage on iron absorption was only slightly less that of black tea (Assam tea, *Camellia sinensis* L.).

(c) Coffee

In a series of studies in healthy subjects, drinking 200 mL of coffee with various test meals containing radiolabelled iron resulted in a 39% to 83% reduction in the absorption of iron. No decrease was observed if the coffee was drunk one hour before the meal, but when the coffee was given one hour after the meal the reduction was the same as taking it simultaneously with the meal. With one meal, the effect of coffee was about half that of tea.[3] In another study, a 275 mL serving of instant coffee reduced the absorption of radiolabelled iron from a 50 g bread roll, and this was not affected by milk.[2]

A controlled study among pregnant women in Costa Rica found that coffee consumption was associated with reductions in the haemoglobin levels and haematocrits of the mothers during pregnancy, and of their babies shortly after birth, despite the fact that the women were taking ferric sulfate 200 mg and 500 micrograms of folate daily. The babies also had a slightly lower birth weight (3189 g versus 3310 g). Almost a quarter of the mothers were considered to have iron-deficiency anaemia (haemoglobin levels of less than 11 g/dL), compared with none among the control group of non-coffee drinkers. Levels of iron in breast milk were reduced by about one-third. The coffee drinkers drank more than 450 mL of coffee daily, equivalent to more than 10 g of ground coffee.[4]

In a randomised study in Guatemalan infants, discontinuing coffee intake in those given an iron supplement led to a greater increase in serum ferritin than continuing coffee consumption (median 891 mL weekly). However, discontinuing coffee had no effect on changes in haemoglobin.[5]

(d) Pennyroyal

In a study in 9 healthy subjects, a 275 mL serving of pennyroyal tea reduced the absorption of iron in a 50 g bread roll by about 70%. The tea was prepared by adding 300 mL of boiling water to 3 g of the herbal tea, then infusing for 10 minutes before straining and serving. In this study, the inhibitory effect of pennyroyal tea on iron absorption was modestly less than that of black tea (Assam tea, *Camellia sinensis* L.).[2]

(e) Peppermint tea

In a study in 9 healthy subjects a 275 mL serving of peppermint tea reduced the absorption of iron from a 50 g bread roll by about 85%. The tea was prepared by adding 300 mL of boiling water to 3 g of the herb tea, then infusing for 10 minutes before straining and serving.[2] In this study, the inhibitory effect of peppermint tea on iron absorption was equivalent to that of black tea (Assam tea, *Camellia sinensis* L.).

(f) Rooibos

In a parallel group study in healthy subjects, mean iron absorption after ingestion of radiolabelled iron 16 mg with a beverage was 7.25% with rooibos tea, 1.7% with tea, and 9.34% with water.[6]

(g) Tea

1. Black tea. There is little data on the effect of tea on the absorption of iron from supplements. One case report describes an impaired response to iron, given to correct iron-deficiency anaemia, in a patient drinking 2 litres of black tea daily. The patient recovered when the black tea was stopped. This report did not specify whether the black tea was tea without milk, or black (fermented) tea.[7]

Some short-term controlled studies show a marked reduction in the absorption of dietary non-haem iron with black (fermented) tea beverage, some of which are cited for information.[2,3,8,9] In one of these, in a series of studies in healthy subjects, a 275 mL serving of black (fermented, Assam) tea reduced the absorption of radiolabelled iron from a 50 g bread roll by 79 to 94%. The tea was prepared by adding 300 mL of boiling water to 3 g of Assam tea, then infusing for 10 minutes before straining and serving. Milk added to the tea had very little effect on the reduction in iron absorption.[2] A study found that 150 mL of black tea reduced the absorption of radiolabelled iron from a test meal by 59% in 10 women with iron deficiency anaemia and by 49% in 10 control subjects without anaemia. When the quantity of tea was increased to 300 mL iron absorption was reduced by about 66% in both groups.[10]

Whether these reductions in iron absorption are important in the development of iron deficiency anaemia is less clear. Various epidemiological studies have looked at the correlation between tea consumption and iron deficiency in different populations. In one review of 16 of these studies, tea consumption did not influence iron status in people with adequate iron stores (as is common in the West), but there seemed to be a negative association between tea consumption and iron status in people with marginal iron status.[11] Another report describes no change in the absorption of a single dose of iron (2 to 15.8 mg/kg) in 10 iron-deficient children when the iron was given with 150 mL of tea (type unspecified) instead of water.[12]

2. Green tea. A study found that green tea extract (37 mg catechins) showed a modest 26% reduction in iron absorption,[13] and another study, of pure epigallocatechin gallate 150 mg and 300 mg, found only a 14% and 27% reduction in iron absorption, respectively.[14] A study in 4 elderly patients with iron deficiency anaemia and 11 control patients found no evidence that green tea inhibited the absorption of iron from sodium ferrous citrate.[15] Another study in pregnant women with iron deficiency anaemia reported a slightly higher resolution rate for anaemia in patients taking green tea.[16]

Note that tea has been used with some success in reducing iron accumulation and the frequency of phlebotomy in patients with iron overload syndromes.[17]

Mechanism

Tannins found in tea and polyphenolics found in cocoa, coffee, pennyroyal and peppermint tea are thought to form insoluble complexes with non-haem iron and thus reduce its absorption.[12] Chamomile tea and rooibos tea, which appear not to interact, contain much lower levels of tannins than black tea.

Importance and management

The general importance of these findings is uncertain, but be aware that black tea consumption may contribute to iron-deficiency anaemia. However, it has been suggested that no restrictions are required in healthy patients not at risk of iron deficiency.[18] Conversely, the suggestion is that patients at risk of iron deficiency (which would include those requiring iron supplements) should be advised to avoid tea with meals and for one hour after eating.[18] Note that tea is not generally considered to be a suitable drink for babies and children, because of its effects on iron absorption. Milk does not attenuate the effect of black (fermented) teas on iron absorption.

Other teas and beverages that may have similar effects to black tea appear to include cocoa, coffee, pennyroyal tea and peppermint tea.

Other teas that appear to have minimal interactions with iron include chamomile tea, green tea, and rooibos tea.

Iron compounds + Calcium compounds

Calcium carbonate and calcium acetate (in large doses) modestly reduce the absorption of iron from ferrous sulfate.

Clinical evidence, mechanism, importance and management

In a single-dose study in 23 fasting healthy subjects,[1] the bioavailability of iron from **ferrous sulfate** 200 mg was reduced by 27% by **calcium acetate** 2.7 g, and by 19% by **calcium carbonate** 3 g.

A study in healthy subjects who were mildly iron-deficient (due to blood donation or menstruation) found that **calcium carbonate** 500 mg reduced the absorption of 10 or 20 mg of **ferrous sulfate** by two-thirds. Conversely, iron absorption from a multivitamin and mineral preparation was little affected by whether or not the tablet contained 200 mg of calcium (as **calcium carbonate**).[2]

It was suggested that calcium may form insoluble complexes with iron, so reducing its absorption.

The evidence is limited, but in general it appears that large doses of calcium compounds (500 mg of calcium or more) may reduce the absorption of iron; this would be expected to be clinically relevant. Ideally the findings of the study using calcium in phosphate-binding doses need replicating clinically, that is, in an appropriate patient group taking the calcium compounds long-term with meals. Nevertheless, a reasonable 'blanket precaution' to achieve maximal absorption would be to separate the administration of iron preparations and calcium as much as possible to avoid admixture in the gut. It would also seem prudent to monitor the response to iron. If the response is inadequate in those using calcium as a phosphate binder, an alternative may be to use sevelamer, which does not appear to affect iron absorption, see 'Iron compounds + Sevelamer', p.1406.

Iron compounds + Colestyramine

Early *animal* studies found that colestyramine binds with ferrous sulfate in the gut and reduces its absorption, but iron deficiency was not seen in one small long-term clinical study.

Clinical evidence, mechanism, importance and management

In vitro studies have found that colestyramine binds with iron, and in *rats* this was found to halve the absorption of a single 100-microgram dose of **ferrous sulfate**,[1] and to significantly decrease serum iron and tissue iron stores with prolonged colestyramine use (in the absence of iron supplementation).[2] However, in 18 children, the prolonged use (1 to 2.5 years) of colestyramine did not change serum iron levels.[3]

Evidence is extremely limited, but it might suggest that no special precautions are required on concurrent use. Nevertheless, it is often advised to avoid other drugs for one hour before or 4 to 6 hours after colestyramine to minimise the possibility of interactions.

Iron compounds + H_2-receptor antagonists

Apart from a brief and unconfirmed report alleging that cimetidine reduced the response to ferrous sulfate, there appears to be no other evidence that H_2-receptor antagonists reduce the absorption of iron to a clinically relevant extent. Iron causes only a small and clinically irrelevant reduction in the serum levels of cimetidine and famotidine.

Clinical evidence, mechanism, importance and management

(a) Effect on iron

A brief report describes 3 patients taking **cimetidine** 1 g and **ferrous sulfate** 600 mg daily, whose ulcers healed after 2 months but whose anaemia and altered iron metabolism persisted. When the **cimetidine** was reduced to 400 mg daily the blood picture resolved satisfactorily within a month, without an alteration in the iron dose.[1] The author of the report attributed this response to the **cimetidine**-induced rise in gastric pH, which reduced the absorption of the iron. However, this suggested mechanism was subsequently disputed, as medicinal iron is already in the most absorbable form, Fe^{2+}, and so does not need an acidic environment to aid absorption.[2]
A study in patients with iron deficiency, or iron-deficiency anaemia, found that the concurrent use of **famotidine**, **nizatidine**, or **ranitidine**, did not affect their response to 2.4 g of **iron succinyl-protein complex** (equiva-

lent to 60 mg of iron twice daily).[3] No special precautions would seem necessary on concurrent use.

(b) Effect on H_2-receptor antagonists

In a series of three studies, healthy subjects were given **cimetidine** 300 mg with **ferrous sulfate** 300 mg, either as a tablet or a solution. The reductions in the AUC and the maximum serum levels of **cimetidine** were small (less than 16%). In the third experiment they were given **famotidine** 40 mg with **ferrous sulfate** 300 mg (as a tablet). Again, the AUC and maximum serum level reductions were also very small (10% or less). These small reductions are almost certainly due to the formation of a weak complex between the iron and these H_2-receptor antagonists.[4] An *in vitro* study with **ranitidine** found that, while it also binds with iron, it forms a very weak complex, and is less likely to bind than **cimetidine** or **famotidine**.[4] It was concluded that no clinically relevant interaction occurs between **ferrous sulfate** and any of these H_2-receptor antagonists.[4]

Iron compounds + Neomycin

Neomycin may alter the absorption of iron.

Clinical evidence, mechanism, importance and management

A study in 6 patients found that neomycin markedly reduced the absorption of iron ($iron^{59}$ as **ferrous citrate**) in 4 patients, but increased its absorption in the other 2 patients who initially had low serum iron levels. None of the patients were anaemic at any time.[1] The importance of this is uncertain, but consider this possible interaction if the response to iron is poor.

1. Jacobson ED, Chodos RB, Faloon WW. An experimental malabsorption syndrome induced by neomycin. *Am J Med* (1960) 28, 524–33.

Iron compounds + Sevelamer

Sevelamer does not appear to affect the absorption of iron from ferrous sulfate to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a single-dose study in 23 fasting healthy subjects,[1] the bioavailability of iron from **ferrous sulfate** 200 mg was reduced by a modest 10% by sevelamer 2.8 g. This study suggests that sevelamer is unlikely to have a clinically relevant effect on iron absorption; however, the findings need replicating in an appropriate patient group taking sevelamer long-term with meals.

1. Pruchnicki MC, Coyle JD, Hoshaw-Woodard S, Bay WH. Effect of phosphate binders on supplemental iron absorption in healthy subjects. *J Clin Pharmacol* (2002) 42, 1171–6.

Iron compounds + Vitamin E substances

Vitamin E impaired the response to iron in a group of anaemic children.

Clinical evidence, mechanism, importance and management

A group of 26 anaemic children aged 7 to 40 months were given **iron dextran** 5 mg/kg daily for 3 days. Vitamin E 200 units daily was also given to 9 of the children, starting 24 hours before the **iron dextran** and continued for a total of 4 days. It was noted that after 6 days, those taking vitamin E had a reticulocyte response of only 4.4%, compared with 14.4% in the patients not given vitamin E. The vitamin E group also had reduced haemoglobin levels and a lower haematocrit. The reasons are not understood. Check for any evidence of a reduced haematological response in anaemic patients given iron and vitamin E. The authors of the report point out that this dosage of vitamin E was well above the recommended daily dietary intake.[1]

1. Melhorn DK, Gross S. Relationships between iron-dextran and vitamin E in iron deficiency anemia in children. *J Lab Clin Med* (1969) 74, 789–802.

Iron compounds or Vitamin B_{12} + Chloramphenicol

In addition to the serious and potentially fatal bone marrow depression that can occur with chloramphenicol, it may also cause a milder, reversible bone marrow depression, which can oppose the treatment of anaemias with iron or vitamin B_{12}.

Clinical evidence

Two patients receiving **iron dextran** for iron-deficiency anaemia and also given oral chloramphenicol 3 g daily, did not have the expected haematological response to the iron.[1] Four patients receiving vitamin B_{12} for pernicious anaemia were all similarly refractory to **iron dextran** until chloramphenicol (52 to 60 mg/kg for 3 to 7 days) was withdrawn.[1]

Mechanism

Chloramphenicol can cause two forms of bone marrow depression. One is serious and irreversible, and can result in fatal aplastic anaemia, whereas the other is probably unrelated, milder and reversible, and appears to occur at chloramphenicol serum levels of 25 micrograms/mL or more. This occurs because chloramphenicol can inhibit protein synthesis, the first sign of which is a fall in the reticulocyte count, which reflects inadequate red cell maturation. This response to chloramphenicol has been seen in healthy individuals,[2] a series of patients with liver disease,[3] and in anaemic patients[1] receiving iron dextran or vitamin B_{12}.

Importance and management

An established interaction of clinical importance. The authors of one study recommend that chloramphenicol dosages of 25 to 30 mg/kg are usually adequate for treating infections without running the risk of elevating serum levels to 25 micrograms/mL or more, which is when this type of marrow depression can occur.[4] Monitor the effects of using iron or vitamin B_{12} together with chloramphenicol. A preferable alternative would be to use a different antibacterial. Note that chloramphenicol should not be used in patients with pre-existing bone-marrow depression or blood dyscrasias.

Melatonin + Caffeine

Caffeine increases the levels of both endogenous and orally administered melatonin.

Clinical evidence

In a crossover study, 12 healthy subjects were given a single 200-mg dose of caffeine (equivalent to one large or two small cups of coffee), 1 hour before and 1 and 3 hours after a single 6-mg oral dose of melatonin. Caffeine increased the average AUC and maximum levels of melatonin by 120% and 137%, respectively, although the half-life of melatonin was not significantly affected. The interaction was less pronounced in smokers (6 subjects) than in non-smokers (6 subjects).[1] In a similar study, taking caffeine 12 or 24 hours before melatonin did not affect the melatonin levels, although 2 subjects had raised melatonin levels when caffeine was taken 12 hours, but not 24 hours, before melatonin.[2]

In 12 healthy subjects given a single 200-mg dose of caffeine, taken in the evening, *endogenous*, nocturnal melatonin levels were found to be increased, and the AUC of melatonin was increased by 32%.[3]

Mechanism

Caffeine is thought to reduce the metabolism of melatonin by competing for metabolism by the cytochrome P450 isoenzyme CYP1A2.[1-3]

Importance and management

The interaction between caffeine and melatonin appears to be established. Melatonin is produced by the pineal gland in the body and is also available as a supplement in some parts of the world; however, the effects of long-term use of this supplement are unknown. From the above studies, it appears that caffeine significantly increases the levels of single doses of supplementary melatonin, however the long-term effects of caffeine on multiple doses of melatonin do not appear to have been studied. Melatonin can cause drowsiness when taken on its own, so patients who take melatonin should be advised that this effect may be increased (because of increased melatonin levels) if they also take caffeine, including that from beverages. This increased drowsiness may oppose the stimulating effect of caffeine, or alternatively caffeine may diminish the sedating effects of melatonin; the outcome of concurrent use does not appear to have been studied.

Melatonin + Fluvoxamine

Fluvoxamine markedly increases the levels of endogenous and orally administered melatonin.

Clinical evidence

In a study in 5 healthy subjects, a single 50-mg dose of fluvoxamine taken 3 hours before a single 5-mg oral dose of melatonin markedly increased the average AUC and maximum levels of melatonin by 17-fold and 12-fold, respectively, although the half-life of melatonin was not significantly affected. The interaction was more pronounced in the one subject who was of a CYP2D6-poor metaboliser phenotype (meaning that this patient was lacking or totally deficient in this isoenzyme). All subjects reported marked drowsiness after melatonin intake that was even more pronounced when fluvoxamine was also given.[1]

Similarly, fluvoxamine 75 mg raised the levels of oral melatonin 5 mg by about 20-fold and significantly improved the sleep behaviour of a 51-year-old insomniac.[2]

In another study in 7 healthy subjects, fluvoxamine 50 mg doubled the maximum serum levels and excretion of endogenous melatonin and increased the AUC by about threefold.[3]

Mechanism

Previous studies had shown that fluvoxamine increased endogenous melatonin levels. This study demonstrates that this is likely to be via a pharmacokinetic mechanism. Fluvoxamine is known to be a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which melatonin is metabolised.

Importance and management

Evidence is limited, but an interaction between fluvoxamine and melatonin would appear to be established. Melatonin is produced by the pineal gland in the body, and is also available as a supplement; however, the effects of long-term use of this supplement are unknown. From the above study, it appears that fluvoxamine markedly increases the levels of single doses of supplementary melatonin, however the long-term effects of fluvoxamine on multiple doses of melatonin do not appear to have been studied. Be aware that excessive drowsiness and related adverse effects may occur on concurrent use. Note that one UK manufacturer advises that the combination should be avoided.[4] Other inhibitors of CYP1A2 may interact similarly (although to a lesser extent as fluvoxamine is currently the most potent CYP1A2 inhibitor in clinical use). The UK manufacturer specifically mentions the **quinolones**.[4] Of the quinolones in common usage, ciprofloxacin is an example of a clinically important CYP1A2 inhibitor.

Note that this effect would not be expected with other SSRIs, as these are not CYP1A2 inhibitors.

Melatonin + Miscellaneous

Alcohol may reduce the effects of melatonin on sleep. The concurrent use of imipramine and melatonin may lead to increased CNS effects. Cimetidine slightly increases melatonin levels. Psoralens are predicted to increase melatonin levels.

Clinical evidence, mechanism, importance and management

(a) Alcohol

The manufacturer of melatonin briefly notes that alcohol reduces the effectiveness of melatonin on sleep, and that it should not be taken with melatonin.[1] Given the known effects of alcohol on sleep, if melatonin is being taken to improve quality of sleep then this is sensible advice.

(b) Cimetidine

In a single-dose controlled study, cimetidine 800 mg increased the plasma concentration of melatonin after a 2 mg oral dose (magnitude not stated), whereas the plasma levels of cimetidine were unaffected. The pharmacodynamics of melatonin were not affected.[2] Cimetidine is a weak inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which melatonin is principally metabolised. Therefore concurrent use results in raised melatonin levels. However, as cimetidine is a weak CYP1A2 inhibitor, the pharmacokinetic interaction would be unlikely to be clinically relevant. Nevertheless, the manufacturer recommends caution.[1] Be aware of a possible interaction if there is an increase in the adverse effects of melatonin (e.g. irritability, dry mouth, dizziness) on concurrent use. Other H_2-receptor antagonists are unlikely to interact as they are not known to have enzyme-inhibiting effects.

(c) Psoralens

The manufacturer briefly notes that **methoxsalen** and **5-methoxypsoralen** inhibit the metabolism of melatonin and increases its levels (magnitude not stated).[1] Note that 5-methoxypsoralen has been shown to increase endogenous melatonin levels (one study is cited as an example[3]).

Psoralens are potent inhibitors of the cytochrome P450 isoenzyme CYP1A2 by which melatonin is principally metabolised, and therefore concurrent use may be expected to raise melatonin levels. The manufacturer of melatonin recommends caution on concurrent use,[1] which seems prudent as the adverse effects of melatonin may be increased. Any interaction would only apply to these psoralens used orally, and not when they are used topically. Be aware of a possible interaction if there is an increase in the adverse effects of melatonin (e.g. irritability, dry mouth, dizziness) in patients also taking psoralens.

(d) Tricyclics

In a single-dose controlled study, there was no pharmacokinetic interaction between melatonin 2 mg and **imipramine** 75 mg. However, there was a possible pharmacodynamic interaction, with increased feelings of tranquillity and difficulty in performing tasks (undefined) when compared with **imipramine** alone.[1,2] This may potentially occur with all tricyclics. Patients should be warned of a possible additive effect.

Melatonin + Oestrogens

Oestrogens, from oral combined hormonal contraceptives, appear to increase melatonin levels.

Clinical evidence

In a clinical study, the AUC and maximum level of a single 6-mg dose of melatonin was about 4 times higher in subjects taking a an oral combined hormonal contraceptive than those not taking this type of contraceptive. Melatonin alone did not significantly affect alertness in this study, and no reduced alertness was noted in those taking oral contraceptives. The contraceptives being used by the women included **ethinylestradiol** with either cyproterone acetate, desogestrel, drospirenone or gestodene. There did not appear to be any obvious differences between these contraceptives, but the numbers of women taking each were too small for this to be conclusive.[1]

Mechanism

Ethinylestradiol is a moderate inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which melatonin is principally metabolised.

Importance and management

Women taking oral combined hormonal contraceptives may have higher levels of melatonin after using supplements. Although in the study cited, this did not decrease alertness, it would be prudent to bear in mind the possibility of increased drowsiness. One UK manufacturer extends this caution to **hormone replacement therapy**,[2] although it is unclear whether the oestrogens used for HRT will have the same effect as ethinylestradiol.

2. Circadin (Melatonin). Lundbeck Ltd. UK Summary of product characteristics, March 2009.

Melatonin + Tobacco

Tobacco smoking reduces melatonin levels.

Clinical evidence, mechanism, importance and management

In a study in 8 tobacco smokers, the AUC of a single 25-mg dose of melatonin was almost threefold higher when the melatonin was taken after 7 days of smoking abstinence than when taken while smoking.[1]

Constituents of tobacco smoke are minor to moderate inducers of the cytochrome P450 isoenzyme CYP1A2, by which melatonin is principally metabolised.

The finding of this study suggests that melatonin might not be as effective in smokers. Be aware of this possibility, and consider trying an increased melatonin dose if it is not effective in a smoker.

1. Ursing C, von Bahr C, Brismar K, Röjdmark S. Influence of cigarette smoking on melatonin levels in man. *Eur J Clin Pharmacol* (2005) 61, 197–201.

Nicotine + Grapefruit juice

Grapefruit slightly inhibits the metabolism and increases the renal clearance of oral nicotine.

Clinical evidence, mechanism, importance and management

In a single-dose pharmacokinetic study in healthy subjects, administration of oral nicotine 2 mg with full-strength and half-strength grapefruit juice reduced the AUC of conitine (a metabolite of nicotine) by 15% and 2.5%, respectively. Conversely, the renal clearance of nicotine was increased. It was suggested that grapefruit juice inhibits the cytochrome P450 isoenzyme CYP2A6, which is responsible for the metabolism of oral nicotine to cotinine.[1]

The changes seen here were small and unlikely to be clinically relevant. Note that nicotine is not usually given by the oral route as in this study: replacement therapy is by the buccal route (chewing gum or sublingual tablets), or the transdermal route.

1. Hukkanen J, Jacob P, Benowitz NL. Effect of grapefruit juice on cytochrome P450 2A6 and nicotine renal clearance. *Clin Pharmacol Ther* (2006) 80, 522–30.

Nicotine + Tranylcypromine

Tranylcypromine inhibits the metabolism of oral nicotine.

Clinical evidence, mechanism, importance and management

A brief report describes a study in smokers in which low-dose tranylcypromine 2.5 mg three times daily increased plasma levels of oral nicotine by about 75%, but did not affect subcutaneous nicotine. Tranylcypromine inhibits the cytochrome P450 isoenzyme CYP2A6, which is responsible for the metabolism of oral nicotine to cotinine. Inhibiting this step leads to raised nicotine levels.[1]

Note that nicotine is not usually given orally. The clinical relevance of this finding to buccal formulations of nicotine replacement therapy (chewing gum and sublingual tablets) is unknown, but it seems likely to be small.

1. Fernandes LC, Tyndale RF, Sellers EM. Tranylcypromine (TCP) inhibition of nicotine metabolism. *Drug Alcohol Depend* (2002) 66 (Suppl 1) S54–S55.

Nicotine + Vasopressin

A case report described marked hypotension and bradycardia in a young woman during surgery, which was attributed to the combined effects of a vasopressin injection and nicotine from a transdermal patch.

Clinical evidence

A 22-year-old woman in good health was anaesthetised for surgery with nitrous oxide/oxygen and isoflurane. Twenty minutes after induction she was given an injection of 0.2 units of vasopressin into the cervix. Within seconds she developed severe hypotension and bradycardia, and over the next 30 minutes blood pressures as low as 70/35 mmHg and heart rates as low as 38 bpm were recorded. She was given atropine and adrenaline (epinephrine), and eventually made a full recovery. This patient was wearing a transdermal nicotine patch.[1]

Mechanism

The circulatory collapse was attributed by the authors to the combined effects of the injected vasopressin and the nicotine from the transdermal patch. Both of these drugs can increase cardiac afterload and cause coronary artery vasoconstriction, which the authors suggest may have decreased the blood supply to the heart and resulted in cardiac depression.[1]

Importance and management

This is an isolated report and any interaction between nicotine and vasopressin is therefore not well established. Nevertheless the recommendation of the authors seems sensible, namely that nicotine patches should be removed the night before or 24 hours before surgery, and that patients should be asked to avoid smoking before surgery to make sure that nicotine levels are minimal. More study is needed.

Paricalcitol + Miscellaneous

Ketoconazole raises paricalcitol levels; other potent CYP3A4 inhibitors are predicted to interact similarly. The use of paricalcitol increases the risks of raised calcium, phosphate, aluminium, or magnesium levels in patients taking drugs containing these substances, or drugs that raise the levels of these substances (e.g. vitamin D).

Clinical evidence, mechanism, importance and management

(a) CYP3A4 inhibitors

In a study in healthy subjects, **ketoconazole** 200 mg twice daily for 5 days did not significantly alter the maximum levels of paricalcitol, but the AUC of paricalcitol was doubled, and its half-life was prolonged from 9.8 hours

to 17 hours.[1,2] On the basis of this interaction the US manufacturer predicts that other potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 will interact similarly. They specifically name the protease inhibitors **atazanavir**, **indinavir**, **nelfinavir**, **ritonavir** and **saquinavir**; the azole antifungals **itraconazole** and **voriconazole**; and the macrolides **clarithromycin** and **telithromycin**. The manufacturer recommends close monitoring if any of these drugs is given to a patient taking paricalcitol,[2] and recommend monitoring intact parathyroid hormone and calcium levels if drugs such as **ketoconazole** are started or stopped.[1,2]

(b) Other drugs

Paricalcitol use may lead to increased calcium and phosphate levels. The UK manufacturer therefore warns that the concurrent use of **calcium-** or **phosphate-containing substances** may increase this risk. They specifically advise against the concurrent use of **phosphate-containing substances** with paricalcitol.[1] In addition the concurrent use of **vitamin D** may increase the risk of hypercalcaemia, and should therefore be avoided where possible. The UK manufacturer also advises that the use of **aluminium-** and **magnesium-containing substances** (e.g. **antacids**, phosphate binders) should be avoided with paricalcitol because raised blood levels of these substances may occur.[1] However, note that patients with renal impairment are highly likely to be taking these drugs and having serum electrolyte levels frequently monitored. Furthermore the US manufacturer[2] does not advise against their concurrent use.

2. Zemplar Injection (Paricalcitol). Abbott Laboratories. US Prescribing information, January 2009.

Paricalcitol + Omeprazole

The pharmacokinetics of paricalcitol are not affected by omeprazole.

Clinical evidence, mechanism, importance and management

A randomised study in 25 healthy subjects found that a single 40-mg dose of omeprazole, taken 2 hours before a single 16-microgram dose of paricalcitol, had no significant effects on the pharmacokinetics of paricalcitol. No increase in adverse effects was noted and the combination was reported to be well tolerated. No paricalcitol dosage adjustments are therefore necessary if omeprazole is also given.[1]

1. Palaparthy R, Pradhan RS, Chan J, Rieser M, Chira T, Galitz L, Awni W, Williams LA. Effect of omeprazole on the pharmacokinetics of paricalcitol in healthy subjects. *Biopharm Drug Dispos* (2007) 28, 65–71.

St John's wort (*Hypericum perforatum*) + Cimetidine

Cimetidine does not significantly alter the metabolism of the constituents of St John's wort hypericin and pseudohypericin.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in healthy subjects taking St John's wort (*LI160, Lichtwer Pharma*) 300 mg three times daily found that, apart from a modest 25% increase in the AUC of pseudohypericin, cimetidine 1 g daily (in divided doses) did not significantly affect the pharmacokinetics of either the hypericin or pseudohypericin constituents of St John's wort. The available evidence therefore suggests that cimetidine is unlikely to affect the dose requirements of St John's wort.[1]

1. Johne A, Perloff ES, Bauer S, Schmider J, Mai I, Brockmöller J, Roots I. Impact of cytochrome P-450 inhibition by cimetidine and induction by carbamazepine on the kinetics of hypericin and pseudohypericin in healthy volunteers. *Eur J Clin Pharmacol* (2004) 60, 617–22.

St John's wort (*Hypericum perforatum*) + Loperamide

Delirium occurred in a woman taking St John's wort and valerian when she took loperamide.

Clinical evidence, mechanism, importance and management

A 39-year-old woman with a history of depression was hospitalised in a state of delirium. She had been taking St John's wort and valerian for 6 months (products and doses not stated) and had recently taken loperamide for diarrhoea.[1]

The authors speculated that this was an interaction between St John's wort and loperamide attributed to the MAO inhibitory activity of St John's wort, analogous to the interaction between non-selective MAOIs and 'pethidine (meperidine)', (p.1381). However, St John's wort is not thought to act as an MAOI inhibitor, for example, it does not usually cause a hypertensive reaction with 'tyramine-rich food', (below).

This appears to be an isolated report, and its findings cannot be generalised.

1. Khawaja IS, Marotta RF, Lippmann S. Herbal medicines as a factor in delirium. *Psychiatr Serv* (1999) 50, 969–70.

St John's wort (*Hypericum perforatum*) + Tyramine

An isolated report describes a patient taking St John's wort who experienced a hypertensive crisis after consuming tyramine-rich food and drink.

Clinical evidence, mechanism, importance and management

A man who had taken a St John's wort supplement for 7 days (preparation and dose not stated) was admitted to hospital with confusion and disorientation. He was unable to recall events after eating aged cheeses and pouring a glass of red wine 8 hours earlier. On examination he had a pulse rate of 115 bpm, a respiratory rate of 16 breaths per minute and his blood pressure was 210/140 mmHg. He was given intravenous phentolamine and oral labetalol and his blood pressure decreased to 160/100 mmHg after 2 hours and the delirium also resolved. Extensive laboratory investigations did not find any cause for the hypertension and delirium.

It was suggested that the time scale of starting to regularly take St John's wort and the onset of delirium and hypertension after the consumption of tyramine-rich food and drink was suggestive of hypertension associated with MAOIs (see also 'MAOIs or RIMAs + Tyramine-rich foods', p.1395, and 'MAOIs or RIMAs + Tyramine-rich drinks', p.1393). Although St John's wort is a potent inhibitor of monoamine oxidase, this effect has not been demonstrated at recommended doses. It was concluded that the hypertensive crisis in this patient may have been mediated by monoamine oxidase inhibition, but there was also a possibility of another, as yet unknown, pharmacological action of St John's wort being involved.[1] Given the widespread use of St John's wort this case would seem to be unusual, and there is currently little grounds for suggesting any dietary restriction in those taking St John's wort.

Tyramine + Cimetidine

A woman taking cimetidine experienced a severe headache and hypertension when she drank *Bovril* and ate some cheese.

Clinical evidence, mechanism, importance and management

A 77-year-old woman with hiatus hernia, who had been taking cimetidine 400 mg four times daily for 3 years, experienced a severe frontal headache and hypertension, which appeared to be related to the ingestion of a cup of *Bovril* and some English cheddar cheese, both of which can contain substantial amounts of tyramine.[1] Although the authors point out the similarity between this reaction and that seen in patients taking MAOIs who eat tyramine-rich foods (see 'MAOIs or RIMAs + Tyramine-rich foods', p.1395), there is no satisfactory explanation for what occurred. They note that the patient was also taking salbutamol (another sympathomimetic) but rule out any contribution from this drug.

This is an isolated report and there is no reason why in general patients taking cimetidine should avoid tyramine-rich foods.

Vitamin A (Retinol) + Neomycin

Neomycin can markedly reduce the absorption of vitamin A (retinol) from the gut.

Clinical evidence, mechanism, importance and management

In a study in 5 healthy subjects, neomycin 2 g markedly reduced the absorption of a test dose of vitamin A. It is suggested that this was due to a direct chemical interference between the neomycin and bile in the gut, which disrupted the absorption of fats and fat-soluble vitamins.[1] The extent to which long-term treatment with neomycin (or other aminoglycosides) would impair the treatment of vitamin A deficiency has not been determined.

1. Barrowman JA, D'Mello A, Herxheimer A. A single dose of neomycin impairs absorption of vitamin A (Retinol) in man. *Eur J Clin Pharmacol* (1973) 5, 199–201.

Vitamin B_{12} + Miscellaneous

Neomycin, colchicine, aminosalicylic acid and H_2-receptor antagonists can reduce the absorption of vitamin B_{12} from the gut, but no interaction is likely when B_{12} is given by injection.

Clinical evidence, mechanism, importance and management

Neomycin causes a generalised malabsorption syndrome, which has been shown[1] to reduce the absorption of vitamin B_{12}. **Colchicine** has also been shown to decrease B_{12} absorption.[1] **Aminosalicylic acid** reduces vitamin B_{12} absorption for reasons that are not understood, but which are possibly related to a mild generalised malabsorption syndrome.[2] A review of the literature[3] suggests that H_2-receptor antagonists (such as **cimetidine** and **ranitidine**) can also reduce vitamin B_{12} absorption, primarily because they reduce gastric acid production. The acid is needed to aid the release of B_{12} from dietary protein sources. There is therefore a possibility that on long-term use patients could become vitamin B_{12} deficient.

Within the context of adverse drug interactions, none of these findings is normally likely to be clinically important, because for anaemia, vitamin B_{12} should be given parenterally, both for convenience and to avoid well-established problems with absorption.

Vitamin D substances + Antiepileptics; Enzyme-inducing

The long-term use of carbamazepine, phenytoin, phenobarbital, or primidone can disturb vitamin D and calcium metabolism and may result in osteomalacia. There are a few reports of patients taking vitamin D supplements who responded poorly to vitamin replacement while taking phenytoin or barbiturates. Serum phenytoin levels are not altered by vitamin D.

Clinical evidence

A 16-year-old with grand mal epilepsy and idiopathic hypoparathyroidism did not adequately respond to **alfacalcidol** 10 micrograms daily and calcium 6 to 12 g daily, apparently because **phenytoin** 200 mg and **primidone** 500 mg daily were also being taken. However, when **dihydrotachysterol** 0.6 to 2.4 mg daily was given normal calcium levels were achieved.[1]

Other reports describe patients whose response to usual doses of vitamin D was poor, because of the concurrent use of **phenytoin** and **phenobarbital** or **primidone**.[2-4] Other reports clearly show low serum calcium levels,[5,6] low serum vitamin D levels,[7] osteomalacia,[6] and bone structure alterations[5,7] in the presence of **phenytoin**. **Carbamazepine** may have similar effects, but the evidence is less conclusive.[8,9]

A controlled study in 151 epileptic patients taking **phenytoin** and calcium found that the addition of 2000 units of **vitamin D_2** daily over a 3-month period had no significant effect on serum **phenytoin** levels.[10]

Mechanism

The enzyme-inducing effects of phenytoin and other antiepileptics increases the metabolism of the vitamin D, thereby reducing its effects and disturbing calcium metabolism.[3] In addition, phenytoin may possibly reduce the absorption of calcium from the gut.[1]

Importance and management

The disturbance of calcium metabolism by phenytoin and other enzyme-inducing antiepileptics is very well established, but there are only a few reports describing a poor response to vitamin D. The effects of concurrent treatment should be well monitored. Those who need vitamin D supplements may possibly need greater than usual doses.

Vitamin D substances; Alfacalcidol + Danazol

An isolated report describes hypercalcaemia when a woman taking alfacalcidol also took danazol.

Clinical evidence, mechanism, importance and management

A woman with idiopathic hypoparathyroidism, treated with alfacalcidol, developed hypercalcaemia when she was given danazol 400 mg daily for endometriosis. She needed a reduction in the dosage of alfacalcidol from 4 micrograms daily to 0.75 micrograms daily. When the danazol was stopped 6 months later, the alfacalcidol dosage was raised to 4 micrograms daily and she remained normocalcaemic.[1] The reasons for this interaction are not understood. Its general importance is limited as this appears to be an isolated case.

1. Hepburn NC, Abdul-Aziz LAS, Whiteoak R. Danazol-induced hypercalcaemia in alphacalcidol-treated hypoparathyroidism. *Postgrad Med J* (1989) 65, 849–50.

Vitamin K substances + Antibacterials

Seven patients in intensive care did not respond to intravenous vitamin K for hypoprothrombinaemia while receiving gentamicin and clindamycin.

Clinical evidence, mechanism, importance and management

Some patients, particularly those in intensive care who are not eating, can quite rapidly develop acute vitamin K deficiency, which leads to prolonged prothrombin times and possibly bleeding.[1,2] This can normally be controlled by giving vitamin K parenterally. However, one report describes seven such patients, all with normal liver function, who unexpectedly did not respond to intravenous **phytomenadione**. Examination of their records found that all seven were receiving **gentamicin** and **clin-**

damycin.[2] Just why, or if, these two antibacterials might have opposed the effects of intravenous vitamin K is not understood.

Vitamins + Orlistat

Orlistat decreases the absorption of supplemental betacarotene and vitamin E. There is some evidence to suggest that some patients may have low vitamin D levels while taking orlistat, even if they are also taking multivitamins.

Clinical evidence

Studies in healthy subjects have found that about two-thirds of a supplemental dose of **betacarotene**[1] and roughly half the dose of **vitamin E** (**α-tocopherol**)[2] was absorbed in the presence of orlistat, while the absorption of **vitamin A** was not affected.[2] In the first study, betacarotene was given within about 30 minutes of the orlistat,[1] whereas in the second, the vitamin supplement was given at the same time as orlistat.[2] In another study, 17 obese adolescents were given orlistat 120 mg three times daily with meals and a daily multivitamin (containing **vitamins A**, **D**, **E**, and **K**) to be taken at night. Levels of **vitamins A**, **E** and **K** were not significantly altered over 6 months of orlistat use, but **vitamin D** concentrations dropped after the first month, but had returned to baseline by 3 months. Three subjects (all African-Americans) required additional **vitamin D** supplementation, but all had a low dietary intake of **vitamin D**.[3,4]

Mechanism

Orlistat reduces dietary fat absorption by inhibiting gastrointestinal lipase. Consequently, it reduces the absorption of fat soluble vitamins.

Importance and management

An established interaction. To maximise vitamin absorption, the manufacturers recommend that any multivitamin preparation should be taken at least 2 hours before or after orlistat, such as at bedtime.[5,6] The US manufacturer suggests that patients taking orlistat should be advised to take multivitamins, because of the possibility of reduced vitamin levels.[6] Note that the authors of the study in adolescents suggest that monitoring of vitamin D may be required, even if multivitamins are given.[3]

Zinc compounds + Iron compounds

Some studies suggest that giving iron with zinc may reduce the bioavailability of iron and/or zinc, but other studies suggest that combined supplementation is of value in reducing deficiencies of these micronutrients.

Clinical evidence

In a study, 549 Indonesian infants were given dietary supplementation from age 6 months until age 12 months with either iron 10 mg (as **ferrous sulfate**), zinc 10 mg (as **zinc sulfate**), iron 10 mg plus zinc 10 mg, or placebo. After supplementation, the iron group and the iron plus zinc groups had haemoglobin levels of 11.9 g/dL and 11.5 g/dL respectively and serum ferritin of 46.5 micrograms/L and 32.3 micrograms/L respectively. The haemoglobin level in the group receiving zinc and iron was not significantly different from that of the placebo group. Zinc levels were lower in infants given zinc with iron than in those given zinc alone, but this difference was not found to be significant. It was concluded that supplementation with iron plus zinc was less effective than single supplements in improving iron and zinc status.[1] Similar conclusions were reached in another study using the same doses of iron and zinc.[2] A further study in 784 infants aged 4 to 7 months given iron 10 mg or zinc 10 mg alone or combined, or placebo, daily for 6 months found that haemoglobin levels were increased by about 2.3 g/dL and 2.1 g/dL when given alone or with zinc, respectively, and zinc levels were increased by 10.3 micromol/L and 8 micromol/L when given alone or with iron, respectively. Although combined iron and zinc supplements had a positive effect on iron status, iron was found to have a negative effect on zinc status in these infants.[3] Similar conclusions were reached from pooled results from 4 studies in 2468 infants given iron 10 mg and/or zinc 10 mg daily for 6 months.[4]

In a study in 14 healthy subjects, iron 500 micrograms (as **ferrous sulfate** solution) was given alone or with zinc 590 micrograms (as **zinc sulfate**) on day 1, and iron 10 mg was given alone or with zinc 11.71 mg on day 14. At the lower doses, zinc did not affect iron bioavailability, but at the higher doses, iron bioavailability was reduced by 56%.[5]

Another study in ileostomy patients given zinc 12 mg alone, with iron 100 mg or 400 mg (as **ferrous gluconate**) on three consecutive days, found zinc absorption was 44% when given alone and significantly decreased to 26% and 23% when given with iron 100 mg or 400 mg, respectively.[6]

Mechanism

One study suggests that iron affects zinc absorption in a dose-dependent manner.[6] Reduced bioavailability of iron supplements when given with zinc may depend on the total amount of both iron and zinc in the intestine, as at high doses, but not low doses, zinc appears to affect iron bioavailability.[5] In some studies in infants and children, it has been suggested that the age of the child and initial serum zinc status may partly explain differences in reported effects.[7,8] Iron supplementation may have a greater effect on haemoglobin levels in boys than in girls.[4]

Importance and management

Iron and zinc deficiencies are global problems and they often co-exist.[1,9] Some studies suggest that giving zinc with iron may not improve iron status as much as iron given alone,[1,2,4,5,7] while others suggest zinc status may be negatively affected if it is given with iron.[1,3,6] Even so, some studies found that giving combined iron and zinc was beneficial, even if not optimal.[2-4,7] One study suggests that zinc supplementation has a positive effect on growth if low haemoglobin levels and iron status is also corrected.[10] It has been suggested that supplementation programmes that provide iron and zinc together are an efficient way to provide both micronutrients, provided the benefits of individual supplementation are not lost, but more study is needed before such programmes can be established.[9]

Zinc sulphate + Calcium compounds

Calcium compounds reduce the absorption of zinc.

Clinical evidence, mechanism, importance and management

Elemental calcium, in doses of 600 mg (either as **calcium carbonate** or **calcium citrate**), was given to 9 healthy women with a single 20-mg oral dose of zinc sulphate.[1] The AUC of zinc was reduced by 72% by **calcium carbonate** and by 80% by **calcium citrate**. The reason for this interaction is not understood, nor is the clinical importance of this interaction known, but it would seem prudent to separate the administration of zinc from the administration of any calcium compound. Two to three hours separation is often sufficient to achieve maximal absorption with interactions like this. More study of this interaction is needed to confirm the extent and to determine if separation of the doses is an adequate precaution.

34

Respiratory drugs

This section includes the diverse drugs that are principally used in the management of asthma and chronic obstructive pulmonary disease (COPD), with the exception of corticosteroids, which are covered elsewhere.

(a) Antimuscarinic bronchodilators

The parasympathetic nervous system is involved in the regulation of bronchomotor tone and antimuscarinic drugs have bronchodilator properties. Ipratropium bromide and other antimuscarinic bronchodilators used in COPD are listed in 'Table 34.1', (p.1414). A wide range of drugs have antimuscarinic (anticholinergic) adverse effects. Enhanced antimuscarinic effects occur when drugs with these properties are given concurrently, see 'Antimuscarinics + Antimuscarinics', p.786. However, these interactions do not usually occur with drugs such as ipratropium, given by inhalation.

(b) Beta$_2$-agonist bronchodilators

Salbutamol and terbutaline are examples of short-acting beta agonists that selectively stimulate the beta$_2$ receptors in the bronchi causing bronchodilation. They are used in the treatment of asthma and the management of COPD. Long-acting beta$_2$ agonists such as salmeterol are used in patients with asthma who also require anti-inflammatory therapy. 'Table 34.1', (p.1414) lists the beta$_2$ agonists available. The beta$_2$ agonists represent a significant improvement on isoprenaline (isoproterenol), which also stimulates beta$_1$ receptors in the heart, and on ephedrine, which also stimulates alpha receptors. The beta$_2$ agonists can cause hypokalaemia, which can be increased by the concurrent use of other 'potassium-depleting drugs', (p.1417).

(c) Leukotriene receptor antagonists

Montelukast and zafirlukast block the effects of cysteinyl leukotrienes, which cause effects such as airways oedema, bronchoconstriction and inflammation. The leukotriene receptor antagonists are used in the treatment of asthma, either alone, or with inhaled corticosteroids. They should not be used to relieve an acute asthma attack. Both drugs are metabolised in the liver by the cytochrome P450 isoenzymes such as CYP3A4 and CYP2C9 (montelukast) and CYP2C9 (zafirlukast). Zafirlukast is thought to inhibit CYP2C9 and CYP3A4, and this is thought to be the mechanism for its interaction with 'warfarin', (p.475). There is therefore a possibility that interactions could occur with other drugs that undergo metabolism by these isoenzymes but clinical evidence of this varies.

(d) Phosphodiesterase type-4 inhibitors

Phosphodiesterase type-4 inhibition results in suppression of a number of inflammatory cell functions that are involved in respiratory disease states such as asthma and COPD. Drugs that inhibit this process are currently under investigation, and include roflumilast. Roflumilast is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP1A2, and therefore may be subject to interactions with other drugs that are inducers or inhibitors of these enzymes.

(e) Xanthines

The main xanthines used in medicine are theophylline and aminophylline, the latter generally being preferred when greater water solubility is needed (e.g. in the formulation of injections). Xanthines are given in the treatment of asthma because they relax the bronchial smooth muscle. In an attempt to improve upon theophylline, various different derivatives have been made, such as diprophylline and enprofylline. 'Table 34.1', (p.1414) lists these xanthines. Theophylline is metabolised by the cytochrome P450 isoenzymes in the liver, principally CYP1A2, to demethylated and hydroxylated products. Many drugs interact with theophylline by inhibition or potentiation of its metabolism. In addition, the metabolism of theophylline is affected by gender, smoking, liver and cardiac disease, viral infections and genetic differences in CYP1A2 function. Theophylline has a narrow therapeutic range, and small increases in serum levels can result in toxicity. Moreover, symptoms of serious toxicity such as convulsions and arrhythmias can occur before minor symptoms suggestive of toxicity. Within the context of interactions, aminophylline generally behaves like theophylline, because it is a complex of theophylline with ethylenediamine.

Caffeine is also a xanthine and it is principally used as a central nervous system stimulant, increasing wakefulness, and mental and physical activity. It is most commonly taken in the form of tea, coffee, cola drinks ('*Coke*') and cocoa. 'Table 34.2', (p.1414) lists the usual caffeine content of these drinks. Caffeine is also included in hundreds of non-prescription analgesic preparations with aspirin, codeine and/or paracetamol, but whether it enhances the analgesic effect is debatable. Caffeine is also used to assess the activity of the cytochrome P450 isoenzyme CYP1A2 and can usefully demonstrate altered liver function, notably from drugs, as well as disease states.

Caffeine, like theophylline, also undergoes extensive hepatic metabolism, principally by CYP1A2, and interacts with many drugs, but it has a wider therapeutic range. However, other xanthines may act differently (e.g. diprophylline does not undergo hepatic metabolism), so it should not be assumed that they all share common interactions.

Note though, that all xanthines can potentiate hypokalaemia caused by other drugs and that the toxic effects of different xanthines are additive.

Table 34.1 Respiratory drugs

Group	*Route*	*Drugs*
Antimuscarinics (Anticholinergics)	Inhaled	Ipratropium bromide, Oxitropium, Tiotropium
Beta-2 adrenoceptor agonists	Oral	Bambuterol, Clenbuterol, Reproterol, Salbutamol (Albuterol), Terbutaline
	Inhaled	Short-acting: Bitolterol, Clenbuterol, Fenoterol, Levosalbutamol, Pirbuterol, Procaterol, Reproterol, Salbutamol (Albuterol), Terbutaline, Tulobuterol Long-acting: Arformoterol, Formoterol, Salmeterol
	Intravenous	Reproterol, Salbutamol (Albuterol), Terbutaline
Leukotriene antagonists and inhibitors	Oral	Amlexanox, Ibudilast, Montelukast, Pemirolast, Pranlukast, Zafirlukast
Lipoxygenase inhibitors	Oral	Zileuton
Mast cell stabilisers	Inhaled	Nedocromil sodium, Sodium cromoglicate
	Oral	Amlexanox, Ketotifen, Pemirolast, Tranilast
PDE-4 Inhibitors	Oral	Roflumilast
Sympathomimetics	Oral	Ephedrine, Hexoprenaline, Orciprenaline
Xanthine derivatives	Oral	Aminophylline, Bamifylline, Bufylline, Choline theophyllinate, Diprophylline, Doxofylline, Etamiphylline camsilate, Etofylline, Heptaminol acefyllinate, Proxyphylline, Theophylline
	Intravenous	Aminophylline, Bamifylline

Table 34.2 Caffeine-containing herbs and caffeine-containing drinks

Source	*Caffeine-content*	*Caffeine-content of drink*
Coffee	Coffee beans 1 to 2%[1]	Up to 100 mg/100 mL, decaffeinated up to about 3 mg/100 mL.[1] Instant coffee, 75 mg per cup and 100 mg per mug.[3] Can range from 210 to 340 mg/L,[4] or 21 to 120 mg per serving.[5] Brewed coffee, 100 mg per cup.[5] Ground coffee, 15 to 254 mg per serving.[5] Filter coffee, between 105 and 215 mg/L,[4] or up to 140 mg per mug.[3]
Chocolate		Plain chocolate, up to 50 mg in 50 g.[3] Milk chocolate, up to 25 mg in 50 g.[3] Chocolate bars, between 110 and 710 mg/kg.[4] Chocolate milk drinks, between 8 and 20 mg/L.[4] Chocolate powdered drinks, between 5.5 and 41 mg/L.[4]
Cola drinks		Up to 40 mg per drink;[3] 69 mg/L (range 33 to 213 mg/L)[4] Decaffeinated cola drinks less than 0.2 mg/L.[4]
Energy drinks		Guarana and caffeine containing energy drinks, average 269 mg/L (range 122 to 234 mg/L).[4]
Guarana*	2.5 to 7%[2]	Guarana-containing energy drinks, around 180 mg/L.[4]
Maté (Paraguay tea)	0.2 to 2%[1]	
Tea	1 to 5%[3]	Up to 60 mg/100 mL,[1] caffeine content appears to vary with form (bags, loose tea, instant tea etc.); between 102 and 326 mg/L,[4] or 1 to 90 mg per serving.[5]

*Note that guarana contains guaranine (which is known to be identical to caffeine) as well as small quantities of other xanthines.

Anti-asthma drugs + Areca (Betel nuts)

The chewing of betel nuts may worsen the symptoms of asthma.

Clinical evidence

A study of a possible interaction with betel nuts was prompted by the observation that the severe asthma of two Bangladeshi patients appeared to have been considerably worsened by chewing betel nuts. One out of 4 other patients with asthma who regularly chewed betel nuts developed severe bronchoconstriction (a 30% fall in FEV_1) on two occasions when given betel nuts to chew, and all 4 patients said that prolonged betel nut chewing induced coughing and wheezing. A double-blind study found that the inhalation of **arecoline** (the major constituent of the nut) caused bronchoconstriction in 6 of 7 asthmatics, and one of 6 healthy control subjects.[1] A study in patients with asthma who regularly chewed betel nuts found that 4 patients had a mean increase in their FEV_1 of 10 to 25%, whereas 11 patients had significant falls in their FEV_1 of 11 to 25%. Interestingly, 5 of the patients who did not think chewing betel nut affected their asthma experienced a reduction in their FEV_1.[2]

A survey in 61 patients with asthma found that 22 of the 34 patients who still chewed betel nuts, either for occasional use or regularly, reported that it worsened their asthma.[3]

Mechanism

Betel nut 'quids' consist of areca nut (*Areca catechu*) wrapped in betel vine leaf (*Piper betle*) and smeared with a paste of burnt (slaked) lime. It is chewed for the euphoric effects of the major constituent, arecoline, a cholinergic alkaloid, which appears to be absorbed through the mucous membrane of the mouth. Arecoline has identical properties to pilocarpine and normally has only mild systemic cholinergic properties; however asthmatic subjects seem to be particularly sensitive to the bronchoconstrictor effects of this alkaloid and possibly other substances contained in the nut.

Importance and management

Direct evidence appears to be limited to the above reports, but the interaction seems to be established. It would not normally appear to be a serious interaction, but asthmatics should be encouraged to avoid betel nuts. This is a drug-disease interaction rather than a drug-drug interaction.

Anti-asthma drugs + Beta blockers

Non-cardioselective beta blockers (e.g. propranolol, timolol) should not be used in asthmatic subjects because they may cause serious bronchoconstriction, even if given as eye drops. Non-cardioselective beta blockers oppose the bronchodilator effects of beta-agonist bronchodilators, and higher doses may be required to reverse bronchospasm. Even cardioselective blockers (e.g. atenolol) can sometimes cause acute bronchospasm in asthmatics. However, cardioselective beta blockers do not generally inhibit the bronchodilator effect of beta-agonist bronchodilators.

Clinical evidence

(a) Cardioselective beta blockers

A review of 29 studies (including 19 single-dose studies) on the use of cardioselective beta blockers in patients with reversible airway disease indicated that in patients with mild to moderate disease, the short-term use of cardioselective beta blockers does not cause significant adverse respiratory effects. Information on the effects in patients with more severe or less reversible disease, or on the frequency or severity of acute exacerbations was not available.[1] Another review indicated that when low doses of cardioselective beta blockers are given to patients with mild, intermittent or persistent asthma, or moderate persistent asthma, and heart failure or myocardial infarction, the benefits of treatment outweigh the risks. However, it was considered that further study is required to establish long-term safety, and also that beta blockers should be avoided in severe persistent asthma.[2] A review of patients with asthma or COPD taking a cardioselective beta blocker (2810 patients) or a non-selective beta blocker (287) found no significant difference in admissions to hospital or in length of stay in these patients when compared with 5293 patients with asthma or COPD receiving other cardiovascular medicines.[3]

The cardioselective beta blockers would not be expected to affect the beta receptors in the bronchi, but bronchospasm can sometimes occur following their use by asthmatics and others with obstructive airways diseases, particularly if high doses are used. Deterioration of asthma was reported in a patient taking oral **betaxolol** with **theophylline** and **pranlukast**, although **betaxolol** is considered to be highly cardioselective and less likely to cause pulmonary adverse effects than other cardioselective beta blockers.[4]

No adverse pharmacodynamic interaction normally occurs between beta-agonist bronchodilators and cardioselective beta blockers. This has been demonstrated in studies with:

- **Atenolol** with **salbutamol** (**albuterol**) inhalation.[5,6]
- **Celiprolol** in patients with asthma with **isoprenaline** (**isoproterenol**), or **salbutamol**,[5,7,8] or **terbutaline** infusion or inhalation.[9]
- **Metoprolol** in patients with asthma at rest with **isoprenaline** infusion.[10,11]

In contrast, another study found that the increase in forced expiratory volume (FEV) with a **terbutaline** inhalation and infusion was reduced by about 300 mL by **atenolol** and **metoprolol**. The authors considered that this would be clinically relevant in severe asthma.[12] Another study in 12 patients with mild asthma found that single doses of **celiprolol** 200 mg or **nebivolol** 5 mg reduced the FEV_1 by 272 mL and 193 mL, respectively, when compared with placebo. Increasing inhalation of **salbutamol** to a to tal dose of 800 micrograms reversed these reductions but did not restore the FEV_1 back to its initial value. None of these changes was considered to be clinically significant by the authors.[13]

Fifteen patients with mild to moderate COPD and airways hyperresponsiveness were given **celiprolol** 200 mg daily, **metoprolol** 100 mg daily or **propranolol** 80 mg daily for 4 days. Propranolol significantly reduced the FEV_1 and increased airways hyper-responsiveness, when compared with placebo, whereas metoprolol only increased airways hyperresponsiveness. **Celiprolol** had no significant effects on pulmonary function. The bronchodilating effects of a single 12-microgram dose of **formoterol** were significantly reduced by **propranolol**, but not by **metoprolol** or **celiprolol**.[8]

(b) Non-selective beta blockers

Non-selective beta blockers (e.g. **propranolol**) are contraindicated in patients with asthma because they can cause bronchospasm, reduce lung ventilation and may possibly precipitate a severe asthmatic attack in some subjects. An example of the danger is illustrated by a patient with asthma who developed fatal status asthmaticus after taking just one dose of **propranolol**.[14] Another case report describes a patient with bronchial asthma receiving **salbutamol** who collapsed and died after taking three 20-mg **propranolol** tablets, which had been supplied in error instead of 20-mg prednisone tablets.[15] The manufacturers of **propranolol** note that from 1965 to 1996, the CSM in the UK had received 51 reports of bronchospasm due to **propranolol**, 13 of them fatal, and 5 of them in patients who had a history of asthma, bronchospasm or wheeze.[16] The non-cardioselective beta blockers **oxprenolol**[6] and **propranolol**[5,6,9-11] oppose the effects of bronchodilators such as **isoprenaline** (**isoproterenol**),[5,10,11] **salbutamol** (**albuterol**),[5,6] and **terbutaline**.[9] Even eye drops containing the non-selective beta blockers **timolol**[17,18] and **metipranolol**[19] have been reported to precipitate acute bronchospasm. In patients with heart failure taking **carvedilol**, 3 of 12 with concurrent asthma had wheezing requiring **carvedilol** withdrawal. In contrast, only 1 of 31 patients with COPD had wheezing.[20]

Mechanism

Non-selective beta blockers such as propranolol also block the $beta_2$ receptors in the bronchi so that the normal bronchodilation, which is under the control of the sympathetic nervous system, is reduced or abolished. As a result the bronchoconstriction of asthma can be made worse. Cardioselective beta blockers on the other hand, preferentially block $beta_1$ receptors in the heart, with less effect on the $beta_2$ receptors, so that $beta_2$

stimulating bronchodilators, such as isoprenaline (isoproterenol), salbutamol (albuterol) and terbutaline, continue to have bronchodilator effects.

Importance and management

A well established drug-disease interaction. In 1996, the CSM in the UK[21] re-issued the advice that beta blockers, including cardioselective beta blockers should not be given to patients with a history of asthma and/or bronchospasm. Non-cardioselective beta blockers (see 'Table 22.1', (p.995)) should certainly be avoided in patients with asthma and those with COPD, whether given systemically or as eye drops, because serious and life-threatening bronchospasm may occur. The cardioselective beta blockers are generally safer but not entirely free from risk in some patients, particularly in high dosage. In contrast to the 1996 recommendations of the CSM on cardioselective beta blockers, a subsequent review[1,22] recommended that cardioselective beta blockers should not be withheld from patients with mild to moderate reversible airway disease. However, some concern has been expressed that this conclusion was based on results from short-term studies and state that the question of safety in asthmatics over the long term has not been answered.[23] Further, there are no studies to suggest the safety of cardioselective beta blockers in patients with exacerbations of asthma,[24] and even a highly cardioselective drug such as betaxolol may cause bronchospasm.[4] In 2004, the American College of Cardiology and American Heart Association guidelines for management of ST-elevation myocardial infarction stated that the benefits of using beta blockers strongly outweigh the risk of adverse events in patients with COPD or mild asthma (non-active), and noted that most patients with asthma are able to tolerate cardioselective beta blockers. Therefore if a beta blocker is required a cardioselective beta blocker should be used, and the patient's pulmonary function monitored.[25] An update to these guidelines in 2007 specifically notes that *active* asthma, or reactive airway disease, are contraindications to the use of an intravenous or oral beta blocker.[26] A 2007 Cochrane review concluded that cardioselective beta blockers did not produce any significant adverse respiratory effects or reduction in the response to $beta_2$ agonists, and it recommended that cardioselective beta blockers should not be withheld from patients with COPD.[27]

Celiprolol (a cardioselective beta blocker) appears to be exceptional in causing mild bronchodilatation in asthmatics and not bronchoconstriction, although it may still produce a reduction in expiratory volume, as seen in one study,[13] but some caution is still necessary as this requires confirmation.[7]

The bronchoconstrictive effects of the beta blockers can be opposed by $beta_2$ agonist bronchodilators such as salbutamol, but as the manufacturers point out, large doses may be needed and they suggest that ipratropium and intravenous aminophylline may also be needed.[16]

Anti-asthma drugs + NSAIDs

Aspirin and many other NSAIDs can cause bronchoconstriction in some patients with asthma. Celecoxib, etoricoxib and meloxicam do not usually cause bronchospasm in aspirin or NSAID-sensitive patients. Aspirin, nimesulide and piroxicam appear not to alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) NSAIDs in asthma

About 10% of patients with asthma are hypersensitive to **aspirin**, and in some individuals life-threatening bronchoconstriction can occur. This is not a drug-drug interaction but an adverse response to **aspirin**, whether the patient is taking an anti-asthma drug or not. The reasons are not fully understood. Those known to be sensitive to **aspirin** may also possibly react to other NSAIDs, in particular the acetylated salicylates, the indole and indene acetic acids, and the propionic acid derivatives (see 'Table 6.1', (p.150)). The fenamates, oxicams, pyrazolones and pyrazolidinediones are better tolerated.[1] The nonacetylated salicylates (**sodium salicylate**, **salicylamide**, **choline magnesium trisalicylate**) are normally well tolerated. Aspirin-sensitive individuals are also less likely to react to **nimesulide**.[1,2] In a study in which 381 patients with a pseudoallergic reaction to NSAIDs, (urticaria, angioedema, rhinitis, asthma or anaphylactoid reaction) were challenged with **nimesulide** 50 or 100 mg, only 6 experienced an adverse reaction. One patient developed an asthma attack, and this resolved following inhalation of 200 micrograms of salbutamol (albuterol).[2]

In 60 patients with proven **aspirin**-sensitivity, **celecoxib** 100 mg on day one and 200 mg on day two caused no decline in forced expiratory volume.[3] Two more studies found similar results.[4,5] **Celecoxib** is a selective inhibitor of cyclo-oxygenase-2 and this supports the suggestion that inhibition of cyclo-oxygenase-1 may be a critical factor in the precipitation of respiratory reactions in **aspirin**-exacerbated respiratory disease.[3] This suggests that **celecoxib** may be an alternative in patients who are known to be aspirin sensitive. Nevertheless, the manufacturer of **celecoxib** contraindicates its use in patients who are sensitive to aspirin or NSAIDs.[6]

In a study in 21 patients with either asthma, nasal polyps, allergic rhinitis or a combination of these, challenged with **meloxicam** 7.5 mg, only one patient with a history of aspirin allergy developed bronchospasm and erythema.[7] Another study found no reaction in 24 patients with a history of NSAID-induced respiratory hypersensitivity given **meloxicam** 7.5 to 15 mg daily.[4] However, the manufacturer of **meloxicam** contraindicates its use in patients who are sensitive to aspirin or NSAIDs.[8]

In a study 77 rheumatology patients with a history of asthma caused by

aspirin or a NSAID and given ascending doses of **etoricoxib** 60 to 120 mg daily for 3 days had no respiratory or cutaneous reaction to **etoricoxib** even after rechallenge 5 days later.[9]

(b) NSAIDs with theophylline

In 6 healthy subjects, **piroxicam** 20 mg daily for 7 days had no effect on the pharmacokinetics of theophylline (given as a single 6-mg/kg intravenous dose of aminophylline).[10] In 8 elderly patients (aged 60 to 81 years) with COPD, **enteric-coated aspirin** 650 mg daily for 4 weeks had no effect on the steady-state serum levels of theophylline.[11] **Nimesulide** 100 mg twice daily for 7 days did not affect lung function in 10 patients with COPD taking slow-release theophylline 200 mg twice daily, although there was a slight, clinically insignificant fall in theophylline levels, possibly due to enzyme induction. The pharmacokinetics of the **nimesulide** were unchanged.[12]

Apart from checking that the patient is not sensitive to **aspirin** or any other NSAID (see *NSAIDs in asthma*, above), there would seem to be no reason for avoiding **aspirin** or **piroxicam** in patients taking theophylline (or probably aminophylline).

In a placebo-controlled study, 36 healthy subjects were given **rofecoxib** 12.5 mg, 25 mg or 50 mg daily for 7 days, with a single 300-mg dose of theophylline given on day 7. There were no significant changes in the maximum plasma levels of theophylline. However, **rofecoxib** 12.5 mg, 25 mg or 50 mg, increased the AUC of theophylline by 38%, 51% and 60%, respectively, and increased the half-life of theophylline by 40%, 59% and 64%, respectively. It was suggested that the changes occurred because **rofecoxib** inhibits the cytochrome P450 isoenzyme CYP1A2 by which theophylline is metabolised.[13] This study suggests that dose reductions of theophylline (and probably aminophylline) would be necessary if patients were also given **rofecoxib**: given the range of NSAIDs available, it would probably be better to use a non-interacting alternative (**rofecoxib** is the only NSAID known to inhibit CYP1A2 to a clinically relevant extent). However, note that **rofecoxib** was generally withdrawn worldwide in 2004 because of its cardiovascular adverse effects; this study is included for completeness.

Beta-agonist bronchodilators + Potassium-depleting drugs

Beta agonists (e.g. fenoterol, salbutamol (albuterol), terbutaline) can cause hypokalaemia. This can be increased by other potassium-depleting drugs such as amphotericin B, the corticosteroids, diuretics (e.g. bendroflumethiazide, furosemide) and theophylline. The risk of serious cardiac arrhythmias may be increased.

Clinical evidence

(a) Corticosteroids

1. Anti-inflammatory/bronchodilator effects. A marked rise in asthma deaths was noted in New Zealand in the 1980s. A case-control study found that the risk of death was increased in oral corticosteroid-dependent asthmatics (severe asthma) who were also taking inhaled **fenoterol**.[1] This, and other data, suggested that the concurrent use of short-acting $beta_2$ agonists and corticosteroids might be deleterious in some situations, prompting numerous studies, which were reviewed in 2000.[2] The overall findings were, that although inhaled corticosteroids do not prevent the pro-inflammatory effects of short-acting $beta_2$ agonists, the combination is beneficial in the treatment of asthma at usual therapeutic doses of both drugs. The authors caution that this might not apply with excessive use of short-acting $beta_2$ agonists.[2]

The addition of a long-acting $beta_2$ agonist (e.g. **salmeterol**) to treatment in patients with chronic asthma inadequately controlled by inhaled corticosteroids and 'as required' short-acting $beta_2$ agonists is beneficial,[2,3] provided current guidance advising that a long-acting $beta_2$ agonist is always prescribed with an inhaled corticosteroid is followed.[4]

2. Hypokalaemia. The hypokalaemic effects of $beta_2$ agonists may be increased by corticosteroids. Twenty-four healthy subjects had a fall in their serum potassium levels when they were given either **salbutamol** (**albuterol**) 5 mg or **fenoterol** 5 mg by nebuliser over 30 minutes. The fall in potassium levels was increased after they took **prednisone** 30 mg daily for a week. The greatest fall (from 3.75 mmol/L to 2.78 mmol/L) was found 90 minutes after **fenoterol** and **prednisone** were taken. The ECG effects observed included ectopic beats and transient T wave inversion, but no significant ECG disturbances were noted.[5]

3. Pharmacokinetics. A study in 28 healthy subjects found that the pharmacokinetics of a single 1.28-milligram dose of **budesonide** and a single 36-microgram dose of **formoterol** were unaltered when each drug was given together (via separate inhalers). In a similar study by the same authors, it was found that when these drugs were given together via the same inhaler (*Symbicort*,® **budesonide** 1.28 milligrams, **formoterol** 36 micrograms per dose), the AUC of **formoterol** was 20% lower compared with administration via separate inhalers.[6] This is unlikely to be clinically relevant.

When 28 healthy subjects received **salmeterol** 100 micrograms, **fluticasone** 500 micrograms, or the two drugs together twice daily for 11 days, no pharmacokinetic interaction was noted.[7]

(b) Diuretics

1. Bendroflumethiazide. In a study, 10 healthy subjects were given bendroflumethiazide 5 mg daily. After 7 days the serum potassium levels had fallen by 0.71 mmol/L. When 100 micrograms to 2 mg of inhaled **salbutamol** (**albuterol**) was also given, the potassium levels fell by 1.06 mmol/L (to 2.72 mmol/L). ECG changes consistent with hypokalaemia and hypomagnesaemia were seen.[8] In another study the same authors found that the addition of bendroflumethiazide 5 mg daily to inhaled **salbutamol** 2 mg further reduced serum potassium levels by 0.4 mmol/L (to 2.92 mmol/L). This reduction was abolished by the addition of **triamterene** 200 mg (serum potassium 3.43 mmol/L) or **spironolactone** 100 mg (serum potassium 3.53 mmol/L) but **triamterene** 50 mg only attenuated the effect of bendroflumethiazide (serum potassium 3.1 mmol/L). ECG effects with this combination were also reduced by the addition of **triamterene** or **spironolactone**.[9] In another similar study by the same authors, the addition of 24 mmol potassium supplementation daily did not alter the hypokalaemia or ECG changes caused by the concurrent use of bendroflumethiazide and **salbutamol**. The use of **triamterene** attenuated the ECG changes in some subjects.[10]

2. Furosemide. The serum potassium level of 15 healthy subjects was measured after they were given inhaled **terbutaline** 5 mg with either a placebo, furosemide 40 mg daily, or furosemide 40 mg with **triamterene** 50 mg daily for 4 days. With **terbutaline** alone the potassium levels fell by 0.53 mmol/L; when furosemide was also given they fell by 0.75 mmol/L; and after furosemide and **triamterene** were also given they fell by 0.59 mmol/L. These falls were reflected in some ECG (T wave) changes.[11]

(c) Theophylline

The concurrent use of **salbutamol** (**albuterol**) or **terbutaline** and theophylline can cause an additional fall in serum potassium levels, and other $beta_2$ agonists are expected to interact similarly. See 'Theophylline + Beta-agonist bronchodilators', p.1432.

Mechanism

The use of two or more drugs with hypokalaemic adverse effects results in additive potassium-depleting effects.

Importance and management

Established interactions. The CSM in the UK[12] advises that, as potentially serious hypokalaemia may result from the use of a beta$_2$ agonist, particular caution is required in severe asthma, as this effect may be potentiated by theophylline and its derivatives, corticosteroids, diuretics, and by hypoxia. Hypokalaemia with concurrent use of a beta$_2$ agonist and a thiazide or loop diuretic (see 'Table 26.1', (p.1121), for a list) may be reduced or even abolished by the addition of spironolactone or high-dose triamterene. Plasma potassium levels should therefore be monitored in patients with severe asthma. Drugs such as **amphotericin B**, which commonly cause severe hypokalaemia are likely to present a similar risk. Hypokalaemia may result in cardiac arrhythmias in patients with ischaemic heart disease and may also affect the response of patients to drugs such as the digitalis glycosides and antiarrhythmics.

Note that the combined use of beta$_2$ agonists and corticosteroids in asthma is usually beneficial, indeed the combination of a long-acting beta$_2$ agonist and corticosteroid gives enhanced anti-inflammatory activity than with either drug alone.[13]

Caffeine + Allopurinol

Allopurinol may invalidate the results of studies using caffeine as a probe drug for determining acetylator status or CYP1A2 activity.

Clinical evidence, mechanism, importance and management

In 21 healthy subjects, allopurinol 300 mg daily for 8 days altered the levels of the urinary caffeine metabolites of a single 200-mg dose of caffeine. In particular, the metabolic ratio used to determine whether people are fast or slow acetylators was substantially changed. Thus, allopurinol may invalidate the results of phenotyping with the urinary caffeine test. In addition, the caffeine metabolite ratio used to express the activity of the cytochrome P450 isoenzyme CYP1A2 was not stable when allopurinol was used.[1] This interaction is of relevance to research rather than clinical practice.

1. Fuchs P, Haefeli WE, Ledermann HR, Wenk M. Xanthine oxidase inhibition by allopurinol affects the reliability of urinary caffeine metabolic ratios as markers for *N*-acetyltransferase 2 and CYP1A2 activities. *Eur J Clin Pharmacol* (1999) 54, 869–76.

Caffeine + Antiepileptics

Phenytoin can increase the clearance of caffeine, and possibly invalidates the caffeine breath test. Whether carbamazepine increases caffeine metabolism is unclear. The concurrent use of valproate and caffeine does not appear to affect the pharmacokinetics of either drug.

Clinical evidence

The clearance of caffeine was about twofold higher and its half-life was reduced by about 50% in patients with epilepsy taking **phenytoin**, when compared with healthy subjects not taking any medication. In the same study, there were no significant differences in caffeine pharmacokinetics between healthy subjects and patients receiving **carbamazepine** or **sodium valproate**.[1] Conversely, **carbamazepine** was considered to have induced the metabolism of caffeine in 5 children with epilepsy, as assessed by the caffeine breath test.[2] In another study in healthy subjects, there was a reduction in the AUC of **carbamazepine** when it was given with caffeine. Caffeine had no effect on the pharmacokinetics of **sodium valproate**.[3]

Mechanism

Phenytoin acts as an enzyme inducer, thereby increasing the metabolism of caffeine, lowering its levels. Carbamazepine possibly has the same effect.

Importance and management

Phenytoin may possibly invalidate the caffeine breath test, but normally no special precautions are needed if both drugs are taken. The interaction between carbamazepine and caffeine is not established and requires further study.

Caffeine + Antifungals

Fluconazole and terbinafine cause a modest rise in serum caffeine levels. Ketoconazole appears to have less effect. Posaconazole does not affect caffeine pharmacokinetics.

Clinical evidence, mechanism, importance and management

A study in 6 young subjects (average age 24 years) given **fluconazole** 400 mg daily and 5 elderly subjects (average age 69 years) given **fluconazole** 200 mg daily for 10 days found that fluconazole reduced the plasma clearance of caffeine by an average of 25% (32% in the young and 17% in the elderly).[1]

In a single-dose study in 8 healthy subjects, **terbinafine** 500 mg and **ketoconazole** 400 mg decreased caffeine clearance by 21% and 10%, respectively, and increased its half-life by 31% and 16%, respectively.[2]

In 12 healthy subjects **posaconazole** 200 mg daily for 10 days did not affect the pharmacokinetics of a single 200-mg dose of caffeine.[3]

It seems unlikely that the moderately increased serum caffeine levels seen with fluconazole, ketoconazole and terbinafine, will have a clinically important effect.

Caffeine + Armodafinil

In a study, 24 healthy subjects were given a single 200-mg dose of caffeine before and after taking armodafinil 250 mg daily for at least 22 days. There were no clinically significant changes in the pharmacokinetics of caffeine, and the combination was well tolerated.[1]

1. Darwish M, Kirby M, Robertson P, Hellriegel ET. Interaction profile of armodafinil with medications metabolized by cytochrome P450 enzymes 1A2, 3A4 and 2C19 in healthy subjects. Clin Pharmacokinet (2008) 47, 61–74.

Caffeine + Artemisinin derivatives

Artemisinin, artenimol and artemotil reduce the metabolism of caffeine.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of **artemisinin** reduced the clearance of a single 136.5-mg dose of caffeine by 35%. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 66%.[1] Another study, in 15 healthy subjects given **artemisinin** 500 mg daily for 5 days, found that the metabolism of a single 100-mg dose of caffeine to paraxanthine was reduced by 73%. As part of this study, 14 subjects were given **dihydroartemisinin** [**artenimol**] 60 mg daily for 5 days, and 15 subjects were given intramuscular **artemotil** 100 mg daily for 5 days. The metabolism of a single 100-mg dose of caffeine to paraxanthine was reduced by 27% and 30%, respectively. There was no significant change in the metabolism of caffeine in the 15 subjects who were given **artemether** 100 mg daily for 5 days, or **artesunate** 100 mg daily for 5 days.[2] It was suggested that **artemisinin**, **dihydroartemisinin** [**artenimol**] and **artemotil** inhibit the metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2 in the liver.[1,2]

There is too little information to advise patients taking artemisinin derivatives to completely avoid caffeine-containing beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (insomnia, jitteriness etc) become troublesome.

1. Bapiro TE, Sayi J, Hasler JA, Jande M, Rimoy G, Masselle A, Masimirembwa CM. Artemisinin and thiabendazole are potent inhibitors of cytochrome P450 1A2 (CYP1A2) activity in humans. *Eur J Clin Pharmacol* (2005) 61, 755–61.

Caffeine + Cimetidine

The clearance of caffeine is decreased by cimetidine.

Clinical evidence, mechanism, importance and management

In 5 subjects cimetidine 1 g daily for 6 days increased the half-life of a single 300-mg dose of caffeine by about 70% and reduced caffeine clearance.[1] In another study, cimetidine 1.2 g daily for 4 days increased the caffeine half-life by 45% in 6 smokers and by 96% in 6 non-smokers. The caffeine clearance was reduced by 31% in the smokers and by 42% in the non-smokers.[2] A further study found that the caffeine half-life was increased by 59% and its clearance decreased by 40% by cimetidine.[3] Conversely, in a study in children, cimetidine was not found to affect caffeine metabolism, as assessed by the caffeine breath test.[4]

The changes seen in some studies probably occurred because cimetidine, a well-known non-specific enzyme inhibitor, reduced the metabolism of caffeine by the liver, resulting in its accumulation in the body.

Any increased caffeine effects are normally unlikely to be of much importance in most people, but they might have a small part to play in exaggerating the undesirable effects of caffeine from food, drinks (e.g. tea, coffee, cola drinks, chocolate) and analgesics, which are sometimes formulated with caffeine. If these become troublesome, advise patients to reduce their caffeine intake.

Caffeine + Class I antiarrhythmics

Caffeine clearance is reduced by 30 to 60% by mexiletine, resulting in raised serum caffeine levels. Similarly, propafenone reduces the clearance of caffeine by 35%. Lidocaine, flecainide and tocainide do not appear to affect caffeine clearance. Caffeine does not significantly alter mexiletine levels.

Clinical evidence

(a) Mexiletine

In a study in 7 patients with cardiac arrhythmias taking long-term mexiletine 600 mg daily the clearance of caffeine was found to be reduced by 48%.[1] In 5 healthy subjects given a single 200-mg dose of mexiletine, the clearance of a single 366-mg dose of caffeine was reduced by 57%, and the elimination half-life rose from about 4 hours to 7 hours.[1] The clearance of mexiletine was not affected by caffeine. A preliminary report of this study also noted that fasting caffeine levels were almost sixfold higher during the mexiletine treatment period (1.99 micrograms/mL compared with 0.35 micrograms/mL).[2]

Another study in 14 healthy subjects found that caffeine 100 mg four times daily, for 2 days before and 2 days after mexiletine, did not cause any significant changes in the plasma levels of a single 200-mg dose of mexiletine. Caffeine levels tended to be increased 24 hours after taking mexiletine.[3]

(b) Propafenone

In a study in 8 healthy subjects, the clearance of a single 300-mg dose of caffeine was reduced by 35% and the half-life of caffeine was extended from 3.82 hours to 5.9 hours when propafenone 300 mg was given.[4]

(c) Other antiarrhythmics

In 7 healthy subjects given caffeine, single doses of **lidocaine** 200 mg, **flecainide** 100 mg and **tocainide** 500 mg had no effect on the clearance of a single 366-mg dose of caffeine.[2]

Mechanism

It is likely that, as with theophylline (see 'Theophylline + Mexiletine or Tocainide', p.1448, and 'Theophylline + Propafenone', p.1451), mexiletine and propafenone inhibit the hepatic metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2.

Importance and management

The interaction between caffeine and mexiletine appears to be established, but its clinical importance is uncertain. Some of the adverse effects of mexiletine might be partially due to caffeine-retention (from drinking tea, coffee, cola drinks, etc.).[1] In excess, caffeine can cause jitteriness, tremor and insomnia. It has also been suggested that the caffeine test for liver function might be impaired by mexiletine.[1] The clinical significance of the interaction with propafenone is less clear, as no details on the clinical state of the subjects was recorded.[4] Be alert for possible adverse effects of caffeine and advise patients to reduce caffeine intake if these become troublesome.

Caffeine + Disulfiram

Disulfiram reduces the clearance of caffeine, which might complicate the withdrawal from alcohol.

Clinical evidence, mechanism, importance and management

A study in healthy subjects and recovering alcoholics found that disulfiram 250 or 500 mg daily reduced the clearance of caffeine by about 30%, but a few of the alcoholics had a more than 50% reduction.[1] As a result the levels of caffeine in the body increased. Raised levels of caffeine can cause irritability, insomnia and anxiety, similar to the symptoms of alcohol withdrawal. As coffee consumption is often particularly high among recovering alcoholics, there is the risk that they may turn to alcohol to calm themselves down. To avoid this possible complication it might be wise for recovering alcoholics not to drink too much tea or coffee. Decaffeinated coffee and tea are widely available.

1. Beach CA, Mays DC, Guiler RC, Jacober CH, Gerber N. Inhibition of elimination of caffeine by disulfiram in normal subjects and recovering alcoholics. *Clin Pharmacol Ther* (1986) 39, 265–70.

Caffeine + Food

Foods such as broccoli and green beans increase the rate of metabolism of caffeine.

Clinical evidence, mechanism, importance and management

In a study in 9 healthy subjects, the metabolism of caffeine, measured by the appearance of metabolites in the urine, was increased after the ingestion of 500 g of green beans or broccoli daily for 10 days.[1] Caffeine is metabolised by the cytochrome P450 isoenzyme CYP1A2, *N*-acetyl transferase and xanthine oxidase. Some foodstuffs can induce the activity of CYP1A2, resulting in an increased rate of metabolism of substrates such as caffeine. However, this finding is unlikely to be of clinical significance, as caffeine is commonly ingested as part of the diet, and the amount of green vegetables given was quite large.

Caffeine + Grapefruit juice

Grapefruit juice does not interact with caffeine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects grapefruit juice, at a dose of 1.2 litres, decreased the clearance of caffeine from coffee by 23% and prolonged its half-life by 31%, but these changes were not considered clinically relevant.[1] A crossover study in 6 healthy subjects given caffeine 3.3 mg/kg found that multiple doses of grapefruit juice (equivalent to 6 glasses) caused a non-significant increase in the AUC of caffeine. No changes in ambulatory systolic or diastolic blood pressure or heart rate were seen.[2]

Caffeine + Hormonal contraceptives or HRT

The half-life of caffeine is prolonged to some extent in women taking oral combined hormonal contraceptives or HRT.

Clinical evidence

(a) Contraceptives

In 9 women taking low-dose oral combined hormonal contraceptives for at least 3 months the clearance of a single 162-mg dose of caffeine was reduced, the half-life prolonged (7.9 hours compared with 5.4 hours), and the plasma levels were raised, when compared with 9 other women not taking a contraceptive.[1] This finding was confirmed in three other studies,[2-4] which found that caffeine elimination was prolonged, from 4 to 6 hours before the use of combined oral contraceptives, to about 9 hours by the end of the first cycle, and to about 11 hours by the end of the third cycle.[3,4] A further study found that there was little difference between the effects of two oral hormonal contraceptives (**ethinylestradiol** 30 micrograms with gestodene 75 micrograms or levonorgestrel 125 micrograms) on caffeine: both increased the half-life of caffeine by a little over 50%, but the maximum serum levels were unchanged.[5] A study in 7 women similarly found that the use of an oral contraceptive containing **ethinylestradiol** sulphonate 3 mg and **norethisterone** acetate 10 mg per menstrual cycle (*Depositon*) prolonged the half-life of caffeine from 4.9 hours to 8 hours.[6]

A review of the bone mineral content of 263 users of depot **medroxyprogesterone** found that the women who reported a high caffeine intake (over 200 mg daily) had a significantly lower spinal bone mineral content than the women who reported no caffeine intake. However, there was no significant difference in bone mineral density between the two groups.[7]

(b) HRT

In one study, 12 healthy postmenopausal women were given a single 200-mg dose of caffeine after taking **estradiol** (*Estrace*) for 8 weeks, titrated to give **estradiol** plasma concentrations of 50 to 150 picograms/mL. The metabolism of caffeine was reduced by 29% overall. If the data for 2 subjects who were found to have taken extra caffeine during the study period are excluded, the reduction in caffeine metabolism was even greater (average reduction of 38%).[8]

Mechanism

Uncertain. Estrogens can inhibit the cytochrome P450 isoenzyme CYP1A2, by which caffeine is metabolised, which may explain its accumulation in the body.

Importance and management

An established interaction that is probably of limited clinical importance. Women taking hormonal contraceptives containing estrogens or HRT who take caffeine-containing analgesics or drink caffeine-containing drinks (tea, coffee, cola drinks, etc.) may find the effects of caffeine, such as jitteriness and insomnia, increased and prolonged. The effect of high caffeine use and depot medroxyprogesterone on bone mineral content is unlikely to be of clinical significance.

Caffeine + Idrocilamide

Oral idrocilamide reduces the clearance of caffeine, which can lead to caffeine toxicity.

Clinical evidence, mechanism, importance and management

The possibility that caffeine intake might have had some part to play in the development of psychiatric disorders seen in patients taking idrocilamide, prompted a pharmacokinetic study in 4 healthy subjects. While taking oral idrocilamide 400 mg three times daily the half-life of caffeine (150 to 200 mg of caffeine from one cup of coffee) was prolonged from about 7 hours to 59 hours. The overall clearance of caffeine was decreased by about 90%.[1,2]

Idrocilamide can inhibit the cytochrome P450 isoenzyme CYP1A2 by which caffeine is metabolised, leading to its accumulation.

Evidence is limited but the interaction appears to be established. Patients taking oral idrocilamide should probably avoid or minimise their intake of caffeine, including caffeine-containing drinks (tea, coffee, cola drinks,

etc.), otherwise caffeine toxicity may develop. Decaffeinated teas and coffee are widely available. Some medicines may contain caffeine, so these should also be used with care.

Caffeine + Kava

It appears that kava is unlikely to affect the pharmacokinetics of caffeine, although further study is required to confirm this.

Clinical evidence, mechanism, importance and management

In a study in 6 subjects (3 of whom smoked tobacco) who regularly took 7 to 27 g of kavalactones weekly as an aqueous kava extract, the metabolic ratio of caffeine was increased twofold when kava was withheld for 30 days, which suggested that kava inhibits the cytochrome P450 isoenzyme CYP1A2, which is involved in the metabolism of caffeine.[1]

However, in a study in 12 non-smoking healthy subjects given kava kava root extract 1 g twice daily for 28 days before receiving a single 100-mg dose of oral caffeine, no significant change in the metabolic ratio of caffeine was noted.[2] It is possible that the inhibitory effect of tobacco smoke on CYP1A2, and the lack of standardisation of kava intake may have influenced the results.

1. Russman S, Lauterburg BH, Barguil Y, Choblet E, Cabalion P, Rentsch K, Wenk M. Traditional aqueous kava extracts inhibit cytochrome P450 1A2 in humans: protective effect against environmental carcinogens? *Clin Pharmacol Ther* (2005) 77, 451–4.

Caffeine + Menthol

Menthol modestly affects the pharmacokinetics of caffeine.

Clinical evidence, mechanism, importance and management

A crossover study in 11 healthy subjects found that a single 100-mg dose of menthol taken with coffee containing 200 mg caffeine increased the time to maximum caffeine levels by about 30 minutes. The increase in the actual maximum level was not significant, and there were no significant effects on caffeine half-life. It was thought that menthol reduced the rate of caffeine absorption.[1] The clinical importance of this is not clear but it is seems likely to be small.

Caffeine + Nicotine

Caffeine may boost some of the stimulant effects of nicotine, but it only appears to cause a small, if any, rise in nicotine levels.

Clinical evidence

In a study in 21 smokers who regularly drank one to six cups of coffee daily, a 50-mg tablet of caffeine increased self-ratings of 'stimulated', 'alert' and 'jittery' at various doses of nicotine chewing gum (0.25 mg, 0.5 mg and 1 mg) when compared with the nicotine gum alone.[1] In a placebo-controlled study, 12 healthy subjects were given nicotine 1 mg or 2 mg with caffeine 50 mg or 100 mg, given in a chewing gum. Nicotine alone and caffeine alone increased energy expenditure, but adding caffeine 50 mg to nicotine 1 mg had almost double the effects of simply increasing the nicotine dose from 1 to 2 mg. Similar effects were seen in both smokers and non-smokers. No adverse effects were reported with either nicotine 1 mg alone or combined with caffeine.[2] In a similar study by the same authors, caffeine enhanced the appetite-suppressant effects of nicotine.[3] In another study in 13 smokers who regularly drank at least one cup of coffee daily, pre-treatment with oral caffeine 2.5 or 5 mg/kg (added to 180 mL of decaffeinated coffee) did not alter the subjects ability to discriminate between nasal nicotine and placebo, and did not alter the amount of caffeine they self-administered during a period of smoking cessation. Caffeine pretreatment caused a modest dose-related increase in nicotine levels (maximum 21%).[4] In a study in 12 smokers, two doses of caffeine 150 mg (given in a decaffeinated cola drink before and during smoking) had no effect on the plasma levels of nicotine achieved by smoking 5 cigarettes.[5]

Mechanism

Not understood.

Importance and management

A fairly well studied interaction. Caffeine may boost some of the stimulant effects of nicotine (energy consumption, appetite suppression, but also adverse effects such as jitteriness), but it only appears to cause a small, if any, rise in nicotine levels. Bear the potential for this increase in effects in mind should a patient receiving nicotine replacement therapy and also taking caffeine supplements develop troublesome nicotine-related adverse effects.

Caffeine + Psoralens

Oral methoxsalen and 5-methoxypsoralen markedly reduce caffeine clearance. Topical methoxsalen does not interact with caffeine.

Clinical evidence

In 5 subjects with psoriasis, a single 1.2-mg/kg oral dose of **methoxsalen** (8-methoxypsoralen), given one hour before a single 200-mg oral dose of caffeine, reduced the clearance of caffeine by 69%. The elimination half-life of caffeine over the period from 2 to 16 hours after taking the **methoxsalen** increased tenfold (from 5.6 to 57 hours).[1] In a similar study, 8 patients with psoriasis were given caffeine 200 mg with or without **5-methoxypsoralen** 1.2 mg/kg. The AUC of caffeine increased about threefold and there was a threefold decrease in its clearance.[2]

A study in patients receiving PUVA therapy (**methoxsalen** either orally, in 4 patients, or topically as a bath in 7 patients, plus UVA) found that the clearance of a single 150-mg dose of caffeine was markedly reduced in the patients given oral **methoxsalen** but not altered in those given topical **methoxsalen**.[3]

Mechanism

Both methoxsalen and 5-methoxypsoralen inhibit the metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby markedly increasing caffeine levels.[2,3]

Importance and management

An interaction between oral methoxsalen and caffeine appears to be established, but its practical consequences are as yet uncertain. However, it seems possible that the adverse effects of caffeine will be increased. In excess, caffeine (including that from tea, coffee and cola drinks) can cause jitteriness, headache and insomnia. If these effects develop in a patient receiving methoxsalen it may be prudent to advise them to decrease their caffeine intake. The interaction does not appear to occur with topical methoxsalen.

Caffeine + Quinolones

Enoxacin markedly increases caffeine levels. The effects of caffeine derived from drinks such as tea, coffee or cola, would be expected to be increased. Pipemidic acid interacts to a lesser extent, and ciprofloxacin, norfloxacin and pefloxacin interact less still. Fleroxacin, lomefloxacin, ofloxacin, rufloxacin, and trovafloxacin appear not to interact.

Clinical evidence

The effects of various quinolones on the pharmacokinetics of caffeine[1-13] are summarised in 'Table 34.3', (p.1423). In one study ciprofloxacin and fleroxacin increased caffeine levels more in women than men, but this difference in effect was not significant when the results were normalised for body weight.[13]

Mechanism

It would seem that the metabolism (*N*-demethylation) of caffeine is markedly reduced by some quinolones (notably pipemidic acid and enoxacin) resulting in greater levels and possibly greater effects. Other quinolones have either a much smaller effect or no effect at all. The quinolones that interact appear to inhibit the cytochrome P450 isoenzyme CYP1A2[14] by which caffeine is metabolised.

Importance and management

Established interactions. Based on the results of two studies, on a scale of 100 to 0, the relative potencies of these quinolones as inhibitors of caffeine elimination have been determined as follows: enoxacin 100, pipemidic acid 29, ciprofloxacin 11, norfloxacin 9 and ofloxacin 0.[15] From further studies, clinafloxacin appears to be similar to enoxacin (profound effect), pefloxacin to norfloxacin (to which it is metabolised; modest effect), and fleroxacin, lomefloxacin, rufloxacin, and trovafloxacin appear to behave like ofloxacin (no effect). Patients taking enoxacin might be expected to experience an increase in the effects of caffeine (such as headache, jitteriness, restlessness, insomnia) if, for example, they continue to drink their usual amounts of caffeine-containing drinks (tea, coffee, cola drinks, etc.). They should be warned to cut out or reduce their intake of caffeine if this occurs. The authors of one report[1] suggest that patients with hepatic disorders, cardiac arrhythmias or latent epilepsy should avoid caffeine if they take enoxacin for one week or more. The effects of pipemidic acid and ciprofloxacin on caffeine are less, and those of norfloxacin and pefloxacin are probably of little or no clinical importance. Fleroxacin, lomefloxacin, ofloxacin, rufloxacin, and trovafloxacin do not interact.

Note that caffeine can be used as a probe substrate for the activity of the cytochrome P450 isoenzyme CYP1A2: those quinolones that have the greatest effect on caffeine are the most potent CYP1A2 inhibitors (e.g. enoxacin), those that have modest effects are moderate CYP1A2 inhibitors (e.g. ciprofloxacin), and those that have little or no effect on caffeine metabolism are unlikely to have a clinically relevant effect on other CYP1A2 substrates (e.g. ofloxacin). Note that the strength of the effect varies with the dose of quinolone used.

Caffeine + SSRIs

The clearance of caffeine is considerably reduced by fluvoxamine. An increase in the stimulant and adverse effects of caffeine would be expected, however this was not demonstrated in one study. Caffeine may cause a reduction in the bioavailability of fluvoxamine. A possible case of serotonin syndrome was attributed to the concurrent use of paroxetine and caffeine.

Clinical evidence

(a) Fluvoxamine

In a randomised, crossover study, 8 healthy subjects were given fluvoxamine 50 mg daily for 4 days and then 100 mg daily for a further 8 days, with a single 200-mg oral dose of caffeine before and on day 8 of fluvoxamine use. Fluvoxamine reduced the total clearance of caffeine by about 80% (from 107 to 21 mL/minute) and increased its half-life from 5 hours to 31 hours. Specifically, the clearance of caffeine by *N*3-, *N*1- and *N*7-demethylation was decreased.[1] Another study in 30 patients found a positive correlation between plasma fluvoxamine and plasma caffeine levels, suggesting that the interaction is dose-related.[2] A further study found that low, sub-therapeutic doses of fluvoxamine 10 or 20 mg daily were sufficient to markedly inhibit caffeine metabolism.[3] A study in 7 subjects found that fluvoxamine 100 mg twice daily for 4 doses significantly increased the maximum levels of a single 250-mg dose of caffeine by 40%, and increased the AUC and half-life of caffeine 12.7-fold and 10-fold, respectively. However, this did not result in an increase in caffeine-related adverse effects, and none of the subjects felt they were more alert with the combination than with either drug alone.[4]

A study in 12 healthy subjects (6 smokers and 6 non-smokers) found that caffeine 150 mg twice daily for 11 days reduced the AUC of a single 50-mg dose of fluvoxamine taken on day 8, by about 24%. The plasma concentration of fluvoxamine was also decreased by 12% but this was not statistically significant.[5]

(b) Paroxetine

A case report describes a patient who took amoxapine 200 mg, paroxetine 20 mg, and a preparation containing 4.8 g of caffeine. She became restless and incoherent, with a raised temperature, pulse rate and respiratory rate, diaphoresis, myoclonus and mild muscle rigidity. Her symptoms resolved when she was given dantrolene and diazepam. The authors of the report attribute these symptoms to serotonin syndrome, and suggest that the large dose of caffeine was a contributing factor.[6] However, serotonin syndrome has been reported in a number of patients taking tricyclics and SSRIs (see 'Tricyclic and related antidepressants + SSRIs', p.1513), and so an effect of caffeine is not established.

Mechanism

Fluvoxamine is a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the principal enzyme concerned with the metabolism of caffeine. As a result caffeine is cleared from the body much more slowly and accumulates.[1-3] It has been suggested that large doses of caffeine may promote serotonin activity.[6]

Importance and management

The increase in caffeine levels that occurs with fluvoxamine is established. There are no reports of caffeine toxicity arising from this interaction and one study[4] found no increase in the pharmacodynamic or adverse effects of caffeine despite a large increase in the levels. However, an increase in the stimulant and adverse effects of caffeine (headache, jitteriness, restlessness, insomnia) may be possible in susceptible patients if they continue

Table 34.3 Effect of quinolones on caffeine pharmacokinetics in healthy subjects

Quinolone[*]	*Daily caffeine intake*[†]	*Change in AUC*	*Change in clearance*	*Refs*
Ciprofloxacin				
100 mg twice daily	220 to 230 mg	+17%		1
250 mg twice daily	220 to 230 mg	+57%	-33%	1-3
500 mg twice daily	230 mg	+58%		1
500 mg twice daily	100 mg three times daily	+127%	-49%	4

to consume large amounts of caffeine-containing food or drinks (tea, coffee, cola drinks, chocolate, etc.) or take caffeine-containing medications. They should be warned to reduce their caffeine intake if problems develop. It has been suggested that some of the adverse effects of fluvoxamine (i.e. nervousness, restlessness and insomnia) could in fact be caused by caffeine toxicity. However, a preliminary study, as well as the study reported above,[4] found that caffeine intake had a limited effect on the frequency of adverse effects of fluvoxamine.[7] The clinical significance of the change in the AUC of fluvoxamine with caffeine intake is unclear. This slight decrease is unlikely to be important in most patients.

There appears to be only one isolated case of serotonin syndrome attributed to an interaction with caffeine, and as such, no general recommendations can be made.

Caffeine + Tiabendazole

Tiabendazole reduces the metabolism of caffeine.

Clinical evidence, mechanism, importance and management

A study in 7 healthy subjects found that a single 500-mg dose of tiabendazole reduced the clearance of caffeine by 66% and increased its half-life and AUC by 140% and 57%, respectively. The metabolism of caffeine to one of its major metabolites, paraxanthine, was reduced by 92%.[1] It was suggested that tiabendazole inhibits the metabolism of caffeine by the cytochrome P450 isoenzyme CYP1A2 in the liver. There is too little information to suggest that patients taking tiabendazole should avoid caffeine-containing beverages, foods or medication, but bear this interaction in mind if the adverse effects of caffeine (e.g. insomnia, jitteriness) become troublesome.

Caffeine + Tobacco

Tobacco smoking increases the rate of metabolism of caffeine.

Clinical evidence

In a study, the metabolism of caffeine, measured by the appearance of metabolites in the urine of healthy subjects, was found to be increased in those subjects who smoked, compared with those who were non-smokers.[1] Mathematical modelling of caffeine plasma levels in smokers and non-smokers confirmed that after adjustment for caffeine intake, the plasma levels of caffeine in non-smokers were two to three times higher than in those subjects who smoked.[2] A study in 12 otherwise healthy smokers found that on stopping smoking the metabolism of caffeine was reduced by about 36%.[3]

Mechanism

Caffeine is metabolised by the cytochrome P450 isoenzyme CYP1A2, *N*-acetyl transferase and xanthine oxidase. Smoking can induce the activity of CYP1A2, resulting in an increased rate of metabolism of caffeine.

Importance and management

Evidence regarding an interaction between caffeine and smoking appears to be limited to these studies, which were mainly using caffeine to assess the effect of smoking on enzyme induction. Nevertheless, they do suggest that the levels of caffeine may rise, all be it modestly, in those that stop smoking. If the adverse effects of caffeine (headache, jitteriness, restlessness, insomnia) become troublesome, it would be prudent to advise patients to decrease their caffeine intake. Note that, the use of nicotine replacement therapy may also exacerbate the adverse effects of caffeine, see 'Caffeine + Nicotine', p.1421.

Caffeine + Venlafaxine

Venlafaxine does not affect the pharmacokinetics of caffeine to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In 15 healthy subjects venlafaxine 37.5 mg twice daily for 3 days then 75 mg twice daily for 4 days did not affect the AUC or clearance of caffeine 200 mg daily (equivalent to about 3 cups of coffee). A slight but statistically significant decrease in the half-life from 6.1 hours to 5.5 hours was noted.[1] On the basis of this study, no special precautions are needed if both drugs are taken together.

1. Amchin J, Zarycranski W, Taylor KP, Albano D, Klockowski PM. Effect of venlafaxine on CYP1A2-dependent pharmacokinetics and metabolism of caffeine. *J Clin Pharmacol* (1999) 39, 252–9.

Caffeine + Verapamil

A small and relatively unimportant decrease in the clearance of caffeine may occur in patients given verapamil.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects verapamil 80 mg three times daily for 2 days decreased the total clearance of a single 200-mg dose of caffeine by 25%,

and increased its half-life by 25% (from 4.6 to 5.8 hours).[1] These changes are small, and unlikely to be of much importance in most patients.

1. Nawoot S, Wong D, Mays DC, Gerber N. Inhibition of caffeine elimination by verapamil. *Clin Pharmacol Ther* (1988) 43, 148.

Doxofylline + Miscellaneous

There is some limited evidence to suggest that erythromycin may increase the effects of doxofylline, but the clinical importance of this is uncertain. Digoxin initially raises, then lowers serum doxofylline levels, but the bronchodilator effects do not appear to be significantly affected. Allopurinol and lithium carbonate appear to have no significant effects on doxofylline.

Clinical evidence, mechanism, importance and management

Healthy subjects were given doxofylline 400 mg three times daily, either alone, or with **allopurinol** 100 mg daily, **erythromycin** 400 mg three times daily or **lithium carbonate** 300 mg three times daily. None of the pharmacokinetic parameters measured, including the maximum serum levels, were significantly altered by any of these drugs apart from the AUC of doxofylline, which was raised by about 40% by **allopurinol**, 70% by **erythromycin**, and 35% by **lithium carbonate**. Only the **erythromycin** result was statistically significant.[1] The clinical significance of these changes is uncertain, and their mechanism is not understood. Until the situation is much clearer it would be prudent to check the outcome of adding **erythromycin** to established treatment with doxofylline, being alert for evidence of increased effects.

In a comparative study in 9 patients taking doxofylline 800 mg daily, **digoxin** 500 micrograms daily was given to 5 patients. It was found that **digoxin** *increased* the serum levels of doxofylline by 50% on the first day of treatment, 3 hours after administration but then *reduced* doxofylline levels by about 30% at steady-state (day 30). Nevertheless, the bronchodilating effects of the doxofylline were little different between the two groups. It was concluded that concurrent use is normally safe and effective, but the initial doxofylline dose should be chosen to avoid too high a serum level on the first day, and pulmonary function should be well monitored.[2]

Ipratropium bromide + Salbutamol (Albuterol)

Acute angle-closure glaucoma developed rapidly in eight patients given nebulised ipratropium and salbutamol. Increased intra-ocular pressure has been reported in others, including one patient using an ipratropium metered-dose inhaler with nebulised salbutamol.

Clinical evidence

Five patients with an acute exacerbation of chronic obstructive airways disease given nebulised ipratropium and **salbutamol**, developed acute angle-closure glaucoma, four of them within one to 36 hours of starting treatment. Two of the patients had a history of angle-closure glaucoma.[1] Seven other similar cases of acute angle-closure glaucoma due to the concurrent use of **salbutamol** and ipratropium are reported elsewhere.[2-6] An increase in intra-ocular pressure has also been reported in other patients given both drugs by nebuliser.[7] One case of acute angle-closure glaucoma has been reported in a patient given inhaled ipratropium, via a metered-dose inhaler, and nebulised **salbutamol**.[8]

Mechanism

This reaction appears to occur because the antimuscarinic action of the ipratropium causes semi-dilatation of the pupil, partially blocking the flow of aqueous humour from the posterior to the anterior chamber, thereby causing anterior bowing of the iris and obstructing the drainage angle. The salbutamol increases the production of aqueous humour, therefore exacerbating the situation. An additional factor that may contribute is the route of administration: higher levels of both drugs are achieved by using a nebuliser, and some drug may escape round the edge of the mask and have a direct action on the eye.[1]

Importance and management

An established but uncommon interaction, which appears to occur mainly in patients receiving salbutamol and ipratropium by nebuliser and those already predisposed to angle-closure glaucoma. The authors of the first report[1] advise care in the placing of the mask to avoid the escape of droplets. The use of goggles[7,9] and continuing the application of any glaucoma treatment is also effective.[7] It has been suggested that, if possible, nebulised salbutamol and ipratropium should be avoided in patients predisposed to angle-closure glaucoma.

Montelukast + Anti-asthma drugs

An isolated report describes severe oedema in a patient taking oral prednisone and montelukast, but studies suggest that the concurrent use of montelukast and prednisolone or prednisone are useful and well-tolerated. Montelukast in normal doses does not appear to interact adversely with salbutamol (albuterol).

Clinical evidence, mechanism, importance and management

(a) Beta$_2$ agonists

A study in patients with moderately severe asthma found no adverse interactions when **salbutamol** (**albuterol**) was given with montelukast 100 mg or 250 mg, with or without inhaled corticosteroids.[1] The British Thoracic Society guidelines suggest that a leukotriene antagonist may be used as an add-on therapy in patients using short-acting inhaled beta$_2$ agonists.[2]

(b) Corticosteroids

A study in healthy subjects (55 taking montelukast and 36 taking placebo) found that the plasma profiles of oral **prednisone** 20 mg and of intravenous **prednisolone** 250 mg were unaffected by montelukast 200 mg daily for 6 weeks.[3] Other studies in patients using inhaled and/or oral corticosteroids have found that concurrent use is beneficial and well tolerated.[4-6]

However, an isolated report describes a case of marked peripheral oedema possibly linked to the use of **prednisone** and montelukast. A 23-year-old patient with severe allergic and exercise-induced asthma and rhinoconjunctivitis treated with salmeterol and fluticasone by inhalation and oral cetirizine was given **prednisone** 40 mg daily for one week then 20 mg daily for a further week. When **prednisone** was stopped, severe asthma recurred and he was given **prednisone** 60 mg daily for one week then 40 mg daily for a further week with montelukast 10 mg daily. After 10 days he developed severe peripheral oedema, gaining 13 kg in weight. Renal and cardiovascular function were normal. **Prednisone** was stopped and the asthma was controlled by continued montelukast and the excess weight was lost as the oedema resolved. The patient had good tolerance of both **prednisone** and montelukast alone. The reason for this adverse reaction is unclear, but it was suggested that corticosteroid-induced renal tubular sodium and fluid retention may have occurred when montelukast was also given.[7]

This isolated report is probably of limited general relevance. Usually, no

special precautions appear to be needed if these drugs are used concurrently, and the British Thoracic Society guidelines suggests that a leukotriene antagonist can be used as an add-on therapy to inhaled steroids.[2]

Montelukast + Antiepileptics; Enzyme-inducing

Phenobarbital modestly reduces montelukast levels. Phenytoin is predicted to interact similarly.

Clinical evidence, mechanism, importance and management

Montelukast 10 mg was given to 14 healthy subjects before and after they took **phenobarbital** 100 mg daily for 14 days. It was found that the geometric mean AUC and the maximum serum levels of the montelukast were reduced by 38% and 20%, respectively, but it was concluded that no montelukast dose adjustment is needed.[1] The reason for these reductions is almost certainly because phenobarbital induces the cytochrome P450 isoenzyme CYP3A4 so that montelukast metabolism is increased. The manufacturer therefore cautions the use of montelukast with inducers of CYP3A4, such as **phenytoin** and **phenobarbital**, especially in children.[2] It would seem prudent to extend this caution to **fosphenytoin** and **primidone**, which are metabolised to phenytoin and phenobarbital, respectively. However, there does not appear to be any clinical evidence to suggest that the montelukast dose needs adjustment in the presence of any of these drugs.

2. Singulair (Montelukast sodium). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, August 2009.

Montelukast + Antihistamines

Montelukast does not interact to a clinically relevant extent with loratadine or terfenadine.

Clinical evidence, mechanism, importance and management

In a study, healthy subjects were given terfenadine 60 mg every 12 hours for 14 days, with montelukast 10 mg daily from day 8 to day 14. It was found that the pharmacokinetics of **terfenadine** and its effect on the QTc interval were unaltered by concurrent use.[1] No adverse interactions were seen in large numbers of patients given montelukast 10 or 20 mg and **loratadine** 10 mg, and the combination was found to be beneficial in the treatment of allergic rhinitis and conjunctivitis.[2] No special precautions are therefore needed if either of these antihistamines are given with montelukast.

1. Holland S, Gertz B, DeSmet M, Michiels N, Larson P, Freeman A, Keymeulen B. Montelukast (MON) has no effect on terfenadine (T) pharmacokinetics (PK) or QTc. *Clin Pharmacol Ther* (1998) 63, 232.
2. Malstrom K, Meltzer E, Prenner B, Lu S, Weinstein S, Wolfe J, Wei LX, Reiss TF. Effects of montelukast (a leukotriene receptor antagonist), loratadine, montelukast + loratadine and placebo in seasonal allergic rhinitis and conjunctivitis. *J Allergy Clin Immunol* (1998) 101, S97.

Montelukast + Rifampicin (Rifampin)

Rifampicin is predicted to reduce montelukast levels.

Clinical evidence, mechanism, importance and management

The manufacturer of montelukast cautions its use with inducers of the cytochrome P450 isoenzyme CYP3A4, such as rifampicin, especially in children.[1] This is because phenobarbital (an inducer of CYP3A4) has been found to reduce the AUC and serum levels of montelukast (see 'Montelukast + Antiepileptics; Enzyme-inducing', p.1426). However, there is currently no clinical evidence to suggest that the montelukast dose needs adjustment in patients taking rifampicin.

1. Singulair (Montelukast sodium). Merck Sharp & Dohme Ltd. UK Summary of product characteristics, August 2009.

Roflumilast + Antacids

Aluminium/magnesium hydroxide antacids do not appear to affect the pharmacokinetics of roflumilast or its active metabolite.

Clinical evidence, mechanism, importance and management

In a study, 30 healthy subjects were given a single 500-microgram dose of roflumilast alone, with, or 2 hours before, 30 mL of an **aluminium/magnesium hydroxide**-containing antacid (*Maalox*). There were no significant changes in the pharmacokinetics of roflumilast or its active metabolite, roflumilast *N*-oxide.[1] There would appear to be no reason to avoid the concurrent use of roflumilast and this type of antacid.

1. Nassr N, Lahu G, Hünnemeyer A, von Richter O, Knoerzer D, Reutter F, Zech K, Hermann R. Magnesium hydroxide/aluminium hydroxide-containing antacid does not affect the pharmacokinetics of the targeted phosphodiesterase 4 inhibitor roflumilast. *J Clin Pharmacol* (2007) 47, 660–6.

Roflumilast + Antiasthma drugs

The pharmacokinetics of montelukast and salbutamol are not affected by roflumilast, nor are the pharmacokinetics of roflumilast and its active metabolite roflumilast *N*-oxide altered by either montelukast or salbutamol.

Clinical evidence, mechanism, importance and management

(a) Montelukast

In a study, 24 healthy subjects were given roflumilast 500 micrograms daily with montelukast 10 mg daily for 9 days. Compared with the use of either drug alone, concurrent use did not result in any clinically relevant changes in the pharmacokinetics of either drug.[1]

(b) Salbutamol

In a study, 12 healthy subjects were given oral roflumilast 500 micrograms daily, inhaled salbutamol 200 micrograms three times daily, or both drugs together, for 7 days. The pharmacokinetics of roflumilast and its active metabolite, roflumilast *N*-oxide, were not significantly altered by salbutamol.[2]

1. Böhmer GM, Nassr N, Wenger M, Hünnemeyer A, Lahu G, Templin S, Gleiter CH, Hermann R. The targeted oral, once-daily phosphodiesterase 4 inhibitor roflumilast and the leukotriene receptor antagonist montelukast do not exhibit significant pharmacokinetic interactions. J Clin Pharmacol (2009) 49, 389–97.
2. Bethke TD, Giessmann T, Westphal K, Weinbrenner A, Hauns B, Hauschke D, David M, Lahu G, Zech K, Hermann R, Siegmund W. Roflumilast, a once-daily oral phosphodiesterase 4 inhibitor, lacks relevant pharmacokinetic interactions with inhaled salbutamol when co-administered in healthy subjects. *Int J Clin Pharmacol Ther* (2006) 44, 572–9.

Roflumilast + Azoles

The pharmacokinetics of roflumilast are not affected by the concurrent use of ketoconazole.

Clinical evidence

In a study, 24 healthy subjects were given a single 200-mg dose of ketoconazole on day 11 of taking roflumilast 500 micrograms daily for 11 days. Ketoconazole increased the AUC of roflumilast by 34%, but its maximum plasma levels were unaffected. The AUC of the active metabolite, roflumilast *N*-oxide was reduced by 12%, and its maximum plasma levels were reduced by 20%. However, the total phosphodiesterase-4 inhibitory activity of roflumilast and its active metabolite was unaltered, suggesting that these changes were not clinically significant.[1]

In a related crossover study, 16 healthy subjects were given ketoconazole 200 mg twice daily, with single 500-microgram dose of roflumilast when ketoconazole steady-state levels were achieved. Ketoconazole increased the AUC and maximum plasma levels of roflumilast by 99% and 23%, respectively. The maximum plasma levels of the active metabolite, roflumilast *N*-oxide were reduced by 38%, and its half-life was prolonged from 9.6 hours to 21.5 hours. However, the total phosphodiesterase-4 inhibitory activity of roflumilast and its active metabolite was unaltered, and no clinically relevant adverse effects were seen, suggesting that these changes are not clinically significant.[1]

Mechanism

Roflumilast *N*-oxide is formed by the metabolism of roflumilast by the cytochrome P450 isoenzyme CYP3A4, and it is thought that the clearance of roflumilast *N*-oxide is also reliant on CYP3A4. Ketoconazole, an inhibitor of CYP3A4 therefore reduces the formation of the active metabolite, but also reduces roflumilast clearance.

Importance and management

Evidence appears to be limited to these two studies, which are in line with the known CYP3A4-inhibitory effects of ketoconazole. An interaction is therefore established. However, as the overall effect of roflumilast appears to be unchanged, the pharmacokinetic changes seen do not appear to be clinically relevant. No dose adjustments are expected to be necessary if roflumilast is given with ketoconazole. Other azoles are expected to similarly lack a clinically relevant effect on roflumilast metabolism, but this needs confirmation.

1. Lahu G, Huennemeyer A, von Richter O, Hermann R, Herzog R, McCracken N, Zech K. Effect of single and repeated doses of ketoconazole on the pharmacokinetics of roflumilast and roflumilast N-oxide. J Clin Pharmacol (2008) 48, 1339–49.

Roflumilast + Corticosteroids

The concurrent use of roflumilast and budesonide does not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a crossover study, 12 healthy subjects were given oral roflumilast 500 micrograms daily for 7 days, inhaled budesonide 800 micrograms twice daily for 7 days, or both drugs together. Budesonide did not affect the pharmacokinetics of roflumilast measured on day 7, nor was there any significant change in the pharmacokinetics of budesonide when taken with roflumilast. There was, however, a wide variation in parameters between subjects. There were no significant changes in the clinical status of the subjects.[1] No dose adjustments of either drug are therefore expected to be necessary on concurrent use.

1. Hermann R, Siegmund W, Giessmann T, Westphal K, Weinbrenner A, Hauns B, Reutter F, Lahu G, Zech K, Bethke TD. The oral, once-daily phosphodiesterase 4 inhibitor roflumilast lacks relevant pharmacokinetic interactions with inhaled budesonide. *J Clin Pharmacol* (2007) 47, 1005–13.

Roflumilast + Food

Food delays and reduces the maximum plasma levels of roflumilast, but has no effect on its active metabolite.

Clinical evidence, mechanism, importance and management

In a crossover study in 12 healthy subjects, a single 500-microgram dose of roflumilast was given after an overnight fast, or within 5 minutes of a high-fat, high-calorie breakfast. The time to reach maximum plasma levels was delayed from one hour to 2 hours when roflumilast was taken with food, and its maximum plasma levels were reduced by 40%. However, the pharmacokinetics of the active metabolite, roflumilast *N*-oxide, were not significantly altered. It is suggested that as the activity of roflumilast is predominantly exerted by roflumilast *N*-oxide, food will have little effect on the clinical outcome of treatment with roflumilast.[1]

1. Hauns B, Hermann R, Hünnemeyer A, Herzog R, Hauschke D, Zech K, Bethke TD. Investigation of a potential food effect on the pharmacokinetics of roflumilast, an oral once-daily phosphodiesterase 4 inhibitor, in healthy subjects. *J Clin Pharmacol* (2006) 46, 1146–53.

Roflumilast + Macrolides

Erythromycin increases the exposure to roflumilast but this does not appear to increase its adverse effects.

Clinical evidence, mechanism, importance and management

In a study 18 healthy subjects were given a single 588-mg dose of erythromycin alone or on day 11 of taking roflumilast 500 micrograms daily for 11 days. The pharmacokinetics of roflumilast and its active metabolite roflumilast *N*-oxide were unaltered, and there were no clinically significant changes in the pharmacokinetics of **erythromycin**. In addition, vital signs, ECG and laboratory parameters were not altered to a clinically relevant extent by concurrent use.[1] In a crossover study, 15 healthy subjects were given a single 500-microgram dose of roflumilast before and on day 7 of taking **erythromycin** 500 mg three times daily. Erythromycin increased the maximum levels and AUC of roflumilast by 40% and 70%, respectively. The AUC of the metabolite, roflumilast *N*-oxide was unchanged, whereas the maximum levels were decreased by 34%, and the time to maximum levels was delayed. However, the overall phosphodiesterase type-4 inhibitory effects of roflumilast were unaffected, and the incidence of adverse effects was not increased by concurrent use.[2]

Roflumilast is metabolised to roflumilast *N*-oxide by the cytochrome P450 isoenzyme CYP3A4, and it is thought that the clearance of roflumilast *N*-oxide is also reliant on CYP3A4. Drugs that are inhibitors of CYP3A4, such as a number of the macrolides, including **erythromycin**, may therefore reduce the formation of the active metabolite, but also reduce its clearance.

Evidence appears to be limited to these two studies, but an interaction appears to be established. However, as the overall effect of roflumilast appears to be unchanged, the pharmacokinetic changes seen do not appear to be clinically relevant. No dose adjustments are expected to be necessary if roflumilast is given with erythromycin. The adverse effects of roflumilast are thought to be related to its phosphodiesterase type-4 inhibitory effects, and therefore increased adverse effects would not be expected on concurrent use. Other macrolides are expected to similarly lack a clinically relevant effect on roflumilast metabolism, but this needs confirmation.

Pharmacokinetics of the selective PDE4 inhibitor roflumilast and its active metabolite roflumilast N-oxide are not affected by concomitant budesonide, salbutamol or erythromycin. *J Allergy Clin Immunol* (2004) 113 (Suppl), S222.
2. Lahu G, Huennemeyer A, Herzog R, McCracken N, Hermann R, Elmlinger M, Zech K. Effect of repeated dose of erythromycin on the pharmacokinetics of roflumilast and roflumilast N-oxide. Int J Clin Pharmacol Ther (2009) 47, 236–45.

Roflumilast + Rifampicin (Rifampin)

Rifampicin increases the metabolism of roflumilast to its active metabolite, roflumilast *N*-oxide, but decreases the overall bioavailability of roflumilast *N*-oxide.

Clinical evidence, mechanism, importance and management

In a study, 15 healthy subjects were given a single 500-microgram dose of roflumilast alone or after taking rifampicin 600 mg daily for 8 days. The AUC and maximum plasma levels of roflumilast were reduced by 79% and 68%, respectively. The AUC of the active metabolite, roflumilast *N*-oxide was reduced by 56%, while the maximum plasma levels of roflumilast *N*-oxide were increased by 30%.[1]

Rifampicin induces the activity of the cytochrome P450 isoenzyme CYP3A4, which is involved in the metabolism of roflumilast and roflumilast-*N*-oxide.

It is likely that the dose of roflumilast will need to be increased in patients also taking rifampicin.

1. Nassr N, Huennemeyer A, Herzog R, von Richter O, Hermann R, Koch M, Duffy K, Zech K, Lahu G. Effects of rifampicin on the pharmacokinetics of roflumilast and roflumilast-N-oxide in healthy subjects. Br J Clin Pharmacol (2009) 68, 580–7.

Roflumilast + SSRIs

The exposure to roflumilast and its active metabolite roflumilast *N*-oxide is increased by fluvoxamine.

Clinical evidence

In a crossover study, 14 healthy subjects were given a single 500-microgram dose of roflumilast alone, or after they had taken fluvoxamine 50 mg daily for 8 days. The AUC of roflumilast increased 2.6-fold, and the AUC of the active metabolite, roflumilast *N*-oxide increased by 50%. The maximum plasma levels of roflumilast *N*-oxide decreased by 20%. There was an overall increase of 59% in total phosphodiesterase-4 inhibitory activity, but there were no clinically relevant changes in laboratory measurements, blood pressure, pulse or ECG, nor were there any serious or unexpected adverse effects.[1]

Mechanism

Roflumilast is metabolised by the cytochrome P450 isoenzyme CYP1A2 and CYP3A4 to its active metabolite roflumilast *N*-oxide. Roflumilast *N*-oxide is in turn metabolised by CYP3A4, and probably to a lesser extent by CYP2C19. Fluvoxamine inhibits CYP1A2 and CYP2C19, and therefore concurrent use increases the exposure to roflumilast *N*-oxide.

Importance and management

Evidence appears to be limited to this study, in which the subjects were mainly overweight or obese. Nevertheless, the increases in the levels of roflumilast would be expected to be generally relevant. Although concurrent use may increase the efficacy of the roflumilast (phosphodiesterase-4 activity was increased), it seems possible that some patients may develop roflumilast adverse effects (e.g. nausea, diarrhoea, headache). If these develop in a patient taking fluvoxamine, consider an interaction as a possible cause. Note that other SSRIs do not affect CYP1A2, and would therefore not be expected to interact with roflumilast. However, this needs confirmation.

Terbutaline + Magnesium sulfate

Subcutaneous terbutaline and intravenous magnesium sulfate appear not to interact adversely.

Clinical evidence, mechanism, importance and management

Eight healthy adults were given two subcutaneous doses of terbutaline 250 micrograms 30 minutes apart, with and without intravenous magnesium sulfate 4 g in 250 mL of sodium chloride 0.9%, given over the same 30-minute period.[1] Most of the effects of terbutaline, such as those on respiratory rate, blood pressure, glucose and calcium levels, were found to be moderately increased by magnesium sulfate at 60 minutes but these changes were all considered to be small. It was concluded that there appear to be no good reasons for avoiding the concurrent use of terbutaline and magnesium sulfate, for example in the emergency treatment of asthma and other conditions.

Theophylline + Aciclovir

Preliminary evidence suggests that aciclovir can increase the serum levels of theophylline (given as aminophylline).

Clinical evidence

Prompted by a case of increased theophylline adverse effects in a patient given aciclovir, a study was carried out in 5 healthy subjects who were given single 320-mg doses of theophylline (as 400 mg of aminophylline) before and with the sixth dose of aciclovir 800 mg five times daily for 2 days. The AUC of the theophylline was increased by 45% and its total body clearance was reduced by 30% by the aciclovir.[1]

Mechanism

Uncertain, but the evidence suggests that aciclovir inhibits the oxidative metabolism of theophylline, resulting in accumulation.[1]

Importance and management

Evidence appears to be limited to this report. However, be alert for an increase in the adverse effects of theophylline (nausea, headache, tremor) if aciclovir is added to established treatment, and consider monitoring levels. More study is needed to establish an interaction.

Theophylline + Allopurinol

Allopurinol may increase theophylline levels, but not all studies have found this effect.

Clinical evidence

The peak plasma levels of theophylline 450 mg daily rose by 38% in a patient who took allopurinol for 3 days.[1] Another case report describes a patient taking theophylline 240 mg four times daily who experienced a grand mal seizure one day after starting allopurinol 100 mg three times daily. His theophylline levels were, however, elevated at 59 mg/L the day before starting allopurinol, and rose further to 86 mg/L the day after starting allopurinol. It is unclear whether the allopurinol was implicated in this case as the patient demonstrated slow metabolism of theophylline upon rechallenge.[2]

In a study in 12 healthy subjects, allopurinol 300 mg twice daily for 14 days increased the half-life of a single 5-mg/kg oral dose of theophylline by 25%, and increased its AUC by 27%.[3] Similar increases were seen when a second dose of theophylline was given 28 days after starting the allopurinol.[3] However, in two other studies allopurinol 300 mg daily for 7 days did not have any effect on the pharmacokinetics of theophylline, following a single 5-mg/kg intravenous dose of aminophylline.[4,5] Similarly, steady-state theophylline levels were not affected by allopurinol 100 mg three times daily in 4 subjects. However, there was an alteration in the proportion of different urinary theophylline metabolites: methyluric acid decreased and methylxanthine increased.[5]

Mechanism

Uncertain. Allopurinol, a xanthine oxidase inhibitor, can block the conversion of methylxanthine to methyluric acid, but this had no effect on theophylline levels in two studies. It has been suggested that allopurinol inhibits the oxidative metabolism of theophylline by the liver.[1]

Importance and management

Evidence appears to be limited to two case reports and the studies in healthy subjects. The interaction only appears to be of moderate importance. Nevertheless, it would seem prudent to check for any signs of theophylline adverse effects (headache, nausea, tremor) during concurrent use, particularly in situations where the metabolism of the theophylline may already be reduced (other drugs or diseases), or where high doses of allopurinol are used. If theophylline adverse effects are troublesome, monitor levels and adjust the dose accordingly.

Theophylline + Alosetron

Alosetron does not alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 10 healthy women were given alosetron 1 mg twice daily for 16 days with oral theophylline 200 mg twice daily from day 8 to day 16. No clinically relevant changes in the pharmacokinetics of theophylline were seen, and concurrent use was well tolerated. The effect of theophylline on alosetron pharmacokinetics was not measured but the authors of the report say that no metabolic interaction seems likely.[1] No dose adjustments would therefore appear to be needed if these drugs are used together.

1. Koch KM, Ricci BM, Hedayetullah NS, Jewell D, Kersey KE. Effect of alosetron on theophylline pharmacokinetics. *Br J Clin Pharmacol* (2001) 52, 596–600.

Theophylline + Aminoglutethimide

Theophylline clearance is increased by aminoglutethimide, which may result in a moderate reduction in the serum levels and therapeutic effects of theophylline.

Clinical evidence, mechanism, importance and management

Aminoglutethimide 250 mg four times a day increased the clearance of sustained-release theophylline 200 mg twice daily by 18 to 43% in 3 patients.[1] Theophylline clearance was assessed before starting aminoglutethimide as well as during weeks 2 to 12 of concurrent use.

It seems probable that aminoglutethimide, a known enzyme inducer, increases the metabolism of theophylline by the liver, thereby decreasing its levels. The clinical importance of this is uncertain, but it seems likely that the effects of theophylline (and aminophylline, which is metabolised to theophylline) would be reduced to some extent. Monitor the effects and if necessary take theophylline levels. Increase the theophylline dose accordingly.

Theophylline + Amiodarone

An isolated case report describes an elderly man who developed raised theophylline levels and toxicity when he was given amiodarone.

Clinical evidence, mechanism, importance and management

An 86-year-old man taking furosemide, digoxin, domperidone and sustained-release theophylline developed signs of theophylline toxicity when amiodarone 600 mg daily was given. After 9 days his serum theophylline levels had doubled, from about 16.8 mg/L to 35 mg/L. The toxicity disappeared when the theophylline was stopped.[1] The reason for this adverse reaction is not understood but it has been suggested that amiodarone may reduce the metabolism of the theophylline by the liver.[1] This is an isolated case and its general importance is uncertain. More study is needed.

Amiodarone may cause thyroid dysfunction, which may affect aminophylline and theophylline requirements, see also 'Theophylline + Thyroid and Antithyroid compounds', p.1461.

Theophylline + Antacids

The extent of absorption of theophylline from the gut does not appear to be significantly affected by aluminium or magnesium hydroxide antacids. However, an increase in the rate of absorption of some sustained-release theophylline preparations may occur.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, there was no difference in the steady-state maximum serum concentrations or AUC of theophylline given as *Nuelin-Depot* or *Theodur* when an antacid (*Novalucid*, containing **aluminium**/**magnesium hydroxide** and **magnesium carbonate**) was given. However, the antacid caused a faster absorption of theophylline from *Nuelin-Depot*, which resulted in greater fluctuations in the serum levels. It was considered that the adverse effects of theophylline might be increased in those patients with serum levels at the top of the range.[1] Similar results have been found in single-dose studies when aminophylline,[2] *Slo-Phyllin Gyrocaps*,[3] *Somophyllin CRT*,[4] and *Theo-Dur*[5] were given with **aluminium**/**magnesium hydroxide** antacids, and in multiple dose studies in patients when *Armophylline*,[6] *Aminophyllin*[7] or *Theodur*[7] were given with **aluminium**/**magnesium hydroxide** antacids. Administration of 30 mL of an **aluminium**/**magnesium hydroxide** antacid (*Maalox*) four times daily did not affect the trough levels of theophylline in a patient taking *Theo-Dur* 400 mg three times daily.[8] Care should be taken extrapolating this information to other preparations of theophylline and aminophylline, but generally speaking no special precautions seem to be necessary if antacids are given with theophylline or aminophylline.

Theophylline + Anthelmintics; Benzimidazoles

Theophylline levels can be markedly increased by tiabendazole and toxicity may develop. Albendazole and mebendazole do not appear to interact with theophylline.

Clinical evidence

(a) Albendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of theophylline were unaffected by a single 400-mg dose of albendazole.[1]

(b) Mebendazole

A study in 6 healthy subjects found that the pharmacokinetics of a single dose of intravenous aminophylline were unaffected by mebendazole 100 mg twice daily for 3 days.[1] The absence of a significant interaction was reported in another similar study using the same mebendazole dose.[2]

(c) Tiabendazole

An elderly man taking prednisone, furosemide, terbutaline and orciprenaline was switched from oral to intravenous aminophylline, giving a stable serum level of 21 mg/L after 48 hours. When he was also given tiabendazole 4 g daily for 5 days, for persistence of a *Strongyloides stercoralis* infestation, he developed theophylline toxicity (severe nausea) and his serum levels were found to be 46 mg/L. Three months previously, he had taken tiabendazole 3 g daily for 3 days without any symptoms of toxicity (no theophylline levels were measured).[3] The theophylline levels of another patient rose from 15 mg/L to 22 mg/L when he was given tiabendazole 1.8 g twice daily for 3 days, despite a theophylline dose reduction of one-third, made in anticipation of the interaction. Theophylline levels were still elevated 2 days after the tiabendazole was stopped, and the theophylline dose was further reduced. Levels returned to normal after 5 days, and the theophylline dose was eventually increased again.[4]

A retrospective study of patients given theophylline and tiabendazole

found that 9 out of 40 (23%) had developed elevated serum theophylline levels and of those 9 patients, 5 experienced significant toxicity, with 3 requiring hospitalisation. The other 31 patients did not have theophylline levels taken.[5] A further report describes a patient receiving intravenous aminophylline who had an increase in theophylline levels from 18 mg/L to 26 mg/L within 2 days of starting tiabendazole 1.5 g twice daily.[2] The authors of this report then studied 6 healthy subjects who received a single dose of aminophylline before and while taking tiabendazole 1.5 g twice daily for 3 days. Three of the subjects had to discontinue the study because of severe nausea, vomiting or dizziness. In the remaining three, tiabendazole markedly affected the pharmacokinetics of aminophylline; the half-life increased from 6.7 hours to 18.6 hours, the clearance fell by 66% and the elimination rate constant decreased by 65%.[2]

Mechanism

Uncertain. It is suggested that tiabendazole inhibits the metabolism of theophylline, probably by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby prolonging its stay in the body and raising its serum levels. The nausea and vomiting may have been due to the adverse effects of both theophylline and tiabendazole.

Importance and management

The interaction between theophylline or aminophylline and tiabendazole is established and of clinical importance. Monitor theophylline levels and reduce the theophylline dose accordingly. A 50% reduction in the theophylline dose has been suggested,[4] or, where practical, stopping theophylline for 2 to 3 days while giving the tiabendazole.[5] Albendazole and mebendazole do not appear to interact with theophylline (and therefore seem unlikely to interact with aminophylline), and so may be suitable alternative anthelmintics depending on the condition being treated.

Theophylline + Anticholinesterases; Centrally acting

The levels of theophylline are increased by tacrine. Donepezil has no effect on theophylline levels.

Clinical evidence, mechanism, importance and management

(a) Donepezil

An open-label, crossover study in 12 healthy subjects found that donepezil 5 mg daily for 10 days had no significant effects on the pharmacokinetics of theophylline. Theophylline dose adjustments or additional monitoring are not considered necessary during concurrent use.[1]

(b) Tacrine

In a study, healthy subjects were given theophylline 158 mg alone or while taking tacrine 20 mg every 6 hours. The clearance of the theophylline was reduced by 50%, probably because the tacrine inhibits the metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver.[2] Be alert for the need to reduce the dose of theophylline (and probably aminophylline) to avoid toxicity if tacrine is added. More study of this interaction is needed in patients given multiple doses of both drugs.

Theophylline + Antihistamines and related drugs

Azelastine, cetirizine, ketotifen, mequitazine, mizolastine, pemirolast, repirinast, and terfenadine do not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

Azelastine 2 mg twice daily had no significant effect on the clearance of theophylline 300 mg twice daily in 10 subjects with bronchial asthma. However, one patient had a 21% increase and another a 25% decrease in clearance.[1] These changes are generally unlikely to be clinically significant.

A single 240-mg dose of *intravenous* theophylline was given to 6 healthy subjects after they had taken **cetirizine** 10 mg twice daily for 3.5 days. There was no change in theophylline pharmacokinetics, but the half-life of cetirizine was decreased by 19%. This change in cetirizine pharmacokinetics was not considered to be clinically relevant.[2]

Two studies, one in healthy adults[3] and one in asthmatic children,[4] found that **ketotifen** did not affect the pharmacokinetics of a single oral dose of either theophylline[3] or aminophylline.[4] It was suggested that concurrent use might actually decrease the CNS adverse effects of each drug.[3] Another crossover study was conducted in asthmatic patients sensitive to at least one commonly inhaled allergen who received **ketotifen** or placebo twice daily for 12 weeks. Patients received aminophylline from week 5 and week 9, which was dose adjusted to give either low theophylline levels (1 to 10 mg/L) for 4 weeks or high theophylline levels (10 to 20 mg/L) for 4 weeks. An indicator of disease control, the combined symptom score and inhaler use, indicated that the bronchodilating action of aminophylline had been potentiated by **ketotifen**, but there was no significant effect on theophylline levels.[5]

In 7 patients with asthma the steady-state pharmacokinetics of theophylline were not significantly affected when **mequitazine** 6 mg daily was given for 3 weeks.[6]

In 17 healthy subjects, **mizolastine** 10 mg daily had virtually no effect on the steady-state pharmacokinetics of theophylline, although a 13% increase in mean trough level and an 8% increase in the AUC was seen. These changes were not considered clinically relevant.[7]

In 7 healthy subjects, **pemirolast** 10 mg daily for 4 days was found to have no significant effect on the steady-state serum levels or clearance of theophylline.[8]

In 10 patients with asthma given a single dose of aminophylline, **repirinast** 300 mg daily had no effect on the pharmacokinetics of theophylline.[9] Another study in 7 asthmatics found that **repirinast** (dose unclear) for 3 weeks had no effect on the pharmacokinetics of theophylline 400 to 800 mg, given in two divided doses.[10]

In 10 healthy subjects the pharmacokinetics of a single 250-mg dose of theophylline were unchanged by **terfenadine** 120 mg twice daily for 16 days.[11] Similarly, **terfenadine** 60 mg twice daily did not affect the steady-state pharmacokinetics of theophylline 4 mg/kg daily.[12] Another study in 17 healthy, male subjects found no change in the pharmacokinetics of a single 4-mg/kg oral dose of theophylline (rounded to nearest 50 mg) when taken with a single 60-mg dose of **terfenadine**.[13]

No special precautions seem to be necessary if any of these drugs is given with theophylline or aminophylline.

Theophylline + Azoles

Theophylline levels are normally unaffected or only minimally affected by fluconazole and ketoconazole. An isolated report describes a rise in serum theophylline levels due to fluconazole, and another describes falls in theophylline levels in three patients taking ketoconazole.

Clinical evidence

(a) Fluconazole

A crossover study in 5 healthy subjects found that fluconazole 100 mg given every 12 hours for 7 doses caused only a non-significant 16% decrease in the clearance of a single 300-mg oral dose of aminophylline.[1] Another study in 10 healthy subjects found that fluconazole 100 mg daily for one week had no significant effect on the serum levels of theophylline 150 mg twice daily.[2] In 9 subjects who took fluconazole 400 mg daily for 10 days, the clearance of a single 6-mg/kg oral dose of theophylline was reduced by 13%.[3] In contrast, an isolated and brief report says that one of 2 patients given theophylline and fluconazole had a rise (amount not specified) in serum theophylline levels.[4]

(b) Ketoconazole

No significant changes in the pharmacokinetics of a single 3-mg/kg intravenous dose of theophylline (given as aminophylline) were seen in 12 healthy subjects who took a single 400-mg dose of ketoconazole, or in 4 subjects who took ketoconazole 400 mg daily for 5 days.[5] Similar results were found in another study in 10 healthy subjects who took ketoconazole 200 mg daily for 7 days.[6] In 6 healthy subjects ketoconazole 400 mg daily for 6 days increased the half-life of a single 250-mg oral dose of theophylline by 22%, but had no effect on its clearance.[7] In contrast, a case report describes a man whose serum theophylline levels fell sharply from about 16.5 mg/L to 9 mg/L (reference range 10 to 20 mg/L) over the 2 hours immediately after taking 200 mg of ketoconazole. A less striking fall was seen in 2 other patients.[8]

Mechanism

Fluconazole and ketoconazole (and the other azoles) appear to have minimal effects on the cytochrome P450 isoenzyme CYP1A2, which is concerned with the oxidative metabolism of theophylline.[1,7] It is not clear why a few individuals had some changes in theophylline levels.

Importance and management

Information seems to be limited to these reports. Neither fluconazole nor ketoconazole normally appears to interact with aminophylline or theophylline to a relevant extent in most patients. However, it seems that very occasionally some changes occur, so bear this interaction in mind in the case of unexpected changes in theophylline levels, adverse effects or uncontrolled symptoms. Other azole antifungals are also unlikely to interact with theophylline, but ideally this needs confirmation.

Theophylline + Barbiturates

Theophylline serum levels can be reduced by phenobarbital or pentobarbital. A single report describes a similar interaction with secobarbital and the same effect would be expected with other barbiturates.

Clinical evidence

(a) Pentobarbital

A single case report describes a man receiving intravenous aminophylline who had a 95% rise in the clearance of theophylline after he was given high-dose intravenous pentobarbital.[1] In healthy subjects pentobarbital 100 mg daily for 10 days increased the clearance of oral theophylline by a mean of 40% and reduced the AUC by 26%, although there were marked intersubject differences in the findings.[2]

(b) Phenobarbital

In 7 children aged 6 to 12 years with asthma, phenobarbital (2 mg/kg daily to a maximum of 60 mg) for 19 days reduced the mean steady-state serum theophylline levels by 30%, and increased the clearance by 35% (range 12 to 71%).[3] In contrast, two earlier studies (one by the same group of authors) found no significant change in the pharmacokinetics of theophylline, in children with asthma given phenobarbital 2 mg/kg daily, 16 mg three times daily or 32 mg three times daily.[4,5]

In healthy adult subjects given phenobarbital, the mean theophylline clearance, from a single intravenous dose of aminophylline, was increased by 34%.[6] In another study the clearance of theophylline was increased by 17% when phenobarbital was given for 2 weeks, although this was not statistically significant.[7]

The effects of phenobarbital can be additive with the effects of phenytoin and smoking; one patient required 4 g of theophylline daily to maintain therapeutic serum levels and to control her asthma.[8]

One retrospective study found that premature infants needed a higher dose of intravenous aminophylline for neonatal apnoea when they were given phenobarbital,[9] but a later prospective study did not confirm this.[10] A study in one set of newborn twins given intravenous aminophylline found that the serum theophylline levels of the twin given phenobarbital were about half those of the twin not given phenobarbital.[11]

(c) Secobarbital

The clearance of theophylline increased by 337% over a 4-week period in a child given periodic doses of secobarbital and regular doses of phenobarbital.[12]

Mechanism

The barbiturates are potent liver-enzyme inducers, which possibly increases the metabolism of theophylline by the liver, thereby hastening its removal from the body. This has been shown in *animal* studies, although *N*-demethylation (the main metabolic route for theophylline) was not affected.[13]

Importance and management

A moderately well documented, established and clinically important interaction. Patients given phenobarbital or pentobarbital may need above-average doses of theophylline or aminophylline to achieve and maintain adequate serum levels. Concurrent use should be monitored and appropriate dose increases made. All of the barbiturates can cause enzyme induction and may, to a greater or lesser extent, be expected to behave similarly. This is illustrated by the single report involving secobarbital. However, direct information about other barbiturates seems to be lacking. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + BCG vaccine

BCG vaccination can increase the half-life of theophylline.

Clinical evidence, mechanism, importance and management

Two weeks after 12 healthy subjects were vaccinated with 0.1 mL of BCG vaccine, the clearance of a single 128-mg dose of theophylline (as choline theophyllinate) was reduced by 21% and the theophylline half-life was prolonged by 14% (range 10% reduction to 47% increase).[1] It therefore seems possible that the occasional patient may develop some signs of theophylline toxicity if their serum levels are already towards the top end of the therapeutic range but theophylline levels are unlikely to be affected in most patients given BCG vaccine. No action is necessary as any interaction seems likely to resolve spontaneously.

Theophylline + Beta-agonist bronchodilators

The concurrent use of aminophylline or theophylline and beta-agonist bronchodilators is a useful option in the management of asthma and COPD, but potentiation of some adverse reactions can occur, the most serious being hypokalaemia and tachycardia, particularly with high-dose theophylline. Some patients may have a reduction in their theophylline levels if given oral or intravenous salbutamol (albuterol) or intravenous isoprenaline (isoproterenol).

Clinical evidence

(a) Fenoterol

A study in 12 patients with chronic airways disease found that oral fenoterol 2.5 mg three times daily did not affect the steady-state level of sustained-release theophylline 10.1 mg/kg twice daily.[1]

Another study in 8 healthy subjects found that the addition of sutained-release theophylline to inhaled fenoterol 600 and 800 micrograms increased the heart rate and systolic blood pressure. Theophylline levels were not affected.[2] A study in 6 healthy subjects found that the fall in plasma potassium levels seen after inhalation of three doses of 600 micrograms of fenoterol given over one hour was not exacerbated by a 7-mg/kg infusion of theophylline.[3]

(b) Formoterol

In a single-dose study, 8 healthy subjects were given oral doses of theophylline 375 mg and formoterol 144 micrograms. Concurrent use caused no significant pharmacokinetic interaction, but a significantly greater drop in the potassium level was seen, when compared with either drug given alone.[4]

(c) Isoprenaline (Isoproterenol)

An infusion of isoprenaline increased the clearance of theophylline (given as intravenous aminophylline) by a mean of 19% in 6 children with status asthmaticus and respiratory failure. Two of them had increases in clearance of greater than 30%.[5] Another study in 12 patients with status asthmaticus found that an isoprenaline infusion (mean maximum rate 0.77 micrograms/kg per minute) caused a mean fall in serum theophylline levels of almost 6 micrograms/mL.[6] The levels rose again when isoprenaline was stopped.[6] A critically ill patient receiving intravenous aminophylline, phenytoin and nebulised terbutaline had a marked 4.5-fold increase in theophylline clearance when an isoprenaline infusion and intravenous methylprednisolone were added to the regimen.[7]

(d) Orciprenaline (Metaproterenol)

In 6 healthy subjects, oral orciprenaline 20 mg every 8 hours or inhaled orciprenaline 1.95 mg every 6 hours for 3 days had no effect on the pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline).[8] This confirms a previous finding in asthmatic children, in whom it was shown that oral orciprenaline did not alter steady-state serum theophylline levels.[9]

(e) Salbutamol (Albuterol)

1. Effects on heart rate or potassium levels. In healthy subjects, pretreatment with oral theophylline for 9 days significantly increased the hypokalaemia and tachycardia caused by an infusion of salbutamol (4 micrograms/kg loading dose then 8 micrograms/kg for an hour).[10] In one study in 9 patients with COPD a potentially dangerous additive increase in heart rate of about 35 to 40% was seen in when infusions of aminophylline and salbutamol were given.[11] Similarly, heart rate was significantly higher in 15 children with asthma given single doses of oral theophylline and salbutamol (109 bpm) when compared with a control group given oral theophylline alone (91 bpm).[12] However, another study in 18 patients with COPD and heart disease found that neither the occurrence nor the severity of arrhythmias seemed to be changed when oral theophylline was given with inhaled salbutamol.[13] One report describes a 10-year-old girl given theophylline and salbutamol who had a respiratory arrest, possibly related to hypokalaemia.[14]

2. Effects on theophylline levels. In 10 healthy subjects, theophylline clearance was increased by a mean of 14%, and in 3 cases by greater than 30%, when salbutamol was given orally, but no changes in clearance were seen when salbutamol was given by inhalation.[15] Another study reported a 25% reduction in serum theophylline levels in 10 patients who took oral salbutamol 16 mg.[16] A child of 19 months given intravenous theophylline was also given an infusion of salbutamol: theophylline clearance was increased and the theophylline dose needed to be increased threefold to compensate.[17] Peak flow readings were decreased in 15 children (aged 5 to 13 years) given single doses of oral salbutamol and theophylline, but theophylline levels were not significantly decreased.[12] These reports contrast with another study in 8 healthy subjects, which found no change in the steady-state pharmacokinetics of oral theophylline when oral salbutamol was also given.[18]

(f) Terbutaline

In 7 healthy subjects pretreatment with oral theophylline for at least 4 days significantly increased the fall in serum potassium levels and rises in blood glucose, pulse rate, and systolic blood pressure caused by an infusion of terbutaline.[19] A study in children given slow-release formulations of both theophylline and terbutaline found no increases in reported adverse effects and simple additive effects on the control of their asthma.[20]

Oral terbutaline decreased serum theophylline levels by about 10% in 6 patients with asthma, and the control of asthma was improved.[21] Another study, in children with asthma, found that terbutaline elixir 75 micrograms/kg three times daily reduced the steady-state serum levels of theophylline by 22%, but the symptoms of cough and wheeze improved.[22] In 9 healthy subjects the mean half-life of theophylline, given as a single 6-mg/kg dose of intravenous aminophylline, was not significantly altered after oral terbutaline 5 mg was given three times daily for 4 days, although some subjects had an increase in theophylline clearance, and some a decrease.[23] Yet another study found no changes in the pharmacokinetics of aminophylline in children with asthma given terbutaline;[24] a study in 12 healthy adults found no clinically significant changes in the pharmacokinetics of terbutaline and theophylline when both drugs were given orally for 7 days,[25] and a study in 8 healthy subjects given subcutaneous terbutaline 250 micrograms at 0, 0.5, 4.5 and 5 hours after a single

7-mg/kg dose of oral theophylline similarly found no change in theophylline pharmacokinetics.[26]

(g) Unspecified beta$_2$ agonists

In 1990, the CSM in the UK noted that, of 26 reports they had on record of hypokalaemia with unnamed xanthines or beta$_2$ agonists, 9 occurred in patients receiving both groups of drugs. In 5 of these 9 cases, the hypokalaemia had no clinical consequence. However, in 2 cases it resulted in cardiorespiratory arrest, in one case confusion, and in a further case intestinal pseudo-obstruction.[27]

Mechanism

Beta$_2$ agonists can cause hypokalaemia, particularly when they are given parenterally or by nebulisation. Aminophylline and theophylline can also cause hypokalaemia, and this is a common feature of theophylline toxicity. The potassium-lowering effects of both these groups of drugs are additive. Why some beta agonists lower serum theophylline levels is not known.

Importance and management

The concurrent use of aminophylline or theophylline and beta$_2$ agonist bronchodilators is beneficial, but the reports outlined above illustrate some of the disadvantages and adverse effects that have been identified. In particular, it has been suggested that the use of intravenous beta agonists in acutely ill patients receiving theophylline may be hazardous because of the risk of profound hypokalaemia and cardiac arrhythmias.[10,19] Monitoring of serum potassium in these situations was suggested.[19] Moreover, the CSM in the UK particularly recommends monitoring potassium levels in those with severe asthma as the hypokalaemic effects of beta$_2$ agonists can be potentiated by theophylline and its derivatives, corticosteroids, diuretics and hypoxia.[27]

Theophylline + Beta blockers

Propranolol reduces the clearance of theophylline. More importantly, non-cardioselective beta blockers such as nadolol and propranolol, should not be given to asthmatic patients because they can cause bronchospasm. The concurrent use of theophylline and cardioselective beta blockers such as atenolol, bisoprolol or metoprolol is not contraindicated, but some caution is still appropriate. Atenolol and bisoprolol do not affect the pharmacokinetics of theophylline.

Clinical evidence

(a) Pharmacokinetics

A study in 8 healthy subjects (5 of whom smoked 10 to 30 cigarettes daily) found that the clearance of a single 5.7- to 6.4-mg/kg dose of theophylline (as intravenous aminophylline) was reduced by 37% by **propranolol** 40 mg every 6 hours, when compared with theophylline alone. **Metoprolol** 50 mg every 6 hours did not alter the clearance in the group as a whole, but the smokers had an 11% reduction in clearance.[1] Another study, in 7 healthy subjects, found that the steady-state plasma clearance of theophylline was reduced by 30% by **propranolol** 40 mg every 8 hours, and by 52% by **propranolol** 240 mg every 8 hours,[2] whereas a study in 5 healthy subjects who had received **propranolol** 60 mg every 8 hours for 3 days found that the half-life of theophylline, given as a single 6-mg/kg dose of intravenous aminophylline was prolonged by 59%.[3] However, a further study found no significant pharmacokinetic interaction between theophylline and **propranolol**.[4] Three other studies found that the cardioselective beta blockers **atenolol** 50 to 150 mg,[5,6] and **bisoprolol** 10 mg,[7] and the non-selective beta blocker **nadolol** 80 mg[5] did not affect the pharmacokinetics of theophylline.

(b) Pharmacodynamics

Beta blockers, particularly those that are not cardioselective, can cause bronchoconstriction, which opposes the bronchodilatory effects of theophylline. See 'Anti-asthma drugs + Beta blockers', p.1415, for mention of a patient who had a deterioration of asthma when taking betaxolol with theophylline and pranlukast.

In a study in 8 healthy subjects both **propranolol** 40 mg every 6 hours and **metoprolol** 50 mg every 6 hours prevented the mild inotropic effect seen with theophylline alone.[8]

An infusion of **propranolol** reduced the hypokalaemia and tachycardia that occurred after a theophylline overdose.[9,10] **Esmolol** has been used similarly.[11]

Mechanism

Propranolol possibly affects the clearance of theophylline by inhibiting its metabolism (demethylation and hydroxylation).[2,12]

Importance and management

The risk of severe, possibly even fatal bronchospasm when beta blockers are taken by asthmatics would seem to be far more important than any pharmacokinetic interaction with theophylline. For more detailed advice on the use of beta blockers in patients with respiratory disease, see 'Anti-asthma drugs + Beta blockers', p.1415. Bronchospasm can occur with beta blockers given by any route of administration, even topically as eye drops. Cardioselective beta blockers have less effect on the airways, but can still cause bronchoconstriction. See 'Table 22.1', (p.995), for details of the selectivity of beta blockers.

Theophylline + Caffeine

The consumption of caffeine-containing beverages can raise theophylline levels, but the clinical relevance of this is unclear. Similarly, removal of caffeine-containing foods from the diet may reduce the half-life of theophylline.

Clinical evidence

Caffeine can decrease the clearance of theophylline by 18 to 29%, prolong its half-life by up to 44% and increase its average serum levels by up to 23%.[1-3] In addition, caffeine plasma levels were increased about twofold when theophylline was given, and this may have caused the headaches and nausea reported in 2 subjects that did not usually drink coffee.[2] In these studies, caffeine was given in the form of tablets[1,2] or as 2 to 7 cups of instant coffee.[3] Another study found that, when 4 healthy subjects removed methylxanthines from their diet, the half-life of theophylline was reduced from 9.8 hours to 7 hours.[4]

Mechanism

These modest pharmacokinetic changes probably occur because the two drugs compete for the same metabolic pathway resulting in a reduction in their metabolism and accumulation. In addition, when caffeine levels are high, a small percentage of it is converted to theophylline.

Importance and management

An interaction between caffeine and theophylline is reasonably well studied and established. There would, however, seem to be no good reason for patients taking theophylline to avoid caffeine (in **coffee**, **tea**, **cola drinks**, medications, etc.), but if otherwise unexplained adverse effects occur it might be worth checking if caffeine is responsible. Removal of caffeine from the diet may have a modest effect on theophylline levels, but the clinical relevance of this is unclear. In addition, caffeine intake could have an impact on the interaction of theophylline with other drugs. Aminophylline does not seem to have been studied, but as it is metabolised to theophylline, it would be expected to interact similarly.

Theophylline + Calcium-channel blockers

Giving calcium-channel blockers to patients taking theophylline normally has no adverse effect on the control of asthma, despite the small or modest alteration that may occur in theophylline levels with diltiazem, felodipine, nifedipine and verapamil. However, there are isolated case reports of unexplained theophylline toxicity in two patients given nifedipine and two patients given verapamil. Isradipine appears not to interact with theophylline.

Clinical evidence

(a) Diltiazem

In 9 healthy subjects diltiazem 90 mg twice daily for 10 days reduced the clearance of theophylline (given as a single 6-mg/kg dose of aminophylline) by 21%, and increased its half-life from 6.1 hours to 7.5 hours.[1] A 12% fall in the clearance of a single 5-mg/kg oral dose of theophylline was found when healthy subjects were given diltiazem 90 mg three times daily.[2] A further study in 9 healthy subjects given diltiazem 60 mg three times daily for 3 days found that the half-life of a single 200-mg dose of theophylline was increased from 7.58 hours to 8.59 hours and the clearance was reduced by 9%.[3] In 8 patients with asthma or COPD, diltiazem 60 mg three times daily for 5 days reduced the clearance of steady-state theophylline (given as a continuous infusion of aminophylline 12 mg/kg per day) by 22% and increased its half-life from 5.7 hours to 7.5 hours.[4]

Conversely, other studies found no significant changes in peak steady-state theophylline levels in 18 patients with asthma given diltiazem 240 to 480 mg daily for 7 days,[5] or in 7 healthy subjects given diltiazem 120 mg twice daily for 7 days.[6] Similarly, there was no significant change in the half-life or clearance of theophylline (given as a single 250-mg intravenous dose of aminophylline) in healthy subjects given diltiazem 120 mg three times daily for 6 days.[7] One study found that the pharmacokinetics of a single 5-mg/kg intravenous dose of theophylline, given as aminophylline, were unaffected by diltiazem 60 mg given four times daily. However, in an extension of this study, the reduction in theophylline half-life and the increase in theophylline clearance caused by rifampicin 600 mg daily (see 'Theophylline + Rifamycins and/or Isoniazid', p.1456), were slightly attenuated by diltiazem.[8]

(b) Felodipine

In 10 healthy subjects felodipine 5 mg every 8 hours for 4 days reduced the plasma AUC of theophylline (given as theophylline aminopropanol) by 18%, but had no effect on metabolic or renal clearance.[9]

(c) Isradipine

A three-way, crossover study in 11 healthy subjects found that isradipine 2.5 or 5 mg every 12 hours for 6 days had no significant effect on the pharmacokinetics of a single 5-mg/kg dose of aminophylline oral solution.[10]

(d) Nifedipine

In one study in 8 patients with asthma, slow-release nifedipine 20 mg twice daily reduced the mean steady-state theophylline levels by 30%, from 9.7 mg/L to 6.8 mg/L. Levels fell by 50%, 56%, and 64% in three of the patients, but no changes in the control of the asthma (as measured by peak flow determinations and symptom scores) were seen.[11] However, many other studies have found no changes, or only small to modest changes, in the pharmacokinetics of theophylline (given as oral theophylline or as intravenous lysine theophylline[12] or aminophylline[13]) in healthy subjects[6,12-14] or patients with asthma[5,15,16] given nifedipine. The control of the asthma was unchanged by nifedipine.[15,16] Yet another study found that the combined use of slow-release theophylline and nifedipine improved pulmonary function and blood pressure control.[17]

In contrast, there are 2 case reports of patients who developed theophylline toxicity (theophylline levels raised to 30 mg/L and 41 mg/L, respectively), apparently due to the addition of nifedipine.[18,19] In one case, toxicity recurred on rechallenge, and resolved when the theophylline dose was reduced by 60%.[19] During a Swan Ganz catheter study of patient response to nifedipine for pulmonary hypertension, 2 patients developed serious nifedipine adverse effects, which responded to intravenous aminophylline.[20]

(e) Verapamil

In one study in 5 patients with asthma, verapamil 80 mg every 6 hours for 2 days had no effect on the pharmacokinetics of theophylline (200 mg aminophylline every 6 hours) and no effect on their spirometry (FVC, FEV_1, FEF_{25-75}).[21] Similarly, a study in healthy subjects found that verapamil 80 mg every 8 hours had no effect on the steady-state levels of sustained-release theophylline 3 mg/kg per day.[22] In contrast, numerous other studies in healthy subjects (given intravenous or oral aminophylline or theophylline) have found modest reductions in theophylline clearance, of 8 to 23% with verapamil 40 to 120 mg taken every 6 to 8 hours.[2,7,14,23-25]

One study found that the extent of reduction in clearance depended on the verapamil dose.[25] An isolated report describes a woman taking digoxin and sustained-release theophylline who developed signs of toxicity (tachycardia, nausea, vomiting) after starting to take verapamil 80 mg, increased to 120 mg, every 8 hours. Her theophylline serum levels doubled over a 6-day period. Theophylline was later successfully reintroduced at one-third of the original dose.[26] Another isolated report describes a patient who needed a 50% reduction in their theophylline dose while taking verapamil 120 mg daily.[27]

Mechanism

It is believed that diltiazem and verapamil can, to a limited extent, decrease the metabolism of theophylline by the liver, possibly by inhibiting the cytochrome P450 isoenzyme CYP1A2.[28] Similarly, nifedipine may alter hepatic theophylline metabolism,[14] or it may increase the volume of distribution of theophylline.[12,13] Felodipine possibly reduces theophylline absorption.[9]

Importance and management

The evidence for this interaction is adequately documented but the results are not entirely consistent. However, the overall picture is that the concurrent use of theophylline and these calcium-channel blockers is normally safe. Despite the small or modest decreases in the clearance or absorption of theophylline seen with diltiazem, felodipine and verapamil, and the quite large reductions in serum levels seen in one study with nifedipine, no adverse changes in the control of the asthma were seen in any of the studies. However, very occasionally and unpredictably theophylline levels have risen enough to cause toxicity in patients given nifedipine (2 case reports) or verapamil (2 case reports), so that it would be prudent to be aware of the possibility of an interaction when these drugs are given.

Theophylline + Cannabis

Cannabis smokers may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly.

Clinical evidence, mechanism, importance and management

One study found that tobacco or cannabis smoking similarly caused higher total clearances of theophylline (given as oral aminophylline) than in non-smokers (about 74 mL/kg per hour compared with 52 mL/kg per hour), and that clearance was even higher (93 mL/kg per hour) in those who smoked both.[1] A later analysis by the same authors, of factors affecting theophylline clearance, found that smoking two or more joints of cannabis weekly was associated with a higher total clearance of theophylline than non-use (82.9 mL/kg per hour versus 56.1 mL/kg per hour).[2] A study in which 16 of 49 healthy subjects admitted to smoking cannabis in the months before taking a single 4-mg/kg oral dose of theophylline found that cannabis use did not have a significant effect on the pharmacokinetics of theophylline. Their use was considered not to exceed normal social use of one joint per week.[3]

Tobacco and cannabis smoke contain polycyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2, and this results in a more rapid clearance of theophylline from the body.

Little is known about the effects of smoking cannabis on theophylline levels, but be alert for the need to increase the theophylline dose in regular users. Note that irregular cannabis use might cause fluctuations in theophylline levels.

Theophylline + Carbamazepine

Two case reports describe a marked fall in theophylline levels when carbamazepine was given. Another single case report and a pharmacokinetic study describe a fall in carbamazepine levels when theophylline was given.

Clinical evidence

(a) Theophylline serum levels reduced

An 11-year-old girl with asthma was stable for 2 months taking theophylline and phenobarbital until the phenobarbital was replaced by carbamazepine. The asthma worsened, her theophylline serum levels became subtherapeutic and the half-life of the theophylline was reduced from 5.25 hours to 2.75 hours. Asthmatic control was restored, and the half-life returned to pre-treatment levels 3 weeks after the carbamazepine was replaced by ethotoin.[1] Another report noted that the clearance of theophylline in an adult patient was doubled by carbamazepine 600 mg daily.[2]

(b) Carbamazepine serum levels reduced

The trough carbamazepine levels of a 10-year-old girl were roughly halved when she was given theophylline for 2 days, and she experienced a grand mal seizure. Her serum theophylline levels were also unusually high at 26 mg/L for the 5 mg/kg dose she was taking, so it may be that the convulsions were as much due to this as to the fall in carbamazepine levels.[3]

A single-dose pharmacokinetic study in healthy subjects found that the AUC and maximum serum levels of carbamazepine were reduced by 31% and 45%, respectively, by oral aminophylline.[4]

Mechanism

Not established, but it seems probable that each drug increases the liver metabolism and clearance of the other drug, resulting in a reduction in their effects.[1,3] It is also possible that aminophylline interferes with the absorption of carbamazepine.[4]

Importance and management

Information seems to be limited to the reports cited and therefore the general importance of the effects noted is uncertain. Concurrent use need not be avoided, but it would be prudent to check that the serum concentrations of each drug (and their effects) do not become subtherapeutic. Note that theophylline should be used with caution in patients with epilepsy as it can cause seizures, although this is usually a sign of toxicity.

Theophylline + Cephalosporins

Ceftibuten and cefalexin appear not to interact with theophylline. Cefaclor has been implicated in two cases of theophylline toxicity in children, but studies in adult subjects found no pharmacokinetic interaction.

Clinical evidence, mechanism, importance and management

Ceftibuten 200 mg twice daily for 7 days was found to have no significant effect on the pharmacokinetics of a single intravenous dose of theophylline given to 12 healthy subjects.[1] A study in 9 healthy adults given a single 5-mg/kg intravenous dose of aminophylline found that **cefalexin** 500 mg, then 250 mg every 6 hours for 48 hours, had no significant effect on the pharmacokinetics of theophylline.[2]

A case report[3] suggested that **cefaclor** might have been responsible for the development of theophylline toxicity in 2 children. However, a single-dose study[4] and a steady-state study[5] in healthy adults found that **cefaclor** 250 mg three times daily for 8 and 9 days, respectively, had no effect on the pharmacokinetics of oral or intravenous theophylline. Although the pharmacokinetics of theophylline differ in adults and children a significant interaction with **cefaclor** seems unlikely.

No special precautions seem to be necessary with any of these antibacterials. Note that acute infections *per se* can alter theophylline pharmacokinetics.[6]

Theophylline + Clopidogrel or Ticlopidine

Ticlopidine reduces the clearance of theophylline and is expected to raise its serum levels. Clopidogrel, an analogue of ticlopidine, appears not to interact.

Clinical evidence, mechanism, importance and management

(a) Clopidogrel

Clopidogrel 75 mg daily for 10 days did not alter the steady-state pharmacokinetics of theophylline given to 12 healthy subjects.[1] No problems are therefore anticipated with the concurrent use of these two drugs.

(b) Ticlopidine

In 10 healthy subjects, ticlopidine 250 mg twice daily for 10 days reduced the clearance of a single 5-mg/kg oral dose of theophylline by 37% and increased its half-life by 44%, from about 8.5 hours to 12 hours.[2] The reason for these effects is not known but it seems possible that ticlopidine inhibits the metabolism of theophylline by the liver. Information is limited, but it would seem prudent to monitor the effects of concurrent use: it may be necessary to reduce the dose of theophylline (or aminophylline, which is metabolised to theophylline), particularly when theophylline serum levels are already at the top end of the range.

2. Colli A, Buccino G, Cocciolo M, Parravicini R, Elli GM, Scaltrini G. Ticlopidine-theophylline interaction. *Clin Pharmacol Ther* (1987) 41, 358–62.

Theophylline + Codeine

Codeine does not affect the extent of theophylline absorption.

Clinical evidence, mechanism, importance and management

A study in 6 healthy subjects found that codeine 30 mg prolonged the oral to caecal transit time of a single 500-mg dose of sustained-release theophylline (*Theo-Dur*). The mean amount of theophylline left to be absorbed from the colon was reduced from 58% to 33%, but the time to 90% absorption of theophylline was not significantly affected (7.1 hours compared with 8.5 hours). Therefore codeine does not appear to significantly affect the rate or extent of absorption of theophylline, and concurrent use need not be avoided.[1]

1. Sommers DK, Meyer EC, Van Wyk M, Moncrieff J, Snyman JR, Grimbeek RJ. The influence of codeine, propantheline and metoclopramide on small bowel transit and theophylline absorption from a sustained-release formulation. *Br J Clin Pharmacol* (1992) 33, 305–8.

Theophylline + Corticosteroids

Theophylline and corticosteroids have established roles in the management of asthma and their concurrent use is not uncommon. There are isolated reports of increases in theophylline levels (sometimes associated with toxicity) when oral or parenteral corticosteroids are given, but other reports show no changes. Both theophylline and corticosteroids can cause hypokalaemia, which may be additive.

Clinical evidence

(a) Betamethasone

The elimination half-life of theophylline (given as intravenous aminophylline) was no different in premature infants who had been exposed to betamethasone *in utero* than in those who had not, although the exposed neonates had a wider range of theophylline metabolites indicating greater hepatic metabolism.[1,2]

(b) Dexamethasone

In one study it was briefly mentioned that theophylline did not appear to affect dexamethasone metabolism.[3]

(c) Hydrocortisone

Three patients in status asthmaticus with relatively stable serum concentrations of theophylline were given a 500-mg intravenous bolus of hydrocortisone followed 6 hours later by 200 mg of hydrocortisone given every 2 hours for 3 doses. In each case the serum theophylline levels rose from about 20 mg/L to between 30 and 50 mg/L. At least 2 of the patients complained of nausea and headache.[4] In contrast, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clearance when they were given a single 33-mg/kg dose of intravenous hydrocortisone, although there was a trend towards increased clearance.[5] Intravenous bolus doses of hydrocortisone 500 mg or 1 g did not affect theophylline levels in patients taking choline theophyllinate 400 mg every 12 hours for 8 days.[6]

(d) Methylprednisolone

An 88% increase in the clearance of a single dose of intravenous aminophylline was seen in one of 3 healthy subjects pretreated with oral methylprednisolone.[7] There was no significant change in clearance in the other 2 subjects. Another study in 10 children (aged 2 to 6 years) with status asthmaticus found that intramuscular methylprednisolone tended to increase the half-life of theophylline (given as oral aminophylline or theophylline).[8] A further study also reported that when intravenous aminophylline was given to 16 children taking corticosteroids (route and type not specified) the theophylline half-life was prolonged from 5 hours to

6.2 hours, and the clearance was reduced by about one-third, when compared with 10 children not taking corticosteroids.[9] Similarly, 7 healthy subjects given sustained-release theophylline had no significant change in steady-state theophylline clearance when they were given a single 1.6-mg/kg dose of intravenous methylprednisolone, although there was a trend towards increased clearance.[5]

(e) Prednisone or Prednisolone

A study in 6 healthy subjects found that a single 20-mg oral dose of prednisone had no significant effect on the pharmacokinetics of a single 200-mg oral dose of aminophylline.[10] The pharmacokinetics of a single 5.6-mg/kg intravenous dose of aminophylline was unchanged in 9 patients with chronic airflow obstruction when they were given prednisolone 20 mg daily for 3 weeks.[11]

Mechanism

Not understood.

Importance and management

The concurrent use of theophylline and corticosteroids is common and therapeutically valuable, whereas the few reported interactions of theophylline with oral or parenteral corticosteroids are poorly documented and their clinical importance is difficult to assess because both increases, small decreases and no changes in the serum levels of theophylline have been seen. It is also questionable whether the results of studies in healthy subjects can validly be extrapolated to patients with status asthmaticus. There do not appear to be any data on the effect of *inhaled* corticosteroids on the clearance of theophylline. Both theophylline and corticosteroids can cause hypokalaemia, and the possibility that this may be potentiated by concurrent use should be considered.

Theophylline + Co-trimoxazole

Co-trimoxazole (trimethoprim/sulfamethoxazole) does not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects co-trimoxazole 960 mg twice daily for 8 days had no effect on the pharmacokinetics of theophylline, given as a single 341-mg intravenous dose of aminophylline.[1] Another study, in 8 healthy subjects, found that co-trimoxazole 960 mg twice daily for 5 days had no effect on the pharmacokinetics of a single 267-mg oral dose of theophylline.[2] No special precautions would seem necessary if these drugs are given concurrently. However, note that acute infections *per se* can alter theophylline pharmacokinetics.[3]

Theophylline + Dextropropoxyphene (Propoxyphene)

Dextropropoxyphene does not significantly alter steady-state theophylline levels.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects pre-treatment with dextropropoxyphene 65 mg every 8 hours for 5 days did not significantly change the total plasma clearance of steady-state theophylline 125 mg every 8 hours.[1] There was a small reduction in the formation of the hydroxylated metabolite of theophylline. There would seem to be no need to avoid concurrent use or to take particular precautions. There seems to be no information regarding aminophylline, but it would be expected to behave similarly.

Theophylline + Disulfiram

Theophylline clearance is decreased by disulfiram.

Clinical evidence

After 20 recovering alcoholics took disulfiram 250 mg daily for one week, the clearance of a 5-mg/kg intravenous dose of theophylline was decreased by a mean of about 21% (range 15 to 30%). Those taking disulfiram 500 mg daily had a mean decrease of 33% (range 22 to 50%).[1] Smoking appeared to have no important effects on the extent of this interaction. None of the patients were reported to have any significant liver disease, such as cirrhosis, which may also affect theophylline metabolism.

Mechanism

Disulfiram inhibits the liver enzymes concerned with the both the hydroxylation and demethylation of theophylline, thereby reducing its clearance from the body.

Importance and management

Information appears to be limited to this study but it would seem to be a clinically important interaction. Monitor the serum levels of theophylline and its effects if disulfiram is added, anticipating the need to reduce the theophylline dose. Note that the extent of this interaction appears to depend upon the dose of disulfiram used; higher doses present a greater risk. As aminophylline is metabolised to theophylline, it would be expected to interact similarly.

Theophylline + Diuretics

Furosemide is reported to increase, decrease or to have no effect on theophylline levels. An isolated case describes severe hyponatraemia and syndrome of inappropriate secretion of antidiuretic hormone in a premature neonate receiving chlorothiazide, spironolactone and theophylline. Both theophylline and diuretics can cause hypokalaemia, which may be additive.

Clinical evidence

In 8 patients with asthma the mean peak serum level of a 300-mg dose of sustained-release theophylline was reduced by 41% (from 12.14 to 7.16 mg/L) by a single 25-mg oral dose of **furosemide**.[1] A crossover study in 12 healthy subjects did not find any change in steady-state plasma theophylline levels when two 20-mg doses of oral **furosemide** were given 4 hours apart, although the overall renal clearance of theophylline was reduced.[2] However, 10 patients with asthma, chronic bronchitis or emphysema, receiving a continuous maintenance infusion of aminophylline, had a 21% rise in their serum theophylline levels (from 13.7 to 16.6 mg/L)

4 hours after being given a 40-mg intravenous dose of **furosemide** over 2 minutes.[3]

Four premature neonates, two given oral and two given intravenous theophylline with **furosemide** had a fall in their steady-state serum theophylline levels from 8 mg/L down to 2 to 3 mg/L when **furosemide** was given within 30 minutes of the theophylline.[4] A randomised, placebo-controlled study in 24 infants receiving ECMO (extracorporeal membrane oxygenation) found that theophylline 2 mg/kg enhanced the response to diuresis with **furosemide** 1 mg/kg. If the response were maintained over a 24-hour period an extra 110 mL/kg of fluid would have been lost.[5]

A case of severe hyponatraemia and syndrome of inappropriate secretion of antidiuretic hormone has been reported in a pre-term neonate who received theophylline, as aminophylline (maintenance dose 4 mg/kg every 12 hours), and then started to receive **chlorothiazide** 25 mg/kg every 12 hours and **spironolactone** 1 mg/kg every 12 hours. His sodium level was restored by the intravenous administration of 3% sodium chloride.[6]

The manufacturer of **torasemide** notes that it may potentiate the action of theophylline,[7] but there appears to be no published data supporting this suggestion.

Mechanism

Not understood, although in theory furosemide may cause increased renal excretion of theophylline, which could explain the reduced levels. The thiazides, spironolactone and theophylline[8] have each been reported to cause hyponatraemia, and therefore the low sodium levels may have occurred as a result of the additive effects of these drugs.

Importance and management

Information regarding an interaction between furosemide and aminophylline or theophylline is limited and the outcome of concurrent use is inconsistent and uncertain. More study is needed to assess the clinical significance of the effects of theophylline and furosemide on diuresis. However, note also that theophylline clearance may be reduced by some conditions such as chronic heart failure or pulmonary oedema. Theophylline clearance could therefore be increased when the health of the patient is improved, possibly through the use of furosemide.[9] Whatever the reason for the effects seen, if both drugs are used, be aware of the potential for changes in serum theophylline levels. Consider measuring levels, and make appropriate dose adjustments as necessary. Both theophylline and diuretics can cause hypokalaemia, and the possibility that this may be additive on concurrent use should be considered. The general relevance of the isolated case describing hyponatraemia is unclear.

Theophylline + Dobutamine

A man taking theophylline developed marked tachycardia when he was given dobutamine.

Clinical evidence, mechanism, importance and management

A patient with asthma taking sustained-release theophylline 150 mg twice daily, digoxin and spironolactone was anaesthetised for an aortic valve replacement with fentanyl, midazolam and pipecuronium. Following induction, intubation, and ventilation with 100% oxygen, his systolic blood pressure fell from 120 mmHg to 80 mmHg, and his heart rate slowed from 70 bpm to 50 bpm. Dobutamine was given at a dose of 5 micrograms/kg per minute, and after 2 to 3 minutes his heart rate rose to 150 bpm and his systolic blood pressure rose to 190 mmHg. The authors of the report[1] attribute the tachycardia to an interaction between dobutamine and theophylline. They suggested that the interaction was possibly as a result of a synergistic increase in cyclic AMP levels in cardiac muscle and/or theophylline-induced potentiation of catecholamine action. They advise the careful titration of dobutamine in any patient with asthma taking theophylline, particularly if a slow-release preparation is being used. However, more study of this apparent interaction is needed as this appears to be the only report, and so its general importance is unknown.

Theophylline + Doxapram

Doxapram pharmacokinetics are unchanged by theophylline in premature infants, but agitation and increased muscle activity may occur in adults.

Clinical evidence, mechanism, importance and management

Intravenous theophylline does not affect the pharmacokinetics of doxapram given to treat apnoea in premature infants, and no adjustment of the dose of doxapram is needed in the presence of theophylline.[1] However, the manufacturers of doxapram say that there may be an interaction between doxapram and aminophylline, which is manifested by agitation muscle fasciculation and hyperactivity. Care should therefore be taken if these drugs are used together.[2]

2. Dopram (Doxapram hydrochloride). Goldshield plc. UK Summary of product characteristics, August 2008.

Theophylline + Duloxetine

Duloxetine does not affect the pharmacokinetics of theophylline to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a controlled study in 28 healthy subjects, duloxetine 60 mg was given twice daily for 4 days, and with a single 197.5-mg intravenous dose of theophylline (given as aminophylline 250 mg) on day 5. Duloxetine increased the AUC of theophylline by 20% in the women who participated in the study, but no statistically significant increase in the AUC of theophylline was seen in the men. Overall, the AUC of theophylline was increased by 13%. However, this increase is not expected to be clinically significant and no dose adjustment of theophylline is likely to be required.[1]

Theophylline + Enoximone

Aminophylline possibly reduces the beneficial cardiovascular effects of enoximone. Theoretically, milrinone would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

An experimental study into the mechanism of action of enoximone in 14 patients with ischaemic or idiopathic dilative cardiomyopathy found that pretreatment with intravenous aminophylline 7 mg/kg given over 15 minutes reduced the beneficial haemodynamic effects of intravenous enoximone 1 mg/kg given over 15 minutes.[1] This appears to occur because each drug competes for inhibition of cAMP-specific phosphodiesterases in cardiac and vascular smooth muscle. **Milrinone**, another phosphodiesterase inhibitor similar to enoximone, would be expected to interact in the same way. However, there are, at present, no published reports of a possible interaction with milrinone, and no case reports of a

problem occurring with the concurrent use of either drug with theophylline. The clinical importance of this study therefore awaits evaluation.

1. Morgagni GL, Bugiardini R, Borghi A, Pozzati A, Ottani F, Puddu P. Aminophylline counteracts the hemodynamic effects of enoximone. *Clin Pharmacol Ther* (1990) 47, 140.

Theophylline + Ephedrine

Some data suggest that an increased frequency of adverse effects occurs when ephedrine is given with theophylline.

Clinical evidence, mechanism, importance and management

A double-blind, randomised study in 23 children aged 4 to 14 years found that when ephedrine was given with theophylline (in a ratio of 25 mg ephedrine to 130 mg theophylline), the number of adverse reactions increased significantly, when compared with each drug taken separately. Moreover, the combination was no more effective than theophylline alone. The combination was associated with insomnia (14 patients), nervousness (13 patients) and gastrointestinal complaints (18 patients), including vomiting (12 patients). The serum theophylline levels were unchanged by ephedrine.[1] A previous study by the same authors in 12 children with asthma given ephedrine and aminophylline found similar results.[2] In contrast, a later study suggested that ephedrine 25 mg every 8 hours given with aminophylline did produce improvements in spirometry and no adverse effects were seen. However, it was calculated that the theophylline dose used was about half that used in the previous study.[3]

In the treatment of asthma, ephedrine has been largely superseded by more selective sympathomimetics, which have fewer adverse effects. Ephedrine is still an ingredient of a number of non-prescription cough and cold remedies, when it may be combined with theophylline (e.g. *Franol*). Patients taking theophylline requiring ephedrine should be advised to report any adverse effects.

Theophylline + Flutamide

The manufacturer of flutamide notes that cases of increased theophylline plasma levels have been reported in patients taking these two drugs together. They suggest the reason for this is that flutamide and theophylline are both metabolised by the cytochrome P450 isoenzyme CYP1A2.[1] Note that interactions by this mechanism are rarely clinically relevant.

1. Drogenil (Flutamide). Schering-Plough Ltd. UK Summary of product characteristics, August 2007.

Theophylline + Food

The effect of food on theophylline bioavailability is unclear. In general it appears that fat or fibre in food has no effect, whereas high-protein diets decrease the theophylline half-life. High-carbohydrate diets may increase, or have no effect on the theophylline half-life. Significant changes in theophylline bioavailability have been seen in patients given both enteral feeds and total parenteral nutrition.

Clinical evidence

(a) Food

The bioavailability of theophylline from sustained-release preparations has been shown to be reduced,[1,2] increased,[1,3,4] or unaffected[5-12] when theophylline was given immediately after breakfast. In one study the bioavailability of theophylline from a sustained-release preparation was increased by 10% when it was given after food, the trough theophylline concentration was increased by 0.7 mg/L, and the time to reach maximum plasma levels was increased from 8.6 hours to 11.4 hours.[4] Dose dumping, leading to signs of theophylline toxicity, was seen in 3 children with asthma who were given a dose of *Uniphyllin* immediately after breakfast.[7] The fat content[11,13,14] or fibre content[15] of meals does not seem to significantly affect theophylline absorption. High-protein meals appear to decrease the half-life of theophylline.[16,17] In one study high-carbohydrate meals increased the half-life of theophylline,[17] while in another study a high-carbohydrate meal had no effect on the half-life of a single 350-mg dose of sustained-release theophylline, but the maximum plasma levels were increased by 56%. There was no overall effect on the extent of absorption.[18] There was no difference in theophylline metabolism in one study when patients were changed from a high-carbohydrate/low-protein diet to a high-protein/low-carbohydrate diet.[19] One study found that changing from a high-protein to a high-carbohydrate meal had an effect on the metabolism of theophylline similar to that of cimetidine, and that the effects of the meal change and cimetidine were additive.[20] The effects of spicy food have been studied, but the clinical significance of the changes are uncertain.[21]

(b) Enteral feeds

A patient with COPD had a 53% reduction in his serum theophylline levels accompanied by bronchospasm when he was fed continuously through a nasogastric tube with *Osmolite*. The interaction occurred with both theophylline tablets (*Theo-Dur*) and liquid theophylline, but not when the theophylline was given intravenously as aminophylline. It was also found that the interaction could be avoided by interrupting feeding one hour either side of the oral liquid theophylline dose.[22] Conversely, hourly administration of 100 mL of *Osmolite* did not affect the extent of theophylline absorption from a slow-release preparation (*Slo-bid Gyrocaps*) in healthy subjects, although the rate of absorption was slowed.[23] Similarly, in healthy subjects, hourly administration of 100 mL of *Ensure* for 10 hours did not affect the rate or extent of absorption of theophylline from *Theo-24* tablets.[24]

(c) Parenteral nutrition

An isolated report describes an elderly woman given intravenous aminophylline who had a marked fall in her serum theophylline levels (from 16.3 mg/L to 6.3 mg/L) when the amino acid concentration of her parenteral nutrition regimen was increased from 4.25% to 7%.[25] A study in 7 patients with malnutrition (marasmus-kwashiorkor) found only a small, probably clinically irrelevant increase in the elimination of a single intravenous dose of theophylline when they were fed intravenously.[26]

Mechanism

Not fully understood. As with any sustained-release formulation, the presence of food in the gut may alter the rate or extent of drug absorption by altering gastrointestinal transit time. It has been suggested that high-protein diets stimulate liver enzymes thereby increasing the metabolism of the theophylline and hastening its clearance from the body. High carbohydrate diets may have the opposite effect. The cytochrome P450 isoenzyme CYP1A2 (the principal enzyme involved in the metabolism of theophylline) is known to be induced by chemicals contained in cruciferous vegetables[27] or formed by the action of high temperatures or smoke on meat.[28] This suggestion is supported by a study in which charcoal-grilled (broiled) beef decreased the half-life of theophylline by an average of 22%.[29] Further, high doses of daidzein, the principal isoflavone in soybeans, may inhibit CYP1A2 resulting in an increase in theophylline levels and half-life of about 33% and 41%, respectively.[30]

Importance and management

Interactions between theophylline and food have been thoroughly studied but there seems to be no consistent pattern in the way the absorption of different theophylline preparations is affected. Be alert for any evidence of an inadequate response that can be related to food intake. Avoid switching between different preparations, and monitor the effects if this is necessary. Consult the product literature for any specific information on food and encourage patients to take their theophylline consistently in relation to meals where this is considered necessary. Advise patients not make major changes in their diet without consultation. Monitor the effects of both enteral and parenteral nutrition, as aminophylline or theophylline dose adjustments may be required.

Theophylline + Gold

Gold may reduce theophylline levels.

Clinical evidence, mechanism, importance and management

A review of theophylline serum levels in 6 steroid-dependent asthmatic patients who were taking methylprednisolone and gold (auranofin) and had also taken theophylline for at least 3 months, found that the actual theophylline levels were lower than the predicted levels, and that the levels were all below 10 mg/L. No information was provided regarding the control of asthma in these patients.[1] The authors of this review suggest that the gastrointestinal adverse effects and protein binding of auranofin may have altered the absorption and distribution of theophylline. An interaction is not established as the theophylline levels were only reduced compared with those predicted using two different pharmacokinetic tools. The clinical relevance of any interaction is also unclear, as these 'low' levels were identified retrospectively. The evidence available is too limited to warrant any general precautions. Further study is needed.

Theophylline + Grapefruit and other fruit juices

Grapefruit and kinnow (mandarin) juice do not alter theophylline pharmacokinetics to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

(a) Grapefruit juice

In one study, 12 healthy subjects were given a single 200-mg oral dose of theophylline solution (*Euphyllin*) diluted in either 100 mL of grapefruit juice or water, followed by another 900 mL of juice or water over the next 16 hours. The pharmacokinetics of the theophylline were found to be unchanged by the grapefruit juice.[1] Another study, in 10 healthy subjects who took a single 300-mg dose of sustained-release theophylline (*Theobid*) with 300 mL of water or grapefruit juice, found that although the grapefruit juice lowered the plasma levels of theophylline between one and 4 hours after the dose, the AUC of theophylline was not significantly changed, nor were there any other significant pharmacokinetic changes.[2]

The authors of the first study had previously shown that grapefruit juice had a small effect on the pharmacokinetics of 'caffeine', (p.1420), which is metabolised in a similar way to theophylline, and that one of the constituents of grapefruit juice (naringenin) inhibited the cytochrome P450 isoenzyme CYP1A2 (the principal enzyme in theophylline metabolism) *in vitro*. Therefore, in theory, an interaction was possible. However, these studies suggest that no clinically relevant interaction occurs, and therefore there would seem to be no reason why patients taking theophylline (or probably aminophylline) should avoid grapefruit juice.

(b) Kinnow juice

In a study, 10 healthy subjects took a single 300-mg dose of sustained-release theophylline (*Theobid*) with 300 mL of water or kinnow (mandarin) juice. The maximum plasma levels and the AUC of theophylline were not different between the two groups. The maximum plasma theophylline levels were 9.54 mg/L and 8.43 mg/L when taken with water and kinnow juice, respectively. The plasma level of theophylline taken with kinnow juice was lower at every time point than when taken with water, but this difference was only statistically significant between one and 4 hours after the start of the study.[3] However, this change would not be expected to be of clinical significance.

Theophylline + Griseofulvin

Griseofulvin does not appear to alter the pharmacokinetics of theophylline to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

In a study in 12 healthy subjects, griseofulvin 500 mg daily for 8 days reduced the half-life of theophylline (after a single oral dose of aminophylline) from 6.6 hours to 5.7 hours, and increased the clearance of two of its metabolites. However, these changes were far too small to usually have any clinical relevance.[1] There would therefore appear to be no reason for avoiding concurrent use.

Theophylline + H_2-receptor antagonists

Cimetidine raises theophylline levels and toxicity may develop. However, the extent of the interaction is only modest with low-dose cimetidine. Although there are some contrasting reports, on the whole famotidine, nizatidine, ranitidine and roxatidine appear not to interact with theophylline.

Clinical evidence

(a) Cimetidine

A number of case reports describe significantly increased theophylline levels, including many that were toxic, in patients (adults and children) given oral or intravenous aminophylline or theophylline with cimetidine.[1-6] A few cases describe serious adverse effects such as seizures.[3,4]

In a large number of pharmacokinetic studies healthy subjects were given oral or intravenous aminophylline or theophylline[7-16] and patients were given oral or intravenous theophylline[17-21] with oral cimetidine 800 mg to 1.2 g daily in divided doses for 4 to 10 days. It was clearly shown that cimetidine prolonged the theophylline half-life by about 30 to 65% and reduced theophylline clearance by about 20 to 40%. Steady-state serum theophylline levels were raised about one-third.[17,18,21] One of these studies[21] has also been published elsewhere.[22] The effect of cimetidine was maximal in 3 days in the one study assessing this.[17] The extent of the interaction did not differ between cimetidine 1.2 g daily and 2.4 g daily in one study,[10] although two further studies found that cimetidine 800 mg daily had less effect than cimetidine 1.2 g daily.[12,23] A study investigating low-dose cimetidine (200 mg twice daily) found only a 12% decrease in theophylline clearance.[24]

Two studies found that the effect of cimetidine did not differ between young and elderly subjects,[12,25] whereas another found that it was more pronounced in the elderly.[23] The effects of cimetidine did not differ between smokers and non-smokers in one study,[26] but were more pronounced in smokers in another.[27] In a further study the effects of cimetidine were not affected by gender.[23] Three studies found that the inhibitory effects of cimetidine and ciprofloxacin were additive.[25,28,29] For the effect of ciprofloxacin, see 'Theophylline + Quinolones', p.1452.

Three studies found that intravenous cimetidine also inhibited the clearance of theophylline (given as intravenous aminophylline or sustained-release theophylline).[30-32] In one of these, oral and intravenous cimetidine reduced theophylline clearance to the same extent, but when clearance was corrected for the lower bioavailability of the oral cimetidine, oral cimetidine resulted in a greater inhibition than intravenous cimetidine.[30] Another study found that the effects of a continuous 50-mg/hour infusion of cimetidine were similar to those of an intermittent infusion of 300 mg every 6 hours.[31]

In contrast, a further study in healthy subjects found no clinically important interaction between intravenous aminophylline and an intravenous cimetidine infusion, but the aminophylline was given only 12 hours after starting the cimetidine, which may be insufficient for cimetidine to have had an effect.[33] Similarly, a subsequent study in 18 critically ill patients given a continuous 50-mg/hour intravenous infusion of cimetidine and low-dose aminophylline 10.8 mg/hour for just 48 hours found no clinically important interaction.[34]

(b) Famotidine

In 10 healthy subjects famotidine 40 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as intravenous aminophylline).[14] In another study, 16 patients with bronchial asthma or COPD found that famotidine 20 mg twice daily for at least 3 days did not affect the clearance of theophylline.[35] Two further studies also found no interaction between intravenous theophylline and famotidine 20 or 40 mg twice daily for 4 or 9 days in patients with COPD.[20,36] In a post-marketing surveillance study it was noted that 4 patients with asthma taking theophylline had also taken famotidine 40 mg daily for 4 to 8 weeks without any problems.[37] In contrast, in a patient with COPD and liver impairment, the AUC and serum levels of an intravenous dose of theophylline were raised by 78% and the clearance was halved by famotidine 40 mg daily for 8 days.[38] A later study by the same authors in 7 patients with COPD similarly treated, but with normal liver function, found that the AUC of theophylline was increased by 56% and its clearance was reduced by 35% by famotidine.[39]

(c) Nizatidine

A study in 17 patients with COPD found that nizatidine 150 mg twice daily for a month had no effect on the steady-state pharmacokinetics of theophylline.[21] However, up to the end of August 1989 there were 6 reports of apparent interactions in the Spontaneous Adverse Drug Reaction Database of the FDA in the US. Four patients taking theophylline developed elevated serum theophylline levels, with symptoms of toxicity in at least one case, when given nizatidine. The problems resolved when either both drugs, or just nizatidine were stopped.[40]

(d) Ranitidine

Many studies in healthy subjects (given intravenous aminophylline or oral theophylline)[10,11,15,41-43] and patients (given sustained-release theophylline)[18,21,44-47] have found that ranitidine does not affect the pharmacokinetics of theophylline, even in daily doses far in excess of those used clinically (up to 4.2 g of ranitidine daily).[41] However, there are 7 reports describing a total of 10 patients, who developed theophylline toxicity when given ranitidine with sustained-release theophylline[48-53] or intravenous aminophylline.[54] The validity of a number of these reports has been questioned,[55-58] with the authors subsequently modifying some.[59,60]

(e) Roxatidine

Roxatidine 150 mg daily did not affect the clearance of theophylline.[61] Similarly, in 9 healthy subjects, roxatidine 150 mg twice daily did not significantly change the pharmacokinetics of a single 250-mg intravenous dose of aminophylline.[62]

Mechanism

Cimetidine is an enzyme inhibitor that reduces the metabolism (predominantly *N*-demethylation)[63] of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby raising its serum levels. Famotidine, nizatidine and ranitidine do not have enzyme-inhibiting effects so that it is not clear why they sometimes appear to behave like cimetidine.

Importance and management

The interaction between theophylline or aminophylline and cimetidine is very well documented (not all the references being listed here), very well established and clinically important. Theophylline serum levels normally rise by about one-third, but much greater increases have been seen in individual patients. Monitor theophylline levels closely. Note that in one study the peak effect was reached in 3 days. Initial theophylline dose reductions of 30 to 50% have been suggested to avoid toxicity.[4] Alternatively, use one of the other H_2-receptor antagonists, or consider changing to a proton pump inhibitor, see 'Theophylline + Proton pump inhibitors', p.1451. The effect of low-dose cimetidine (200 mg twice daily) is unlikely to be clinically relevant unless theophylline levels are at the higher end of the therapeutic range. The situation with famotidine, nizatidine and ranitidine is not totally clear. They would not be expected to interact because they are not enzyme inhibitors like cimetidine, but very occasionally and unpredictably they appear to do so. Nevertheless, the general picture is that normally no special precautions are needed if these H_2-receptor antagonists,[56] or roxatidine are given with aminophylline or theophylline.

Note that some of the symptoms of theophylline toxicity, such as nausea, vomiting and abdominal pain, are similar to those of gastrointestinal ulceration. If a patient taking theophylline presents with these symptoms, it would seem prudent to monitor theophylline levels.

Theophylline + Hormonal contraceptives

Theophylline clearance is reduced to some extent in women taking oral combined hormonal contraceptives, but no toxicity has been reported.

Clinical evidence

The total plasma clearance of a single 4-mg/kg oral dose of aminophylline was about 30% lower in 8 women taking a combined oral contraceptive (**ethinylestradiol**/**norgestrel**, *Ovral*) than in 8 other women not taking oral contraceptives.[1] The theophylline half-life was also prolonged by about 30%, from 7.34 hours to 9.79 hours. Similar results were found in other studies in subjects given intravenous or oral aminophylline and oral combined hormonal contraceptives (**ethinylestradiol**/**norgestrel**, *Ovral* and **mestranol**/**etynodiol diacetate**, *Ovulen* or unnamed products).[2,3] In contrast, no significant differences were seen in the pharmacokinetics of theophylline (given as intravenous aminophylline) in 10 adolescent women (15 to 18 years) taking oral low-dose combined or sequential hormonal contraceptives (**ethinylestradiol**/**norethisterone**), when compared with age matched controls.[4] However, in the same women the clearance of oral theophylline was found to be reduced by 33% after they took an oral triphasic combined hormonal contraceptive for 3 to 4 months.[5] In a retrospective analysis of factors affecting theophylline clearance, the use of oral hormonal contraceptives was associated with a reduced theophylline clearance in women who smoked.[6]

Mechanism

Uncertain, but it seems possible that the oestrogenic component of the contraceptive may inhibit the metabolism of the theophylline by the liver microsomal enzymes, thereby reducing its clearance.

Importance and management

An established interaction, but there seem to be no reports of theophylline toxicity resulting from the concurrent use of hormonal contraceptives. Women taking combined hormonal contraceptives may need less aminophylline or theophylline than those not taking these contraceptives. There is a small risk that patients with serum theophylline levels at the top end of the range may develop some toxicity when hormonal contraceptives are added. It has been proposed that the effects may be more apparent with long-term, high-dose contraceptive use.[1,4]

Theophylline + Idrocilamide

Idrocilamide given orally can increase theophylline levels.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects oral idrocilamide 600 mg daily for 3 days then 1.2 g for 4 days increased the half-life of a single dose of theophylline 2.5-fold, from 8.5 hours to 21.6 hours, and reduced its clearance by 67%.[1] This is due to a reduction in the liver metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2, which is inhibited by idrocilamide. In-

formation is very limited but it indicates that concurrent use should be closely monitored. Anticipate the need to reduce the theophylline dose with *oral* idrocilamide. As aminophylline is metabolised to theophylline it seems likely to be similarly affected.

Theophylline + Imipenem

Seizures developed in three patients taking aminophylline or theophylline when they were given imipenem.

Clinical evidence, mechanism, importance and management

Two patients receiving intravenous aminophylline developed seizures within 11 to 56 hours of starting treatment with intravenous imipenem 500 mg every 6 to 8 hours. Seizures developed in a third patient taking theophylline after imipenem had been given for 6 days. In all 3 patients, seizures occurred 2 to 3 hours after a dose of imipenem.[1] The reasons for this effect are not known. Theophylline serum levels appeared to be unchanged.[1] In an analysis of data from 1754 patients who had received imipenem in dose-ranging studies, 3% had seizures, and imipenem was judged to be associated with a third of these cases. However, the concurrent use of theophylline or aminophylline was not found to be a significant risk factor for the development of seizures with imipenem.[2] The general importance of these cases is therefore uncertain.

Theophylline + Influenza vaccines

Normally none of the influenza vaccines (whole-virion, split-virion and surface antigen) interact with theophylline, but there are three reports describing rises in serum theophylline levels in a few patients (some to toxic levels), which were attributed to the use of an influenza vaccine.

Clinical evidence

(a) Evidence of no interaction

In 12 patients with asthma, the mean steady-state serum theophylline levels were not altered by a trivalent split-virion influenza vaccine (*Fluzone*), although one patient had an increase in levels (see *Evidence of an interaction*, below). Levels were measured before vaccination and one, 3, 7 and 14 days after vaccination.[1] Theophylline levels were unchanged in 5 patients with COPD when they were given 0.5 mL of influenza vaccine (*Fluogen*).[2] Similarly, no evidence of a rise in theophylline levels was found in a number of other studies in both adults and children, receiving maintenance theophylline or aminophylline, and given various trivalent split-virion vaccines[3-6] including *Fluzone*,[7] *Fluogen*,[8-10] *Influvac*,[11] *Mutagrip*.[12] In addition, no change in the pharmacokinetics of theophylline (given as oral aminophylline) was found after the use of a whole-virion vaccine in healthy adults.[13] No evidence of serious theophylline toxicity was seen in 119 elderly patients taking maintenance theophylline and given an unspecified influenza vaccine.[14]

(b) Evidence of an interaction

Three patients who had been taking oral choline theophyllinate 200 mg (equivalent to 128 mg of theophylline) every 6 hours for at least 7 days had a rise in their serum theophylline levels of 219%, 89%, and 85%, respectively, within 12 to 24 hours of receiving 0.5 mL of trivalent split-virion influenza vaccine (*Fluogen*, Parke Davis). In some cases effects persisted for up to 72 hours, and two patients had signs of theophylline toxicity. A subsequent study in 4 healthy subjects found that the same dose of vaccine more than doubled the half-life of theophylline, from 3.3 hours to 7.3 hours, and halved its clearance.[15]

A girl had a rise in theophylline levels from 20 mg/L to 34 mg/L (with no sign of toxicity) within 5 hours of being given a trivalent split-virion vaccine.[16] In a study where 11 of 12 patients had no increase in theophylline levels after vaccination with *Fluzone*, one woman showed a rise in levels (from 10 mg/L to 24.5 mg/L) accompanied by headaches and palpitations.[1]

In 8 healthy subjects the clearance of theophylline (given as choline theophyllinate) was reduced by 25% one day after influenza vaccination (trivalent influenza vaccine, *Fluogen*, Parke Davis), but this was of borderline significance. Theophylline metabolism had returned to pre-vaccination levels after 7 days.[17]

A patient with COPD taking sustained-release theophylline 300 mg twice daily (theophylline levels between 7 and 12 mg/L) developed nausea and palpitations the day after he received a trivalent influenza vaccination (*Fluogen*). His theophylline level was increased to 26 [mg/L]. His dose was reduced to 200 mg twice daily and the adverse effects resolved. However, a few days later his COPD had become symptomatic and the theophylline level was found to be subtherapeutic, so the dose was raised to 300 mg twice daily, as before.[18]

Mechanism

Uncertain. If an interaction occurs, it has been suggested it is probably due to inhibition of the liver enzymes concerned with the metabolism of theophylline, possibly secondary to interferon production, resulting in theophylline accumulation in the body.[15,17] One suggestion is that vaccine contaminants, which are potent interferon-inducing agents, may be responsible (rather than the vaccine itself), so that an interaction would seem to be less likely with modern highly-purified subunit vaccines.[19] In one study where an interaction occurred, an increase in serum interferon levels was detected,[17] whereas, in two of the studies showing no interaction, no interferon production was detected.[10,13] Influenza infection *per se* can result in decreased theophylline clearance and theophylline toxicity.[20]

Importance and management

A very thoroughly investigated interaction, the weight of evidence being that no adverse interaction normally occurs between aminophylline or theophylline and any type of influenza vaccine in children, adults or the elderly. Even so, bearing in mind the occasional and unexplained reports of an interaction[1,15,16,18] it would seem prudent to monitor the effects of concurrent use (for nausea, headaches, palpitations), although problems are very unlikely to arise now that purer vaccines are available (see 'Mechanism'). Note that any rise in theophylline levels is likely to be transient.

Theophylline + Interferons

Theophylline clearance is reduced by up to 50% by interferons, but the extent of the interaction varies greatly, with different types of interferon having slightly different effects.

Clinical evidence

A study in 9 subjects (5 with stable chronic active hepatitis B and 4 healthy subjects) found that 20 hours after being given a single 9- or 18-million unit intramuscular injection of interferon (recombinant human interferon alfa A), the clearance of theophylline (given as intravenous aminophylline) was approximately halved (range 33 to 81%) in 8 of the 9 subjects. The mean theophylline elimination half-life was increased from 6.3 hours to 10.7 hours (1.5- to sixfold increases). In the healthy subjects the theophylline clearances were noted to have returned to their former values 4 weeks after the study.[1]

Another study, in 11 healthy subjects given interferon alfa (*Roferon-A*) 3 million units daily for 3 days, found that the terminal half-life and AUC of theophylline (given as aminophylline) were only increased by 10 to 15%, with a similar decrease in clearance.[2] In 7 patients with cancer, interferon alfa (*Intron-A*) 3 million units given three times a week for 2 weeks decreased the clearance of a single 150-mg oral dose of theophylline by 33%.[3]

Seven patients with chronic hepatitis C receiving interferon beta 3 to 9 million units daily for 8 weeks were given a single 250-mg dose of intravenous aminophylline. Interferon beta reduced the total body clearance of theophylline by 26% (range 6 to 57%) and increased the elimination half-life by 39% (range 27 to 139%), but had no significant effect on the volume of distribution, although there was wide inter-patient variability.[4]

In a study in 14 healthy male subjects who received peginterferon alfa-2a for 4 weeks, there was a 33% increase in the AUC of a single dose of theophylline.[5]

Mechanism

Interferon alfa inhibits the liver enzymes concerned with the metabolism of theophylline. Therefore the metabolism of theophylline is reduced, and it accumulates. Interferon beta also appears to inhibit liver enzymes.[4] It has been suggested that the cytochrome P450 isoenzyme CYP1A2, by which theophylline is metabolised may be the route affected. However, one study in which the activity of CYP1A2 was determined in 14 patients with active hepatitis C after receiving interferon alfa and ribavirin for 4 weeks did not determine any significant change in CYP1A2 activity.[6]

Importance and management

Direct information appears to be limited to these reports. So far there appear to be no reports of toxicity but it would seem prudent to monitor the concurrent use of an interferon and aminophylline or theophylline closely (for nausea, headaches, palpitations), taking theophylline levels if necessary. Patients with enhanced metabolism (e.g. smokers) are predicted to be most at risk.[1] The manufacturers of peginterferon alfa-2a suggest that the interaction with theophylline may not be maximal until after more than 4 weeks of concurrent use.[7]

Theophylline + Ipriflavone

An isolated report describes increased theophylline levels in a patient given ipriflavone.

Clinical evidence, mechanism, importance and management

The theophylline serum levels of a patient with COPD, taking sustained-release theophylline 300 mg twice daily, rose from 9.5 mg/L to 17.3 mg/L when ipriflavone 600 mg daily for about 4 weeks was taken. No symptoms of toxicity occurred. The serum theophylline levels returned to roughly the initial level when the ipriflavone was stopped, and rose again when it was restarted.[1] *In vitro* studies with human liver microsomes suggest that ipriflavone can inhibit the cytochrome P450 isoenzyme CYP1A2 and the demethylation of theophylline,[2,3] which would reduce the metabolism of theophylline and increase its levels.

Although so far only one case of this interaction has been reported, the *in vitro* studies suggest that it would be prudent to monitor the theophylline levels of any patient given ipriflavone, making any dose reductions as necessary. Aminophylline does not appear to have been studied, but as it is metabolised to theophylline, a similar interaction seems likely.

Theophylline + Leukotriene antagonists

Montelukast does not appear to alter theophylline levels. A single published case report describes a rapid rise in theophylline levels in a patient given zafirlukast. Zafirlukast levels are modestly reduced by theophylline, but this does not appear to be clinically important.

Clinical evidence

(a) Montelukast

In a study of 16 healthy subjects, the pharmacokinetics of a single intravenous dose of theophylline were not significantly changed by montelukast 10 mg daily for 10 days. However, when the subjects were given montelukast 200 mg and 600 mg daily, the AUC of theophylline was reduced by 43% and 66%, respectively. These doses are 20- and 60-fold higher than the usual 10 mg daily dose,[1] and therefore the clinical relevance of these effects is unclear.

(b) Zafirlukast

In a study in 13 patients with asthma, when zafirlukast 80 mg daily was given with a single 6-mg/kg dose of theophylline, the mean serum levels of zafirlukast were reduced by 30%, but the serum theophylline levels remained unchanged.[2] In another study in 16 healthy children, zafirlukast 20 mg daily did not affect the pharmacokinetics of a single 6-mg/kg dose of theophylline.[2] In contrast, an isolated report describes a 15-year-old girl with asthma taking sustained-release theophylline 300 mg twice daily (as well as inhaled fluticasone, salbutamol (albuterol) and salmeterol, and oral prednisolone) who became nauseous shortly after zafirlukast (dose not stated) was started. An increase in her theophylline level from 11 mg/L to 24 mg/L was noted. The theophylline was stopped, and later attempts to reintroduce theophylline at lower doses resulted in the same dramatic increases in serum theophylline levels.[3] The manufacturer of zafirlukast has received a limited number of reports of patients experiencing increased theophylline levels with or without clinical signs or symptoms of theophylline toxicity after the addition of zafirlukast. No further details are available.[4]

Mechanism

Not understood.

Importance and management

Information about the interaction between theophylline and montelukast seems to be limited. The study above indicates that when using normal clinical doses of montelukast no special precautions or dose alterations are needed. Similarly, no adverse interaction would normally seem to occur with zafirlukast and theophylline; the published case involving zafirlukast is of doubtful general significance, and as further details of the reports made to the company are unavailable, their clinical significance cannot be assessed.

Theophylline + Loperamide

Loperamide delays the absorption of theophylline from a sustained-release preparation.

Clinical evidence, mechanism, importance and management

A study of the effects of altering the transit time of drugs through the small intestine found that when 12 healthy subjects were given high-dose loperamide (8 mg every 6 hours for a total of 8 doses), the rate, but not extent, of absorption of a single 600-mg dose of sustained-release theophylline (*Theo-24*) was decreased. The maximum serum theophylline levels were reduced from 4.6 mg/L to 3.2 mg/L, and this peak level occurred at 20 hours instead of 11 hours. One suggested reason for these effects is that loperamide inhibits the movement of the gut, thereby decreasing the dissolution rate of the *Theo-24* pellets.[1] More study is needed to establish the clinical significance of the interaction in patients receiving long-term theophylline, and to establish if aminophylline is similarly affected.

1. Bryson JC, Dukes GE, Kirby MG, Heizer WD, Powell JR. Effect of altering small bowel transit time on sustained release theophylline absorption. *J Clin Pharmacol* (1989) 29, 733–8.

Theophylline + Macrolides

Troleandomycin can increase serum theophylline levels, causing toxicity. Azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin, spiramycin, and telithromycin normally only cause modest changes in theophylline levels or do not interact at all. There are unexplained and isolated case reports of theophylline toxicity with josamycin and clarithromycin. Roxithromycin usually has no relevant interaction but an increase in theophylline levels was seen in one study. See also 'Theophylline + Macrolides; Erythromycin', p.1446.

Clinical evidence

(a) Azithromycin

In an analysis of the safety data from clinical studies of azithromycin, there was no evidence that the plasma levels of theophylline were affected in patients given both drugs.[1] Similarly, no adverse effects were reported in another clinical study of patients taking azithromycin and theophylline.[2] Azithromycin 250 mg twice daily did not affect the clearance or serum levels of theophylline in patients with asthma.[3] However, a 68-year-old man had a marked but transient fall in his serum theophylline level when azithromycin was withdrawn, and this was confirmed on rechallenge.[4] The same authors conducted a study in 4 healthy subjects given azithromycin 500 mg on day one then 250 mg daily for 4 days and sustained-release theophylline 200 mg twice daily. Theophylline levels were slightly elevated during the use of azithromycin, and a transient drop occurred 5 days after azithromycin was stopped.[5]

(b) Clarithromycin

In 10 elderly patients with COPD, clarithromycin 250 mg twice daily for 7 days had no effect on the steady-state serum theophylline levels.[6] Similarly, two other studies found that clarithromycin had little or no effect on theophylline pharmacokinetics.[3,7] Another study in healthy subjects given clarithromycin 500 mg twice daily for 4 days found a 17% increase in the AUC and an 18% increase in the maximum plasma levels of theophylline, but this was considered clinically unimportant.[8] In two clinical studies in patients with an acute bacterial exacerbation of chronic bronchitis the number of patients requiring an adjustment in theophylline dose was similar when those who took clarithromycin were compared with those who took ampicillin.[9,10] However, there are isolated reports of possible theophylline toxicity in patients taking clarithromycin, including a case that resulted in rhabdomyolysis with renal failure requiring haemodialysis.[11,12] For a report of theophylline toxicity in a patient also taking clarithromycin and levofloxacin, see 'Theophylline + Quinolones', p.1452.

(c) Dirithromycin

In one study, 13 healthy subjects had a fall in their steady-state trough theophylline level of 18%, and a fall in their peak serum level of 26% while taking dirithromycin 500 mg daily for 10 days, although this was not considered clinically relevant.[13] No significant changes in theophylline pharmacokinetics were seen in 14 patients with COPD who were given dirithromycin 500 mg daily for 10 days.[14] This is supported by a similar single-dose study in 12 healthy subjects.[15]

(d) Josamycin

No clinically significant changes in serum theophylline levels were seen in 5 studies in patients (both adults and children)[16-18] or healthy subjects[19] given josamycin, but a modest rise in theophylline levels was described in one study in children.[20] Another study reported a 23% reduction in the levels of theophylline (given as intravenous aminophylline) in 5 patients with particularly severe respiratory impairment, but no significant effect was found in 5 other patients with less severe disease.[21] However, an isolated report describes theophylline toxicity in a 80-year-old man who was given josamycin.[22]

(e) Midecamycin/Midecamycin diacetate

In one study, 18 children with asthma had a slight decrease in serum theophylline levels when they were given midecamycin 40 mg/kg daily for 10 days for a bronchopulmonary infection, but no changes were seen in 5 healthy adult subjects.[23]

Similarly, no significant changes in serum theophylline levels were seen in 20 patients taking slow-release theophylline (*Theo-dur*) 300 mg twice daily, or intravenous theophylline 4 mg/kg three times daily, when they were given midecamycin diacetate (miocamycin; ponsinomycin) 1.2 g daily for 10 days.[24] A number of other studies confirm the absence of a clinically important interaction between oral or intravenous theophylline or intravenous aminophylline and midecamycin diacetate in children and adults.[25-28]

(f) Rokitamycin

Two studies, in 12 adults with COPD and 11 elderly patients taking theophylline, found no significant changes in serum theophylline levels when they were given rokitamycin 600 to 800 mg daily for a week.[29,30]

(g) Roxithromycin

One study in 12 healthy subjects and another in 16 patients with COPD found only minor increases in steady-state theophylline levels, which were not considered clinically relevant, when they were given roxithromycin 150 mg twice daily.[31,32] Another study in 5 healthy subjects similarly found that roxithromycin 300 mg twice daily did not affect the pharmacokinetics of theophylline.[33] However, further study in 14 patients with asthma reported an increase in serum theophylline levels who were given roxithromycin 150 mg twice daily, but as the rise was not quantified it is difficult to assess the clinical relevance of this finding.[3]

(h) Spiramycin

A study in 15 patients with asthma taking theophylline found that spiramycin 1 g twice daily for at least 5 days had no significant effect on their steady-state serum theophylline levels.[34]

(i) Telithromycin

A study in 24 healthy subjects given theophylline found that telithromycin 800 mg daily for 4 days did not have a clinically relevant effect on theophylline exposure.[35]

(j) Troleandomycin

A series of 8 patients with severe chronic asthma found that troleandomycin 250 mg four times daily caused an average reduction in the clearance of theophylline (given as intravenous aminophylline) of 50%. One patient had a theophylline-induced seizure after 10 days, with a serum theophylline level of 43 mg/mL (reference range 10 to 20 mg/L). The theophylline half-life in this patient had increased from 4.6 hours to 11.3 hours.[36] Other studies in healthy subjects[23,37] and patients[18] given oral theophylline with troleandomycin have also found reductions in theophylline clearance and marked rises in serum theophylline levels and half-life, even at low troleandomycin doses.[38]

Mechanism

It is believed that troleandomycin forms inactive cytochrome P450-metabolite complexes within the liver, the effect of which is to reduce the metabolism (*N*-demethylation and 8-hydroxylation)[37] of theophylline (which are mediated by the cytochrome P450 isoenzyme CYP1A2), thereby reducing its clearance and increasing its levels. Clarithromycin, josamycin, midecamycin, and roxithromycin are thought to rarely form these complexes, and azithromycin, dirithromycin, rokitamycin and spiramycin are not thought to inactivate cytochrome P450.[39]

Importance and management

The interaction between theophylline and troleandomycin is established and well documented. If troleandomycin is given, monitor the levels of theophylline closely and adjust the dose as necessary. Reductions of 25 to 50% may be needed.[38,40] The situation with roxithromycin is uncertain since only one of four studies suggested an interaction, but it would be prudent to be alert for the need to reduce the theophylline dose. Alternative macrolides that usually interact only moderately, or not at all are azithromycin, clarithromycin, dirithromycin, josamycin, midecamycin, rokitamycin and spiramycin. Telithromycin may also be a suitable alternative. However, even with these macrolides it would still be prudent to monitor the outcome because a few patients, especially those with theophylline levels at the high end of the range, may need some small theophylline dose adjustments. In the case of azithromycin, care should be taken in adjusting the dose based on theophylline levels taken after about 5 days of concurrent use, as they may only be a reflection of a transient decrease. In addition, acute infection *per se* may alter theophylline pharmacokinetics.[41]

Theophylline + Macrolides; Erythromycin

Theophylline levels can be increased by erythromycin. Toxicity may develop in some patients. The onset may be delayed for several days, and not all patients demonstrate this interaction. Erythromycin levels may be modestly reduced by theophylline.

Clinical evidence

(a) Effect on theophylline

The peak serum theophylline levels of 12 patients with COPD given aminophylline 4 mg/kg orally every 6 hours were raised by 28% by erythromycin stearate 500 mg every 6 hours for 2 days. The clearance was reduced by 22%. Only one patient developed clinical signs of toxicity, although the authors suggest this may be because the other patients had low theophylline levels (11 mg/L) to start with and they may not have been studied for long enough to detect the full effect of the erythromycin.[1] Several single-dose studies in healthy subjects or adults with asthma given aminophylline or theophylline have demonstrated this interaction[2-6] and multiple-dose studies with aminophylline have also shown that erythromycin alters theophylline pharmacokinetics.[7,8] A multiple-dose study in children with asthma found a 40% rise in the levels of theophylline (given as intravenous aminophylline).[9] There was often wide inter-subject variability, and not all patients demonstrated the interaction.[1,4,6-9] In addition to the studies, there are several case reports where erythromycin was thought to have caused previously therapeutic theophylline levels to rise to toxic levels. In 3 cases the level rose twofold, with accompanying symptoms of toxicity,[10-12] and in one case the patient developed a fatal cardiac arrhythmia.[13] Toxic theophylline levels of 41 mg/L have also been reported in one patient 3 days after a 6-day course of erythromycin was finished, although this patient did not have any clinical signs or symptoms or theophylline toxicity.[14]

Several studies in both healthy adults,[15-18] and adults with COPD[5,19] did not demonstrate any clinically significant interaction, although two of

these studies did find a reduction in the clearance of theophylline in some subjects.[15,19]

(b) Effect on erythromycin

The peak serum levels of erythromycin 500 mg every 8 hours were almost halved and the AUC_{0-8} was reduced by 38% when 6 healthy subjects were given a single 250-mg intravenous dose of theophylline.[6] Another pharmacokinetic study found that serum erythromycin levels fell by more than 30% when intravenous theophylline was given with oral erythromycin.[8] Other studies using intravenous erythromycin found no significant pharmacokinetic changes. The renal clearance was increased, but this did not affect the overall clearance.[18,20]

Mechanism

The mechanism for the effects of erythromycin on theophylline levels is not fully understood. It seems most likely that erythromycin inhibits the metabolism of theophylline by the liver resulting in a reduction in its clearance and a rise in its serum levels. The human organic anion transporter (OAT) 2 in the liver may also be involved in this interaction.[21] The reduction in erythromycin levels may be caused by theophylline affecting the absorption of oral erythromycin.[18]

Importance and management

The effects of erythromycin on theophylline and aminophylline are established (but still debated) and well documented. Not all the reports are referenced here. It does not seem to matter which erythromycin salt is used. Monitor theophylline levels and anticipate the need to reduce the aminophylline or theophylline dose to avoid toxicity. Not all patients will develop this interaction but remember it may take several days (most commonly 2 to 7 days) to manifest itself. Some patients may have a high theophylline level but no clinical signs or symptoms, therefore do not rely on symptoms alone to monitor for toxicity.[14] Limited evidence suggests that levels may return to normal 2 to 7 days after stopping erythromycin.[10-12,14] There are many factors, such as smoking,[3,19] which also affect theophylline pharmacokinetics, and which may play a role in altering the significance of the interaction in different patients. Those particularly at risk are patients with already high serum theophylline levels and/or taking high doses (20 mg/kg or more). Ideally, use a non-interacting antibacterial if possible. However, where concurrent treatment cannot be avoided, a 25% reduction in theophylline dose has been recommended for patients with levels in the 15 to 20 mg/L range,[1,2,22] but little dose adjustment is probably needed for those at the lower end of the range, (below 15 mg/L) unless toxic symptoms appear.[1,4] In practice erythromycin can probably be safely started with theophylline, with the levels monitored after 48 hours and appropriate dose adjustments then made.

The fall in erythromycin levels caused by theophylline is not well documented, but what is known suggests that it may be clinically important. Be alert for any evidence of an inadequate response to the erythromycin and increase the dose or change the antibacterial if necessary. Intravenous erythromycin appears not to be affected.

Theophylline + Methoxsalen

Oral methoxsalen markedly increases theophylline levels. Topical methoxsalen would not be expected to interact.

Clinical evidence, mechanism, importance and management

In a single-dose study in 3 healthy subjects a 1.2-mg/kg oral dose of methoxsalen increased the AUC of a single 600-mg dose of theophylline (given one hour later) 1.7-fold, 2.1-fold and 2.7-fold, in the 3 subjects, respectively.[1] Methoxsalen probably inhibits the metabolism of theophylline[2] by the cytochrome P450 isoenzyme CYP1A2. Although information is limited, the findings are in line with what is known about caffeine, which is similarly metabolised, and methoxsalen, see 'Caffeine + Psoralens', p.1421. Theophylline (and therefore probably aminophylline) dose reductions are likely to be required during concurrent use with systemic methoxsalen but seem unlikely to be necessary with topical treatment such as PUVA.

Theophylline + Metoclopramide

Metoclopramide does not appear to interact with slow-release theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 10-mg dose of metoclopramide taken 20 minutes before a 600-mg dose of slow-release theophylline (*Theo-Dur*), caused a small but insignificant 15% reduction in the bioavailability of theophylline. However, adverse effects (nausea, headache, tremors, CNS stimulation) were seen more often in those taking metoclopramide than in those taking placebo, possibly because metoclopramide caused an earlier rise in theophylline levels, and because some of the adverse effects of these two drugs may be additive.[1] A later study in 12 healthy subjects found that metoclopramide 15 mg every 6 hours had no effect on the rate or extent of absorption of a 600-mg dose of sustained-release theophylline (*Theo-24*).[2] A similar lack of interaction was found in another study using *Theo-Dur*.[3] There would seem to be no reason for avoiding concurrent use.

Theophylline + Metronidazole

No interaction of clinical importance normally takes place if metronidazole is given to patients taking theophylline, but an isolated

report describes seizures in one patient taking theophylline, metronidazole and ciprofloxacin.

Clinical evidence, mechanism, importance and management

In 5 women taking metronidazole 250 mg three times a day for trichomoniasis there were no significant changes in the pharmacokinetics of theophylline, given as a single intravenous dose of aminophylline.[1] Another study in 10 healthy subjects confirmed this finding.[2] However, an acutely ill elderly woman taking theophylline had a generalised seizure while taking metronidazole and ciprofloxacin, despite her theophylline level being within the therapeutic range (10 to 20 mg/L).[3] Both ciprofloxacin and, more rarely, metronidazole are associated with seizures.[3] Although the evidence is limited, no special precautions would seem to be necessary during concurrent use.

Theophylline + Mexiletine or Tocainide

Theophylline levels are increased by mexiletine and toxicity may occur. Tocainide has only a small and probably clinically unimportant effect on theophylline pharmacokinetics.

Clinical evidence

(a) Mexiletine

A man developed theophylline toxicity within a few days of starting to take mexiletine 200 mg three times daily. His serum theophylline level rose from 15.3 mg/L to 25 mg/L, but fell to 14.2 mg/L, and the symptoms of toxicity resolved, when the theophylline dose was reduced by two-thirds.[1]

Other case reports describe 1.5- to threefold increases in theophylline serum levels (accompanied by clear signs of toxicity in some instances) in a total of 10 patients who were given mexiletine.[2-7] Theophylline dose reductions of 50% were required in 3 cases,[2,6] although 2 of the patients that did not require dose reductions had initial theophylline levels below the therapeutic range.[3] In another report, the arrhythmia of one patient was aggravated even at therapeutic serum theophylline levels, and mexiletine was discontinued.[4]

In 15 healthy subjects, mexiletine 200 mg three times daily for 5 days reduced the clearance of a single 5-mg/kg intravenous dose of theophylline by 46% in women and 40% in men. The theophylline half-life was prolonged by 96% (from 7.4 to 14.5 hours) in women and 71% (from 8.7 to 14.9 hours) in men.[8] Two further studies in healthy subjects given theophylline with mexiletine for 5 days found a reduction in steady-state theophylline clearance of about 45%, and an increase in the AUC of about 60%.[9,10]

(b) Tocainide

After taking tocainide 400 mg every 8 hours for 5 days, the pharmacokinetics of a single 5-mg/kg intravenous dose of theophylline was measured in 8 healthy subjects. The clearance was decreased by about 10% and the half-life slightly prolonged (from 9.7 to 10.4 hours), but these changes were not thought to be large enough to warrant altering theophylline doses.[11]

Mechanism

Mexiletine inhibits the metabolism (demethylation) of theophylline by the liver, thereby increasing its effects.[8,10,12] It is possible that the interaction is due to competitive inhibition of the cytochrome P450 isoenzyme CYP1A2.[13]

Importance and management

The interaction between theophylline and mexiletine is established and of clinical importance. Monitor concurrent use and reduce the theophylline dose as necessary to prevent the development of theophylline toxicity. It has been suggested that 50% dose reductions may be necessary.[8] It seems doubtful if the interaction between theophylline and tocainide is clinically important.

Theophylline + Moracizine

Moracizine modestly increases theophylline clearance.

Clinical evidence

Single oral doses of aminophylline and a sustained-release theophylline preparation (*TheoDur*) were given to 12 healthy subjects. After they took moracizine 250 mg three times daily for 2 weeks, the AUC of theophylline and aminophylline were reduced by 32% and 36%, respectively, the clearance was increased by 44% and 66%, respectively, and the elimination half-life was decreased by 33% and 20%, respectively.[1]

Mechanism

Uncertain. Moracizine is an enzyme inducer and appears to increase the metabolism of theophylline.[1] In contrast, *in vitro* and *animal* data show moracizine to be an inhibitor of the cytochrome P450 isoenzyme CYP1A2, which is the main isoenzyme involved in the metabolism of theophylline.[2] This would, in theory, be expected to lead to raised theophylline levels, but as these studies illustrate, *in vitro* findings do not always translate in to clinically relevant effects.

Importance and management

Information seems to be limited to this study. The clinical importance of this interaction has not been assessed, but monitor the effects of concurrent use and be alert for the need to adjust the theophylline dose.

1. Pieniaszek HJ, Davidson AF, Benedek IH. Effect of moricizine on the pharmacokinetics of single-dose theophylline in healthy subjects. *Ther Drug Monit* (1993) 15, 199–203.

Theophylline + Nefazodone

Nefazodone does not appear to interact adversely with theophylline.

Clinical evidence, mechanism, importance and management

Nefazodone 200 mg twice daily for 7 days had no effect on the pharmacokinetics or pharmacodynamics of theophylline 600 mg to 1.2 g daily in patients with chronic obstructive airways disease, nor was there any effect

on their FEV_1 values.[1] No special theophylline dose adjustment would seem necessary if both drugs are used. There appears to be no data for aminophylline, but a similar lack of interaction would be expected.

1. Dockens RC, Rapoport D, Roberts D, Greene DS, Barbhaiya RH. Lack of an effect of nefazodone on the pharmacokinetics and pharmacodynamics of theophylline during concurrent administration in patients with chronic obstructive airways disease. *Br J Clin Pharmacol* (1995) 40, 598–601.

Theophylline + Non-prescription theophylline products

Patients taking theophylline should not take other medications containing theophylline (some of which are non-prescription products) unless the total dose of theophylline can be adjusted appropriately.

Clinical evidence, mechanism, importance and management

A patient taking theophylline developed elevated serum theophylline levels of 35.7 micrograms/mL while taking *Quinamm* for leg cramps (a formulation containing quinine 260 mg and aminophylline 195 mg).[1] Another case report describes a patient taking theophylline, who increased her intake of *Franol plus*, which contained theophylline and ephedrine. Theophylline levels measured on admission to hospital were 64 mg/L.[2] These case reports highlight the need to avoid the inadvertent intake of additional doses of theophylline if toxicity is to be avoided. Note that non-prescription preparations containing theophylline are available in many countries. For example, some cough and cold preparations in the UK contain theophylline (e.g. *Do-Do Chesteze*). Patients should be warned.

Theophylline + Olanzapine

There appears to be no clinically significant pharmacokinetic interaction between theophylline and olanzapine.

Clinical evidence, mechanism, importance and management

A study in 18 healthy subjects given olanzapine 5 mg on day one, 7.5 mg on day 2 and then 10 mg daily for 7 days found no significant changes in the pharmacokinetics of theophylline (given as a single 350-mg intravenous dose of aminophylline). The pharmacokinetics of olanzapine also appeared to be unchanged when both drugs were given.[1] No special precautions would appear to be necessary on concurrent use.

1. Macias WL, Bergstrom RF, Cerimele BJ, Kassahun K, Tatum DE, Callaghan JT. Lack of effect of olanzapine on the pharmacokinetics of a single aminophylline dose in healthy men. *Pharmacotherapy* (1998) 18, 1237–48.

Theophylline + Ozagrel

Ozagrel does not appear to alter theophylline pharmacokinetics.

Clinical evidence, mechanism, importance and management

Ozagrel 200 mg twice daily was given to 4 patients with asthma taking sustained-release theophylline. After 24 weeks the ozagrel was stopped without any significant effect on the pharmacokinetics of theophylline. Similarly, in another 8 patients with bronchial asthma, there were no significant differences in the pharmacokinetics of theophylline (given as a single infusion of aminophylline) before and after taking ozagrel 200 mg twice daily for 7 days.[1] No special precautions would seem to be needed during concurrent use.

1. Kawakatsu K, Kino T, Yasuba H, Kawaguchi H, Tsubata R, Satake N, Oshima S. Effect of ozagrel (OKY-046), a thromboxane synthetase inhibitor, on theophylline pharmacokinetics in asthmatic patients. *Int J Clin Pharmacol Ther Toxicol* (1990) 28, 158–63.

Theophylline + Penicillins

Ampicillin, with or without sulbactam, and amoxicillin do not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

A retrospective study in asthmatic children aged 3 months to 6 years found that the mean half-life of theophylline did not differ between those children given ampicillin and those not given ampicillin.[1] The pharmacokinetics of theophylline 8.5 mg/kg daily were not altered in 12 adult patients with COPD when they were given ampicillin 1 g plus sulbactam 500 mg every 12 hours for 7 days.[2] A study in 9 healthy adult subjects found that amoxicillin 750 mg daily for 9 days did not affect the pharmacokinetics of theophylline 540 mg twice daily.[3,4]

No special precautions would seem to be necessary during concurrent use of these antibacterials and theophylline (and therefore probably aminophylline). However, note that acute infections *per se* can alter theophylline pharmacokinetics.[5]

Theophylline + Pentoxifylline

Pentoxifylline can raise theophylline levels.

Clinical evidence, mechanism, importance and management

The mean trough steady-state theophylline serum levels of 9 healthy subjects given sustained-release theophylline (*TheoDur*) 200 or 300 mg twice daily for 7 days were increased by 30% by pentoxifylline 400 mg three times daily. However, the change in levels ranged from a 13% decrease to a 95% increase. The subjects complained of insomnia, nausea, diarrhoea and tachycardia more frequently while taking both drugs, but this did not reach statistical significance.[1] The mechanism of this interaction is not understood, although note, pentoxifylline is also a xanthine derivative, and one manufacturer of aminophylline injection contraindicates its use in patients also receiving pentoxifylline.[2] Patients should be well monitored for theophylline adverse effects (headache, nausea, palpitations) while taking aminophylline or theophylline with pentoxifylline. More study is needed to clarify this highly variable interaction.

2. Aminophylline. Hameln Pharmaceuticals Ltd. UK Summary of product characteristics, October 2008.

Theophylline + Phenylpropanolamine

Phenylpropanolamine reduces the clearance of theophylline.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects a single 150-mg oral dose of phenylpropanolamine decreased the clearance of theophylline (given as a single 4-mg/kg intravenous dose of aminophylline one hour after the phenylpropanolamine) by 50%.[1] Such a large reduction in clearance would be expected to result in some increase in serum theophylline levels, but so far no studies of this potentially clinically important interaction seem to have been carried out in patients. Be alert for evidence of toxicity if both drugs are used. More study is needed.

1. Wilson HA, Chin R, Adair NE, Zaloga GP. Phenylpropanolamine significantly reduces the clearance of theophylline. *Am Rev Respir Dis* (1991) 143, A629.

Theophylline + Phenytoin

The serum levels of theophylline can be markedly reduced by phenytoin. Some limited evidence suggests that theophylline may also reduce phenytoin levels.

Clinical evidence

(a) Reduced phenytoin serum levels

A preliminary report noted that the seizure frequency of a woman with epilepsy taking phenytoin 100 mg four times daily increased when she was given intravenous theophylline, and then later oral theophylline. Her serum phenytoin levels had more than halved, from 15.7 mg/L to around 5 to 8 mg/L. An increase in the phenytoin dose to 200 mg three times daily raised her serum phenytoin levels to only 7 to 11 mg/L until the drugs were given one to 2 hours apart. The patient then developed phenytoin toxicity with a serum level of 33 mg/L. A subsequent single-dose study in 4 healthy subjects confirmed that higher serum levels of both drugs were achieved when the theophylline and phenytoin were given 2 hours apart rather than simultaneously.[1] Another study in 7 healthy subjects found that the AUC of a single 400-mg dose of phenytoin was reduced by 21% when it was given at the same time as a single 7.5-mg/kg dose of theophylline, compared with a reduction of 7% when the same doses were given 2 hours apart.[2] A later preliminary study (by some of the same authors) in 14 subjects found that after 2 weeks of concurrent use, the mean serum phenytoin levels of 5 of the subjects rose by 40% and the mean levels of the group as a whole rose by about 27% when the theophylline was stopped. Urinary concentrations of a phenytoin metabolite were raised.[3]

(b) Reduced theophylline serum levels

The observation that a patient taking phenytoin had lower than expected theophylline levels prompted a study in 10 healthy subjects. After taking phenytoin for 10 days the clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 73%, and both its AUC and half-life were reduced by about 50%.[4] Another study in 6 healthy subjects found that after taking phenytoin 300 mg daily for 3 weeks the mean clearance of theophylline (after a single intravenous dose of aminophylline) was increased by 45% (range 31 to 65%).[5] Similar results were found in a further study.[6] Other reports on individual asthmatic patients have shown that phenytoin can increase the clearance of theophylline by between about 30% and 3.5-fold.[7-9] Another study[10] and a case report[11] found that the reduction in theophylline levels caused by phenytoin can be additive with the effects of smoking (consider also 'Theophylline + Tobacco', p.1461). A subsequent study found that the extent of phenytoin-induced metabolism of theophylline was not affected by age, despite an age-related reduction in theophylline metabolism.[12]

Mechanism

Uncertain. It has been suggested that theophylline either impairs phenytoin absorption or induces phenytoin metabolism, but neither suggestion seem likely.

It seems probable that phenytoin, a known enzyme inducer, increases the metabolism of theophylline by the cytochrome P450 isoenzyme CYP1A2 in the liver, thereby increasing its clearance.

Importance and management

The effect of phenytoin on theophylline is established and of clinical importance. Patients given both drugs should be monitored to confirm that theophylline remains effective. Ideally the serum levels should be measured to confirm that they remain within the therapeutic range. Theophylline dose increases of up to 50% or more may be required.[13] Conversely, patients should be monitored for signs of toxicity and theophylline levels should be checked if they stop phenytoin.

The effect of theophylline on phenytoin is not established and the documentation is limited. It may be prudent to monitor phenytoin levels. Separating the doses appears to minimise any interaction. Note that theophylline itself can cause seizures, although mostly in overdose, and should be used with caution in patients with epilepsy.

Theophylline + Pirenzepine

Pirenzepine does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 5 healthy subjects, pirenzepine 50 mg twice daily for 5 days had no effect on the pharmacokinetics of theophylline (given as aminophylline 6.5 mg/kg, intravenously).[1] This would suggest that no special precautions are needed on concurrent use.

1. Sertl K, Rameis H, Meryn S. Pirenzepin does not alter the pharmacokinetics of theophylline. *Int J Clin Pharmacol Ther Toxicol* (1987) 25, 15–17.

Theophylline + Pneumococcal vaccine

Pneumococcal vaccination does not appear to affect the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects the pharmacokinetics of oral theophylline 250 mg three times daily for 10 days were unaltered both the day after and one week after they received 0.5 mL of a pneumococcal vaccine.[1] Based on this study, and the fact that pneumococcal vaccination is routinely undertaken in patients with chronic respiratory disease, and no adverse effects appear to have been reported, no special precautions are needed during concurrent use. There appears to be no direct evidence regarding aminophylline, but a similar lack of adverse interaction would be expected.

1. Cupit GC, Self TH, Bekemeyer WB. The effect of pneumococcal vaccine on the disposition of theophylline. *Eur J Clin Pharmacol* (1988) 34, 505–7.

Theophylline or Diprophylline + Probenecid

Theophylline levels are unaffected by probenecid, but diprophylline levels can be raised.

Clinical evidence

(a) Diprophylline

A study in 12 healthy subjects found that the half-life of a single 20-mg/kg oral dose of diprophylline was doubled (from 2.6 to 4.9 hours) and the clearance approximately halved by probenecid 1 g, which resulted in raised serum diprophylline levels.[1]

(b) Theophylline

A study in 7 healthy subjects found that probenecid 1 g given 30 minutes before a 5.6-mg/kg oral dose of aminophylline had no significant effect on the pharmacokinetics of theophylline.[2]

Mechanism

Diprophylline is largely excreted unchanged by the kidneys, and probenecid inhibits its renal tubular secretion.[3] Theophylline is largely cleared from the body by hepatic metabolism, and would therefore not be expected to be affected by probenecid.

Importance and management

Based on the findings of this single-dose study, it would seem to be prudent to monitor serum diprophylline levels if probenecid is started or stopped. No special precautions are needed if aminophylline or theophylline and probenecid are given concurrently.

Theophylline + Propafenone

Two isolated reports describe raised serum theophylline levels, with symptoms of toxicity, when two patients were given propafenone.

Clinical evidence

In a 71-year-old man, propafenone 150 mg daily raised the levels of sustained-release theophylline 300 mg twice daily from a range of 10.2 to 12.8 mg/L, up to 19 mg/L, and signs of theophylline toxicity developed. The day after propafenone was withdrawn the level fell to 10.8 mg/L. When the propafenone was later restarted the theophylline levels rose to 17.7 mg/L within one week, but fell when the theophylline dose was reduced by one-third.[1]

In another report, a 63-year-old man had a marked reduction in the clearance of sustained-release theophylline and a rise in his theophylline levels from 10.8 mg/L to a maximum of 20.3 mg/L over 7 days when he took propafenone 150 mg every 8 hours, increasing to 300 mg every 8 hours.[2] Theophylline was discontinued.

Mechanism

Uncertain. It has been suggested that propafenone may reduce the metabolism of theophylline by the liver, thereby increasing its levels. Note that propafenone is not usually considered an inhibitor of the cytochrome P450 isoenzyme CYP1A2, by which theophylline is mainly metabolised. However, it is also, in part, metabolised by CYP1A2, although competition for metabolism by the same isoenzyme does not usually result in such a large increase in levels as that seen in the cases.

Importance and management

Evidence for an interaction between theophylline and propafenone appears to be limited to these two case reports, which are an insufficient basis for recommending monitoring in all patients. If a patient taking theophylline is given propafenone, it may be prudent to consider an interaction as a possible cause, if theophylline adverse effects (nausea, headache, tremor) develop. Controlled studies are needed to further investigate this potential interaction.

2. Spinler SA, Gammaitoni A, Charland SL, Hurwitz J. Propafenone-theophylline interaction. *Pharmacotherapy* (1993) 13, 68–71.

Theophylline + Propantheline

A study in 6 healthy subjects found that propantheline 30 mg did not affect the rate or extent of absorption of a single 500-mg dose of theophylline (*Theo-Dur*). No special precautions would seem necessary on concurrent use.[1]

1. Sommers DK, Meyer EC, Van Wyk M, Moncrieff J, Snyman JR, Grimbeek RJ. The influence of codeine, propantheline and metoclopramide on small bowel transit and theophylline absorption from a sustained-release formulation. *Br J Clin Pharmacol* (1992) 33, 305–8.

Theophylline + Protease inhibitors

Ritonavir reduces the levels of theophylline. Indinavir appears not to interact with theophylline.

Clinical evidence, mechanism, importance and management

(a) Indinavir

A study in 12 healthy subjects given a single 250-mg oral dose of theophylline before and after indinavir 800 mg three times daily for 5 days found an 18% increase in the AUC of theophylline, which was not considered clinically significant.[1] There have been no further published studies or cases to date to confirm this result, and as indinavir does not inhibit the cytochrome P450 isoenzyme CYP1A2 (see 'Table 21.2', (p.914)), the main isoenzyme that metabolises theophylline, it would seem unlikely that special precautions are necessary during concurrent use.

(b) Ritonavir

In a placebo-controlled study, 27 subjects taking theophylline 3 mg/kg every 8 hours were given ritonavir 300 mg increased to 500 mg twice daily for 10 days. Ritonavir reduced the AUC of theophylline by 43% and reduced its maximum and minimum steady-state levels by 32% and 57%, respectively. The interaction achieved its maximal effect 6 days after starting ritonavir.[2] Ritonavir is an inducer of the cytochrome P450 isoenzyme CYP1A2 by which theophylline is metabolised, and therefore concurrent use leads to an increase in theophylline metabolism, and a reduction in its levels. Information is very limited but the interaction appears to be established. Monitor theophylline levels if ritonavir is started and be alert for the need to increase the theophylline dose. It seems likely that aminophylline, which is metabolised to theophylline, will be similarly affected.

2. Hsu A, Granneman GR, Witt G, Cavanaugh JH, Leonard J. Assessment of multiple doses of ritonavir on the pharmacokinetics of theophylline. 11th Int Conf AIDS, Vancouver, 1996. Mo.B.1200.

Theophylline + Proton pump inhibitors

Omeprazole may cause a small increase in theophylline clearance, and lansoprazole may cause a small decrease in theophylline levels. Pantoprazole and rabeprazole do not appear to interact with theophylline.

Clinical evidence

(a) Lansoprazole

Lansoprazole 60 mg daily for 9 days caused only a very slight reduction in the steady-state theophylline levels of 14 healthy subjects.[1] Other studies have also shown little or no change in theophylline pharmacokinetics on the concurrent use of lansoprazole.[2-6]

(b) Omeprazole

The changes in the half-life and clearance of theophylline caused by omeprazole were found to be small and clinically unimportant in two studies,[7,8] and no changes in the steady-state pharmacokinetics of theophylline were found in other studies.[5,9,10] However, one study found that omeprazole produced an 11% increase in the clearance of theophylline in poor metabolisers of omeprazole (i.e. those with low levels of the cytochrome P450 isoenzyme CYP2C19 and therefore higher levels of omeprazole),[11] but this seems unlikely to be clinically significant.

(c) Pantoprazole

A crossover study in 8 healthy subjects found that intravenous pantoprazole 30 mg daily had no clinically important effect on the pharmacokinetics of theophylline given by infusion. No clinically relevant changes in blood pressure, heart rate, ECG and routine clinical laboratory parameters were seen.[12] Other studies have also found no significant change in theophylline pharmacokinetics when pantoprazole was given.[4,5]

(d) Rabeprazole

In a placebo-controlled study in 25 healthy subjects a single 250-mg oral dose of theophylline was given before and after rabeprazole 20 mg daily

for 7 days. No significant changes in the pharmacokinetics of theophylline were seen.[13,14]

Mechanism, importance and management

Lansoprazole possibly induces cytochrome P450 isoenzyme CYP1A2 (the enzyme by which theophylline is metabolised) to a small extent, but this is unlikely to be significant unless an individual is particularly sensitive to this effect.[1] Other proton pump inhibitors are unlikely to interact with theophylline, and so no special precautions would seem necessary on concurrent use. A similar lack of effect would be expected with aminophylline.

Theophylline + Pyrantel

A single case report describes increased theophylline levels when a child was also given pyrantel.

Clinical evidence

An 8-year-old boy with status asthmaticus was given intravenous aminophylline and then switched to sustained-release oral theophylline on day 3, at which point his serum theophylline level was 15 mg/L. On day 4 he was given a single 160-mg dose of pyrantel (for an *Ascaris lumbricoides* infection) at the same time as his second theophylline dose. About 2.5 hours later his serum theophylline level was 24 mg/L, and a further 1.5 hours later it had risen to 30 mg/L. No further theophylline was given and no symptoms of theophylline toxicity occurred. The patient was discharged later in the day without theophylline.[1]

Mechanism

Not understood. One suggestion is that pyrantel inhibited the liver enzymes concerned with the metabolism of theophylline, thereby increasing its levels. However, this is unlikely as the interaction occurred so rapidly. Another suggestion was that pyrantel may have increased drug release from the sustained-release theophylline preparation.

Importance and management

Information is limited to this single case report. No general conclusions can be based on such slim evidence, but concurrent use should be well monitored because, in this case, the serum theophylline concentration increase was very rapid. More study is needed.

Theophylline + Pyridoxal

There is no evidence of an adverse interaction if pyridoxal (a vitamin B_6 substance) and theophylline are taken concurrently. There may be some reduction in theophylline-induced hand tremor.

Clinical evidence, mechanism, importance and management

In a crossover study, 15 young healthy adults were given theophylline (*Theo-Dur*) for 4 weeks, with the dose adjusted to give plasma levels of 10 mg/L, with a vitamin B_6 supplement containing pyridoxal hydrochloride 15 mg daily, or placebo. A variety of psychomotor and electrophysiological tests and self-report questionnaires failed to distinguish between the effects of the placebo or the vitamin B_6 supplement, except that the hand tremor induced by the theophylline tended to be reduced.[1] In another study by the same research group, 15 healthy subjects (smoking status not indicated) took pyridoxal 15 mg daily for 2 weeks before starting, and when also taking, sustained-release theophylline (*Theo-Dur*), 5 mg/kg daily for one week increased to 8 mg/kg daily for the next 3 weeks, which resulted in theophylline levels of 7.6 to 9.9 [mg/L]. Supplementation with pyridoxal did not prevent theophylline-induced reductions in pyridoxine 5-phosphate levels, as an indicator of vitamin B_6 status, although these did not drop below the normal reference range.[2]

There would seem to be no reason for avoiding concurrent use and it may even have some advantage.

Theophylline + Quinolones

Theophylline levels can be markedly increased in most patients by enoxacin. Pipemidic acid and clinafloxacin probably interact similarly. Theophylline levels can also be markedly increased in some patients by ciprofloxacin, and possibly pefloxacin. Norfloxacin, ofloxacin, pazufloxacin, or prulifloxacin normally cause a much smaller rise in theophylline levels. However, serious toxicity has been seen in few patients given norfloxacin. Fleroxacin, flumequine, gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, rufloxacin, sparfloxacin and trovafloxacin appear not to interact with theophylline.

Clinical evidence

A. Pharmacokinetic studies

The effects of the quinolones on the pharmacokinetics of theophylline in clinical studies in healthy subjects or patients are listed in 'Table 34.4', (p.1453).

B. Case reports

(a) Ciprofloxacin

There are numerous cases that describe the interaction between ciprofloxacin and theophylline or aminophylline, which commonly report large increases in serum theophylline levels (of 32 to 478%), often associated with toxicity.[1-11] From 1987 to 1988, the CSM in the UK had received 8 reports of clinically important adverse interactions between these two drugs, with one fatal case.[1] By 1991, the FDA in the US had received 39 reports of the interaction, with three deaths.[9]

An elderly woman taking theophylline developed toxic serum levels and died shortly after starting to take ciprofloxacin.[7] Seizures, associated with toxic levels of theophylline, were described in a number of the case reports.[5,9-12] Seizures have also occurred when ciprofloxacin was used with theophylline or aminophylline, even when theophylline levels were within the therapeutic range (10 to 20 mg/L).[9,13,14] Ciprofloxacin and toxic levels of theophylline are both known to cause seizures independently. It was suggested that, in the case of seizures, there may be a pharmacodynamic interaction between theophylline and the fluoroquinolones as well as a pharmacokinetic interaction.[9] In each case seizures began within 1 to 7 days of starting the combination and were reported as being either partial

Table 34.4 Effect of quinolones on theophylline pharmacokinetics

Quinolone (daily dose)	*Increase in theophylline level*	*Increase in AUC*	*Decrease in clearance*	*Refs*
Ciprofloxacin 600 to 1500 mg	17 to 113%	22 to 52%	18 to 55%	1–12

or grand mal. The addition of clarithromycin does not appear to increase the effects of ciprofloxacin on theophylline.[15] One report notes that of 20 patients receiving ciprofloxacin 500 mg twice daily and theophylline none complained of any unwanted drug effects. Of the 12 patients who received ciprofloxacin 750 mg twice daily, one patient experienced hallucinations, but theophylline plasma levels were not elevated, and 5 other patients had no rise in theophylline levels, nor were there any reports of unwanted drug effects. Details of the remaining 6 patients were not given.[16]

(b) Clinafloxacin

The apparently stable serum theophylline levels of a 78-year-old man with steroid-dependent COPD were approximately doubled after he received intravenous clinafloxacin 200 mg every 12 hours for 5 days. Two theophylline doses were withheld, and then the dose was reduced from 300 mg every 8 hours to 200 mg every 8 hours. Within another 5 days his serum theophylline levels had returned to his previous steady-state level.[17]

(c) Enoxacin

Some patients in early studies of enoxacin experienced adverse effects (serious nausea and vomiting, tachycardia, seizures)[18,19] and this was found to be associated with unexpectedly high plasma theophylline levels.[18,20]

(d) Levofloxacin

Levofloxacin has not significantly altered the pharmacokinetics of theophylline in studies, see 'Table 34.4', (p.1453). However, a 59-year-old man developed theophylline toxicity 7 days and 5 days after starting clarithromycin and levofloxacin, respectively. His theophylline clearance decreased by about 40% when compared with the value before starting these drugs and so the theophylline dose was reduced. After stopping levofloxacin, the theophylline level fell, and the theophylline clearance returned to its initial value. Clarithromycin was continued.[21]

(e) Norfloxacin

No clinically significant changes in theophylline levels occurred in a patient given norfloxacin who subsequently had marked changes when given ciprofloxacin.[3] This report and the studies in 'Table 34.4', (p.1453) contrast with the records of the FDA in the US, which describe 3 patients (up to 1989)[22] and 9 patients (up to 1991)[9] who experienced marked increases in theophylline levels ranging from 64 to 171% (mean 103%) when they were given norfloxacin. Three patients developed seizures, and one died.[9]

(f) Pefloxacin

An isolated report describes convulsions in a patient, which were attributed to the use of theophylline with pefloxacin.[23] A brief report notes that 43 patients who were given pefloxacin 400 mg twice daily and theophylline did not report any unwanted drug effects.[16]

Mechanism

The interacting quinolones appear to inhibit the metabolism (*N*-demethylation) of theophylline to different extents (some hardly at all), so that it is cleared from the body more slowly and its serum levels rise. The quinolones are known to inhibit the cytochrome P450 isoenzyme CYP1A2 by which theophylline is metabolised. There is some evidence that combined use of theophylline and quinolones may amplify the epileptogenic activity of the quinolones.[9,24]

Importance and management

The interactions of enoxacin and ciprofloxacin with theophylline are well documented, well established and of clinical importance. The effect of enoxacin is marked and occurs in most patients, whereas the incidence with ciprofloxacin is uncertain and problems do not develop in all patients. The risk seems greatest in the elderly[25] and those with theophylline levels already towards the top end of the therapeutic range. Toxicity may develop rapidly (within 2 to 3 days) unless the theophylline dose is reduced.

With **enoxacin**, it has been suggested that the dose of theophylline should be reduced by 50%,[20,26-28] although reductions of 75% may possibly be necessary for those with high theophylline clearances.[28] Alterations in the theophylline dose should be based on careful monitoring of theophylline levels. New steady-state serum theophylline levels are achieved within about 2 to 3 days of starting and stopping enoxacin.[28,29]

Although problems do not develop in all patients taking theophylline and **ciprofloxacin** it would be prudent to be alert for this interaction in any patient. Some recommend an initial reduction in theophylline dose, in the order of 30 to 50% when ciprofloxacin is started.[9,30,31] However, as a proportion of patients will not require a dose reduction, others suggest that the dose should be modified based on the theophylline level on day 2 of ciprofloxacin use.[11,26,32-34]

Direct information about **clinafloxacin** and **pipemidic acid** is more limited, but they also appear to cause a considerable rise in serum theophylline levels and therefore it would seem prudent to anticipate the need for a dose reduction and monitor theophylline levels closely.

Be alert for the adverse effects of theophylline if norfloxacin, ofloxacin, pazufloxacin, or pefloxacin are used because theophylline serum levels may possibly rise to a small extent (10 to 22%), but these antibacterials normally appear to be much safer. However, be aware that norfloxacin has caused a much larger rise on occasions.[9,22] Fleroxacin, flumequine, gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, rufloxacin, sparfloxacin and trovafloxacin appear not to interact significantly, and no special precautions seem necessary with these drugs. However, note that acute infection *per se* can alter theophylline pharmacokinetics.[35] The manufacturers of some quinolones include a warning in their product literature about the risk of combining theophylline with quinolones because of their potential additive effects on reducing the seizure threshold. Convulsions have been reported with theophylline and ciprofloxacin, norfloxacin, or pefloxacin. With some of these cases it is difficult to know whether what happened was due to increased theophylline levels, to patient pre-disposition, to potential additive effects on the seizure threshold, or to all three factors combined. However, the literature suggests that seizures attributed to concurrent use are relatively rare, so that the general warning about the risks with all quinolones may possibly be an overstatement.

Theophylline + Ramelteon

The concurrent use of theophylline and ramelteon does not appear to cause a clinically relevant alteration in the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

A well controlled study in 36 healthy subjects who took ramelteon 32 mg daily with theophylline 300 mg daily found that the pharmacokinetics of theophylline were not significantly altered by ramelteon. The exposure to ramelteon was increased by 40% by theophylline, but the authors considered that as this drug has a wide therapeutic margin and therefore the increase seen was not expected to be clinically significant.[1] There appears to be no information about an interaction with aminophylline, but it would be expected to interact in much the same way as theophylline.

Theophylline + Rasagiline

The US manufacturer of rasagiline reports that, in 24 healthy subjects, the concurrent use of rasagiline 1 mg daily and theophylline up to 500 mg twice daily did not affect the pharmacokinetics of either drug.[1] No dose adjustment is therefore needed on the concurrent use of these drugs.

1. Azilect (Rasagiline mesylate). Teva Pharmaceutical Industries Ltd. US Prescribing information, May 2009.

Theophylline + Repaglinide

In 14 healthy subjects, repaglinide 2 mg three times daily for 4 days did not significantly affect the steady-state pharmacokinetics of theophylline, although the peak plasma concentration was slightly reduced.[1] No theophylline dose adjustments would appear to be necessary during concurrent use.

1. Hartop V, Thomsen MS. Drug interaction studies with repaglinide: repaglinide on digoxin or theophylline pharmacokinetics and cimetidine on repaglinide pharmacokinetics. *J Clin Pharmacol* (2000) 40, 184–92.

Theophylline + Ribavirin

Ribavirin does not alter theophylline levels.

Clinical evidence, mechanism, importance and management

Oral ribavirin 200 mg every 6 hours had no effect on the plasma theophylline levels of 13 healthy subjects given immediate or sustained-release aminophylline. Similarly, ribavirin 10 mg/kg daily did not affect the plasma theophylline levels in 6 children with influenza and asthma.[1] No special precautions seem necessary on concurrent use.

Theophylline + Rifamycins and/or Isoniazid

Rifampicin (rifampin) lowers the levels of theophylline, but rifabutin appears to have little effect. Isoniazid may decrease or increase theophylline clearance and may increase theophylline levels. An isolated report describes theophylline toxicity one month after a patient started to take theophylline with isoniazid. Isoniazid and rifampicin increased theophylline clearance during the initial few days of tuberculosis treatment in one study, but there is some evidence that it decreases it within 4 weeks in another.

Clinical evidence

(a) Isoniazid

Theophylline toxicity has been described in one patient receiving isoniazid 5 mg/kg daily and theophylline, and this subsequently recurred on rechallenge.[1] In 7 healthy subjects, high-dose isoniazid (10 mg/kg daily) for 10 days increased the $AUC_{0\text{-}6}$ of theophylline by only 8%. The theophylline was given as an intravenous infusion of aminophylline and the plasma levels after 6 hours were 22% higher (about 10.5 mg/L compared with 8.7 mg/L). Five subjects also had an increase in the half-life and AUC of isoniazid, but these changes were not statistically significant.[2] Another study, in 13 healthy subjects, found that isoniazid 400 mg daily for 2 weeks reduced the mean clearance of theophylline (given as intravenous aminophylline) by 21%.[3]

However, another study in 4 healthy subjects given isoniazid 300 mg daily for 6 days found that the clearance of oral theophylline was increased by 16%, but no consistent changes were seen in any of the other pharmacokinetic parameters measured.[4]

(b) Rifabutin

The AUC of a single 5-mg/kg dose of theophylline was reduced by 6% in 11 healthy subjects who took rifabutin 300 mg daily for 12 days. The half-life and clearance of theophylline were not affected.[5]

(c) Rifampicin (Rifampin)

The AUC of theophylline (given as sustained-release aminophylline 450 mg) was reduced by 18% in 7 healthy subjects who took rifampicin 600 mg daily for one week. A parallel study in another 8 healthy subjects given the same dose of rifampicin found that the metabolic clearance of theophylline (given as intravenous aminophylline 5 mg/kg) was increased by 45%.[6]

Similarly, other studies in healthy subjects given oral or intravenous

theophylline or intravenous aminophylline and rifampicin 300 to 600 mg daily for 6 to 14 days found 25 to 82% rises in theophylline clearance, and 19 to 31% decreases in its half-life.[5,7-12] A 61% fall in the 5-hour post-dose serum levels of theophylline (given as choline theophyllinate) occurred in a 15-month-old boy when he was given a 4-day course of rifampicin 20 mg/kg daily as meningitis prophylaxis.[13]

(d) Antimycobacterials in combination

A study in patients taking a combination of **isoniazid**, **rifampicin**, **ethambutol** and **pyrazinamide** for pulmonary tuberculosis with intravenous aminophylline 7.35 mg/kg daily for 7 days found that the clearance of theophylline progressively increased, and was 53% faster on day 7.[14] In contrast, in an earlier study by the same authors, after 4 weeks of the same antimycobacterials (isoniazid, rifampicin, ethambutol with or without pyrazinamide) the theophylline clearance in patients receiving long-term theophylline was about 35% slower than in a control group of similar patients not taking antimycobacterials.[15] A single report describes unexpectedly *high* serum theophylline levels 4 days after theophylline 300 mg twice daily was started in an alcoholic patient with hepatic impairment who had started to take **rifampicin** and **isoniazid** 2 weeks previously.[16]

Mechanism

Rifampicin is a potent liver enzyme inducer, which increases the metabolism of the theophylline, thereby increasing its clearance and reducing its serum levels.[8] Rifabutin is a much less potent liver enzyme inducer than rifampicin, and consequently has less of an effect on theophylline metabolism. It has been suggested that isoniazid inhibits the metabolism of theophylline by the liver, thereby reducing its clearance and increasing its plasma levels.

With combined therapy, it was suggested that the effects of rifampicin might be more apparent during the initial 7 days, but that by week 4 the effect of isoniazid might predominate, because of its reduced inactivation by rifampicin combined with a reduction in the effect of rifampicin by auto-induction of its own metabolism.[15] High theophylline levels in the isolated case above may have been due to liver impairment brought about by the combined use of rifampicin and isoniazid, or alcoholism.[13]

Importance and management

The interaction between aminophylline or theophylline and **rifampicin** is established. The levels and therapeutic effects of theophylline are likely to be reduced during concurrent use, and this effect can usually be detected within 36 hours.[13] The wide range of increases in clearance that have been reported (25 to 82%) and the large inter-subject variation make it difficult to predict the increase in theophylline dose required, but in some instances a twofold increase may be needed.[8] Monitor theophylline levels if rifampicin is started or stopped and adjust the aminophylline or theophylline dose accordingly.

The effects of **rifabutin** are considerably less than those of rifampicin, with the one available study showing no significant interaction. On the basis of this, no special precautions appear to be necessary, but it may be prudent to monitor the efficacy of aminophylline and theophylline on concurrent use.

The reason for the inconsistent results with **isoniazid** alone is not understood, nor is this interaction well established. It has been suggested that it may take 3 to 4 weeks for any significant increase in theophylline levels to occur.[1] However, if enzyme inhibition was the cause, the effects would be expected more rapidly than this. All of the studies cited covered a period of only 6 to 14 days, whereas the case report describes the effects over a period up to 55 days.[1] It has also been suggested that the dose of isoniazid may be important, with the clearance of theophylline being unaffected by 'usual doses' of isoniazid, but reduced by larger doses.[17] The outcome of concurrent isoniazid and theophylline use is uncertain and may be affected by other antimycobacterials, but it would clearly be prudent to be alert for any evidence of changes in theophylline levels and toxicity if isoniazid is given.

Isoniazid and rifampicin are usually taken as part of a combination chemotherapy regimen in the treatment of tuberculosis. There is some evidence that, in the short-term, combined use of these drugs will decrease theophylline levels, but that theophylline levels may increase during long-term use. However this requires confirmation. Patients taking theophylline with a combined anti-tubercular regimen including isoniazid and rifampicin should have their theophylline levels closely monitored and the dose adjusted according to the response, bearing in mind that these changes may occur over a longer period of time as reported in the case with isoniazid.

Theophylline + Ropinirole

Ropinirole does not appear to affect the pharmacokinetics of theophylline in patients given aminophylline. Theophylline does not affect the pharmacokinetics of ropinirole.

Clinical evidence, mechanism, importance and management

An interaction between ropinirole and theophylline had originally been suspected because both drugs are metabolised by the cytochrome P450 isoenzyme CYP1A2. The UK manufacturer of ropinirole warns of the potential for an interaction and suggests that in patients already receiving ropinirole, the dose of ropinirole may need to be adjusted when theophylline is introduced or withdrawn.[1] However, in one study, 12 patients with parkinsonism were given ropinirole, increased from 0.5 mg to 2 mg three times daily over 28 days, then continued for a further 19 days. The pharmacokinetics of theophylline, given as a single intravenous dose of aminophylline, were assessed before ropinirole was started, and again on day 27. The pharmacokinetics of ropinirole were then assessed before, during and after, the use of oral controlled-release theophylline twice daily for 13 days (dose titrated to achieve plasma levels in the range 8 to 15 mg/L). In both cases it was found that concurrent use did not alter the pharmacokinetics of either drug, and concurrent use was well tolerated.[2] There would therefore appear to be no reason to take special precautions if both drugs are used, and no need to adjust the dose of either drug.

Theophylline + SSRIs

Theophylline levels can be markedly and rapidly increased by fluvoxamine. Some preliminary clinical evidence suggests that fluoxetine and citalopram may not interact. Paroxetine and sertraline are also unlikely to interact.

Clinical evidence

(a) Citalopram

In a study in 13 healthy subjects citalopram 40 mg daily for 21 days (to achieve steady-state) did not affect the pharmacokinetics of a single 300-mg oral dose of theophylline.[1]

(b) Fluoxetine

In 8 healthy subjects the pharmacokinetics of theophylline were unchanged when they were given a 6-mg/kg infusion of aminophylline over 30 minutes, 8 hours after a single 40-mg dose of fluoxetine.[2]

(c) Fluvoxamine

The effect of fluvoxamine on theophylline pharmacokinetics has been characterised in several studies in healthy subjects. In the first study the AUC of theophylline (given as a single 442-mg oral dose of aminophylline) was increased almost threefold, the clearance was reduced by 62% and the half-life was prolonged from 7.4 hours to 32.1 hours by fluvoxamine 50 mg daily for 3 days then 100 mg daily for 13 days.[3] In a second study, the clearance of theophylline (given as a single 300-mg oral dose of aminophylline) was reduced by about 70% and the half-life was increased from 6.6 hours to 22 hours by fluvoxamine 50 to 100 mg daily for 7 days.[4] In a further study in 9 healthy subjects, the half-life of a single 250-mg dose of theophylline given on day 8 of the study, was increased from 7.6 hours to 19.2 hours when the subjects took fluvoxamine 50 mg on day one, and 75 mg daily for the following 8 days. The AUC of theophylline increased by 138%, and the clearance was reduced by 59%.[5] This interaction was shown to be reduced in patients with mild and severe liver cirrhosis (Child class A and C, respectively), whereas the clearance of a single 4-mg/kg dose of theophylline elixir was reduced by 62%, 52%, and 11% in healthy subjects, patients with mild cirrhosis, and patients with severe cirrhosis, respectively. The half-life of theophylline was increased by 13.6 hours in healthy subjects compared with 10.5 hours in patients with mild cirrhosis and one hour in patients with severe cirrhosis, demonstrating the reduced metabolic capabilities of the cirrhotic liver.[6]

A number of case reports have described fluvoxamine-induced theophylline toxicity. Agitation and tachycardia (120 bpm) developed in an 83-year-old man taking theophylline 600 mg daily (*Theostat*) about a week after he started to take fluvoxamine 100 mg daily. His serum theophylline levels were found to have risen from under 15 mg/L to 40 mg/L.[7] A 70-year-old man similarly developed theophylline toxicity, with theophylline levels of about 32 mg/L (reference range 10 to 20 mg/L), when fluvoxamine was added. Subsequently the theophylline concentrations were found to parallel a number of changes in the fluvoxamine dose.[8] The clearance of theophylline in an 84-year-old man was approximately halved while he was taking fluvoxamine.[9] An 11-year-old boy complained of headaches, tiredness and vomiting within a week of starting to take fluvoxamine. His serum theophylline levels were found to have doubled, from 14.2 mg/L to 27.4 mg/L.[10] A 78-year-old woman became nauseous within 2 days of starting to take fluvoxamine 50 mg daily, and by day 6, when the fluvoxamine was stopped, her serum theophylline levels were found to have increased about threefold. She had a seizure, became comatose, and developed supraventricular tachycardia (200 bpm) requiring intravenous digoxin and verapamil. She recovered uneventfully.[11] A patient taking fluvoxamine 100 mg daily developed nausea, vomiting, confusion, reduced sleep and a poor appetite 5 days after she began to take theophylline 300 mg twice daily for COPD. Her theophylline level was found to be 25.9 mg/L.[12]

Mechanism

Fluvoxamine is a known, potent inhibitor of the cytochrome P450 isoenzyme CYP1A2 in the liver, by which theophylline is metabolised. Concurrent use therefore results in raised theophylline levels and toxicity. This metabolic function, and hence interaction, appears to be severely reduced in patients with severe cirrhosis, probably due to reduced hepatic expression of CYP1A2 and reduced uptake of fluvoxamine.[6] The other SSRIs, citalopram, fluoxetine, **paroxetine** and **sertraline** only weakly inhibited CYP1A2 *in vitro*, and consequently would not be expected to interact.[13,14]

Importance and management

The interaction between fluvoxamine and aminophylline or theophylline is established and clinically important. The CSM in the UK advise that concurrent use should usually be avoided, but that if this is not possible, reduce the theophylline dose by half when fluvoxamine is added and monitor theophylline levels.[15] There is evidence to suggest that the extent of this interaction is markedly reduced in patients with liver cirrhosis, particularly severe Child class C, despite higher levels of fluvoxamine,[6] although caution should still be applied with concurrent use in this patient group as they are more likely to have high levels of theophylline due to reduced metabolism. There is good evidence to suggest that fluvoxamine is the only SSRI likely to interact (because it is the only one that significantly affects CYP1A2). This would seem to be borne out by the studies with citalopram and fluoxetine, and the lack of case reports in the literature describing problems with any of the other SSRIs.

Theophylline + St John's wort (*Hypericum perforatum*)

A patient needed a marked increase in the dose of theophylline while taking St John's wort. In contrast, no pharmacokinetic interaction was found in a two-week study in healthy subjects.

Clinical evidence

A study in 12 healthy subjects found that a standardised preparation of St John's wort 300 mg (hypericin 0.27%) three times daily for 15 days had no significant effects on the plasma level of a single 400-mg oral dose of theophylline.[1]

However, an isolated case describes a woman, previously stable for several months taking theophylline 300 mg twice daily, who was found to need a markedly increased theophylline dose of 800 mg twice daily to achieve serum levels of 9.2 mg/L. Two months previously she had started to take 300 mg of a St John's wort supplement (hypericin 0.3%) each day. When she stopped taking the St John's wort, her serum theophylline levels doubled within a week to 19.6 mg/L and her theophylline dose was consequently reduced. This patient was also taking a whole spectrum of other drugs (amitriptyline, furosemide, ibuprofen, inhaled triamcinolone, morphine, potassium, prednisone, salbutamol (albuterol), valproic acid, zafirlukast and zolpidem) and was also a smoker. No changes in the use of these drugs or altered compliance were identified that might have offered an alternative explanation for the changed theophylline requirements.[2]

Mechanism

Uncertain. *In vitro* data suggest that one component of St John's wort (hypericin) can act as an inducer of the cytochrome P450 isoenzyme CYP1A2.[2] It has also been suggested that treatment with St John's wort for 15 days was unlikely to induce the isoenzymes sufficiently to cause changes in plasma theophylline.[1] The patient in the case report had been taking St John's wort for 2 months, although at a lower dose, therefore differences in duration of treatment may account for the discrepancy. This is supported by studies in which the use of St John's wort for 4 weeks,[3] but

not 2 weeks,[4] modestly increased the paraxanthine/caffeine ratio, used as a measure of CYP1A2 activity.

Importance and management

Direct information about this apparent interaction between theophylline and St John's wort appears to be limited. Despite the isolated case report of a marked decrease in theophylline levels, no pharmacokinetic interaction was noted in healthy subjects, and any pharmacokinetic interaction appears likely to be minor. Mechanistic studies suggest a modest interaction at most. Furthermore most clinically significant interactions with St John's wort are mediated by the cytochrome P450 isoenzyme CYP3A4. However, until further evidence is available, it would be prudent to be aware of the possibility of an interaction. Patients should be warned of the possible effects of concurrent use. In 2000, the CSM in the UK recommended that patients taking theophylline should not take St John's wort. In those patients already taking the combination, the St John's wort should be stopped and the theophylline dose monitored and adjusted if necessary.[5,6] However, this guidance was issued before the pharmacokinetic study that suggests that an interaction is generally unlikely.

Theophylline + Succimer

A single case report describes a reduction in the theophylline levels of a man given succimer.

Clinical evidence, mechanism, importance and management

A 65-year-old man with COPD and chronic lead intoxication was given a 19-day course of lead chelation with succimer. His theophylline level was found to be reduced from about 11 mg/L to 7 mg/L on day 6 and remained at this level until about 9 days after the course of succimer was completed, when it returned to pretreatment levels. His clinical status did not alter despite these changes; possibly because he was also taking prednisone.[1] The reason for these alterations is not understood, although as succimer is known to chelate heavy metals, it seems possible that theophylline may have been chelated, resulting in a reduction in its levels.

The general importance of this interaction is not known, but given that succimer is known to chelate some substances it would seem prudent to monitor the situation closely if succimer is added to established treatment with theophylline or aminophylline.

Theophylline + Sucralfate

Two studies found that sucralfate caused only minor changes in theophylline pharmacokinetics, but another suggests that the absorption of sustained-release theophylline is significantly reduced by sucralfate.

Clinical evidence, mechanism, importance and management

In 8 healthy subjects no clinically important changes occurred in the absorption of a single 5-mg/kg dose of an oral non-sustained release theophylline preparation given at the same time as sucralfate 1 g four times daily. A slight 5% decrease in the AUC was detected.[1] Another study found that sucralfate 1 g four times daily reduced the AUC of a single dose of a sustained-release theophylline preparation (*Theodur*) by 9% (timing of the theophylline dose in relation to the sucralfate dose not noted).[2] In contrast, another group of workers found that when sucralfate 1 g was given 30 minutes before a 350 mg dose of sustained-release theophylline (*PEG capsules*), the theophylline AUC was reduced by 40%.[3] Many patients are given sustained-release theophylline preparations, but neither of these studies clearly shows what is likely to happen in clinical practice, so be alert for any evidence of a reduced response to theophylline. Usually, separating the administration of sucralfate from other drugs by 2 hours is considered sufficient to avoid interactions that occur by reduced absorption.[4] However, the study showing decreased theophylline absorption did not examine the effect of separating the doses. Further study is needed, both to establish the effects of sucralfate on theophylline, and to establish if an interaction occurs with aminophylline preparations.

Theophylline + Sulfinpyrazone

Sulfinpyrazone can cause a small increase in theophylline clearance.

Clinical evidence, mechanism, importance and management

In 6 healthy subjects the total clearance of theophylline 125 mg every 8 hours for 4 days was increased by 22% (range 9 to 42%) when they were given sulfinpyrazone 200 mg every 6 hours.[1] This appeared to be the sum of an increase in the metabolism of theophylline by the liver and a decrease in its renal clearance.

Information seems to be limited to this study. The resulting fall in serum theophylline levels is unlikely to be clinically relevant. Aminophylline, which is metabolised to theophylline, would be expected to behave similarly.

Theophylline + Tadalafil

Tadalafil does not alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

A placebo-controlled, randomised, crossover study in 17 healthy subjects given enough oral theophylline (a non-selective phosphodiesterase inhibitor) to achieve steady-state levels of about 12 mg/L found that the concurrent use of the phosphodiesterase type-5 inhibitor tadalafil 10 mg daily for 7 days did not affect the pharmacokinetics of either drug. There was a small increase of 3.5 bpm in the heart rate, which was not considered to be clinically relevant in the healthy subjects.[1] However, the UK manufacturer advises that this should be considered when both drugs are used concurrently.[2] However, most conditions where a 3.5 bpm increase in heart rate may possibly of clinical relevance (e.g. uncontrolled arrhythmias) are contraindications to the use of tadalafil. Note that aminophylline, which is metabolised to theophylline, would be expected to behave similarly.

Theophylline + Tamsulosin

No clinically relevant pharmacokinetic interaction occurs between theophylline and tamsulosin.

Clinical evidence, mechanism, importance and management

In a double-blind study, 10 healthy subjects were given tamsulosin 400 micrograms daily for 2 days then 800 micrograms on the following 5 days, with a single 5-mg/kg dose of intravenous theophylline one hour after the last dose of tamsulosin. The pharmacokinetics of theophylline

and tamsulosin were not affected by concurrent use. Theophylline is mainly metabolised by the cytochrome P450 isoenzyme CYP1A2, while tamsulosin is metabolised by CYP3A4 and CYP2D6, and therefore a pharmacokinetic interaction would not be expected.[1] The safety of concurrent use was considered acceptable and dose adjustments were not considered necessary.[1]

1. Miyazawa Y, Starkey LP, Forrest A, Schentag JJ, Kamimura H, Swarz H, Ito Y. Effects of the concomitant administration of tamsulosin (0.8 mg/day) on the pharmacokinetics and safety profile of theophylline (5 mg/kg): a placebo-controlled evaluation. *J Int Med Res* (2002) 30, 34–43.

Theophylline + Tegaserod

Tegaserod does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects, the pharmacokinetics of a single 600-mg dose of controlled-release theophylline were unchanged when it was given with three doses of tegaserod 6 mg (the first was given about 24 hours before the theophylline, the second simultaneously, and the third 12 hours later).[1] No theophylline dose adjustments would therefore appear necessary on concurrent use.

1. Zhou H, Khalilieh S, Svendsen K, Pommier F, Osborne S, Appel-Dingemanse S, Lasseter K, McLeod JF. Tegaserod coadministration does not alter the pharmacokinetics of theophylline in healthy subjects. *J Clin Pharmacol* (2001) 41, 987–93.

Theophylline + Teicoplanin

Clinical studies in 20 patients with COPD found that teicoplanin 200 mg twice daily and aminophylline 240 mg twice daily (both given as intravenous infusions) had no significant effect on the steady-state pharmacokinetics of either teicoplanin or theophylline (derived from aminophylline).[1] No special precautions would seem necessary during concurrent use.

Theophylline + Terbinafine

Preliminary evidence indicates that terbinafine can increase the levels of theophylline to some extent.

Clinical evidence, mechanism, importance and management

In a randomised, crossover study, 12 healthy subjects were given a single 5-mg/kg oral dose of aminophylline before and after taking terbinafine 250 mg daily for 3 days. The AUC and half-life of theophylline were increased by 16% and 23%, respectively, and the theophylline clearance was reduced by 14%. It was suggested[1] that this is due to the inhibitory effect of terbinafine on the activity of the cytochrome P450 isoenzyme CYP1A2, which is the main isoenzyme involved in the metabolism of theophylline. The changes seen were only relatively small, but the study periods only lasted 3 days so that the effects of longer concurrent use are uncertain, but a clinically significant interaction seems unlikely.

1. Trépanier EF, Nafziger AN, Amsden GW. Effect of terbinafine on theophylline pharmacokinetics in healthy volunteers. *Antimicrob Agents Chemother* (1998) 42, 695–7.

Theophylline + Tetracyclines

Serum theophylline levels increased in two patients who were also given minocycline or tetracycline. Some controlled studies have shown both increases and decreases in theophylline clearance with doxycycline and tetracycline, with no significant changes overall.

Clinical evidence

(a) Doxycycline

A study in 10 asthmatic subjects given doxycycline 100 mg twice daily on day one and then 100 mg daily for 4 days found that the mean serum theophylline level was not significantly altered. However, there was large inter-individual variation, with 4 subjects having rises of more than 20% (range 24 to 31%) and 2 having decreases of 22% and 33%.[1] Fluctuations of this size are not unusual with theophylline. Another study in 8 healthy subjects given doxycycline 100 mg daily for 7 days with theophylline 350 mg twice daily did not find any significant changes in theophylline pharmacokinetics.[2]

(b) Minocycline

The serum theophylline levels of a 70-year-old woman with normal liver function increased from 9.8 mg/L to 15.5 mg/L after she was given minocycline 100 mg twice daily by infusion for 6 days. Her serum theophylline level was 10.9 mg/L fourteen days after the minocycline was stopped.[3]

(c) Tetracycline

After taking tetracycline hydrochloride 250 mg four times daily for 8 days a patient with COPD had signs of theophylline toxicity. After 10 days of tetracycline her serum theophylline levels had risen from about 13 mg/L to 30.8 mg/L. Both drugs were stopped, and after 24 hours her theophylline level was 12.4 mg/L. A later rechallenge in this patient confirmed that the tetracycline was responsible for the raised theophylline levels.[4]

In an earlier study in 8 healthy subjects, tetracycline 250 mg four times daily for 7 days did not affect the mean pharmacokinetics of theophylline (given as a single intravenous dose of aminophylline), although there was large inter-individual variation. Four subjects had a decrease in clearance of over 15%, (32% in one subject), and conversely, one subject had a 21% increase in clearance.[5] Other studies in subjects and patients given tetracycline for shorter periods have not found evidence of an important interaction. A study in 9 healthy adults given single 5-mg/kg intravenous doses of aminophylline found that tetracycline 250 mg every 6 hours for 48 hours had no significant effect on theophylline pharmacokinetics.[6] Five non-smoking patients with COPD or asthma had an average 14% rise in serum theophylline levels and an 11% decrease its clearance after 5 days of treatment with tetracycline 250 mg four times daily. However, when a sixth patient was included (a smoker) the results were no longer statistically significant.[7]

Mechanism

Not understood. Inhibition of theophylline metabolism and clearance by the tetracyclines has been suggested.[4]

Importance and management

Information seems to be limited. There are two isolated cases of increased theophylline levels with minocycline and tetracycline, but controlled studies have not found any significant changes in overall theophylline pharmacokinetics. It has been suggested that a clinically important interaction may possibly only occur in a few patients.[1,4] Further study is needed. There seems to be no evidence of adverse interactions with any of the other tetracyclines. However, note that acute infections *per se* can alter theophylline pharmacokinetics.[8]

Theophylline + Thyroid and Antithyroid compounds

Thyroid dysfunction may modestly affect theophylline requirements. There are two isolated cases of theophylline toxicity in patients being treated for hypothyroidism.

Clinical evidence

The theophylline elimination rate constant after a single intravenous dose of aminophylline was found to be greater in hyperthyroid patients (0.155 h^{-1}) than in euthyroid (0.107 h^{-1}) or hypothyroid patients (0.060 h^{-1}); some other pharmacokinetic parameters were also changed.[1] The authors concluded that thyroid dysfunction may modestly alter theophylline requirements. It is therefore also likely that drug-induced changes in the thyroid status, such as those caused by amiodarone, may also alter the amount of theophylline needed to maintain therapeutic levels.

(a) Antithyroid compounds

The serum theophylline level of an asthmatic patient was found to have doubled, from 15.2 mg/L to 30.9 mg/L, accompanied by toxicity, 3 months after treatment for hyperthyroidism with **radioactive iodine** (^{131}I). At this point the patient was hypothyroid, and after treatment with levothyroxine was started, his serum theophylline returned to approximately the same level as before radioactive iodine treatment (13.9 mg/L).[2] Another patient with Graves' disease treated with a combination of **thiamazole** (**methimazole**) 10 mg three times daily and Lugol's solution (**iodine** and **potassium iodide**) and taking theophylline 500 mg twice daily (*TheoDur*), had a theophylline level of 4.7 mg/L before radioactive iodine therapy. His level increased to 13.6 mg/L seven months after thyroid ablation.[3] Five hyperthyroid patients had a 20% reduction in theophylline clearance and an increase in their theophylline half-life, from 4.6 hours to 5.9 hours, when they were given **carbimazole** 45 mg and propranolol 60 mg daily. In this study, a single intravenous dose of aminophylline was given before the treatment of thyrotoxicosis and after the euthyroid state had been achieved.[4] Note that propranolol can reduce the clearance of theophylline but should be avoided in patients with respiratory disease, see 'Theophylline + Beta blockers', p.1433, for more information.

(b) Thyroid hormones

One week after starting to take theophylline 1 g daily, a patient who was hypothyroid (serum thyroxine 1.4 micrograms/dL, reference range 4 to 11 micrograms/dL) developed severe theophylline toxicity, with serum theophylline levels of 34.7 mg/L, manifested by ventricular fibrillation (from which he was successfully resuscitated) and repeated seizures over 24 hours. After 2 months of treatment with **thyroid hormones**, which increased his serum thyroxine levels to 4.3 micrograms/dL, his serum theophylline level was 13.2 mg/L, 10 days after reinstitution of the same dose of theophylline.[5]

Mechanism

Thyroid status may affect the rate at which theophylline is metabolised. In hyperthyroidism it is increased, whereas in hypothyroidism it is decreased.

Importance and management

It is established that changes in thyroid status may affect how the body handles theophylline (including that derived from aminophylline). Monitor the effects and anticipate the possible need to begin to reduce the theophylline dose if treatment for hyperthyroidism is started (e.g. with radioactive iodine, carbimazole, **thiamazole**, **propylthiouracil**, etc.). Similarly, anticipate the possible need to increase the theophylline dose if treatment is started for hypothyroidism (e.g. with levothyroxine). Stabilisation of the thyroid status may take weeks or even months to achieve so that if monitoring of the theophylline dose is considered necessary, it will need to extend over the whole of this period. This monitoring would also apply to drug-induced thyroid dysfunction.

Theophylline + Tobacco

Tobacco smokers, and non-smokers heavily exposed to tobacco smoke, may need more theophylline than non-smokers to achieve the same therapeutic benefits, because the theophylline is cleared from the body more quickly. This may also occur in those who chew tobacco or take snuff but not if they chew nicotine gum.

Clinical evidence

A study found that the mean half-life of theophylline (given as a single oral dose of aminophylline) was 4.3 hours in a group of tobacco smokers (20 to 40 cigarettes a day) compared with 7 hours in a group of non-smokers, and that theophylline clearance was higher (mean increase 126%) and more variable in the smokers.[1] Almost identical results were found in an earlier study,[2] and a number of later studies in subjects given oral or intravenous theophylline or aminophylline confirm these findings.[3-8] The ability of smoking to increase theophylline clearance occurs irrespective of gender,[3,6] and in the presence of congestive heart failure or liver impairment.[7] The effects of ageing on the induction of theophylline metabolism by tobacco smoking is less clear. One study has found that in both young subjects (less than 30-years-old) and elderly subjects (more than 67 years old) smoking decreased the half-life and increased the clearance of theophylline, when compared with non-smokers. The effect was greater in the young subjects.[4] However, another study found no difference in the pharmacokinetics of theophylline between asthmatic and otherwise healthy smokers and non-smokers aged over 65 years.[9] A similar high clearance of theophylline (given as intravenous aminophylline) has been seen in a patient who chewed tobacco (1.11 mL/kg per minute compared with the more usual 0.59 mL/kg per minute).[10] The half-life of theophylline (given as intravenous aminophylline) in passive smokers (non-smokers regularly exposed to tobacco smoke in the air they breathe, for 4 hours a day in this study) is reported to be shorter than in non-smokers (6.93 hours compared with 8.69 hours).[11] The clearance of theophylline (given as intravenous aminophylline) in asthmatic children exposed to passive tobacco smoke was also found to be greater (1.36 mL/kg per minute compared with 0.09 mL/kg per minute) and their steady-state serum theophylline levels were lower than in similar children not exposed to passive smoking.[12]

In one study, 3 of 4 patients who stopped smoking for 3 months (confirmed by serum thiocyanate levels) had a longer theophylline half-life, but only 2 had a slight decrease in theophylline clearance.[1] In another study, ex-smokers who had stopped heavy smoking 2 years previously had values for theophylline clearance and half-life that were intermediate between non-smokers and current heavy smokers.[3] In another study, 7 hospitalised smokers who abstained from smoking for 7 days had a 36% increase in theophylline half-life and a 38% decrease in clearance (although clearance after abstinence was still higher than values usually found in non-smokers).[13]

Mechanism

Tobacco smoke contains polycyclic hydrocarbons, which act as inducers of the cytochrome P450 isoenzyme CYP1A2, and this results in a more rapid clearance of theophylline from the body. Both the *N*-demethylation and 8-hydroxylation of theophylline (both of which are mediated by the cytochrome P450 isoenzyme CYP1A2) are induced.[14] Ageing appears to offset the effects of smoking on theophylline metabolism.[9]

Importance and management

An established interaction of clinical importance. Heavy smokers (20 to 40 cigarettes daily) may need a much greater aminophylline or theophylline dose than non-smokers,[1] and increased doses are likely for those who chew tobacco or take snuff,[10] but not for those who chew nicotine gum.[13,15] In patients who stop smoking, a reduction in the theophylline dose of up to 25 to 33% may be needed after one week,[13] but full normalisation of hepatic function appears to take many months or even years.[1,3] Investigators of the possible interactions of aminophylline and theophylline with other drugs should take smoking habits into account when selecting their subjects.[6,11,12] Note that the effects of cannabis (see

'Theophylline + Cannabis', p.1435, may be additive with those of tobacco smoking.

Theophylline + Trimetazidine

Trimetazidine does not appear to alter the pharmacokinetics of theophylline.

Clinical evidence, mechanism, importance and management

In a study in 13 healthy subjects trimetazidine 20 mg twice daily for at least 14 days did not alter the pharmacokinetics of a single 375-mg dose of theophylline.[1] These results suggest that treatment with theophylline (and therefore probably aminophylline, which is metabolised to theophylline) is unlikely to be altered in patients concurrently treated with trimetazidine, but this needs confirmation in multiple-dose studies.

1. Edeki TI, Johnston A, Campbell DB, Ings RMJ, Brownsill R, Genissel P, Turner P. An examination of the possible pharmacokinetic interaction of trimetazidine with theophylline, digoxin and antipyrine. *Br J Clin Pharmacol* (1989) 26, 657P.

Theophylline + Vidarabine

A single case report describes a woman who had a rise in serum theophylline levels when she took aminophylline oral liquid with vidarabine.

Clinical evidence, mechanism, importance and management

A woman taking aminophylline oral liquid developed elevated serum theophylline levels (an increase from 14 mg/L to 24 mg/L) four days after starting to take vidarabine 400 mg daily for herpes zoster.[1] She was also being treated with ampicillin, gentamicin, clindamycin and digoxin, for congestive heart failure, chronic pulmonary disease and suspected sepsis. It was suggested that the vidarabine inhibited the metabolism of the theophylline resulting in the raised levels seen. The general significance of this case is uncertain, but it would now seem prudent to bear this interaction in mind if vidarabine is given with aminophylline or theophylline.

1. Gannon R, Sullman S, Levy RM, Grober J. Possible interaction between vidarabine and theophylline. *Ann Intern Med* (1984) 101, 148–9.

Theophylline + Viloxazine

Viloxazine increases theophylline levels and toxicity may occur.

Clinical evidence

A study in 8 healthy subjects given a single 200-mg dose of theophylline suggested that pretreatment with viloxazine 100 mg three times daily for 3 days increased the $AUC_{0\text{-}24}$ of theophylline by 47%, increased its maximum serum concentration, and reduced its clearance.[1]

An elderly woman hospitalised for respiratory failure and treated with a variety of drugs including theophylline, developed acute theophylline toxicity (a grand mal seizure) 2 days after starting to take viloxazine 200 mg daily. Her serum theophylline levels had increased threefold (from about 10 to 28 mg/L), but the levels fell when the viloxazine was withdrawn.[2] Nausea and vomiting, associated with raised serum theophylline levels, occurred in another patient also taking viloxazine. Theophylline was stopped, and then reintroduced at one-quarter of the original dose. The theophylline level subsequently became subtherapeutic when viloxazine was stopped.[3] A further case report describes an elderly man who had a marked rise in his serum theophylline levels to toxic concentrations (55.3 mg/L) when viloxazine, 100 mg then 300 mg daily, was started.[4]

Mechanism

It is suggested that viloxazine competitively antagonises the metabolism of theophylline by the liver, thereby reducing its clearance and resulting in an increase in its serum levels.

Importance and management

Information seems to be limited to these reports but it would appear to be a clinically important interaction. Theophylline levels should be well monitored if viloxazine is added, anticipating the need to reduce the dose. There appears to be no direct evidence about aminophylline, but it would be prudent to expect it to interact similarly.

Theophylline + Zileuton

Zileuton raises theophylline levels and increases the incidence of adverse effects.

Clinical evidence

In a double-blind, crossover study, 13 healthy subjects were given 200 mg of theophylline (*Slo-Phyllin*) four times daily for 5 days and either zileuton 800 mg twice daily or a placebo. Zileuton increased the mean steady-state peak serum levels of theophylline by 73% (from 12 to 21 mg/L), increased its AUC by 92%, and halved its apparent plasma clearance. During the use of zileuton the incidence of adverse effects increased (headache, gastrointestinal effects), which was attributed to theophylline toxicity, and this caused 3 of the original 16 subjects to withdraw from the study.[1]

Mechanism

Not fully established but it seems highly likely that zileuton inhibits the metabolism of theophylline by the cytochrome P450 enzymes (probably the isoenzyme CYP1A2 and the subfamily CYP3A) so that its serum levels rise.

Importance and management

Information is limited but the interaction appears to be established and of clinical importance. Concurrent use need not be avoided but be alert for adverse effects (headache, gastrointestinal effects), and if required, monitor theophylline levels and reduce the dose of theophylline as necessary. The report quoted above suggests that a typical asthma patient may initially need the theophylline dose to be halved, and this dose reduction is recommended by the US manufacturers.[2] Similarly, the dose of theophylline should be reduced if it is given to a patient already taking zileuton, and adjusted according to theophylline levels.[2] This is based on the results of a study in over 1000 patients taking zileuton 600 mg four times daily without apparent problems when this course of action was followed.[1] There seems to be no evidence regarding aminophylline, but it would be expect-

ed to behave similarly, and therefore the same precautions would seem advisable.

Zafirlukast + Aspirin

Aspirin 650 mg four times daily is reported to have resulted in a mean increase in the plasma levels of zafirlukast 40 mg daily of 45%. No further details are available.[1,2] The clinical importance of this interaction awaits assessment but it seems likely to be small. The manufacturers do not suggest any alteration in the zafirlukast dose.[3]

3. Zeneca Pharmaceuticals, Personal communication, July 1997.

Zafirlukast + Macrolides

Zafirlukast levels are decreased by erythromycin. Zafirlukast does not affect the pharmacokinetics of azithromycin or clarithromycin.

Clinical evidence, mechanism, importance and management

Zafirlukast is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 *in vitro*. However, a study in 12 healthy subjects found that zafirlukast 20 mg twice daily for 12 days did not significantly affect the pharmacokinetics of a single 500-mg dose of **azithromycin** or **clarithromycin**.[1]

A study in 11 patients with asthma found that **erythromycin** 500 mg three times daily for 5 days reduced the mean plasma level of zafirlukast 40 mg by about 40%.[2,3] This reduction in levels would be expected to reduce its antiasthmatic effects. If these drugs are given concurrently, be alert for a reduced response. However, note that the manufacturers do not suggest that an alteration in the zafirlukast dose is necessary.[4] Other macrolides that inhibit CYP3A4 (e.g. **clarithromycin**, **telithromycin**) would be expected to interact similarly, and therefore some caution is probably warranted if they are given to patients taking zafirlukast.

3. Accolate (Zafirlukast). AstraZeneca UK Ltd. UK Summary of product characteristics, May 2008.
4. Zeneca Pharmaceuticals, Personal communication, July 1997.

Zafirlukast + Miscellaneous

Zafirlukast plasma levels are decreased by terfenadine. Zafirlukast does not increase the levels of terfenadine, and concurrent use does not prolong the QTc interval. Zafirlukast is predicted to increase the levels of a number of CYP3A4 substrates.

Clinical evidence, mechanism, importance and management

A study in 16 healthy men given zafirlukast 160 mg twice daily for 16 days with terfenadine 60 mg twice daily on days 8 to 16 found that the mean maximum serum levels and AUC of zafirlukast were reduced by 70% and 60%, respectively. There was a small, non-significant reduction in the terfenadine AUC and serum levels.[1] The reduction in zafirlukast serum levels would be expected to reduce its antiasthmatic effects, but this needs assessment. If both drugs are given be alert for a reduced response to zafirlukast.

A study in 8 healthy subjects given zafirlukast 160 mg twice daily with terfenadine 60 mg twice daily for 8 days found that the AUC of terfenadine and the QTc interval were not significantly increased on concurrent use, despite the fact that *in vitro* zafirlukast appears to inhibit the cytochrome P450 isoenzyme CYP3A4, the major enzyme involved in terfenadine metabolism.[2] Because of the apparent *in vitro* effect of zafirlukast on CYP3A4 the manufacturer of zafirlukast advises appropriate clinical monitoring when substrates of CYP3A4 are given with zafirlukast. They name **ciclosporin**, **cisapride**, and **dihydropyridine calcium-channel blockers**.[3] However, in light of the lack of effect of zafirlukast on terfenadine, it would appear that any effect of zafirlukast on CYP3A4 is not clinically relevant.

3. Accolate (Zafirlukast). AstraZeneca Pharmaceuticals LP. US Prescribing information, August 2009.

Zafirlukast + Tobacco

The manufacturer notes that the clearance of zafirlukast may be increased by 20% in patients who smoke.[1] This probably occurs because tobacco smoke can induce liver enzymes, which may increase the metabolism of zafirlukast. The clinical significance of this interaction is unclear, but it seems likely to be small.

35

SSRIs, Tricyclics and related antidepressants

The development of the tricyclic antidepressants arose out of work carried out on phenothiazine compounds related to chlorpromazine. The earlier molecules possessed two benzene rings joined by a third ring of carbon atoms, with sometimes a nitrogen, and had antidepressant activity, hence their name. Some of the later antidepressants have one, two or even four rings. 'Table 35.1', (below), lists the common tricyclic and tetracyclic antidepressants, the selective serotonin reuptake inhibitors (SSRIs), the serotonin and noradrenaline reuptake inhibitors (SNRIs) and a number of other drugs that are also used for depression. For interactions involving MAOIs (monoamine oxidase inhibitors), see 'MAOIs', (p.1370).

Table 35.1 SSRIs, Tricyclics and related antidepressants

Group	*Drugs*
SNRIs (Serotonin and noradrenaline reuptake inhibitors)	Duloxetine, Milnacipran, Venlafaxine
SSRIs (Selective serotonin reuptake inhibitors)	Citalopram, Escitalopram, Fluoxetine, Fluvoxamine, Paroxetine, Sertraline
Tetracyclic antidepressants	Maprotiline, Mianserin
Tricyclic antidepressants	Amineptine, Amitriptyline, Amoxapine, Butriptyline, Clomipramine, Desipramine, Dibenzepin, Dosulepin, Doxepin, Imipramine, Lofepramine, Melitracen, Nortriptyline, Opipramol, Protriptyline, Trimipramine
Other antidepressants	Iprindole, Mirtazapine, Nefazodone, Reboxetine, Trazodone, Viloxazine

SNRIs

Antidepressants in this group include duloxetine, milnacipran and venlafaxine. They inhibit both serotonin and noradrenaline reuptake but with differing selectivity. Milnacipran blocks serotonin and noradrenaline reuptake approximately equally, but duloxetine and to a greater extent venlafaxine have selectivity for serotonin and so might be expected to share the pharmacodynamic interactions of the SSRIs, see below. Duloxetine and venlafaxine are reported to weakly inhibit dopamine reuptake. They are also reported to have no significant affinity for histaminergic, muscarinic or adrenergic receptors, and, compared with the tricyclics, appear to lack significant sedative and antimuscarinic effects.

Duloxetine is a moderate inhibitor of CYP2D6 and is a substrate for CYP1A2 and so may interact with drugs that affect these isoenzymes. Similarly, venlafaxine may interact with CYP2D6 inhibitors and to a more minor extent with CYP3A4 inhibitors. Milnacipran, however, does not appear to interact with cytochrome P450 isoenzymes.

SSRIs

These antidepressants act on neurones in a similar way to the tricyclics (see below) but they selectively inhibit the reuptake of serotonin (5-hydroxytryptamine or 5-HT). This can lead to adverse effects such as serotonin syndrome, see 'Additive or synergistic interactions', (p.9). The SSRIs have fewer antimuscarinic effects than the tricyclics and are also less sedative and cardiotoxic. However, they have been associated with bleeding disorders and so caution is advised if they are given with drugs know to affect platelet function.

SSRIs interact with other drugs mainly as a result of their inhibitory activity on cytochrome P450 isoenzymes in the liver; fluoxetine and paroxetine are potent inhibitors of CYP2D6, and fluvoxamine inhibits CYP1A2 and CYP2C19, but citalopram and sertraline are less likely to have any clinical effect, see 'Table 35.2', (p.1465). Note that some SSRIs e.g. fluoxetine have a very long half-life and so interactions may still occur after the drug has been discontinued.

Tricyclic and related antidepressants

The tricyclic antidepressants inhibit the activity of the 'uptake' mechanism by which some chemical transmitters (serotonin (5-HT) or noradrenaline (norepinephrine)) re-enter nerve endings in the CNS. In this way they raise the concentrations of the chemical transmitter in the receptor area. If depression represents some inadequacy in transmission between the nerves in the brain, increasing the amount of transmitter may go some way towards reversing this by improving transmission. Tricyclics vary in the extent that they block the reuptake of these transmitters e.g. clomipramine is more selective for serotonergic transmission and imipramine is more selective for noradrenergic transmission. However, the use of all tricyclics should generally be avoided with MAOIs because of the risk of the serotonin syndrome, see 'MAOIs or RIMAs + Tricyclic and related antidepressants', p.1391.

The tricyclics also have varying degrees of antimuscarinic (sometimes referred to as anticholinergic or atropine-like) activity and can cause dry mouth, blurred vision, constipation, urinary retention and an increase in ocular pressure. They may also cause postural hypotension, sedation, and seizures in certain individuals.

Mianserin and maprotiline are tetracyclic antidepressants, which have actions similar to those of the tricyclic antidepressants. However, while the tetracyclics are more sedating, their antimuscarinic effects are less marked. Maprotiline inhibits the reuptake of noradrenaline (norepinephrine) and has weak affinity for central adrenergic (α_1) receptors. Mianserin does not prevent the peripheral reuptake of noradrenaline; it blocks presynaptic adrenergic (α_2) receptors and increases the turnover of brain noradrenaline. It is also an antagonist of serotonin receptors in some parts of the brain.

All tricyclic antidepressants, mianserin and maprotiline are metabolised by CYP2D6 to some extent and so may be affected by inhibitors of this isoenzyme. See 'Table 35.2', (p.1465), for more detail on the metabolism of individual tricyclics.

Other antidepressant drugs

(a) Mirtazapine

Mirtazapine is a piperazinoazepine and an analogue of mianserin. It is a presynaptic adrenergic α_2-antagonist that increases central noradrenergic and serotonergic transmission. It is a potent inhibitor of histamine (H_1) receptors and this accounts for its sedative properties. It has little antimuscarinic activity.

(b) Nefazodone and Trazodone

Nefazodone is a phenylpiperazine structurally related to trazodone. Both nefazodone and trazodone block the reuptake of serotonin at presynaptic neurones and block α_1-adrenoceptors, but have no apparent effect on dopamine. Unlike trazodone, nefazodone blocks the reuptake of noradrenaline. Compared to the tricyclics, neither drug has very significant

antimuscarinic effects, but trazodone also has marked sedative properties.

Trazodone is a substrate for CYP3A4 and its plasma levels may be affected by inhibitors or inducers of this isoenzyme. Nefazodone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and therefore it will inhibit the metabolism of drugs by this route. For a list of CYP3A4 substrates see 'Table 1.4', (p.6). Note that, nefazodone has largely been withdrawn due to adverse hepatic effects.

(c) Reboxetine

Reboxetine is a potent inhibitor of noradrenaline reuptake. It has a weak effect on serotonin reuptake and no significant affinity for muscarinic receptors.

Reboxetine is a substrate for CYP3A4 and its plasma levels may be increased by inhibitors of this isoenzyme.

Table 35.2 Summary of the main effects of antidepressant drugs on cytochrome P450 isoenzymes

Antidepressant drug		*Isoenzyme*		
		Substrate (major pathway)	*Substrate (plays some part)*	*Inhibits*
Bupropion		CYP2B6		CYP2D6 (potent)
Mirtazapine			CYP1A2, CYP2D6, CYP3A4	
Nefazodone				CYP3A4 (potent)
Reboxetine		CYP3A4		
Trazodone		CYP3A4		
SNRIs	**Duloxetine**	CYP1A2	CYP2D6	CYP2D6 (moderate)
	Milnacipran	None		
	Venlafaxine	CYP2D6	CYP3A4	
SSRIs	**Citalopram**		CYP2D6, CYP2C19, CYP3A4 (minor)	CYP2D6 (weak)
	Fluoxetine		CYP2D6	CYP2D6 (moderate), CYP2C9, CYP3A4 (weak)
	Fluvoxamine	CYP2D6	Other metabolic pathways appear to be involved, but no clinical data available	CYP1A2 (potent), CYP2C9, CYP2C19, CYP3A4
	Paroxetine		CYP2D6	CYP2D6 (moderate)
	Sertraline		CYP3A4, CYP2D6 (minor) and possibly other pathways	CYP2D6 (weak)
Tetracyclics	**Maprotiline**		CYP2D6	
	Mianserin		CYP2D6	
Tricyclics	**Amitriptyline**	CYP1A2, CYP2D6	CYP3A4, CYP2C19	
	Clomipramine	CYP2D6	CYP3A4, CYP1A2, CYP2C19	
	Desipramine	CYP2D6		
	Dosulepin		CYP2D6 and possibly other pathways	
	Doxepin	CYP2D6	CYP1A2 (minor), CYP3A4 (minor)	
	Imipramine	CYP1A2, CYP2D6	CYP3A4, CYP2C19	
	Nortriptyline	CYP2D6		
	Trimipramine		CYP2D6 and possibly other pathways	

Bupropion + Antiepileptics; Enzyme-inducing

Carbamazepine markedly decreases bupropion levels and increases the levels of its active metabolite hydroxybupropion. Phenobarbital (and therefore probably primidone) and phenytoin (and therefore fosphenytoin) would be expected to interact similarly.

Clinical evidence, mechanism, importance and management

In a study in 12 patients with major affective disorders, carbamazepine at steady-state markedly decreased the maximum plasma levels and AUC of a single 150 mg dose of bupropion and two of its metabolites (threohydrobupropion and erythrohydrobupropion) by about 81 to 96%. These two metabolites have only weak potential antidepressant activities. However, the AUC and maximum levels of another metabolite, hydroxybupropion (which has similar potency to the parent compound) were increased by 50% and 71%, respectively.[1] Two patients with bipolar illness have been described who received bupropion at a variety of doses (450 to 600 mg daily and 400 to 525 mg daily). They had undetectable bupropion plasma levels while taking carbamazepine but their plasma levels of hydroxybupropion were markedly increased.[2]

What the sum of all these changes is likely to mean is uncertain, but good monitoring for any evidence of reduced efficacy and/or increased toxicity (due to the raised hydroxybupropion levels) is clearly needed. The same good monitoring would also be appropriate with **phenytoin** (and therefore **fosphenytoin**) and **phenobarbital** (and therefore **primidone**), which would be expected to interact similarly, but clinical studies to confirm this appear to be lacking.

Note that bupropion causes dose-related seizures and is contraindicated in patients with seizure disorders.

Bupropion + Antiplatelet drugs

Clopidogrel and ticlopidine appear to inhibit the metabolism of bupropion to hydroxybupropion.

Clinical evidence

(a) Clopidogrel

A study in healthy subjects given clopidogrel 75 mg daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 60% and the AUC of its active metabolite, hydroxybupropion, was reduced by 52%.[1]

(b) Ticlopidine

A study in healthy subjects given ticlopidine 250 mg twice daily for 4 days found that the AUC of a single 150-mg dose of bupropion was increased by 85% and the AUC of its active metabolite, hydroxybupropion, was reduced by 84%.[1]

Mechanism

Bupropion is metabolised by the cytochrome P450 isoenzyme CYP2B6, which can be inhibited by clopidogrel and ticlopidine.[1,2] Concurrent use therefore decreases bupropion metabolism and increases its levels.

Importance and management

The pharmacokinetic interactions between bupropion and clopidogrel or ticlopidine are established, but the clinical relevance of the increase in active bupropion levels and decrease in active hydroxybupropion levels is unclear. Until more is known about this interaction it would seem prudent to monitor concurrent use for any alterations in bupropion adverse effects (lightheadedness, gastrointestinal effects) and/or efficacy, adjusting the dose if necessary.

Bupropion + Antiretrovirals

Ritonavir, both at doses used to boost the levels of other protease inhibitors and higher doses, *decreases* bupropion levels. This is the opposite effect to that which was originally predicted.

Clinical evidence

In a study in 7 healthy subjects, **ritonavir** 200 mg or placebo was given twice daily for 2 days with a single 75-mg dose of bupropion given with the third dose. The *increases* in bupropion AUC and maximum level (20% and 31%) were not statistically significant. Similarly, the changes in metabolite pharmacokinetics were slight, and mostly non-significant.[1] In contrast, the UK manufacturers of bupropion report a study in healthy subjects in which a higher dose of **ritonavir** (600 mg twice daily) for a longer time period (20 days) *decreased* the AUC and maximum serum levels of bupropion by about 65% and 60%, respectively. The plasma levels of the active metabolites of bupropion were also decreased.[2] Similarly, in another study in healthy subjects, **ritonavir**-boosted **lopinavir** 100/400 mg twice daily for 2 weeks *decreased* the AUC and maximum serum levels of bupropion after a single 100-mg dose of the sustained-release formulation by 57%. The plasma levels of hydroxybupropion were also decreased. The pharmacokinetics of ritonavir-boosted lopinavir were unchanged by the single dose of bupropion.[3]

A retrospective study identified 10 HIV-positive patients who had taken bupropion 150 mg once or twice daily together with **nelfinavir**, **ritonavir** or **efavirenz** for 3 weeks to 2 years (median 8 months). No seizures had occurred in these patients (predicted if a marked increase in bupropion levels had occurred), but note that the number of patients was small. The 2 patients who received **ritonavir** were given 100 mg twice daily.[4]

Mechanism

In vitro data[5] indicated that the antiretroviral drugs efavirenz, nelfinavir and ritonavir are capable of inhibiting the cytochrome P450 isoenzyme CYP2B6, which is the isoenzyme primarily involved in bupropion metabolism. It was therefore predicted that these drugs would cause an *increase* in bupropion concentrations,[5] with an increased risk of seizures. However, more recent *in vitro* evidence shows that ritonavir strongly induces CYP2B6,[6] and this is supported by the clinical evidence showing that ritonavir decreases bupropion levels. This is not the first interaction where ritonavir has caused the opposite effect to that which was originally predicted, other examples being 'methadone', (p.200) and 'contraceptives', (p.1187). A possible explanation is that therapeutically-achieved levels of ritonavir induce UDP-glucuronosyltransferase enzymes and induce CYP2B6.[3]

Importance and management

Taken together, the evidence suggests that ritonavir, irrespective of dose, decreases the levels of bupropion and its active metabolite. This effect is not seen with just 2 days use of ritonavir given to boost the levels of other protease inhibitors (i.e. 100 mg twice daily) in one study, but was apparent at 2 weeks in another. The extent of reduction in bupropion levels seen suggests that the dose of bupropion might need to be doubled to achieve the same effect.[3] It would seem prudent to start bupropion at the recommended starting dose and titrate to effect. Nevertheless, because of the original *in vitro* data, the UK manufacturers of bupropion currently caution that the recommended doses should not be exceeded.[2]

On the basis of the findings with ritonavir, it is not possible to predict what will occur clinically with efavirenz or nelfinavir-containing regimens. In these cases, it would seem prudent to start bupropion at the lowest recommended dose and titrate to effect.

Bupropion + Benzodiazepines and related drugs

Visual hallucinations have been seen in one patient given zolpidem with bupropion. Bupropion is contraindicated during the abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly the benzodiazepines and related drugs.

Clinical evidence, mechanism, importance and management

Visual hallucinations lasting 3 to 4 hours occurred in a 17-year-old boy who had been taking bupropion 450 mg daily for one month and **zolpidem** 5 to 10 mg daily for about 6 months, when he increased the **zolpidem** dose to 60 mg.[1] Note that the recommended dose of **zolpidem** is 10 mg daily and that **zolpidem** itself can cause psychiatric adverse effects such as hallucinations. Therefore an interaction is not established.

Bupropion is contraindicated during abrupt withdrawal from any drug known to be associated with seizures on withdrawal, particularly benzodiazepines and benzodiazepine-like drugs.[2,3]

Bupropion + Carbimazole

An isolated report describes acute liver failure in a patient taking bupropion and carbimazole.

Clinical evidence, mechanism, importance and management

A 41-year-old man treated for hyperthyroidism with carbimazole 15 mg daily and propranolol 10 mg daily for 5 years received a 10-day course of bupropion 150 mg daily to aid smoking cessation. Ten weeks after completing the course of bupropion he was admitted to hospital with severe jaundice, nausea, dyspepsia, lethargy, and epigastric discomfort persisting for 5 days. The only other medication he had taken was paracetamol (acetaminophen) 500 mg to 1 g daily for up to 2 days, about 2 weeks before admission. Both carbimazole and propranolol were discontinued. He developed acute liver failure and a rapid deterioration of renal function, complicated by sepsis and coagulopathy. Liver biopsy showed evidence of non-specific drug-induced acute liver injury. The patient died 19 days after the onset of symptoms.[1]

Both bupropion and carbimazole may cause liver damage. In this case the hepatotoxicity was attributed to bupropion or a combined toxic effect of bupropion and carbimazole. The potential for serious hepatotoxicity should be borne in mind if bupropion is given with other hepatotoxic drugs.

Bupropion + Cimetidine

A randomised, crossover study in 24 healthy subjects found no evidence of any significant pharmacokinetic interaction between a single 300-mg dose of bupropion (sustained release preparation) and a single 800-mg dose of cimetidine.[1] No dose adjustments would seem to be necessary on concurrent use.

1. Kustra R, Corrigan B, Dunn J, Duncan B, Hsyu P-H. Lack of effect of cimetidine on the pharmacokinetics of sustained-release bupropion. *J Clin Pharmacol* (1999) 39, 1184–8.

Bupropion + Corticosteroids

A patient taking bupropion had a seizure after being given an intra-articular injection of methylprednisolone.

Clinical evidence, mechanism, importance and management

A case report describes a patient taking bupropion, who experienced a severe, prolonged seizure 24 hours after receiving intra-articular **methylprednisolone** 30 mg for subacromial bursitis.[1] The author notes that there could be a risk of seizures in patients taking bupropion who are given prophylactic oral steroids.[1] This is in line with the manufacturers' suggestion that systemic steroids could increase the risk of seizures. See 'Bupropion + Miscellaneous', p.1468, for a further discussion of the risk of seizures with bupropion.

1. White P. Interaction of intra-articular steroids and bupropion. *Clin Radiol* (2002) 57, 235.

Bupropion + Guanfacine

A grand mal seizure in a child, which was attributed to an interaction between bupropion and guanfacine, was later identified as being more probably due to a bupropion overdose.

Clinical evidence, mechanism, importance and management

A 10-year-old girl, being treated for attention deficit hyperactivity disorder, was prescribed increasing doses of bupropion, up to 100 mg three times daily, to which guanfacine, initially 500 micrograms twice daily then 500 micrograms three times daily, was added. Ten days later she had a grand mal seizure, which the author of the report attributed to an interaction between the two drugs.[1,2] This was challenged in subsequent correspondence.[3] Furthermore, 2 years later the author of the original report wrote to say that he had now discovered that the girl had in fact taken 500 mg of bupropion and 5 mg of guanfacine before the seizure took place, so that what happened was much more likely to have been due to an overdose of the bupropion (which is known to cause seizures) than to an interaction with guanfacine.[4]

Bupropion + Hormonal contraceptives or HRT

HRT and, to a lesser extent, an oral combined hormonal contraceptive modestly inhibited the metabolism of bupropion to hydroxybupropion in one study.

Clinical evidence

In a three-way crossover study in 12 healthy women, a single 150-mg dose of sustained-release bupropion was given alone or on day 10 of treatment with menopausal hormone replacement therapy (**estradiol/levonorgestrel** 2 mg/250 micrograms; *Cyclabil*) or an oral combined hormonal contraceptive (**ethinylestradiol/desogestrel** 30/150 micrograms; *Marvelon*) for 10 days. The HRT reduced the AUC of hydroxybupropion by 47% and increased the AUC of hydrobupropion by 64%, but the AUC of bupropion was unchanged. The AUC of hydroxybupropion was also reduced by the hormonal contraceptive, but to a slightly lesser extent (31%), the AUC of bupropion was slightly reduced (19%) but hydrobupropion was not significantly affected.[1]

Mechanism

Bupropion is extensively metabolised to hydroxybupropion (an active metabolite) by the cytochrome P450 isoenzyme CYP2B6, and this study suggests that HRT and, to a lesser extent, oral contraceptives may inhibit CYP2B6 activity. Which of the constituents were principally responsible for this effect is unknown.

Importance and management

The clinical effect of the modest reduction in the levels of the active metabolite of bupropion and increase in levels of bupropion with HRT has not been assessed. Until more is known about the consequence of altering the ratio of these active metabolites, it might be prudent to increase monitoring of adverse effects and/or efficacy when bupropion is used with HRT.

The more modest effects of the combined oral contraceptive are unlikely to be clinically relevant.

Bupropion + Lamotrigine

Bupropion does not alter the pharmacokinetics of lamotrigine. Hypomania has been reported in a patient taking bupropion and lamotrigine.

Clinical evidence, mechanism, importance and management

A study in 12 healthy subjects found that bupropion 150 mg twice daily did not affect the pharmacokinetics of a single 100-mg dose of lamotrigine.[1]

A 23-year-old patient with a DSM-IV diagnosis of major depression taking bupropion 400 mg daily had an improvement in mood when she was also given lamotrigine 25 mg at night, and there was further improvement in mood, decreased anxiety and increased energy when lamotrigine was increased to 50 mg daily for 3 weeks. However, when the dose of lamotrigine was increased to 75 mg daily she reported decreased sleep, increased energy, mood lability and increased spending, which was diagnosed as hypomania. The symptoms resolved over about 2 weeks when the lamotrigine dose was reduced to 50 mg at bedtime.

Antidepressants in high doses or in combination can induce hypomania and in this case the effect was attributed to a potentiation of the effects of bupropion, caused by lamotrigine.[2] The general relevance of this single case is uncertain.

Note that bupropion causes dose-related seizures and is contraindicated in patients with seizure disorders.

Bupropion + Linezolid

An isolated report describes intraoperative hypertension in a patient taking bupropion and linezolid, which has weak MAO inhibitory activity.

Clinical evidence, mechanism, importance and management

An isolated report describes severe intermittent intraoperative hypertension in a 57-year-old man undergoing surgical removal of an infected vascular bypass graft. He was taking maintenance bupropion (dosage not stated) and linezolid, which had been started 24 hours previously for treatment of a resistant gram-positive infection.[1] Linezolid is known to have weak reversible MAOI properties, and might therefore interact with bupropion in a way similarly to that predicted for non-selective MAOIs, see 'MAOIs or RIMAs + Bupropion', p.1374. Although concurrent use need not be avoided, this report therefore introduces a note of caution if both drugs are given together.

1. Marcucci C, Sandson NB, Dunlap JA. Linezolid-bupropion interaction as possible etiology of severe intermittent intraoperative hypertension? *Anesthesiology* (2004) 101, 1487–8.

Bupropion + Methylphenidate

Isolated reports describe grand mal seizures in one patient and myocardial infarction in another, which were associated with the concurrent use of bupropion and methylphenidate.

Clinical evidence, mechanism, importance and management

(a) Seizures

A 14-year-old boy taking methylphenidate 60 mg daily was also given bupropion 200 mg increased to 300 mg daily. The patient experienced grand mal seizures 4 weeks after the dosage increase, but remained seizure-free once the bupropion was discontinued.[1] The authors note that bupropion alone could have been the cause of the seizures, but that methylphenidate might have been a contributory factor. Note that the manufacturers of bupropion list stimulants as drugs that increase the risk of seizures with bupropion (see 'Bupropion + Miscellaneous', below) and this case adds weight to that warning.

(b) Myocardial ischaemia

A report describes acute myocardial infarction in a 16-year-old boy who was taking methylphenidate 30 mg twice daily for attention-deficit hyperactivity disorder, bupropion 100 mg twice daily for depression and sustained-release erythromycin 999 mg daily for acne (duration of each not noted). It was proposed that the erythromycin might have caused elevated levels of bupropion leading to a hyperadrenergic state and this, together with the sympathetic effects of the methylphenidate, resulted in excessive vasospasm, leading to myocardial damage.[2] However, there is no clear known mechanism by which erythromycin (a CYP3A4 and P-glycoprotein inhibitor) would increase bupropion levels (a CYP2B6 substrate).

Bupropion + Miscellaneous

The manufacturers of bupropion caution its concurrent use with amantadine and levodopa (higher risk of adverse effects) and drugs that can lower the convulsive threshold (possible increased risk of seizures). Bupropion inhibits the metabolism of drugs that are substrates of the cytochrome P450 isoenzyme CYP2D6. Drugs that inhibit CYP2B6 can reduce the metabolism of bupropion to hydroxybupropion.

Clinical evidence, mechanism, importance and management

(a) Antiparkinsonian drugs

The manufacturers say that the concurrent use of bupropion and **levodopa** or **amantadine** should be undertaken with caution because limited clinical data suggest a higher incidence of undesirable effects (nausea, vomiting, excitement, restlessness, postural tremor) in patients given bupropion with either drug. Good monitoring is therefore appropriate and patients should be given small initial bupropion doses, which are increased gradually.[1,2]

(b) CYP2B6 substrates and inhibitors

The manufacturers advise caution if bupropion is used with drugs that are substrates or inhibitors of the cytochrome P450 isoenzyme CYP2B6 because bupropion is metabolised to its major active metabolite hydroxybupropion by this isoenzyme.[1,2] They list the antineoplastics **cyclophosphamide**, **ifosfamide**, and **thiotepa**, the antiplatelet drugs **clopidogrel** and **ticlopidine**, and the antimuscarinic **orphenadrine**. However, few, if any, pharmacokinetic interactions are found to be attributable to the effects of two substrates of an isoenzyme given together, and it is not usual to issue cautions solely on this basis (note that **cyclophosphamide** and **ifosfamide** are CYP2B6 substrates, and not known to be inhibitors of this isoenzyme). CYP2B6 inhibitors would be predicted to affect the pharmacokinetics of bupropion, and this interaction has been seen with clopidogrel and ticlopidine, see 'Bupropion + Antiplatelet drugs', p.1466, and with contraceptives and HRT, see 'Bupropion + Hormonal contraceptives or HRT', p.1467. **Thiotepa** and **orphenadrine** are predicted to interact similarly. Nevertheless, the clinical relevance of this interaction is far from clear be-

cause both bupropion and hydroxybupropion are active, and the clinical consequences of altering the ratio of these two substances is unknown.

(c) CYP2D6 substrates

Bupropion is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, and has been shown to raise the levels of a number of CYP2D6 substrates including 'desipramine', (p.1501), 'dextromethorphan', (p.1556) and 'metoprolol', (p.1000). Note that CYP2D6 shows genetic polymorphism, with about 10% of the population lacking active CYP2D6 (poor metabolisers). Therefore, pharmacokinetic interactions between CYP2D6 inhibitors and CYP2D6 substrates are often less important than might initially be supposed, because a potent inhibitor of this isoenzyme will effectively be changing a person who is an extensive metaboliser into a poor metaboliser (i.e. any change is still within the range of the existing population). The situation when an interaction is likely to be important is when an extensive metaboliser on established treatment with a CYP2D6 substrate that has a narrow therapeutic window then starts a CYP2D6 inhibitor. Bupropion should therefore be used with some caution with drugs that are known substrates of CYP2D6, particularly those with a narrow therapeutic window. A list of CYP2D6 substrates is given in 'Table 1.3', (p.6), and the manufacturers of bupropion specifically name **haloperidol**, **risperidone**, **thioridazine**, **flecainide**, and **propafenone**. The recommendation is that if any of these drugs is added to treatment with bupropion, doses at the lower end of the range should be used. If bupropion is added to existing treatment, decreased dosages should be considered.[1,2]

(d) Drugs that can lower the convulsive threshold

There is a small dose-related risk of seizures with bupropion. At a daily dose of 300 mg of the sustained-release formulation the risk is 0.1%, which increases to 0.4% at a dose of 450 mg of the immediate-release formulation, and increases tenfold between doses of 450 and 600 mg daily.[2] The manufacturers caution the use of other drugs that lower the convulsive threshold, the concern being that these drugs might further increase the risk of seizures. The UK[1] and US[2] manufacturers list **antipsychotics**, antidepressants, systemic steroids, and **theophylline**. In some cases seizures have been seen when bupropion is given with these drugs, see 'SSRIs + Bupropion', p.1482, 'Tricyclic antidepressants + Bupropion', p.1501, and 'Bupropion + Corticosteroids', p.1467. The UK manufacturers additionally list **antimalarials**, **tramadol**, **quinolones** and **sedating antihistamines**. A maximum dose of 150 mg of bupropion should be considered for patients prescribed such drugs.[1]

Caution is also urged with regard to circumstances that may lower the convulsive threshold, including the use of **anorectics** or **stimulants** (one case seen with methylphenidate, see 'Bupropion + Methylphenidate', p.1468), the excessive use of **sedatives**, and addiction to **cocaine** or **opiates**.[1,2]

2. Zyban (Bupropion hydrochloride). GlaxoSmithKline. US Prescribing information, July 2009.

Bupropion + Pseudoephedrine

An isolated report describes acute myocardial ischaemia associated with bupropion and pseudoephedrine in a recent tobacco smoker.

Clinical evidence, mechanism, importance and management

A 21-year-old man presented to a hospital emergency department with severe chest pain radiating into both arms and between the shoulder blades, diaphoresis and shortness of breath. This was diagnosed as an acute myocardial infarction, and it was concluded that this was due to acute myocardial ischaemia apparently brought on by the combined use of pseudoephedrine (9 tablets of 30 mg taken over the previous 3 days), bupropion for smoking cessation (started in the previous 72 hours) and **nicotine** from tobacco (he had smoked 25 cigarettes daily). The authors of the report postulate that all these drugs acted on the alpha receptors of the coronary arteries to cause vasospasm and acute ischaemia. He had also been taking erythromycin for 3 days (which is not thought to be related to the interaction), and had previously taken pseudoephedrine alone on numerous occasions without problems. He recovered fully.[1]

This is an isolated case from which no general conclusions can be drawn, but some warning might be appropriate for patients who are at risk of coronary ischaemia. For comment on the use of nicotine with bupropion, see 'Bupropion + Tobacco or Nicotine', p.1470.

1. Pederson KJ, Kuntz DH, Garbe GJ. Acute myocardial ischemia associated with ingestion of bupropion and pseudoephedrine in a 21-year-old man. *Can J Cardiol* (2001) 17, 599–601.

Bupropion + Rifampicin (Rifampin)

Rifampicin markedly reduces the AUC of both bupropion and its active metabolite hydroxybupropion.

Clinical evidence

In a controlled study in 16 healthy subjects, rifampicin 600 mg daily for 10 days caused a threefold decrease in the AUC of a single 150-mg dose of bupropion given on day 8. Bupropion clearance was increased threefold, and the elimination half-life was reduced from 15.9 hours to 8.2 hours. The AUC of the main active metabolite, hydroxybupropion, was also reduced (by about 75%), but its maximum level was *increased* by about 75%. There was no difference in the effect of rifampicin on bupropion between the 9 subjects who were ethnically Chinese and the 9 who were white European, after adjusting for body-weight.[1]

Further studies have found that rifampicin has a greater effect on the *S*-enantiomer of bupropion and the *S,S*-hydroxyl bupropion metabolite than on the other enantiomers.[2,3]

Mechanism

Rifampicin induces the cytochrome P450 isoenzyme CYP2B6, which is responsible for the hydroxylation of bupropion, and also the metabolism of hydroxybupropion.

Importance and management

The pharmacokinetic interaction is established. Rifampicin would be expected to markedly increase the metabolism of bupropion and its active metabolite. Although the clinical relevance of this has not been directly assessed, it would be anticipated that reductions in efficacy might result. Monitor the efficacy of bupropion in any patient requiring rifampicin, and titrate the bupropion dose as necessary.

Bupropion + St John's wort (*Hypericum perforatum*)

There is a single case of dystonia when bupropion was started in a patient taking HRT and St John's wort. A case of mania was attributed to the use of St John's wort in a patient taking bupropion.

Clinical evidence, mechanism, importance and management

(a) Dystonia

A 58-year-old woman taking St John's wort 300 mg daily and menopausal HRT (estradiol/medroxyprogesterone) developed acute facial dystonia four days after starting bupropion 150 mg daily for smoking cessation. She was treated with a variety of drugs, and over a couple of weeks the spasm-free interval lengthened, and by 5 months the dystonia resolved completely and all medications were withdrawn without recurrence of the dystonia.[1] Dystonia is a rare adverse effect of bupropion alone, and the authors suggested that the combination of bupropion with St John's wort lead to additive effects on serotonin reuptake inhibition, making dopaminergic adverse effects such as dystonia more likely.[1] Note also that one HRT preparation has been shown to inhibit the metabolism of bupropion to hydroxybupropion (see 'Bupropion + Hormonal contraceptives or HRT', p.1467), so it could be hypothesised that there might also be a pharmacokinetic element to this case.

From a single case report like this is it impossible to establish an interaction. Bear this case in mind in the event of similar adverse effects.

(b) Mania

A report very briefly mentions that St John's wort was suspected of inducing mania in one patient who was also taking bupropion.[2] No other details were given, and no general conclusions can be drawn from this isolated report.

2. Griffiths J, Jordan S, Pilan K. Natural health products and adverse reactions. *Can Adverse React News* (2004) 14 (1), 2–3.

Bupropion + Tobacco or Nicotine

Neither nicotine nor tobacco smoking alter the pharmacokinetics of bupropion. However, combined use of bupropion and nicotine replacement therapy appears to increase the risk of hypertension.

Clinical evidence, mechanism, importance and management

(a) Nicotine

Nicotine transdermal patches are reported not to affect the pharmacokinetics of bupropion or its metabolites.[1] The manufacturers of bupropion say that limited data suggest that giving up smoking is more easily achieved if bupropion is taken while using a nicotine transdermal system, but a higher rate of treatment-emergent hypertension has been noted on concurrent use.[1,2] They recommend weekly monitoring to check for any evidence of a blood pressure increase.[1] The same warning would also seem to be applicable to the use of nicotine in any other form (buccal or nasal).

For a report of acute myocardial ischaemia attributed to combined use of bupropion, nicotine (from smoking) and pseudoephedrine, see 'Bupropion + Pseudoephedrine', p.1469.

(b) Tobacco

In a pharmacokinetic study, there was no difference in the pharmacokinetics of bupropion (given as a single 150-mg sustained release tablet) and its major metabolites between subjects who were tobacco smokers and those who were non-smokers.[3] Similarly, in a study in adolescents, there was no difference in the pharmacokinetics of bupropion or hydroxybupropion between 37 smokers and 38 non-smokers when given a single 150-mg dose of sustained release bupropion.[4]

This suggests that there is no need to alter the dose of bupropion based on smoking status.

Bupropion + Valproate

Valproate appears to increase levels of the major active metabolite of bupropion. Evidence from one case suggests that high-dose bupropion might modestly increase valproate levels. Hallucinations have been reported in a patient taking both drugs.

Clinical evidence, mechanism, importance and management

In a study in 5 patients with major affective disorders, the AUC of hydroxybupropion, an active metabolite of bupropion, almost doubled when a single 150-mg dose of bupropion was given with valproate at steady-state, but the pharmacokinetics of bupropion itself and its two other less active metabolites were unaffected.[1] A case report describes an increase in valproate levels of almost 30% after bupropion was started and increased to 450 mg daily.[2] Visual and auditory hallucinations were reported in a patient taking bupropion when valproate was substituted for lithium. The hallucinations stopped when bupropion was withdrawn.[3]

The UK manufacturer recommends caution when using drugs that may inhibit bupropion metabolism, and they name valproate.[4] As valproate levels might possibly also be modestly increased by bupropion, good monitoring for evidence of increased adverse effects of both drugs would seem appropriate.

Note that bupropion causes dose-related seizures and is contraindicated in patients with seizure disorders.

Mirtazapine + Antiepileptics; Enzyme-inducing

Carbamazepine and phenytoin can decrease the plasma levels of mirtazapine. Other enzyme-inducing antiepileptics would be expected to interact similarly. Carbamazepine and phenytoin levels are unaffected by mirtazapine.

Clinical evidence

In a placebo-controlled study, healthy subjects were given **carbamazepine** (at steady state) with mirtazapine for 7 days. It was found that **carbamazepine** decreased the AUC and maximum plasma levels of mirtazapine by 63% and 44%, respectively, and increased the peak levels (but not the AUC) of demethylmirtazapine. Another related study found that mirtazapine did not affect the pharmacokinetics of **carbamazepine**.[1]

A study in 9 healthy subjects given **phenytoin** 200 mg daily for 17 days, with mirtazapine 15 mg daily for 2 days from day 11, and then 30 mg daily for 5 days, found that mirtazapine had no effect on the steady-state pharmacokinetics of **phenytoin**.[2] In a second associated study, 8 healthy subjects were given mirtazapine 15 mg daily for 2 days then 30 mg daily for 15 days with **phenytoin** 200 mg daily on days 8 to 17. It was found that **phenytoin** decreased the AUC and maximum plasma levels of mirtazapine by 47% and 33%, respectively.[2]

Mechanism

Mirtazapine is metabolised by cytochrome P450 isoenzymes CYP1A2, CYP2D6 and CYP3A4, and it is likely that carbamazepine and phenytoin induce its metabolism by these routes, resulting in the lower levels seen in the studies.

Importance and management

The pharmacokinetic interactions between mirtazapine and carbamazepine and phenytoin would appear to be established. Although the clinical relevance of halving mirtazapine levels has not been established, it would not be unexpected for decreases of this magnitude to result in reduced efficacy in some patients. Monitor concurrent use carefully. The UK manufacturers of mirtazapine advise that if carbamazepine, phenytoin or other drugs that induce drug metabolism (such as **rifampicin** (**rifampin**)) are given with mirtazapine, the mirtazapine dose may have to be increased. Further, if treatment with an inducer is stopped, the mirtazapine dosage may have to be reduced.[3] Although not specifically named, **fosphenytoin**, **phenobarbital** and **primidone** can also induce cytochrome P450 isoenzymes, and they therefore may interact similarly.

Note that, as with other antidepressants, the use of mirtazapine should be carefully considered in patients taking these drugs for epilepsy, because of the possible increased risk of seizures.

Mirtazapine + Benzodiazepines

The sedative effects of mirtazapine are increased by the benzodiazepines.

Clinical evidence, mechanism, importance and management

A single-dose study in 12 healthy subjects found that the pharmacokinetics of mirtazapine 15 mg and **diazepam** 15 mg were not affected by concurrent use. However, **diazepam** further impaired the action of mirtazapine on objectively measured skill performance: the combined actions were mostly additive. The effects seen were of similar magnitude to those found when amitriptyline 50 mg was given with diazepam 15 mg.[1]

Mirtazapine has prominent sedative effects and these are likely to be additive with those of diazepam and any other benzodiazepine.

This additive pharmacodynamic interaction is expected. Caution is required on concurrent use, particularly on starting treatment, and patients should be advised to avoid driving or operating machinery if feeling drowsy (note that this caution would apply to either drug used alone). Note that the US manufacturer actually recommends that patients taking mirtazapine avoid the use of diazepam and similar drugs, but this is probably overly cautious.[2]

2. Remeron (Mirtazapine). Schering-Plough. US Prescribing information, March 2009.

Mirtazapine + Cimetidine

Cimetidine increases the bioavailability of mirtazapine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 12 healthy subjects, cimetidine 800 mg twice daily was given for 14 days, with mirtazapine 30 mg added at night on days 6 to 12. Cimetidine increased the AUC and peak plasma levels of mirtazapine by 54% and 22%, respectively: trough and average mirtazapine plasma levels, at steady state, were increased by 61% and 54%, respectively. The pharmacokinetics of the demethyl metabolite of mirtazapine were little affected. Mirtazapine did not affect the pharmacokinetics of cimetidine.[1]

Mechanism

It seems likely that cimetidine, a non-specific enzyme inhibitor, decreases the metabolism of mirtazapine.

Importance and management

This pharmacokinetic interaction between cimetidine and mirtazapine would appear to be established, but the clinical effect of increasing the levels of mirtazapine by up to about to two-thirds does not appear to have been assessed. The authors suggested that the clinical relevance of this interaction is probably limited because of the variability of plasma mirtazapine levels in patients.[1] Nevertheless, the UK manufacturers advise that the mirtazapine dosage may need to be reduced during concurrent use and increased when cimetidine is stopped.[2] Monitor for an increase in mirtazapine adverse effects (oedema, drowsiness, headache) when starting cimetidine.

Mirtazapine + CYP3A4 inhibitors

Ketoconazole increased the AUC and plasma levels of mirtazapine. Some caution might be appropriate on concurrent use of this and other CYP3A4 inhibitors.

Clinical evidence, mechanism, importance and management

The UK manufacturer of mirtazapine notes that **ketoconazole** increased the peak plasma levels and AUC of mirtazapine by about 30% and 45%, respectively.[1] Mirtazapine is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4, which is thought to be responsible for the formation of the *N*-demethyl and *N*-oxide metabolites. Ketoconazole is a potent inhibitor of CYP3A4.

This pharmacokinetic interaction would appear to be established, but the clinical effect of increasing the exposure to mirtazapine by around half has not been assessed. Until more is known, some caution might be appropriate. Note that the UK manufacturer of mirtazapine advises caution and that a decrease in the dose of mirtazapine may be needed when potent inhibitors of CYP3A4 are also given, and they specifically name **azole antifungals**, **protease inhibitors**, **erythromycin**, and **nefazodone**.[1] For a list of CYP3A4 inhibitors, see 'Table 1.4', (p.6).

1. Zispin (Mirtazapine). Organon Laboratories Ltd. UK Summary of product characteristics, February 2009.

Mirtazapine + SSRIs

There are a couple of isolated cases of possible serotonin syndrome when mirtazapine was used with fluoxetine and fluvoxamine, and there is a report of hypomania associated with the concurrent use of mirtazapine and sertraline. Restless legs syndrome has occurred in a patient taking fluoxetine and mirtazapine. Fluvoxamine markedly increased the plasma levels of mirtazapine in two cases, whereas paroxetine caused a minor increase in the AUC of mirtazapine in a pharmacokinetic study.

Clinical evidence

(a) Escitalopram

For a report of bleeding associated with the combined use of escitalopram, mirtazapine and venlafaxine, see 'SNRIs + SSRIs', p.1475.

(b) Fluoxetine

An isolated report describes a case of possible serotonin syndrome in a 75-year-old woman when fluoxetine 20 mg daily was discontinued and mirtazapine 30 mg daily started soon afterwards (exact interval not stated).[1] Symptoms including dizziness, headache, nausea, dry mouth, anxiety, agitation, suicidal ideas and difficulty in walking occurred within hours of the first dose of mirtazapine. Symptoms worsened until mirtazapine was discontinued on day 5, after which an improvement was noticed. Fluoxetine was restarted on day 7. It has been suggested that this case is more consistent with fluoxetine-withdrawal syndrome, with the mirtazapine worsening the symptoms of anxiety.[2]

Restless legs syndrome occurred in 3 patients taking fluoxetine and mirtazapine as part of a study of major depression with insomnia. Symptoms were bothersome paraesthesias and jerks in both lower extremities, with exacerbation at night, and relief upon movement. Treatment with mirtazapine was discontinued and symptoms ceased after 2 days.[3]

(c) Fluvoxamine

A 26-year-old woman with a 12-year history of anorexia nervosa, taking fluvoxamine 200 mg daily, developed symptoms consistent with serotonin syndrome (tremors, restlessness, twitching, flushing, diaphoresis, nausea) about 4 days after starting mirtazapine 30 mg daily.[4] It has been suggested that this case is not consistent with serotonin syndrome, and that the adverse effects were attributable to raised levels of mirtazapine possibly caused by fluvoxamine.[2]

A 17-year-old boy taking mirtazapine 30 mg daily experienced increased anxiety when fluvoxamine 100 mg daily was also given. Mirtazapine serum levels were increased threefold. In a second patient, a 43-year-old woman taking mirtazapine 15 mg daily, the addition of fluvoxamine 50 mg daily resulted in a fourfold increase in serum mirtazapine concentrations, accompanied by mood improvements.[5]

(d) Paroxetine

A study in 21 healthy subjects given mirtazapine 30 mg daily, paroxetine 40 mg daily or a combination of both, for 9 days, found that paroxetine slightly inhibited the metabolism of mirtazapine (AUC of mirtazapine increased by about 17%). Mirtazapine did not alter the pharmacokinetics of paroxetine. The results of psychometric assessments suggested that concurrent use of mirtazapine and paroxetine did not alter cognitive function, or cause major changes in mood or sleep, compared with the use of either drug alone.[6]

(e) Sertraline

A woman taking sertraline 250 mg daily was also given mirtazapine 15 mg daily because of inadequately controlled depression. Within 4 days she developed hypomanic symptoms and she stopped taking the mirtaza-

pine. The hypomania resolved within 3 days but her depression then recurred.[7]

Mechanism

Mirtazapine is metabolised mainly by the cytochrome P450 isoenzymes CYP1A2, CYP2D6 and CYP3A4. These isoenzymes (particularly CYP1A2) are inhibited by fluvoxamine, and so concurrent use might therefore raise mirtazapine levels. Paroxetine is a moderate inhibitor of CYP2D6, and this appeared to have little effect on mirtazapine levels.

The SSRIs, and mirtazapine affect serotonin transmission, and combined use of serotonergic drugs has rarely caused the symptoms described as serotonin syndrome (for more about serotonin syndrome see under 'Additive or synergistic interactions', (p.9)). However, it has been suggested that serotonin toxicity with mirtazapine is unlikely, because it has 5-HT_2-blocking effects.[2]

Importance and management

The isolated reports would seem to suggest that the combined use of mirtazapine and the SSRIs can lead to serotonin syndrome. However, whether these are cases of serotonin syndrome has been disputed.[2] Nevertheless, these and other reports of anxiety and hypomania highlight the need for some caution during concurrent use. One manufacturer reported that, from postmarketing experience, it appears that serotonin syndrome occurs very rarely in patients taking mirtazapine alone or in combination with SSRIs. They recommend that if the combination is required, dosage alterations should be made with caution and patients closely monitored for any signs of excessive serotonin stimulation.[8]

Extra caution might be appropriate with fluvoxamine, as the limited evidence suggests that this might markedly raise mirtazapine levels. However, this needs confirming.

There is no clinically relevant pharmacokinetic interaction between paroxetine and mirtazapine, and no dosage adjustment is likely to be needed when they are used together.

Mirtazapine + Tricyclic antidepressants

The concurrent use of mirtazapine with amitriptyline may have a minor effect on the maximum levels of both drugs.

Clinical evidence

In a crossover study involving 24 healthy subjects, mirtazapine 15 mg, increasing to 30 mg daily, **amitriptyline** 25 mg, increasing to 75 mg daily or both drugs were given for periods of 9 days. **Amitriptyline** increased the maximum plasma levels of mirtazapine, in male subjects only, by 36%. Mirtazapine increased the maximum plasma levels of **amitriptyline** in male subjects by 23%, but in female subjects the maximum plasma levels were *decreased* by 23%. Other pharmacokinetic parameters of amitriptyline and mirtazapine (AUC, minimum level, time to maximum level) and their main metabolites nortriptyline and demethylmirtazapine were not affected by concurrent use. The authors note that concurrent use had no consistent effects on blood pressure, heart rate and ECG, although they note that four subjects developed postural hypotension.[1]

Mechanism

The pharmacokinetic changes were suggested to be due to differences in rates of absorption of the drugs, since the maximum levels were slightly altered, but the AUCs were not. Mirtazapine has alpha-blocking activity, and can therefore cause hypotension. Amitriptyline can also cause hypotension. Therefore postural hypotension may have developed as a result of the additive effects of the two drugs.

Importance and management

Evidence for an interaction between mirtazapine and amitriptyline appears to be limited to this one study. Although the changes in maximum levels here were statistically significant, they are minor, and there were no changes in the overall amount of drug absorbed. These changes are therefore unlikely to be clinically relevant. There is no pharmacokinetic reason to adjust the dose of either of these drugs on concurrent use.

Nefazodone + Antidepressants

An isolated report describes a woman who developed marked and acute hypotension and weakness when desipramine, fluoxetine and venlafaxine were replaced by nefazodone. Isolated cases describe serotonin syndrome in patients given nefazodone together, or sequentially, with another serotonergic drug (amitriptyline, paroxetine, St John's wort, or trazodone). There is no pharmacokinetic interaction between desipramine and nefazodone. The manufacturer recommended that nefazodone should not be used with an MAOI or within 14 days of discontinuing an MAOI. Note that, due to adverse hepatic effects nefazodone was widely withdrawn from the market.

Clinical evidence, mechanism, importance and management

(a) MAOIs

The manufacturer stated that nefazodone should not be used with an MAOI or within 2 weeks of discontinuing treatment with an MAOI. Conversely at least one week should be allowed after stopping nefazodone before starting an MAOI.[1] There appears to be no direct clinical evidence that an adverse interaction occurs.

(b) Reboxetine

Nefazodone is predicted to increase the plasma concentrations of reboxetine, see 'Reboxetine + CYP3A4 inducers or inhibitors', p.1473.

(c) SSRIs

Anecdotal evidence has suggested that patients who are switched from an SSRI to nefazodone may tolerate nefazodone poorly. Nevertheless, in a 12-week, open study involving 26 depressed patients, nefazodone 100 to 600 mg daily was as equally well tolerated in 13 patients who had discontinued an SSRI within 1 to 4 weeks and 13 patients who had received no antidepressant treatment for the previous 6 months. However, the patients who had recent exposure to an SSRI (within the previous 4 weeks) were given a washout period of 4 to 5 days for short half-life SSRIs or 7 days for **fluoxetine** before starting nefazodone.[2] Cases with specific SSRIs are discussed in the subsections below.

1. Fluoxetine. A woman with a one-year history of DSM-IV major depressive disorder and panic disorder was given daily doses of **desipramine** 75 mg, fluoxetine 20 mg, **venlafaxine** 37.5 mg, **clonazepam** 3 mg and **valproate** 400 mg with no adverse effects, except a dry mouth and sexual difficulties.[3] The first three drugs were stopped and replaced by nefazodone 100 mg twice daily, started about 12 hours later. Within an hour of the first dose she felt very weak and her blood pressure was found to have fallen to only 90/60 mmHg (normally 120/90 mmHg). On waking the next day she had severe weakness, unsteady gait, pale, cool and sweaty skin, and paraesthesia. During the day she took two further 100-mg doses of nefazodone and her condition persisted and worsened with continuing hypotension. The nefazodone was discontinued and by the following day the weakness had improved, disappearing over the next few days. Within a week nefazodone 200 mg daily was reintroduced without problems.

The US manufacturer of nefazodone noted that nefazodone did not alter the pharmacokinetics of fluoxetine, but fluoxetine increased the AUC of the metabolites of nefazodone up to 6-fold.[1] When nefazodone 200 mg twice was given to patients who had been taking fluoxetine for 7 days adverse effects (including headache and nausea) were increased. The manufacturers advised allowing a washout period of at least one week (more may be needed depending on dose and individual patient characteristics)

to minimise these effects.[1] It therefore seems likely that fluoxetine was the interacting drug, but it is impossible to rule out a contribution from the other drugs.

2. Paroxetine. A woman was withdrawn from nefazodone after about 6 months of treatment, tapering over the last fortnight to 75 mg every 12 hours. Within a day she started taking paroxetine 20 mg daily and valproic acid, and was admitted the next day with muscle rigidity, uncoordinated muscle tremors, flailing arms and twitching legs, diaphoresis and agitation. This was identified as serotonin syndrome. Rechallenge with paroxetine 7 days later was uneventful.[4]

(d) St John's wort (Hypericum perforatum)

An elderly patient taking nefazodone 100 mg twice daily, developed symptoms similar to serotonin syndrome within 3 days of starting to take St John's wort 300 mg three times daily. The symptoms included nausea, vomiting, and restlessness. She was asked to stop both medications, but continued the St John's wort and her symptoms gradually improved over a one-week period.[5]

(e) Trazodone

A woman taking irbesartan for hypertension was also given nefazodone at an initial dose of 200 mg daily, followed by 400 mg daily for about 5 weeks. Four days after the dose was increased to 500 mg daily, and trazodone 25 to 50 mg daily was also added as a hypnotic, she was admitted to hospital with a blood pressure of 240/120 mmHg. She was confused, had difficulty concentrating and had numbness on the right side of her lips, nose and right-hand fingers, flushed pruritic skin, nausea, and loose stools. On examination she was restless, hyperreflexic, and diaphoretic. Nefazodone and trazodone were discontinued, and she recovered after treatment with labetalol, clonidine, amlodipine and an increased irbesartan dosage.[6] Although trazodone is used with other serotonergic drugs, it is important to be aware that this may lead to the potentially fatal 'serotonin syndrome', (p.9).

The manufacturers of trazodone say that *in vitro* drug metabolism studies suggest that there is a potential for drug interactions when trazodone is given with a potent CYP3A4 inhibitor such as nefazodone. There may be substantial increases in trazodone levels, with the potential for adverse effects, and a lower dose of trazodone should be considered.[7,8] The UK manufacturer suggests avoidance of the combination where possible.[7]

(f) Tricyclic antidepressants

1. Amitriptyline. A woman who had been taking amitriptyline 10 mg at night and thioridazine developed serotonin syndrome after taking half a tablet of nefazodone (strength unspecified).[9]

2. Desipramine. In a study in healthy subjects, desipramine titrated to 75 mg daily did not change the pharmacokinetics of nefazodone titrated to 150 mg twice daily, but the AUC of the nefazodone metabolite, metachlorophenylpiperazine, was increased by 40%. There was no change in the pharmacokinetics of desipramine or its metabolite. No specific dosage adjustments were said to be required on concurrent use.[10]

Nefazodone + Cimetidine

In a study, 18 healthy subjects were given cimetidine 300 mg four times daily and nefazodone 200 mg every 12 hours for a week. Concurrent use did not affect the steady-state pharmacokinetics of either drug. Therefore no dose adjustments would seem to be necessary if both drugs are used concurrently.[1]

1. Barbhaiya RH, Shukla UA, Greene DS. Lack of interaction between nefazodone and cimetidine: a steady state pharmacokinetic study in humans. *Br J Clin Pharmacol* (1995) 40, 161–5.

Reboxetine + CYP3A4 inducers or inhibitors

Ketoconazole modestly inhibits the metabolism of single-dose reboxetine by inhibiting CYP3A4. Other CYP3A4 inhibitors are expected to interact similarly. Unexpectedly low reboxetine levels have been reported in two patients also taking an inducer of CYP3A4 (carbamazepine and phenobarbital).

Clinical evidence

In a study in 11 healthy subjects, **ketoconazole** 200 mg daily for 5 days increased the AUC of a single 4-mg dose of reboxetine, taken on the second day, by about 50%, without appreciably altering the maximum levels. Reboxetine clearance was decreased by about 25 to 33%. The effect on the two reboxetine enantiomers was of a similar magnitude. In this study, the adverse effect profile of reboxetine alone was similar to that when given with ketoconazole.[1]

A case report describes reboxetine levels that were lower than expected (by comparison with historical controls) in two patients, one receiving **carbamazepine** (with concurrent olanzapine, clonazepam, alprazolam, and buspirone) and one receiving **phenobarbital** (with concurrent clozapine and clonazepam).[2]

Mechanism

Reboxetine is metabolised principally by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is an inhibitor. Concurrent use therefore reduces reboxetine metabolism and increases its levels. Carbamazepine and phenobarbital are inducers of CYP3A4, and they would therefore be expected to increase reboxetine metabolism and decrease its levels.

Importance and management

The pharmacokinetic interaction would appear to be established, but it would be useful to confirm the magnitude at steady-state levels of reboxetine. The clinical relevance of a 50% increase in the AUC of reboxetine is unknown. The authors of the paper suggest that a reduction in reboxetine dose should be considered.[1] However, the manufacturer states that because reboxetine has a narrow therapeutic index, inhibition of metabolism is of major concern, and therefore inhibitors of CYP3A4 should not be given with reboxetine.[3] They list **azoles**, **macrolides** such as **erythromycin**, **nefazodone**, and **fluvoxamine** (although note that fluvoxamine is usually considered to be a weak inhibitor of CYP3A4). For a list of CYP3A4 inhibitors see 'Table 1.4', (p.6). This seems an overly cautious approach, especially given that available data suggest that patients with hepatic impairment have a twofold higher AUC,[4] and the recommendation in this situation is just for a halving of the starting dose of reboxetine.[3]

The cases reports involving carbamazepine and phenobarbital appear to be the only ones reported, and do not wholly confirm an interaction as reboxetine levels were not measured in the absence of these enzyme inducers. The UK manufacturer of reboxetine makes no recommendations with respect to its use with inducers of CYP3A4.[3] Nevertheless, in light of these cases, and in view of the fact that CYP3A4 inhibitors are known to increase reboxetine levels, it would seem prudent to monitor the efficacy of treatment with reboxetine in patients receiving a known inducer of CYP3A4. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

Reboxetine + Dextromethorphan

Reboxetine did not alter dextromethorphan pharmacokinetics in one study.

Clinical evidence, mechanism, importance and management

In a study in 10 healthy subjects who were of the CYP2D6 extensive metaboliser phenotype, the pharmacokinetics of a single 30-mg dose of dextromethorphan were not affected by reboxetine 8 mg daily for one week.[1]

This pharmacokinetic study suggests that dose adjustments of CYP2D6 substrates such as dextromethorphan (see 'Table 1.3', (p.6) for a list) are not likely to be needed when given with reboxetine.

1. Avenoso A, Facciolà G, Scordo MG, Spina E. No effect of the new antidepressant reboxetine on CYP2D6 activity in healthy volunteers. *Ther Drug Monit* (1999) 21, 577–9.

Reboxetine + Miscellaneous

The manufacturer points out that hypokalaemia may occur if reboxetine is used with potassium-depleting diuretics. In addition, they advise the avoidance of MAOIs because of the potential risk of a tyramine-like effect [hypertensive crisis].[1]

1. Edronax (Reboxetine). Pharmacia Ltd. UK Summary of product characteristics, July 2008.

Reboxetine + Quinidine

Quinidine did not alter the pharmacokinetics of reboxetine in one study.

Clinical evidence, mechanism, importance and management

In a study in 8 healthy subjects who were of the CYP2D6 extensive metaboliser phenotype (that is, they had normal levels of this isoenzyme), quinidine (dose not stated) did not alter the pharmacokinetics of reboxetine 1 mg.[1]

This study suggests that reboxetine is not a substrate of the CYP2D6 isoenzyme of cytochrome P450, of which quinidine is an inhibitor. No dosage adjustments of reboxetine are likely to be needed if CYP2D6 inhibitors such as quinidine (see 'Table 1.3', (p.6) for a list) are also given.

Reboxetine + SSRIs

The concurrent use of fluoxetine and reboxetine does not appear to alter the pharmacokinetics of either drug. The manufacturer advises avoidance of fluvoxamine on the basis of a predicted pharmacokinetic interaction.

Clinical evidence

In a placebo-controlled study in 30 healthy subjects given reboxetine 4 mg twice daily and **fluoxetine** 20 mg daily for 8 days, there were no significant changes in the pharmacokinetics of either drug.[1] The only changes were a 25% increase in the AUC of **fluoxetine**, and a 23% increase in the AUC of *S,S*-reboxetine. In this study, combined use did not alter oral temperature and the Digit Symbol Substitution Test, which were used as possible indicators of serotonergic adverse effects. There do not appear to be any published cases of serotonin syndrome in patients taking SSRIs and reboxetine.

Mechanism

Reboxetine is metabolised principally by the cytochrome P450 isoenzyme CYP3A4. **Fluoxetine** has some minor CYP3A4 inhibitory activity (see 'Benzodiazepines and related drugs + SSRIs', p.863), and might therefore have some effect on reboxetine pharmacokinetics, although this would not have been expected to be enantiomer specific.[1] Of the other available SSRIs, only **fluvoxamine** appears to have some minor CYP3A4 inhibitory activity, see 'Benzodiazepines and related drugs + SSRIs', p.863. Note that reboxetine is not a substrate of CYP2D6 (see 'Reboxetine + Quinidine', above) of which a number of SSRIs are inhibitors.

Importance and management

No clinically relevant pharmacokinetic interaction appears to occur between fluoxetine and reboxetine, therefore no dosage adjustment is required on concurrent use. Based on this evidence, no pharmacokinetic interaction would be anticipated with the other available SSRIs. Nevertheless, the manufacturer of reboxetine includes fluvoxamine as an example of a potent inhibitor of CYP3A4, and consequently recommends that its concurrent use with reboxetine should be avoided.[2] This appears to be over-cautious, especially as clinically fluvoxamine only appears to have weak effects on this isoenzyme.

1. Fleishaker JC, Herman BD, Pearson LK, Ionita A, Mucci M. Evaluation of the potential pharmacokinetic/pharmacodynamic interaction between fluoxetine and reboxetine in healthy volunteers. *Clin Drug Invest* (1999) 18, 141–50.
2. Edronax (Reboxetine). Pharmacia Ltd. UK Summary of product characteristics, July 2008.

SNRIs + H_2-receptor antagonists

Cimetidine increases venlafaxine plasma levels, and some caution might be appropriate in the elderly and those with hepatic impairment. Duloxetine is predicted to interact similarly. Famotidine did not alter the absorption of duloxetine.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

The metabolism of duloxetine is reduced by cytochrome P450 isoenzyme CYP1A2 inhibitors and it is recommended that potent inhibitors of CYP1A2 should be avoided (see under fluvoxamine in 'SNRIs + SSRIs', p.1475). The US manufacturer of duloxetine specifically mentions **cimetidine** as an inhibitor of this enzyme.[1] However, **cimetidine** is a much weaker CYP1A2 inhibitor than fluvoxamine, and the UK manufacturer does not mention a possible interaction with **cimetidine**.[2] Any pharmacokinetic interaction between **cimetidine** and duloxetine is probably unlikely to be clinically important, but, until more is known, it might be prudent to be on the look out for an increase in duloxetine adverse effects if **cimetidine** is also given.

One manufacturer reports that **famotidine** had no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine.[1] Duloxetine is formulated with a gastric-resistant coating, but this finding suggests that H_2-receptor antagonists do not lead to an earlier release of duloxetine.[1] **Famotidine** may therefore be a suitable alternative to **cimetidine** in patients taking duloxetine.

(b) Venlafaxine

In a study in 18 healthy subjects, **cimetidine** 800 mg daily for 5 days reduced the oral clearance of venlafaxine 50 mg every 8 hours by 40%, and increased its AUC by 62%. It had no effect on the formation or elimination of the major active metabolite of venlafaxine, *O*-desmethylvenlafaxine (ODV). The total level of venlafaxine with ODV was found to be increased by only 13%. Thus the overall pharmacological activity of the two was only slightly increased by **cimetidine**[3] and no venlafaxine dosage adjustments are necessary on concurrent use.[4,5] However, the manufacturers of venlafaxine suggest that the elderly and those with hepatic impairment might possibly show a more pronounced effect, and they recommend that such patients should be monitored more closely,[4,5] for venlafaxine adverse effects. The US manufacturer additionally advises caution in patients with pre-existing hypertension.[5]

SNRIs + Propafenone

Two isolated reports describe hallucinations and other psychoses in patients taking venlafaxine and propafenone. Duloxetine is predicted to increase propafenone levels.

Clinical evidence, mechanism, importance and management

(a) Duloxetine

Based on data for desipramine (see 'Tricyclic antidepressants + SNRIs', p.1512), duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6 and is therefore predicted to increase the levels of other drugs predominantly metabolised by CYP2D6, such as propafenone. Because propafenone has a narrow therapeutic window, the manufacturer recommends that the concurrent use of duloxetine and propafenone should be approached with caution.[1,2]

(b) Venlafaxine

A 67-year-old woman with bipolar disorder taking venlafaxine 300 mg daily experienced symptoms of paranoia, visual hallucinations and marked confusion, about 2 weeks after starting propafenone 600 mg daily for intermittent atrial fibrillation. Serum levels of venlafaxine had increased from 85 nanograms/mL to 520 nanograms/mL (upper level of reference range 150 nanograms/mL) and levels of the metabolite *O*-desmethylvenlafaxine had increased but were still within normal ranges. Venlafaxine was stopped for a few days then restarted at the lower dose of 75 mg daily and her mental condition (diagnosed as organic psychosis) improved. However, as she also had orthostatic hypotension her propafenone dose was subsequently reduced to 300 mg daily, which necessitated dose adjustments of venlafaxine because of a marked drop in serum level. When propafenone was again increased to 600 mg daily the venlafaxine had to be reduced to 50 mg daily.[3] Another case of visual hallucinations and psychomotor agitation occurred in a woman taking propafenone when her dose of sustained-release venlafaxine was increased from 75 mg daily to 150 mg daily.[4]

The reasons for the interaction are not known, but venlafaxine is partly metabolised by CYP2D6 and propafenone is an inhibitor of this isoenzyme. However, this mechanism usually results in a decrease in *O*-desmethylvenlafaxine levels, and is usually of no clinical consequence, see 'SNRIs; Venlafaxine + Miscellaneous', p.1479. Information is limited to these two case reports, and their general significance is unclear.

SNRIs + St John's wort (*Hypericum perforatum*)

Serotonin syndrome has been reported in one patient taking venlafaxine and St John's wort.

Clinical evidence

An interaction between **venlafaxine** and St John's wort was reported to the Centre Régional de Pharmacovigilance de Marseille involving a 32-year-old man who had been taking **venlafaxine** 250 mg daily for several months. He started taking St John's wort at a dose of 200 drops 3 times daily (usual dose up to 160 drops daily) and on the third day felt faint and anxious, and had symptoms of diaphoresis, shivering and tachycardia. The St John's wort was stopped and his symptoms resolved in 3 days without altering the dose of **venlafaxine**.[1] A search of Health Canada's database of spontaneous adverse reactions for the period 1998 to 2003 also found one case of suspected serotonin syndrome as a result of an interaction between **venlafaxine** and St John's wort.[2]

Mechanism

A pharmacodynamic interaction may occur between St John's wort and venlafaxine because they can both inhibit the reuptake of 5-hydroxytryptamine (serotonin). Serotonin syndrome has been seen with St John's wort alone,[3] and so additive serotonergic effects appear to be the explanation for what occurred in the cases described here. For more information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Importance and management

Information appears to be limited to these reports. **Duloxetine** would be expected to interact similarly and the manufacturers of both duloxetine and venlafaxine advise caution if they are given with drugs that affect the serotonergic neurotransmitter systems,[4] including St John's wort.[5-7] This is probably prudent.

SNRIs + SSRIs

Fluvoxamine markedly increases duloxetine levels. Paroxetine causes a more modest increase in the AUC of duloxetine: fluoxetine is predicted to interact similarly. The pharmacokinetics of milnacipran do not appear to be altered by fluoxetine.

The concurrent use of the SNRIs and SSRIs may increase the risk of the serotonin syndrome. Concurrent use has also led to adverse effects such as blurred vision, constipation, and rarely, bleeding events or hypomania.

Clinical evidence

(a) Duloxetine

The manufacturers report that, in 14 subjects **fluvoxamine** 100 mg daily increased the AUC of duloxetine sixfold, and decreased its clearance by about 77%.[1,2] Similar increases in duloxetine plasma levels were found in 15 healthy subjects (who were known CYP2D6 poor metabolisers, i.e. those lacking in this isoenzyme) when they were given **fluvoxamine** 50 to 100 mg daily and duloxetine 40 mg twice daily.[2,3] In healthy subjects, the concurrent use of **paroxetine** 20 mg daily and duloxetine 40 mg daily increased the AUC of duloxetine at steady state by about 60%.[4]

(b) Milnacipran

In a pharmacokinetic study in 12 healthy subjects, milnacipran 50 mg twice daily for seven doses was given alone and then immediately after **fluoxetine** 20 mg daily for 3 weeks. There was no difference in the maximum and minimum levels of milnacipran when given after **fluoxetine**, and the 90% confidence intervals of the other pharmacokinetic parameters were within the 20% range (not clinically relevant). In this small study in healthy subjects, no difference in adverse events was detected when the drugs were used together.[5]

Fluoxetine has a very long half-life, and this study simulated the situation where **fluoxetine** is stopped and milnacipran started without a washout period.

(c) Venlafaxine

1. Antimuscarinic adverse effects. A woman taking **fluoxetine** 20 mg and clonazepam 1 mg daily developed blurred vision, dry mouth, constipation, dizziness, insomnia and a hand tremor within a week of starting to take venlafaxine 37.5 mg daily. These symptoms worsened by the second week and persisted until the venlafaxine was stopped.[6-8] Several other patients (aged between 21 and 70 years) taking **fluoxetine** developed antimuscarinic adverse effects (including constipation, blurred vision, urinary retention or dry mouth) within 2 to 10 days of starting venlafaxine.[7-9] One patient that only developed urinary retention had some prostate enlargement and had previously had some moderate urinary problems while taking **fluoxetine** and nortriptyline.[7,9]

2. Haemorrhages. A 60-year-old man experienced haemorrhages from his nose and rectum one week after venlafaxine 150 mg daily and mirtazapine 15 mg daily were given with **escitalopram** 20 mg daily. The bleeding progressively worsened during the following 3 weeks and then the patient reduced the doses to **escitalopram** 15 mg, mirtazapine 7.5 mg and venlafaxine 100 mg daily, and the bleeding decreased over the following week. He continued weekly tapering of the medications and the bleeding progressively decreased until it stopped when the doses were **escitalopram**

5 mg, mirtazapine 7.5 mg and venlafaxine 37.5 mg daily. Previous treatments with these three drugs used alone had not caused haemorrhages.[10] Note that SSRIs and SNRIs alone have been associated with bleeding events.

3. Hypomania. A 31-year-old woman with recurrent unipolar depression developed a hypomanic episode the day after **paroxetine** 20 mg daily was stopped and venlafaxine 75 mg daily stated. The hypomania subsided as the dose of venlafaxine was gradually reduced to 18.75 mg daily.[11]

4. Serotonin syndrome. A 21-year-old woman whose long-term treatment with **paroxetine** was stopped a week before starting venlafaxine (37.5 mg daily for 5 days then 75 mg daily for 2 days) developed vomiting, dizziness, incoordination, anxiety and electric shock sensations in her arms and legs within 3 days of starting venlafaxine. She stopped venlafaxine after 7 days of treatment, but symptoms persisted for 5 days until she was treated with cyproheptadine.[12]

Other similar cases resulting in the serotonin syndrome have been reported in a 75-year-old man who stopped **sertraline** and started venlafaxine 48 hours later, although symptoms took 14 days to develop,[13] and in a 39-year-old woman, who stopped **fluoxetine** and started venlafaxine.[14] This patient was also taking trazodone. Further reports of the serotonin syndrome have been described in patients taking venlafaxine with 'amitriptyline', (p.1512), or 'sertraline and bupropion', (p.1482). or 'fluoxetine, trazodone and buspirone', (p.1480).

Mechanism

Duloxetine is metabolised principally by the cytochrome P450 isoenzyme CYP1A2, but also by CYP2D6. Fluvoxamine is a potent inhibitor of CYP1A2 and paroxetine is a moderate inhibitor of CYP2D6. Therefore the concurrent use of these SSRIs decreases duloxetine metabolism and raises its levels. Similarly, venlafaxine is metabolised, in part, by CYP2D6, which fluoxetine moderately inhibits. Concurrent use may therefore increase venlafaxine levels, leading to some of the adverse effects described in the cases. Paroxetine probably interacts similarly.

The case of bleeding, was thought to be due to the combined drugs causing high levels of serotonin

Importance and management

Although the clinical relevance of the increases in duloxetine levels with fluvoxamine have not been assessed, the manufacturer considers that the rise with fluvoxamine is so marked that the combination should be avoided.[1,2] This seems a prudent precaution. The rise in duloxetine levels with paroxetine 20 mg daily is probably not clinically relevant, but the US manufacturer notes that greater increases would be expected with higher doses.[2] Other SSRIs (notably fluoxetine) also inhibit this isoenzyme, and would therefore be expected to interact similarly.

Information about the adverse antimuscarinic adverse effects due to an interaction between fluoxetine and venlafaxine seems to be limited to the reports cited, all by the same author. The incidence is not known, but if venlafaxine and fluoxetine are given concurrently, be alert for any evidence of increased antimuscarinic adverse effects (such as dry mouth, blurred vision and urinary retention). It may be necessary to withdraw one or other of the two drugs.

There appear to be few case reports describing the serotonin syndrome in patients given an SSRI and an SNRI. However, in general, concurrent use should be undertaken with caution, as both classes of drug affect serotonin, and increased serotonin levels can precipitate the serotonin syndrome. For more information on the risks and management of this syndrome, see under 'Additive or synergistic interactions', (p.9).

SNRIs; Duloxetine + Miscellaneous

Ciprofloxacin and enoxacin are predicted to markedly raise duloxetine levels, and quinidine is predicted to modestly raise duloxetine levels. Duloxetine is predicted to raise the levels of flecainide, metoprolol, risperidone and thioridazine. The absorption of duloxetine is not affected by antacids. Smoking may slightly reduce duloxetine exposure.

Due to the theoretical risk of serotonin syndrome, the manufacturers of duloxetine recommend caution with other serotonergic drugs.

Clinical evidence, mechanism, importance and management

(a) Antacids

Aluminium/**magnesium**-containing antacids had no effect on the rate or extent of absorption of a single 40-mg dose of duloxetine.[1-3] Duloxetine is formulated with a gastric-resistant coating, but this finding suggests that antacids do not lead to an earlier release of duloxetine.[3] No separation of administration would appear to be necessary on concurrent use.

(b) CYP1A2

1. Inducers. Population pharmacokinetic studies have shown that **smokers** have almost 50% lower plasma concentrations of duloxetine, when compared with **non-smokers**,[1] or a 33% lower AUC.[3] The clinical significance of these findings has not been evaluated, but is probably minor. The US manufacturer of duloxetine specifically states that dosage modifications are not recommended for smokers.[3]

2. Inhibitors. Fluvoxamine, a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, markedly increases duloxetine levels (see 'SNRIs + SSRIs', p.1475). The manufacturers of duloxetine predict that some **quinolones** (they name **ciprofloxacin** and **enoxacin**) will have the same effect, and suggest that their concurrent use with duloxetine should be avoided.[1-3] This seems a prudent precaution. For a list of clinically significant CYP1A2 inhibitors, see 'Table 1.2', (p.4).

(c) CYP2D6

1. Inhibitors. Paroxetine, an inhibitor of the cytochrome P450 isoenzyme CYP2D6, modestly increases duloxetine levels (see 'SNRIs + SSRIs', p.1475). The US manufacturer of duloxetine suggests that other CYP2D6 inhibitors will interact similarly, and specifically names **quinidine**.[3] The clinical relevance of any interaction is unknown, but probably minor. For a list of clinically significant CYP2D6 inhibitors, see 'Table 1.3', (p.6).

2. Substrates. Based on data for 'tolterodine', (p.1544), and 'desipramine', (p.1512), duloxetine is a moderate inhibitor of the cytochrome P450 isoenzyme CYP2D6. The manufacturers of duloxetine therefore advise caution if duloxetine is given with drugs that are predominantly metabolised by CYP2D6 and have a narrow therapeutic index,[1-3] including **flecainide**,[1-3] **risperidone**[1,2] and **metoprolol**.[1,2] Use with **thioridazine** (withdrawn in the UK) is contraindicated in the US because of the risk of arrhythmias with elevated levels of this drug.[3] CYP2D6 shows genetic polymorphism, and inhibition of this isoenzyme turns extensive metabolisers (i.e. those with normal levels of this isoenzyme) into poor metabolisers (i.e. those lacking this isoenzyme). The situation when inhibition of CYP2D6 metabolism is likely to matter most is when a patient stable taking a CYP2D6 substrate is then given duloxetine.

(d) Serotonergic drugs

Because the concurrent use of more than one serotonergic drug has rarely resulted in serotonin syndrome the manufacturer of duloxetine advises caution if duloxetine is used with other SNRIs (**venlafaxine**),[1-3] **lithium**,[3] **tramadol**,[1-3] and **pethidine**.[1,2] Use with serotonin precursors such as **tryptophan** should be undertaken with caution,[1,2] or avoided.[3] For more

information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

1. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, July 2009.
2. Yentreve (Duloxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, July 2009.
3. Cymbalta (Duloxetine hydrochloride). Eli Lilly and Company. US Prescribing information, February 2009.

SNRIs; Milnacipran + Miscellaneous

The manufacturers of milnacipran contraindicate its use with digitalis glycosides and MAO-B inhibitors such as selegiline and rasagiline. They also warn against concurrent use with clonidine and sympathomimetics such as adrenaline (epinephrine) or noradrenaline (norepinephrine). They suggest careful monitoring with lithium because of the risk of serotonin syndrome.

Clinical evidence, mechanism, importance and management

(a) Cardiovascular drugs

1. Clonidine. The manufacturer of milnacipran advises against the use of milnacipran with clonidine or related drugs because milnacipran might reduce the antihypertensive action of clonidine due to antagonism at the adrenergic receptors, in a way analogous to the tricyclic antidepressants (see 'Clonidine and related drugs + Tricyclic and related antidepressants', p.1054.[1]

Note that this caution is not given for the other available SNRIs, duloxetine and venlafaxine.

2. Digitalis glycosides. The manufacturer of milnacipran contraindicates its use with digitalis glycosides (such as digoxin) because of the risk of potentiating haemodynamic effects, particularly when given parenterally.[1]

3. Inotropes and Vasopressors. The manufacturer of milnacipran advises against the concurrent use of parenteral adrenaline (epinephrine) or noradrenaline (norepinephrine) because of the possible risk of hypertensive crisis with cardiac arrhythmias. This is because milnacipran inhibits noradrenaline re-uptake, see also 'Tricyclic and related antidepressants + Inotropes and Vasopressors', p.1507. They also advise caution if adrenaline or noradrenaline are used as vasoconstrictors in subcutaneous or gingival injections. In this case they recommend that, in adults, the dose of adrenaline should be limited to less than 100 micrograms in 10 minutes or 300 micrograms in one hour.[1]

Note that this caution is not given for the other available SNRIs, duloxetine and venlafaxine.

(b) Lithium

The manufacturer of milnacipran recommends regular clinical monitoring if milnacipran is given with lithium, because of the risk of serotonin syndrome.[1] Cases of serotonin syndrome have been reported with lithium and the SNRI, venlafaxine, see 'Lithium + Venlafaxine', p.1368.

(c) MAO-B inhibitors

The manufacturer of milnacipran contraindicates its use with selective monoamine oxidase type B inhibitors (selegiline and rasagiline) because of the risk of hypertensive crisis. They say that there should be 2 weeks between stopping the MAO-B inhibitor and starting milnacipran and at least one week between stopping milnacipran and starting the MAO-B inhibitor.[1] Note that, the more usual concern with the use of these drugs is the risk of serotonin syndrome, see 'MAO-B inhibitors + SSRIs or SNRIs', p.808.

1. Ixel (Milnacipran). Pierre Fabre Médicament. French Summary of product characteristics, February 2003.

SNRIs; Venlafaxine + Antihypertensives

A case report describes a patient taking captopril who developed hypertension when venlafaxine was started. Venlafaxine alone can cause sustained hypertension.

Clinical evidence, mechanism, importance and management

A 53-year-old woman who had her blood pressure well-controlled (130/80 mmHg) while taking **captopril** 25 mg daily and on a low-salt diet was found to have had an increase in her arterial blood pressure to 180/110 mmHg after she started taking venlafaxine (25 mg daily titrated to 100 mg daily) for depression. It was suggested that the effects of venlafaxine on noradrenaline might have antagonised the efficacy of **captopril**.[1]

Venlafaxine alone commonly causes dose-related hypertension, which can be sustained. The manufacturers advise that venlafaxine should be avoided in patients with uncontrolled hypertension, and that blood pressure should be monitored in all patients receiving venlafaxine. If sustained increases in blood pressure occur, consider reducing the venlafaxine dose, or discontinuing it.[2,3]

2. Efexor (Venlafaxine hydrochloride). Wyeth Pharmaceuticals. UK Summary of product characteristics, March 2008.
3. Effexor XR (Venlafaxine hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, July 2009.

SNRIs; Venlafaxine + Atomoxetine

A case report describes dyskinesia and dysarthria associated with the concurrent use of venlafaxine and atomoxetine.

Clinical evidence, mechanism, importance and management

An 18-year-old woman with attention deficit hyperactivity disorder, panic attacks and generalised anxiety was given venlafaxine, initially 37.5 mg daily, increasing to 225 mg daily, to which atomoxetine 18 mg daily was added. The atomoxetine dose was subsequently increased to 40 mg daily. After 3 weeks of concurrent use (and 5 days after the last dose increase) she presented with tremors, abnormal facial movements and a speech disturbance, which resolved after both medications were discontinued. It was suggested that a pharmacodynamic interaction, resulting from excess synaptic noradrenaline, might have occurred. Furthermore, the patient was a poor metaboliser of CYP2D6 (meaning she lacked or had low levels of this isoenzyme), and it was suggested that a pharmacokinetic interaction might also have occurred;[1] both drugs are substrates for CYP2D6. The manufacturer recommends caution when atomoxetine is given with other drugs that affect noradrenaline, because of the potential for additive or synergistic pharmacological effects.[2] Although this is an isolated case it adds weight to the manufacturers caution. Bear these symptoms in mind if both drugs are given, and consider an interaction if they occur.

2. Strattera (Atomoxetine hydrochloride). Eli Lilly and Company Ltd. UK Summary of product characteristics, May 2009.

SNRIs; Venlafaxine + Bupropion

Bupropion may increase venlafaxine plasma levels, and decrease those of its active metabolite.

Clinical evidence

Bupropion increased trough venlafaxine plasma levels about 2.5-fold and decreased trough levels of the active metabolite, *O*-desmethylvenlafaxine, about 2.3-fold in 7 patients who had been given venlafaxine alone for a minimum of 6 weeks and then with sustained-release bupropion 150 mg daily for a further 8 weeks.[1]

Mechanism

Bupropion is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is responsible for the metabolism of venlafaxine to *O*-desmethylvenlafaxine.

Importance and management

The clinical relevance of this pharmacokinetic interaction has not been assessed. However, because venlafaxine and *O*-desmethylvenlafaxine are considered equipotent as antidepressants, any change in their ratio should not affect clinical efficacy.[2] About 10% of Caucasians are lacking in active CYP2D6 (poor metabolisers), and what bupropion is effectively

doing is changing extensive metabolisers (those with normal levels of CYP2D6) into poor metabolisers.

For a report of worsening symptoms of serotonin syndrome when venlafaxine was given with bupropion and sertraline, see 'SSRIs + Bupropion', p.1482.

2. Effexor XR (Venlafaxine hydrochloride). Wyeth Pharmaceuticals Inc. US Prescribing information, July 2009.

SNRIs; Venlafaxine + Co-amoxiclav

An isolated case of serotonin syndrome has been attributed to the concurrent use of venlafaxine and co-amoxiclav.

Clinical evidence, mechanism, importance and management

A 56-year-old man taking venlafaxine 37.5 mg twice daily for 10 months was given a course of co-amoxiclav (**amoxicillin** with **clavulanate**) 375 mg three times daily to treat gingivitis and a dental abscess. Within 3 hours of a dose of co-amoxiclav he developed tingling in the tip of his tongue, intense paraesthesia in the fingers, severe abdominal cramps, profuse diarrhoea, cold sweats, tremor and uncontrollable shivering. He was also agitated and frightened, but not confused. The symptoms lasted for 6 hours and were initially assumed to be due to gastroenteritis. However, 2 months later while still taking venlafaxine, he developed identical symptoms after a single dose of co-amoxiclav, which was then diagnosed as serotonin syndrome. The patient had taken co-amoxiclav without problem when not taking venlafaxine, and after the second episode, continued venlafaxine without further episodes of serotonin syndrome.[1]

The mechanism for this interaction is unclear. It is probable that many patients have received both venlafaxine and co-amoxiclav without adverse effects, so the general importance of this isolated report is unknown, but it seems likely to be small.

1. Connor H. Serotonin syndrome after single doses of co-amoxiclav during treatment with venlafaxine. *J R Soc Med* (2003) 96, 233–4.

SNRIs; Venlafaxine + Dexamfetamine

An isolated case of serotonin syndrome has been attributed to the concurrent use of dexamfetamine and venlafaxine.

Clinical evidence, mechanism, importance and management

A 32-year-old patient taking dexamfetamine 5 mg three times daily for adult attention deficit hyperactivity disorder (ADHD) presented with marked agitation, anxiety, shivering and tremor 2 weeks after also starting to take venlafaxine 75 mg to 150 mg daily. Other symptoms included generalised hypertonia, hyperreflexia, frequent myoclonic jerking, tonic spasm of the orbicularis oris muscle, and sinus tachycardia. His symptoms resolved completely when both drugs were withdrawn and cyproheptadine, to a total dose of 32 mg over 3 hours, was given. Dexamfetamine was restarted after 3 days.[1] This patient had a second episode of serotonin syndrome when citalopram was given with the dexamfetamine, see 'SSRIs + Nasal decongestants', p.1487.

It was suggested that the combination of serotonin re-uptake blockade and either presynaptic release of serotonin or monoamine oxidase inhibition by dexamfetamine could cause increased serotonin in the CNS.

Caution is advised when dexamfetamine is given with venlafaxine.[1] For more information about the serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

SNRIs; Venlafaxine + Disulfiram

An isolated case describes a hypertensive crisis associated with the use of venlafaxine and disulfiram.

Clinical evidence, mechanism, importance and management

An isolated report describes a hypertensive crisis associated with a low dose of venlafaxine (75 mg daily). It was suggested that the concurrent use of disulfiram might have increased the toxicity of venlafaxine by interfering with its metabolism by the cytochrome P450 isoenzyme CYP3A4. However, disulfiram predominantly inhibits CYP2E1 and has not been reported to significantly affect CYP3A4. Note that disulfiram may provoke hypertension through its interaction with alcohol; however the authors state they found no evidence of a reaction with alcohol in this patient.[1] This is an isolated and unexplained case, its general significance is therefore probably small.

SNRIs; Venlafaxine + Jujube (*Ziziphus jujuba*)

An isolated report describes an acute serotonin reaction when venlafaxine was given with a Chinese herbal remedy, jujube (sour date nut).

Clinical evidence, mechanism, importance and management

A 40-year-old woman with intermittent depression took jujube 500 mg daily (**sour date nut**; **suanzaoren**; *Ziziphus jujuba*), prescribed by a traditional Chinese healer, for several weeks, with minor improvement. She was then prescribed venlafaxine 37.5 mg daily by a psychiatrist, but approximately one hour after taking the first dose of venlafaxine with the jujube she became agitated, restless, nauseated, dizzy and ataxic, and subsequently collapsed. She had symptoms of a severe acute serotonin reaction with some anaphylactic features, which improved over the following 8 hours. She stopped taking the jujube and subsequently took venlafaxine 150 mg daily for one month without adverse effects.[1] This highlights the need for physicians to ask patients about the use of herbal medicines and to advise their discontinuation before prescribing other drugs if there is any possibility of an interaction.

SNRIs; Venlafaxine + Ketoconazole

Ketoconazole modestly inhibits the metabolism of venlafaxine and its active metabolite in patients with normal levels of CYP2D6 (extensive metabolisers). In about half the patients with low levels of CYP2D6 (poor metabolisers), marked increases in the levels of venlafaxine and its active metabolite were seen.

Clinical evidence

In one study in 14 patients with normal levels of CYP2D6 (extensive metabolisers), **ketoconazole** 100 mg twice daily for 2 days increased the plasma levels of venlafaxine and *O*-desmethylvenlafaxine (AUCs increased by 21% and 23%, respectively) when a single dose of venlafaxine given on day 2. However, in 6 poor metabolisers (i.e. those lacking CYP2D6) , the response was erratic with 3 out of 6 displaying marked increases in venlafaxine AUC (81%,126% and 206%, respectively) and the other 3 showing little or no change.[1] In these 6 subjects, the mean increase was 70%, and the AUC of *O*-desmethylvenlafaxine was also increased (mean 33%).[1,2]

Mechanism

The cytochrome P450 isoenzyme CYP3A4 metabolises venlafaxine to the inactive metabolite *N*-desmethylvenlafaxine. This metabolic route is minor in comparison to the metabolism of venlafaxine to O-desmethylvenlafaxine by CYP2D6, but it may assume more importance if CYP2D6 is lacking.[3]

Importance and management

The clinical relevance of these pharmacokinetic changes has not been assessed. However, the modest increases in both venlafaxine and its active metabolite (which have equipotent activity) in extensive metabolisers are probably unlikely to be clinically relevant. However, the marked increases

in the levels of venlafaxine and its active metabolite in poor metabolisers are of more concern. Because CYP2D6 metaboliser status is usually unknown, the manufacturers therefore advise caution with potent CYP3A4 inhibitors (they name **ketoconazole** and **erythromycin**).[2,3] The UK manufacturer also cautions that drug combinations that inhibit both CYP3A4 and CYP2D6 (see under CYP2D6 inhibitors in 'SNRIs; Venlafaxine + Miscellaneous', below), should only be given with venlafaxine if strictly indicated.[3] This seems prudent, as this situation is analogous to giving a CYP3A4 inhibitor to a known CYP2D6 poor metaboliser.

SNRIs; Venlafaxine + Metoclopramide

An isolated case of serotonin syndrome has been attributed to the concurrent use of metoclopramide and venlafaxine.

Clinical evidence, mechanism, importance and management

A 32-year-old woman with depression who had been taking venlafaxine 225 mg daily in divided doses for 3 years was admitted to hospital after a fall. She developed a movement disorder and a period of unresponsiveness after having been given a 10-mg intravenous dose of metoclopramide. After a second dose of metoclopramide the symptoms recurred and were associated with confusion, agitation, fever, diaphoresis, tachypnoea, tachycardia, and hypertension. The symptoms were consistent with serotonin syndrome, with a serious extrapyramidal movement disorder. The venlafaxine was withheld and she was given diazepam. The symptoms resolved over the next two days, after which she continued to take venlafaxine.[1] Information seems to be limited to this report, and the general significance of this interaction is unclear.

1. Fisher AA, Davis MW. Serotonin syndrome caused by selective serotonin reuptake-inhibitors–metoclopramide interaction. *Ann Pharmacother* (2002) 36, 67–71.

SNRIs; Venlafaxine + Mirtazapine

Isolated cases of serotonin syndrome have been reported in patients taking venlafaxine with mirtazapine.

Clinical evidence, mechanism, importance and management

The serotonin syndrome occurred in a patient given extended-release venlafaxine 75 mg daily and mirtazapine 30 mg daily, during cross-tapering of the two drugs (reducing mirtazapine dose and starting venlafaxine).[1] Another case occurred when tramadol was given to a patient taking venlafaxine and mirtazapine.[2]

For a report of haemorrhages associated with the use of mirtazapine, venlafaxine and escitalopram, see 'SNRIs + SSRIs', p.1475.

These isolated cases show that serotonin syndrome might occur with concurrent use of venlafaxine and mirtazapine. As this syndrome is potentially fatal, some caution is warranted if both drugs are given. For more information about the serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

2. Houlihan DJ. Serotonin syndrome resulting from coadministration of tramadol, venlafaxine, and mirtazapine. *Ann Pharmacother* (2004) 38, 411–13.

SNRIs; Venlafaxine + Miscellaneous

The metabolism of venlafaxine to its active metabolite is inhibited by CYP2D6 inhibitors such as diphenhydramine, melperone, and thioridazine, but as venlafaxine and its active metabolite are equipotent, this is not considered clinically relevant. Venlafaxine modestly inhibits the metabolism of dextromethorphan, a CYP2D6 substrate.

Clinical evidence, mechanism, importance and management

(a) CYP2D6 inhibitors

Venlafaxine is primarily metabolised to its active metabolite *O*-desmethylvenlafaxine by the cytochrome P450 isoenzyme CYP2D6.[1,2] Pharmacokinetic studies show that the metabolism of venlafaxine is reduced by the CYP2D6 inhibitors **diphenhydramine**,[3] **melperone**,[4] and bupropion (see 'SNRIs; Venlafaxine + Bupropion', p.1477) in patients who are CYP2D6 extensive metabolisers (i.e. have normal levels of this isoenzyme).[3] However, the concurrent use of these inhibitors with venlafaxine would produce plasma levels of venlafaxine similar to those seen in patients who are genetically CYP2D6 poor metabolisers (about 5 to 10% of the general population), and venlafaxine and *O*-desmethylvenlafaxine are equipotent, therefore no dosage adjustment is necessary.[2] Venlafaxine is also metabolised by CYP3A4 (see 'SNRIs; Venlafaxine + Ketoconazole', p.1478, and this metabolic pathway becomes more important when CYP2D6 is inhibited. Therefore, the UK manufacturer recommends that venlafaxine should only be used with both a CYP2D6 inhibitor and a CYP3A4 inhibitor if strictly indicated.[1]

(b) CYP2D6 substrates

In a pharmacokinetic study in 26 healthy subjects, venlafaxine, titrated to 75 mg twice daily for 4 weeks modestly inhibited the metabolism of a single 30-mg dose of **dextromethorphan**, as assessed by the molar ratio of dextromethorphan to dextrorphan in urine.[5] In another similar study venlafaxine titrated to 75 mg twice daily for 8 days did not affect the metabolism of **dextromethorphan**.[6] This suggests that venlafaxine has a minor to modest ability to inhibit the cytochrome P450 isoenzyme CYP2D6, and is generally unlikely to have a clinically relevant pharmacokinetic interaction with most CYP2D6 substrates.

A case study reports higher than expected trough plasma levels of venlafaxine and lower than expected levels of *O*-desmethylvenlafaxine in a patient also taking **propranolol** and **mianserin** amongst other drugs.[7] The authors suggested that these drugs might have competitively inhibited the metabolism of venlafaxine by CYP2D6. However, neither of these drugs is known to inhibit CYP2D6, and, although they are both substrates for CYP2D6, combining substrates of an isoenzyme is not usually known to cause clinically relevant pharmacokinetic interactions. Moreover, the addition of the CYP2D6 inhibitor **thioridazine** further increased the venlafaxine levels in this case, suggesting that CYP2D6 was available for inhibition. Even if a pharmacokinetic interaction with propranolol or mianserin were to be confirmed, as mentioned above, an alteration in the ratio of venlafaxine to *O*-desmethylvenlafaxine is not considered clinically relevant.

SNRIs; Venlafaxine + Orphenadrine

An acute cutaneous reaction occurred on two occasions when a woman taking venlafaxine took orphenadrine with paracetamol.

Clinical evidence

A 55-year-old woman, who had been taking extended-release venlafaxine 225 mg daily for about 5 months, developed an extensive rash (diffuse and erythematous) accompanied by pruritus, sweating, hot flushes and agitation. The reaction was initially attributed to the extended-release venlafaxine, and the patient was switched to immediate-release venlafaxine 150 mg day, which she had received in the past without problems. However, 3 months later she presented with a less severe case of the cutaneous

reaction, and it transpired that she had taken a non-prescription product containing orphenadrine 35 mg and paracetamol 450 mg on both occasions.[1]

Mechanism

Results of skin testing suggested that the adverse effect was not a type I hypersensitivity reaction to orphenadrine or paracetamol. Early *in vitro* data for orphenadrine suggests that it can inhibit the cytochrome P450 isoenzymes CYP2D6 and CYP3A4, and the authors thought that combined inhibition of these enzymes may have been responsible. This seems possible, see 'SNRIs; Venlafaxine + Miscellaneous', p.1479.

Importance and management

Evidence for an interaction between venlafaxine and orphenadrine is limited, and no general precautions can be issued on the basis of a single case report. Nevertheless, bear the possibility of an interaction in mind in the event of an adverse reaction to the concurrent use of these two drugs.

SNRIs; Venlafaxine + Sibutramine

The use of venlafaxine with sibutramine may lead to serotonin syndrome.

Clinical evidence, mechanism, importance and management

A letter mentions a case of serotonin syndrome, that developed in a woman given venlafaxine and sibutramine (no further details given), both of which are serotonergic drugs.[1] The UK and US manufacturers of venlafaxine and sibutramine caution against its use with other serotonergic drugs,[2-5] but in addition, the UK manufacturer of venlafaxine specifically advises against its use with weight loss drugs.[2] The manufacturers of sibutramine say that it should not be given with other serotonergic drugs.[4,5]

Note that reports of serotonin syndrome are generally rare. If both drugs are given together it would seem prudent to monitor the outcome closely. For more information about serotonin syndrome and its management, see under 'Additive or synergistic interactions', (p.9).

SNRIs; Venlafaxine + Terbinafine

The metabolism of venlafaxine to its active metabolite *O*-desmethylvenlafaxine is reduced in the presence of terbinafine.

Clinical evidence

In a randomised, crossover study, 12 healthy subjects were given a single 75-mg dose of venlafaxine, alone or after taking terbinafine 250 mg daily for 4 days. The AUC and maximum plasma concentration of venlafaxine were increased 4.9-fold and 2.7-fold, respectively, and the half-life of venlafaxine was also increased from 5.1 hours to 8.6 hours. The AUC and maximum plasma concentration of the active metabolite of venlafaxine, *O*-desmethylvenlafaxine, were reduced by 43% and 67%, respectively, and the half-life of this metabolite was almost doubled.[1]

Mechanism

Terbinafine inhibits the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of venlafaxine to *O*-desmethylvenlafaxine.

Importance and management

This appears to be the only study of this interaction and its clinical significance is unclear: both venlafaxine and *O*-desmethylvenlafaxine are active compounds, and their combined AUC was only raised by a modest 22%. Furthermore, this was a single dose study, and so could not assess the potential for venlafaxine accumulation in the presence of terbinafine. Until more is known, it may be prudent to be alert for any indication of increased venlafaxine adverse effects (e.g. nausea, insomnia, dry mouth) in patients also taking terbinafine.

SNRIs; Venlafaxine + Tramadol

Two cases of serotonin syndrome have been reported when tramadol was given with venlafaxine; one patient was also receiving mirtazapine. Fatal seizures occurred in an alcoholic man receiving a number of drugs, including tramadol and venlafaxine.

Clinical evidence, mechanism, importance and management

A 47-year-old man who had been stable taking venlafaxine 300 mg daily and mirtazapine 30 mg daily for 4 months was given tramadol, titrated to 300 mg daily over 4 weeks, without adverse effects. However, about 7 weeks after increasing the dose of tramadol to 400 mg daily he experienced agitation, confusion, severe shivering, diaphoresis, myoclonus, hyperreflexia, mydriasis, and tachycardia. His symptoms resolved over 36 hours after all medications were discontinued and did not recur when venlafaxine and mirtazapine were restarted without tramadol.[1] A 65-year-old woman who had been taking venlafaxine 100 mg daily for 3 weeks, developed symptoms of serotonin syndrome 3 days after tramadol 300 mg daily was started. The symptoms resolved completely 3 days after venlafaxine withdrawal, when tramadol was also withdrawn. No symptoms occurred on rechallenge with venlafaxine alone, 2 weeks later.[2]

A 36-year-old alcoholic died after developing seizures while taking tramadol and several other drugs, including venlafaxine, trazodone and quetiapine, all of which interact with the neurotransmitter serotonin. It was thought that the combination of these drugs and alcohol withdrawal lowered the seizure threshold.[3]

Although these reports are isolated, based on the known mechanism of action of venlafaxine and its potential for 'serotonin syndrome', (p.9), some caution might be appropriate when venlafaxine is used with other drugs that may affect the serotonergic neurotransmitter systems such as tramadol.

3. Ripple MG, Pestaner JP, Levine BS, Smialek JE. Lethal combination of tramadol and multiple drugs affecting serotonin. *Am J Forensic Med Pathol* (2000) 21, 370–4.

SNRIs; Venlafaxine + Trazodone

Isolated cases of serotonin syndrome have been reported in patients taking venlafaxine with trazodone.

Clinical evidence, mechanism, importance and management

A 50-year-old HIV-positive man, who was taking methadone for opioid dependence, developed signs of the serotonin syndrome 18 days after starting to take extended-release venlafaxine (dose increased to 225 mg daily over 7 days) and trazodone 100 mg at bedtime. His clinical status improved rapidly over 24 hours when all medications were discontinued. Serotonin syndrome was thought to have been precipitated by the combination of venlafaxine and trazodone, both of which inhibit the reuptake of serotonin, but methadone may have also been a contributing factor. The patient was not taking any concurrent medication for his HIV infection.[1]

In another report, a 69-year-old woman with major depression failed to respond to monotherapy with various drugs and was then given fluoxetine, trazodone, buspirone and zolpidem. After a partial response at 2 months, she was additionally given venlafaxine 37.5 mg twice daily. On the next day she developed fever, tremor, muscle cramping, diarrhoea, ataxia, irri-

tability, and altered consciousness, which was interpreted as serotonin syndrome. She was admitted, all medication was withdrawn, and the symptoms gradually resolved over 3 days. She then developed a full-blown manic episode.[2] Fluoxetine is known to have serotonergic effects, and may have contributed to the development of serotonin syndrome in this case.

For a case of serotonin syndrome in a patient taking trazodone, that developed when venlafaxine was abruptly switched for fluoxetine, see 'SNRIs + SSRIs', p.1475.

These isolated cases show that serotonin syndrome might occur with concurrent use of venlafaxine and trazodone. Serotonin syndrome is a rare adverse effects, but because of its severity, some caution is warranted if both drugs are given. For more about serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

2. Liau C-H, Shen WW, Su K-P. Venlafaxine-associated serotonin syndrome and manic episode in a geriatric depressive patient. *Psychiatry Clin Neurosci* (2006) 60, 121–2.

SSRIs + Ayahuasca

A man taking fluoxetine experienced symptoms of serotonin syndrome after drinking the psychoactive beverage ayahuasca, which contains monoamine oxidase-inhibiting harmala alkaloids.

Clinical evidence, mechanism, importance and management

A 36-year-old man who was taking **fluoxetine** 20 mg daily for mild depression participated in a religious ceremony using ayahuasca (also known as caapi, daime, hoasca, natema, yage) which is a psychoactive beverage characteristically containing harmala alkaloids (primarily harmine and harmaline) derived from the vine *Banisteriopsis caapi*. One hour after drinking 100 mL of ayahuasca he experienced tremors, sweating, shivering and confusion. His condition deteriorated over the next few hours with gross motor tremors and severe nausea and vomiting, but he rapidly recovered 4 hours later, with no treatment.

The harmala alkaloids are capable of blocking the enzymatic activity of MAO for several hours, and consequently inhibit the metabolic breakdown of neurotransmitters. There is, therefore, the potential for serotonin syndrome to develop with the concurrent use of SSRIs and ayahuasca.[1]

1. Callaway JC, Grob CS. Ayahuasca preparations and serotonin reuptake inhibitors: a potential combination for severe adverse interactions. *J Psychoactive Drugs* (1998) 30, 367–9.

SSRIs + Azoles

Anorexia developed in a patient taking fluoxetine when itraconazole was started, and it disappeared when the itraconazole was stopped. Itraconazole modestly increases the AUC of paroxetine. The pharmacokinetics of citalopram (and therefore probably escitalopram) are not affected by ketoconazole.

Clinical evidence, mechanism, importance and management

(a) Citalopram or Escitalopram

In a placebo-controlled, single-dose, crossover study in 18 healthy subjects, **ketoconazole** 200 mg did not affect the pharmacokinetics of citalopram 40 mg.[1]

Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, which, in part, metabolises citalopram, but as several other cytochrome P450 isoenzymes are also involved in citalopram metabolism it would seem that inhibition of only one pathway does not result in clinically significant effects. Similarly, escitalopram (the *S*-isomer of citalopram), would also not be expected to be affected by **ketoconazole**, and this is supported by an *in vitro* study.[2]

No citalopram or escitalopram dosage adjustment is likely to be need if **ketoconazole** is also taken.

(b) Fluoxetine

A man taking fluoxetine 20 mg daily, diazepam and several anti-asthma drugs (salbutamol (albuterol), salmeterol, budesonide, theophylline) was given **itraconazole** 200 mg daily for allergic bronchopulmonary aspergillosis. Within 1 to 2 days he developed anorexia without nausea. He stopped the **itraconazole** after a week, and the anorexia resolved 1 to 2 days later.

The author of the report suggested that **itraconazole**, a potent enzyme inhibitor, increased the levels of the fluoxetine metabolite, norfluoxetine, which resulted in the anorexia.[3] Anorexia is a recognised adverse effect of fluoxetine. However, drug levels were not taken, so this suggestion has not been confirmed.

This report and the conclusions reached are uncertain, but they draw attention to the possibility of an interaction between fluoxetine and **itraconazole**. Consider this interaction if fluoxetine adverse effects are troublesome.

(c) Paroxetine

In a controlled study in healthy subjects, **itraconazole** 100 mg twice daily for 6 days increased the AUC of paroxetine by 55% when a single 20-mg dose of paroxetine was given on day 6. Paroxetine clearance was reduced by 36%, and there was a small 14% increase in its elimination half-life.[4]

Paroxetine is a substrate for the cytochrome P450 isoenzyme CYP2D6, but **itraconazole** is an inhibitor of CYP3A4, so an interaction as a result of inhibition of the cytochrome P450 isoenzyme system was discounted. It was suggested that itraconazole might have increased the bioavailability of paroxetine by inhibiting P-glycoprotein.[4]

An increase in the AUC of paroxetine of this magnitude is probably not likely to be clinically important in most patients. Bear the possibility of an interaction in mind in the event of an increase in adverse effects.

SSRIs + Barbiturates

Paroxetine appears not to increase the psychomotor effects of amobarbital. Phenobarbital may reduce the AUC of paroxetine. Two cases of hepatotoxicity have been reported when paroxetine was given with a barbiturate.

Clinical evidence, mechanism, importance and management

In a small study in 7 healthy subjects, **phenobarbital** 100 mg daily for 14 days caused reductions of 10 to 86% in the AUC of paroxetine in 6 subjects, and a 57% *increase* in one subject. Overall, the paroxetine AUC was reduced by 25% and the elimination half-life was reduced by 38%, although these differences were not statistically significant.[1]

Phenobarbital is a well-known enzyme inducer, and these data suggest that it might reduce the levels of paroxetine in some patients, but the clinical relevance of the changes seen is uncertain. Bear the possibility of a pharmacokinetic interaction in mind if the efficacy of paroxetine is reduced on starting phenobarbital, and adjust the paroxetine dose as necessary.

The sedative effects and impairment of psychomotor performance caused by **amobarbital** 100 mg were not increased by paroxetine 30 mg.[2] This suggests that no adverse pharmacodynamic interaction occurs.

Two cases of hepatitis in young women were considered to be caused by the concurrent use of *Atrium* (a barbiturate complex) and paroxetine, which are both rarely associated with hepatotoxicity.[3] The relevance of these cases is uncertain.

Note that the SSRIs can cause seizures and so they should be used with caution in patients given barbiturates for epilepsy. This warning is emphasised by an isolated report describing a tonic clonic seizure in a woman taking paroxetine who was anaesthetised with methohexital. See 'Anaesthetics, general + SSRIs', p.117.

SSRIs + Bupropion

There are isolated reports of serotonin syndrome, hypersexuality, psychosis, mania and seizures associated with the use of bupropion and an SSRI. Bupropion modestly increases citalopram levels, but limited evidence suggests that the plasma levels of fluoxetine and paroxetine are not altered by bupropion.

Clinical evidence

(a) Citalopram

In a study in 28 healthy subjects, the addition of sustained-release bupropion 300 mg daily to citalopram 40 mg daily resulted in a 39% increase in the AUC of citalopram and a 30% increase in its maximum level.[1]

(b) Fluoxetine

Bupropion had no effect on trough fluoxetine or norfluoxetine levels in a study in 5 patients who had been given fluoxetine (dose not stated) alone for a minimum of 6 weeks and then also sustained-release bupropion 150 mg daily for a further 8 weeks.[2]

The day after stopping fluoxetine 60 mg daily, a 41-year-old man started taking bupropion 75 mg and later 100 mg three times daily. After 10 days he became edgy and anxious and after 12 days he developed myoclonus. After 14 days he became severely agitated and psychotic, with delirium and hallucinations. His behaviour returned to normal 6 days after the bupropion was stopped.[3] Another patient taking lithium carbonate for bipolar disorder developed anxiety, panic and eventually mania a little over a week after stopping fluoxetine and starting bupropion.[4]

A review briefly mentions an unpublished case of a patient who had a grand mal seizure after being given fluoxetine and bupropion 300 mg daily.[5]

A 35-year-old woman taking fluoxetine 40 mg daily was given low-dose bupropion (100 mg daily) to treat fluoxetine-induced sexual dysfunction. Despite a good initial response, hypersexuality developed, and so the bupropion was stopped.[6]

(c) Paroxetine

Bupropion had no effect on trough paroxetine levels in a study in 4 patients who had been given paroxetine alone for a minimum of 6 weeks and then also sustained-release bupropion 150 mg daily for a further 8 weeks.[2]

(d) Sertraline

A 62-year-old woman taking therapeutic doses of bupropion and sertraline experienced upper extremity tremor, clumsiness and gait difficulties, with fluctuating symptoms of confusion, forgetfulness, and alternating agitation and lethargy, which started after a few days on this regimen. **Venlafaxine** was then added and the clinical picture worsened with deterioration of mental status, hallucinations, insomnia, myoclonic jerks, postural and balance difficulties, incoordination and incontinence. The medications were discontinued and the symptoms, which were indicative of serotonin syndrome, gradually resolved.[7]

An isolated case describes spontaneous orgasm with the combined use of bupropion and sertraline. Bupropion had been successfully used to treat SSRI-induced impaired sexual function, but after 6 weeks of concurrent use she experienced a sudden-onset, spontaneous orgasm; this occurred again on rechallenge with bupropion.[8]

Mechanism

Several mechanisms have been proposed. Bupropion inhibits the cytochrome P450 isoenzyme CYP2D6, by which some SSRIs are predominantly metabolised (see 'Table 35.2', (p.1465)), so it might cause an increase in their plasma levels and increased toxicity. One study did find a modest increase in citalopram levels; however, another small study unexpectedly found no changes in the plasma levels of fluoxetine or paroxetine when given with bupropion.[2] An *in vitro* study demonstrated that several SSRIs (paroxetine, sertraline, norfluoxetine, and fluvoxamine) could inhibit CYP2B6, the isoenzyme involved in bupropion hydroxylation,[9] and in one of the cases described above it was suggested that residual fluoxetine may have inhibited the metabolism of bupropion, leading to toxic levels.[3] A pharmacodynamic mechanism has also been proposed. Bupropion can cause seizures and SSRIs may further lower the seizure threshold, see 'Bupropion + Miscellaneous', p.1468.

Importance and management

Information is limited, but what is known suggests that if concurrent or sequential use of bupropion and an SSRI is thought appropriate, the outcome should be well monitored and reduced doses should be considered. The manufacturers recommend that drugs that are metabolised by CYP2D6 should be given with bupropion with caution and initiated at the lower end of the dose range. If bupropion is given to a patient already taking a drug metabolised by CYP2D6, the need to decrease the dose of this drug should be considered.[10,11] The UK manufacturers specifically name paroxetine and the US manufacturers additionally name fluoxetine and sertraline. In addition, the manufacturers advise caution if bupropion is given with antidepressants that lower the seizure threshold[10,11] and, in this situation, the UK manufacturer says that consideration should be given to reducing the dose of bupropion to a maximum of 150 mg daily for smoking cessation.[10]

SSRIs + Cyproheptadine

Several reports suggest that cyproheptadine can oppose the antidepressant effects of fluoxetine, and another describes the same effect with paroxetine.

Clinical evidence

(a) Fluoxetine

Three men with depression complained of anorgasmia when taking fluoxetine. When this was treated with cyproheptadine their depressive symptoms returned, decreasing again when cyproheptadine was stopped.[1] Two women also complained of anorgasmia within 1 to 3 months of starting to take fluoxetine 40 to 60 mg daily for bulimia nervosa. When cyproheptadine was added to treat the anorgasmia, the urge to binge on food returned in both of them and one experienced increased depression. These symptoms resolved 4 to 7 days after stopping cyproheptadine.[2] A woman successfully treated with fluoxetine 40 mg daily had a re-emergence of her depressive symptoms on two occasions within 36 hours of starting to take cyproheptadine.[3] In a further case, a woman who responded well to fluoxetine 20 mg daily for depression had a recurrence of her depression after she began to take cyproheptadine for migraine. Increasing the dose of fluoxetine to 40 mg daily controlled the depressive symptoms while cyproheptadine was continued for migraine.[4] In contrast, no exacerbation of depression was seen in a study in which both cyproheptadine and fluoxetine were used in 2 patients.[5]

(b) Paroxetine

A woman taking paroxetine 20 mg daily for depression relapsed and worsened, and developed confusion and psychotic symptoms, within 2 days of

starting to take cyproheptadine 2 mg twice daily for anorgasmia.[6] The psychotic symptoms resolved 2 days after stopping cyproheptadine.

Mechanism

Although the mechanism is not fully understood, it has been suggested that because cyproheptadine is a serotonin antagonist it blocks or opposes the serotonergic effects of these SSRIs.[1-3,6]

Importance and management

Direct information about this interaction appears to be limited to these studies although cyproheptadine has also been found to oppose the antidepressant effects of MAOIs (see 'MAOIs or RIMAs + Antihistamines; Cyproheptadine', p.1371). One study suggests that not every patient is affected.[5] If concurrent use is thought appropriate, the outcome should be very well monitored for evidence of a reduced antidepressant response.

Because of its serotonin antagonist effects, cyproheptadine has been used to treat the 'serotonin syndrome', (p.9), including cases resulting from the use of SSRIs.

SSRIs + Dextromethorphan

A few reports describe the development of a serotonin-like syndrome in patients taking citalopram, fluoxetine or paroxetine when they took dextromethorphan. In some of these cases, other serotonergic drugs might have contributed. Another report describes hallucinations in a woman taking fluoxetine and dextromethorphan.

Paroxetine and fluoxetine moderately inhibit the metabolism of dextromethorphan, whereas fluvoxamine and sertraline have modest to minimal effects.

Clinical evidence

(a) Citalopram

A man who had been taking citalopram 30 mg, nefazodone 600 mg and long-acting oxycodone 10 mg at bedtime without problems, started taking a cough syrup containing dextromethorphan and within a day he began to experience fatigue, lethargy, jitteriness and headache. He stopped taking the dextromethorphan and his symptoms gradually disappeared over several hours.[1] Another case of serotonin syndrome occurred a couple of days after taking dextromethorphan (*Night and Day* capsules) in a 46-year-old man who had been taking citalopram 40 mg daily and methadone 70 mg daily for 2 years.[2]

(b) Fluoxetine

In a pharmacokinetic study in healthy subjects, fluoxetine 20 mg daily for 4 weeks moderately inhibited the metabolism of a single 30-mg dose of dextromethorphan, as assessed by the molar ratio of dextromethorphan to dextrorphan in urine.[3] Another study using fluoxetine 60 mg daily for 8 days found an even greater inhibition of metabolism.[4]

A woman who had been taking fluoxetine 20 mg daily for 17 days took about 10 mL of a cough syrup containing dextromethorphan, and a further dose the next morning, with the next dose of fluoxetine. Within 2 hours vivid hallucinations developed (bright colours, distortions of shapes and sizes), which lasted 6 to 8 hours. The patient said they were similar to her past experience with LSD 12 years earlier.[5]

(c) Fluvoxamine

In a pharmacokinetic study in healthy subjects, fluvoxamine 150 mg daily for 4 weeks slightly inhibited the metabolism of a single 30-mg dose of dextromethorphan 30 mg, as assessed by the molar ratio of dextromethorphan to dextrorphan in urine.[6]

(d) Paroxetine

In a pharmacokinetic study in healthy subjects, paroxetine 20 mg daily for 8 days moderately inhibited the metabolism of a single 30-mg dose of dextromethorphan, as assessed by the molar ratio of dextromethorphan to dextrorphan in urine.[4] A smaller increase in the ratio of dextromethorphan to dextrorphan was seen in another study using a single 20-mg dose of paroxetine.[7]

A man with multiple medical problems was admitted to hospital as an emergency, mainly because he was vomiting blood. He was taking diazepam, diltiazem, glyceryl trinitrate, paroxetine, piroxicam, ranitidine and ticlopidine. Four days previously he had begun to take *Nyquil*, a non-prescription remedy for colds, containing dextromethorphan, pseudoephedrine, paracetamol (acetaminophen) and doxylamine. After two days he developed shortness of breath, nausea, headache and confusion, and on admission he was also diaphoretic, tremulous, tachycardic and hypertensive. Later he became rigid. The eventual diagnosis was that he was suffering from serotonin syndrome, attributed to an interaction between paroxetine and dextromethorphan in the presence of vascular disease. He was successfully treated with lorazepam 16 mg intravenously over 1 hour. The bleeding was thought to be from a small prepyloric ulcer.[8]

The authors of this report very briefly describe another patient taking paroxetine who developed symptoms consistent with serotonin syndrome within a few hours of taking a non-prescription cough remedy containing dextromethorphan and guaifenesin. She needed intensive care treatment.[9]

(e) Sertraline

In a pharmacokinetic study in healthy subjects, sertraline 100 mg daily for 8 days did not have a statistically significant effect on the metabolism of a single dose of dextromethorphan 30 mg, as assessed by the molar ratio of dextromethorphan to dextrorphan in urine.[4]

Mechanism

The symptoms that developed with citalopram or paroxetine and dextromethorphan were attributed by the authors of the reports to serotonin syndrome caused by the additive effects of the SSRIs and dextromethorphan on serotonin transmission.

Fluoxetine and paroxetine are moderate inhibitors of the cytochrome P450 isoenzyme CYP2D6, by which dextromethorphan is metabolised, resulting in increased dextromethorphan levels. Fluvoxamine and sertraline have much less effect on CYP2D6. Whether the increased levels of dextromethorphan have any bearing on the likely development of serotonin syndrome remains to be seen.

Importance and management

The pharmacokinetic interaction is established. Paroxetine and fluoxetine are moderate inhibitors of dextromethorphan metabolism, whereas fluvoxamine and sertraline have minimal effects. However, this pharmacokinetic interaction will occur only in individuals who are CYP2D6 extensive metabolisers (i.e. those with normal levels of this isoenzyme). Poor metabolisers lack CYP2D6, and would not be affected. At the most, maximal inhibition of CYP2D6 therefore increases dextromethorphan levels in extensive metabolisers to the levels already seen in poor metabolisers. Dextromethorphan is generally considered to have a wide therapeutic range and the dose is not individually titrated; therefore, the interaction with paroxetine and fluoxetine is unlikely to be clinically relevant in terms of common adverse effects of dextromethorphan. Nevertheless, it is possible that some extensive metaboliser patients might become more sensitive to the adverse effects of dextromethorphan while taking paroxetine or fluoxetine.

Moreover, it is unclear what effect these pharmacokinetic interactions have on the development of serotonin syndrome, if any. So far, these few reports seem to be the only cases of the serotonin syndrome being attributed to an interaction between an SSRI and dextromethorphan. However, it has been suggested that the incidence of mild serotonin excess (as seen in the case with citalopram) may be more common than is known.[1] The general importance of this apparent interaction is therefore very uncertain. The SSRIs are now very widely prescribed and dextromethorphan is a relatively common ingredient of non-prescription medicines. More study is therefore needed to establish this apparent interaction, but in the meantime, it seems unlikely that any general precautions are needed in patients taking SSRIs who use dextromethorphan-containing products.

On the basis of the difference in pharmacokinetic interaction between

SSRIs and dextromethorphan, it had been predicted that sertraline and fluvoxamine might be less likely to cause serotonin syndrome with dextromethorphan than paroxetine and fluoxetine.[9,10] In considering this possibility, it should be noted that cases of serotonin syndrome have been reported with citalopram, which is not a potent CYP2D6 inhibitor.

SSRIs + Grapefruit juice

Grapefruit juice modestly increases fluvoxamine levels, and there is a case report of adverse effects attributed to this pharmacokinetic interaction. Sertraline plasma levels are also modestly increased by grapefruit juice. Excessive consumption of grapefruit caused symptoms similar to serotonin syndrome in a patient taking fluoxetine and trazodone.

Clinical evidence

(a) Fluoxetine

A 57-year-old HIV-positive man had been receiving indinavir, stavudine and lamivudine, as well as other medications including fluoxetine 20 mg daily and trazodone 200 mg daily. He complained of dizziness, mild confusion, diarrhoea, visual changes, and a general feeling of being "out of sorts" for approximately one month. On further questioning it was found that the patient had been having one grapefruit each morning but had increased his consumption to 3 per day. His symptoms resolved when he stopped eating grapefruit.[1]

(b) Fluvoxamine

A randomised, placebo-controlled, crossover study in 10 healthy subjects found that 250 mL of grapefruit juice three times daily for 6 days increased the AUC of a single 75-mg dose of fluvoxamine by 60% and increased its maximum plasma levels by 33%.[2]

A 75-year-old woman taking fluvoxamine 150 mg at night experienced palpitations when on holiday in Florida, which stopped when she returned home. The only change identified was that she drank grapefruit juice daily while in Florida. She had previously experienced palpitations when taking a higher dose of fluvoxamine (200 mg at night).[3]

(c) Sertraline

A study in 5 patients taking sertraline 50 to 75 mg daily found that the concurrent use of grapefruit juice for one week increased serum trough levels by almost 50%.[4]

Mechanism

Grapefruit juice is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and sertraline is partially metabolised by this enzyme. Therefore grapefruit juice would be expected to reduce the metabolism of sertraline. This has been demonstrated *in vitro*; grapefruit juice inhibited the formation of desmethylsertraline in a dose-dependent manner.[4] The other SSRIs mentioned above are not significantly metabolised by CYP3A4, but grapefruit juice also inhibits other isoenzymes that could affect the metabolism of SSRIs especially if the patient is also a poor metaboliser of CYP2D6.[2,3]

Importance and management

The modest pharmacokinetic interactions between grapefruit juice and fluvoxamine and sertraline would appear to be established, but would usually not be clinically relevant. Nevertheless, there are isolated reports of clinically significant interactions between grapefruit and SSRIs, so the possibility of an interaction should be borne in mind especially if unusual amounts of grapefruit have been consumed.

SSRIs + H_2-receptor antagonists

Citalopram, escitalopram, paroxetine and sertraline levels are moderately increased by cimetidine.

Clinical evidence

(a) Citalopram

In a study, 12 healthy subjects were given citalopram 40 mg daily for 21 days and then for the next 8 days they were also given **cimetidine** 400 mg twice daily. **Cimetidine** caused a 29% decrease in the oral clearance of citalopram, a 39% rise in its maximum serum levels and a 43% increase in its AUC. Some changes in the renal clearance of the citalopram metabolites were also seen.[1]

(b) Escitalopram

In a controlled study in 16 healthy subjects, **cimetidine** 400 mg twice daily for 5 days increased the AUC of escitalopram by about 70% when a single 20-mg dose of escitalopram was given on day 4. There was also a 22% increase in the maximum plasma level of escitalopram.[2]

(c) Paroxetine

In a study in 10 healthy subjects, **cimetidine** 200 mg four times daily for 8 days did not affect the mean pharmacokinetic values or bioavailability of a single 30-mg dose of paroxetine. However, in 2 subjects the AUC of paroxetine increased by 55% and 81%, respectively.[3] Another study in 11 healthy subjects found that **cimetidine** 300 mg three times a day increased the AUC of paroxetine 30 mg daily by about 50% after one week of concurrent use.[4]

(d) Sertraline

In a randomised, crossover study, 12 healthy subjects were given either **cimetidine** 800 mg or a placebo at bedtime for 8 days, with a single 100-mg dose of sertraline on day 2. **Cimetidine** increased the AUC of sertraline by 50%, increased its maximum serum levels by 24%, and prolonged the half-life by 26%.[5]

Mechanism

The apparent reason for all these changes is that **cimetidine** inhibits the activity of cytochrome P450 so that the metabolism of the SSRIs is reduced, and as a result their serum levels rise.

Importance and management

The pharmacokinetic interactions between cimetidine and citalopram, escitalopram, paroxetine and sertraline are established. However, the modest increases seen are generally unlikely to be clinically relevant because the SSRIs are usually well tolerated, have a wide therapeutic range, and there are large pharmacokinetic variations between individual subjects.[1,2]. However, the results from the paroxetine study suggest that individual patients may experience greater rises. Therefore it would seem prudent to monitor concurrent use for adverse effects (e.g. dry mouth, nau-

sea, diarrhoea, dyspepsia, tremor, ejaculatory delay, sweating) and consider reducing the SSRI dose if these become troublesome.

If the suggested mechanism of interaction is true, one of the other H_2-receptor antagonists that lack enzyme inhibitory activity, such as ranitidine or famotidine, might be a non-interacting alternative for cimetidine, but this needs confirmation.

SSRIs + 5-HT$_3$-receptor antagonists

Symptoms similar to serotonin syndrome have been reported in one patient receiving paroxetine and ondansetron, and in one patient receiving sertraline and dolasetron who then received sertraline and ondansetron without problems.

Clinical evidence

(a) Paroxetine

A possible case of serotonin syndrome (or possibly neuroleptic malignant syndrome) was reported in a 49-year-old woman who developed postoperative delirium. She had been taking paroxetine 30 mg daily up to 2 days before surgery and was given **ondansetron** 4 mg during surgery and morphine during and after surgery. Approximately one hour after leaving theatre she became agitated and confused. She also displayed uncontrolled limb movements, brisk reflexes, ankle clonus, abnormal ocular function, hypertension, pyrexia, and raised creatinine kinase levels. The delirium did not respond to naloxone, diazepam or flumazenil and lasted for nearly 2 days.[1]

(b) Sertraline

A 49-year-old woman who had been receiving **sertraline** for some time without incident was premedicated with **dolasetron** 100 mg before receiving her first cycle of adjuvant chemotherapy for breast cancer. Shortly afterwards she developed symptoms of profound agitation and elation, but with an overwhelming desire to commit suicide, and was disoriented. The symptoms resolved within hours without pharmacological intervention. Three weeks later she received the same medications except that **ondansetron** was substituted for **dolasetron** and she experienced no adverse effects. The author concluded that a variant of serotonin syndrome may rarely be seen when 5-HT$_3$-receptor antagonists and SSRIs are given together.[2]

Mechanism

Several explanations for these effects, involving the disruption of serotonergic and/or dopaminergic transmission, have been suggested.[1] There has been some debate about whether inhibition of CYP2D6 was another possible mechanism with the paroxetine case, but this seems unlikely.[1,3]

Importance and management

These two cases are isolated, and as such, no general recommendations can be made. Nevertheless, bear in mind the possibility of serotonin syndrome if similar adverse effects occur.[2] For more information on serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

SSRIs + Interferons

In one patient taking paroxetine and trazodone, depression recurred when interferon alfa was given. SSRIs have been used for the prevention of depression caused by interferon alfa.

Clinical evidence, mechanism, importance and management

A 31-year-old woman, whose mood and other depressive symptoms improved during treatment with **paroxetine** 50 mg daily and trazodone 50 mg at night, was later found to have essential thrombocythaemia. After unsuccessful treatment with dipyridamole, she was given **interferon alfa**, stabilised at 3 million units three times weekly. After 3 months her depressive symptoms returned, and worsened over a period of 6 months, despite increased doses of trazodone and cognitive therapy. **Interferon alfa** was discontinued and replaced by hydroxycarbamide, and then anagrelide. After a good response to a course of ECT, her depressive symptoms were controlled by **paroxetine** 50 mg daily and trazodone 150 mg at night.[1] SSRIs have been used to try to prevent depression caused by interferon alfa. For example, in one study, 9 of 20 patients taking high-dose **interferon alfa** developed depression, compared with just 2 of 18 patients also given **paroxetine** (10 mg daily titrated up to 40 mg daily started 2 weeks before the interferon).[2]

Interferon commonly causes depression, and in the case report it appeared to reverse the antidepressant response to paroxetine and trazodone. It was suggested that this might have been due to the capacity of interferon to impair serotonin synthesis, by inducing enzymes that degrade the serotonin precursor tryptophan.[1]

It seems possible that interferon might reduce the antidepressant efficacy of the SSRIs. Bear the possibility in mind if the response to an SSRI is poor in a patient given interferon.

SSRIs + Lysergide (LSD)

Three patients with a history of lysergide (LSD) abuse experienced a new onset or worsening of the LSD flashback syndrome when given fluoxetine, paroxetine or sertraline. Grand mal convulsions occurred when one patient taking LSD was given fluoxetine. In contrast, one study found that SSRIs reduced or eliminated the subjective responses to LSD.

Clinical evidence

An 18-year-old girl with depression, panic and anxiety disorders, and with a long history of illicit drug abuse experienced a 15-hour LSD flashback within 2 days of starting to take **sertraline** 50 mg daily. Another flashback lasting a day occurred when the **sertraline** was replaced by **paroxetine**. No further flashbacks occurred when the SSRIs were stopped. A 17-year-old boy with depression, also with a long history of illicit drug abuse (including LSD), began to experience LSD flashbacks 2 weeks after starting to take **paroxetine**. His father, a chronic drug abuser, had taken both **fluoxetine** and **paroxetine** for depression and had also reported new onset of a flashback syndrome.[1] An isolated report describes a patient taking **fluoxetine**, who developed grand mal convulsions, which were tentatively attributed to the concurrent use of LSD.[2] In contrast, a retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI (**fluoxetine**, **paroxetine** or **sertraline**) or trazodone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD. However, another subject who had taken **fluoxetine** for only one week had an increased response to LSD.[3]

Mechanism

Not understood. Lysergide increases serotonin in the brain, and one suggestion is that when the serotonin re-uptake is blocked in the brain, there is an increased stimulation of 5-HT$_1$ and 5-HT$_2$ receptors.[1] Changes in brain catecholamine systems may also be involved.[3]

Importance and management

Information is very limited and conflicting. The authors of the first report suggest that patients who are given SSRIs should be warned about the possibility of flashback or hallucinations if they have a known history of LSD use.

SSRIs + Macrolides

An isolated case report describes a man who developed apparent acute fluoxetine toxicity while taking clarithromycin. Other isolated reports describe the development of serotonin syndrome in patients taking erythromycin with sertraline, and clarithromycin with citalopram.

Clinical evidence

(a) Citalopram

The Canadian regulatory authorities briefly mention a case of serotonin syndrome and QT prolongation, which occurred when clarithromycin was taken with citalopram for 4 days.[1]

(b) Fluoxetine

A 53-year-old-man taking fluoxetine 80 mg and nitrazepam 10 mg at bedtime for depression and insomnia was given **clarithromycin** 250 mg twice daily for a respiratory infection. Within a day he started to become increasingly confused, and after 3 days was admitted to hospital with a diagnosis of psychosis and delirium. When no organic cause for the delirium could be found, all his medications were stopped, and **erythromycin** was started. His mental state returned to normal after 36 hours. Once the antibacterial course had finished, the fluoxetine and nitrazepam were restarted and no further problems occurred.[2]

(c) Sertraline

A 12-year-old boy with severe obsessive-compulsive disorder and simple phobia, responded to sertraline 12.5 mg daily, titrated over 12 weeks to 37.5 mg daily. Five weeks later, he was given erythromycin 200 mg twice daily for an infection, and 4 days later he began to feel mildly nervous. Over the next 10 days his nervousness grew, culminating in panic, restlessness, irritability, agitation, paraesthesias, tremulousness, decreased concentration and confusion. The symptoms abated within 72 hours of stopping both drugs.[3]

Mechanism

The effects seen in the case with fluoxetine was attributed to fluoxetine toxicity, and that with sertraline to serotonin syndrome. In these two cases, the authors postulated that erythromycin and clarithromycin (known inhibitors of the cytochrome P450 isoenzyme CYP3A4), reduced the metabolism of the SSRIs, thereby raising their serum levels and precipitating the observed toxicity.[2,3]

Importance and management

These are isolated reports and their general importance is unknown. Nevertheless, be aware of these cases when using macrolides with SSRIs.

SSRIs + Methylphenidate

Isolated reports describe delirium in one patient and a seizure in another when methylphenidate was taken with sertraline.

Clinical evidence, mechanism, importance and management

A 61-year-old man with major depression was prescribed **sertraline** 50 mg daily without response. Three months later the dose was increased to 100 mg daily and methylphenidate 2.5 mg daily was started. His symptoms improved and the dose of methylphenidate was increased to 2.5 mg twice daily and then 5 mg twice daily. After several days at the higher dose, the patient experienced visual hallucinations and confusion. The methylphenidate was discontinued and a day later the psychosis resolved. He was maintained on **sertraline** 100 mg daily and his mood and motivation remained good.[1]

An isolated report describes a tonic-clonic seizure in a 13-year-old boy after he had been taking **sertraline** 25 to 50 mg daily and methylphenidate 80 mg daily for about 2 weeks. He had been receiving methylphenidate without significant adverse effects for about 10 months before the seizure and following discontinuation of the **sertraline** experienced no further seizures.[2]

In contrast, beneficial augmentation of effects has been reported with methylphenidate and SSRIs (**fluoxetine**, **paroxetine**, **sertraline**) without significant adverse effects.[3,4]

The general significance of these cases is likely to be small, especially when set in the context of beneficial concurrent use. However, if adverse CNS effects become troublesome, it may be worth considering this interaction as a possible cause: in both cases the adverse effects resolved when one of the drugs was withdrawn.

SSRIs + Metoclopramide

There are two reports of serotonin syndrome in patients taking sertraline when metoclopramide was added. A few reports describe extrapyramidal symptoms in patients given fluoxetine, fluvoxamine or sertraline with metoclopramide.

Clinical evidence

A regional pharmacovigilance centre in France reported 4 cases of extrapyramidal adverse effects linked to the concurrent use of an SSRI (unnamed) and metoclopramide.[1]

(a) Fluoxetine

Two patients developed extrapyramidal symptoms while taking fluoxetine and metoclopramide.[2,3]

(b) Fluvoxamine

A 14-year-old boy taking fluvoxamine 50 mg daily for anorexia nervosa was, after day 7, given metoclopramide 10 mg three times daily. On the third day of concurrent use he developed acute movement disorders including acute dystonia, jaw rigidity, horizontal nystagmus, uncontrolled tongue movements and dysarthria. The boy had taken the same dose of metoclopramide alone on other occasions without experiencing extrapyramidal reactions.[4]

(c) Sertraline

A woman with gastro-oesophageal reflux, controlled with metoclopramide 15 mg four times daily, developed symptoms consistent with a mandibular dystonia (periauricular pain, jaw tightness, the sensation of her teeth clenching and grinding) 2 days after starting sertraline 50 mg daily. A 50-mg dose of diphenhydramine resolved the problem within 30 minutes, but the same symptoms recurred the next day, 8 hours after taking sertraline. The symptoms were relieved by 2 mg of oral benzatropine.[5]

A patient who had been taking sertraline 100 mg daily started taking metoclopramide 10 mg four times daily for nausea. After 24 hours his symptoms had worsened and he developed malaise, cardiac arrhythmia, visual hallucinations, diaphoresis, sialosis, hyperreflexia, and tremor. Serotonin syndrome was diagnosed and his symptoms improved with cyproheptadine.[6] Another patient taking sertraline 100 mg daily for depression over an 18-month period developed agitation, dysarthria, diaphoresis, and

a movement disorder within 2 hours of receiving a single 10-mg intravenous dose of metoclopramide. The symptoms, diagnosed as serotonin syndrome with a serious extrapyramidal movement disorder, resolved within 6 hours of treatment with diazepam.[7]

Mechanism

In the fluvoxamine case, pharmacokinetic interaction was thought unlikely as fluvoxamine is metabolised by a different metabolic pathway to metoclopramide.[4] Both the SSRIs and metoclopramide can cause extrapyramidal reactions; metoclopramide by blocking dopamine D_2 receptors in the basal ganglia, and the SSRIs by inhibition of dopamine neurotransmission.[4,5] Metoclopramide has also been reported to have intermediate affinity to certain serotonin receptors.[7]

Importance and management

Information seems to be limited to these reports, but they highlight the fact that care should be taken if two drugs with the potential to cause the same adverse effects are used together.

SSRIs + Nasal decongestants

A case report describes serotonin syndrome associated with the use of sertraline and etilefrine, and another report describes adverse effects associated with the use of fluoxetine and phenylpropanolamine.

Clinical evidence, mechanism, importance and management

(a) Etilefrine

A case of serotonin syndrome was attributed to an interaction between **sertraline** and etilefrine.[1] The clinical relevance of this isolated case is unclear.

(b) Phenylpropanolamine

A 16-year-old girl with an eating disorder, taking **fluoxetine** 20 mg daily, developed vague medical complaints of dizziness, 'hyper' feelings, diarrhoea, palpitations and a reported weight loss of about 6.5 kg within 2 weeks. The author of the report suggested that these effects might have been the result of an interaction with phenylpropanolamine (1 to 2 capsules of *Dexatrim* daily), which the patient was surreptitiously taking, associated with a restricted food and fluid intake.[2] The clinical relevance of this isolated report is unclear.

SSRIs + NNRTIs

Efavirenz decreases sertraline levels, but does not alter paroxetine levels. Paroxetine and sertraline, and probably also fluoxetine, do not alter efavirenz levels. Serotonin syndrome occurred in a woman taking fluoxetine when efavirenz was added.
There is limited evidence that nevirapine might decrease fluoxetine plasma levels, but appears not to affect fluvoxamine levels. Limited evidence also suggests that fluoxetine has no effect on nevirapine levels, but fluvoxamine may modestly increase them.
Etravirine does not appear to affect paroxetine levels, and paroxetine does not appear to affect etravirine levels.

Clinical evidence

(a) Efavirenz

1. Fluoxetine. A case of serotonin syndrome in a woman taking fluoxetine coincided with the start of a new antiretroviral regimen including efavirenz. Symptoms resolved when the fluoxetine dose was halved.[1] In a retrospective population pharmacokinetic analysis, fluoxetine did not appear to significantly alter efavirenz plasma levels.[2]

2. Paroxetine. The US manufacturer of efavirenz notes that there was no change in the pharmacokinetics of either paroxetine or efavirenz when paroxetine 20 mg daily and efavirenz 600 mg daily were given together for 14 days.[3] In a retrospective population pharmacokinetic analysis, paroxetine did not appear to significantly alter efavirenz plasma levels.[2]

3. Sertraline. In one study, sertraline 50 mg daily for 14 days had no effect on the pharmacokinetics of efavirenz 600 mg daily; however, the sertraline AUC was decreased by 39% and the trough level was decreased by 46% when given with efavirenz.[3,4] In a retrospective population pharmacokinetic analysis, sertraline did not appear to significantly alter efavirenz plasma levels.[2]

(b) Etravirine

The manufacturer of etravirine notes that there was no change in the pharmacokinetics of either **paroxetine** or etravirine when **paroxetine** 20 mg daily and etravirine (dose not stated) were given together.[5]

(c) Nevirapine

1. Fluoxetine. In a pharmacokinetic-modelling study in 173 HIV-positive patients taking a nevirapine-containing regimen, there was little difference in nevirapine clearance (10% decrease) between 7 patients also taking fluoxetine and the rest of the group. In addition, the median plasma levels of fluoxetine and its active metabolite norfluoxetine tended to be lower in these 7 patients than in another control group of 17 patients without HIV infection taking fluoxetine, but this only reached statistical significance when the plasma levels of fluoxetine and norfluoxetine were combined (46% lower).[6]

2. Fluvoxamine. In a pharmacokinetic-modelling study in 173 HIV-positive patients taking a nevirapine-containing regimen, the apparent clearance of nevirapine was 34% lower in 7 patients also taking fluvoxamine, and this appeared to be dependent on the dose of fluvoxamine. The median plasma level of fluvoxamine did not differ between these 7 patients and a control group of 29 patients without HIV infection taking fluvoxamine.[6]

Mechanism

The case of serotonin syndrome in the patient taking efavirenz and fluoxetine was attributed to raised fluoxetine levels caused by efavirenz.[1] However, note that paroxetine, which is similarly metabolised, is not affected by efavirenz. Sertraline, unlike fluoxetine and paroxetine, is in part metabolised by the cytochrome P450 isoenzyme CYP3A4, of which efavirenz is an inducer. Concurrent use therefore causes a moderate decrease in sertraline levels.

Importance and management

The available information suggests that **efavirenz** levels are unaffected by SSRIs (paroxetine, sertraline, fluoxetine), therefore no change in virologic efficacy would be anticipated, and no efavirenz dosage adjustments are likely to be needed. Paroxetine levels are unaffected by efavirenz, but sertraline levels are reduced, so clinical efficacy should be monitored and the dose of sertraline increased if necessary. The general relevance of the case of serotonin syndrome is uncertain, but it introduces a note of caution about concurrent use.

No dosage adjustment of either paroxetine or **etravirine** is expected to be needed on concurrent use.[5]

These findings of the pharmacokinetic-modelling study with **nevirapine** are preliminary, and require confirmation in a controlled study, nevertheless, they provide some evidence that fluoxetine levels might be decreased by nevirapine. Monitoring fluoxetine efficacy might be prudent. They also suggest that nevirapine levels may be modestly increased by fluvoxamine, therefore it might be prudent to monitor for nevirapine adverse effects. More study is needed.

SSRIs + Opioids

Symptoms of the serotonin syndrome have been reported with opioids including fentanyl, hydromorphone, oxycodone, pentazocine, pethidine (meperidine), and possibly also morphine, when given with various SSRIs.
Fluoxetine may slightly reduce the analgesic effects of morphine and oxycodone.

Clinical evidence

(a) Fentanyl

A 65-year-old woman taking **citalopram**, rabeprazole, tolterodine and **hydrocodone** developed probable serotonin syndrome while hospitalised and within 24 hours of starting transdermal fentanyl 25 micrograms/hour. The fentanyl was discontinued, and all signs and symptoms resolved over the next few days, and did not recur when **oxycodone** was started.[1]

(b) Hydrocodone

Visual hallucinations occurred in a 90-year-old woman taking hydrocodone when her antidepressant was changed from **citalopram** 10 mg daily to **escitalopram** 10 mg daily. The hallucinations stopped after her hydrocodone was discontinued because of improvement in pain control. The patient had previously taken **paroxetine** and the same dose of hydrocodone, without experiencing hallucinations or other serotonin-related symptoms.[2]

(c) Hydromorphone

An 81-year-old woman who had been taking **fluoxetine** 20 mg daily along with other medication for several years, developed abnormal movements, confusion, incoherent speech, sweating, facial redness, tremor, hyperreflexia and muscle spasm 2 days after starting to take hydromorphone 12 mg daily. The symptoms resolved within 2 weeks of stopping the **fluoxetine** (the hydromorphone was continued).[3]

(d) Methadone

The SSRIs, particularly fluvoxamine, can raise methadone levels. See 'SSRIs + Opioids; Methadone', p.1489.

(e) Morphine

A placebo-controlled study in 35 patients found that the preoperative use of **fluoxetine** 10 mg daily for 7 days reduced the analgesic effect of intravenous morphine given for postoperative dental pain.[4] In contrast, a crossover study in 15 healthy subjects found that a single 60-mg dose of **fluoxetine** slightly improved (by 3 to 8%) the analgesic effect (as assessed by dental electrical stimulation) of morphine sulfate in doses tailored to produce and maintain steady-state plasma levels of 15, 30 and 60 nanograms/mL for 60 minutes. Plasma levels of morphine were not affected by **fluoxetine**, and morphine was found not to affect plasma levels of **fluoxetine** or norfluoxetine. The subjects experienced less nausea and drowsiness while taking both drugs, but the psychomotor and respiratory depressant effects of morphine were not altered.[5]

A patient experienced postoperative delirium which lasted for nearly 2 days and included agitation, confusion, uncontrolled limb movements, abnormal ocular function, hypertension, pyrexia, brisk reflexes, ankle clonus and raised creatinine kinase. She had been taking **paroxetine** before surgery and during surgery she was given morphine and ondansetron.[6]

(f) Oxycodone

A man with advanced multiple sclerosis found that when he began to take **fluoxetine** 20 mg daily for depression he needed to increase his analgesic dosage of oxycodone (for painful muscle spasms) about fourfold, from 65 to 75 mg daily to about 250 to 275 mg daily.[7]

A bone-marrow transplant recipient taking, amongst other drugs, **sertraline** 50 mg daily, ciclosporin 75 mg daily, and oxycodone 10 mg as needed, developed severe tremors and visual hallucinations. This coincided with him taking oxycodone 200 mg over 48 hours for severe pain. An adverse reaction to ciclosporin was initially suspected (although serum levels were not high), and this was temporarily discontinued along with the oxycodone. The visual hallucinations decreased but the tremors continued, and did not lessen until **sertraline** was discontinued and cyproheptadine given. It was concluded that the patient was experiencing a form of serotonin syndrome as a result of markedly increased opioid use while taking an SSRI.[8] Two other cases describe probable serotonin syndrome in elderly patients taking **sertraline** or **escitalopram** and extended-release oxycodone. In both cases symptoms of serotonin syndrome (agitation, increased muscle tone, ataxia, tremor and/or myoclonic jerks) occurred after increasing the opioid dose.[2] Another case of severe serotonergic symptoms including confusion, nausea, fever, shivering, agitation, clonus, hyperreflexia, hypertonia, and tachycardia occurred in a 70-year-old woman taking **fluvoxamine** 200 mg daily when she started taking oxycodone 40 mg twice daily. Discontinuation of these two drugs resulted in resolution of her symptoms over 48 hours.[9]

(g) Pentazocine

A placebo-controlled study in 35 patients found that **fluoxetine** 10 mg daily for 7 days preoperatively did not appear to reduce the analgesic effects of pentazocine 45 mg given intravenously for postoperative dental pain.[4]

A man who had been taking **fluoxetine** 20 mg daily, later increased to 40 mg daily, was given a single 100-mg oral dose of pentazocine (*Talwin Nx* containing pentazocine 50 mg and naloxone 500 micrograms) for a severe headache. Within 30 minutes he complained of lightheadedness, anxiety, nausea and paraesthesias of the hands. He was diaphoretic, flushed, and ataxic, and had a mild tremor of his arms. His blood pressure was 178/114 mmHg, pulse 62 bpm and respiration 16 breaths per minute. He was given intramuscular diphenhydramine 50 mg and recovered over the following 4 hours.[10]

(h) Pethidine (Meperidine)

A 43-year-old man who had been taking **fluoxetine** approximately every other day experienced symptoms of serotonin syndrome immediately after receiving pethidine 50 mg intravenously for an endoscopic procedure.[11] A 44-year-old woman taking **citalopram** 20 mg daily increased to 40 mg daily, transdermal **fentanyl**, and intravenous **hydromorphone** or oral **hydrocodone**/paracetamol (as needed), promethazine, gatifloxacin, zolpidem and lansoprazole, developed symptoms suggestive of serotonin syndrome within 10 hours of starting pethidine by patient controlled analgesia for breakthrough pain (total dose over 8 hours was 230 mg). Once the pethidine was stopped, the symptoms resolved.[12]

(i) Tramadol

The serotonin syndrome has occurred in a number of patients taking SSRIs with tramadol. See 'SSRIs + Opioids; Tramadol', p.1489.

Mechanism

Fluoxetine inhibits the activity of the cytochrome P450 isoenzyme CYP2D6 within the liver so that the metabolism of oxycodone to an active metabolite oxymorphone is reduced. The metabolism of hydrocodone and similar opioids may also be affected by CYP2D6 inhibitors, see 'Opioids; Codeine and related drugs + Quinidine', p.203. **Buprenorphine** and morphine are not metabolised by CYP2D6, so their metabolism would not be expected to be affected by fluoxetine.

It has been suggested that the reason for the reduced morphine analgesia may have something to do with the initial effects of SSRIs on serotonergic neurotransmission.[5] Serotonin syndrome seems to develop unpredictably in some patients given two or more serotonergic drugs, in this case, opioids and SSRIs.

Importance and management

Adverse interactions between SSRIs and the opioids discussed above seems rare, and there is little evidence to suggest that they cannot be used together safely and effectively. The evidence suggesting that fluoxetine may decrease morphine or oxycodone analgesia is limited and insufficient to suggest any change in practice. However, if a patient does not seem to respond well to either of these opioids consider an interaction as a possible cause.

The incidence of serotonin syndrome-like reactions with opioids and SSRIs is fairly rare; however, the possibility of serotonin syndrome should be considered in patients experiencing altered mental status, autonomic dysfunction and neuromuscular adverse effects while receiving these

drugs. For a further discussion of serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

SSRIs + Opioids; Methadone

Methadone serum levels may rise if fluvoxamine is added, sometimes resulting in increased adverse effects. Sertraline, paroxetine, and possibly fluoxetine, may also modestly increase methadone levels.

Clinical evidence

(a) Fluoxetine

Methadone 30 to 100 mg daily, and fluoxetine 20 mg daily were given to 9 patients (two of them also taking fluvoxamine). Although there were possible compliance problems with some of the patients, the methadone plasma/dose ratio of the group as a whole was not altered by the addition of the fluoxetine.[1] This is consistent with the results of two other studies, which found that fluoxetine did not appear to alter the plasma methadone levels of patients treated for cocaine dependence.[2,3] However, the plasma samples for 7 of the 9 patients in the first study[1] were subsequently analysed again to measure the *S*- and *R*-enantiomers of methadone separately. This analysis revealed that fluoxetine 20 mg daily modestly increased the levels-to-dose ratio of the active *R*-methadone (by 33%) without significantly changing either the total or inactive *S*-methadone level-to-dose ratios.[4] Moreover, a patient taking methadone developed opioid toxicity when given ciprofloxacin and fluoxetine, see 'Quinolones + Opioids; Methadone', p.380.

(b) Fluvoxamine

Five patients taking maintenance doses of methadone were given fluvoxamine. Two of them had an increase of about 20% in the methadone plasma/dose ratio, while the other 3 had 40 to 100% rises in the methadone plasma/dose ratio (suggesting increased methadone levels). One of them developed asthenia, marked drowsiness and nausea, which disappeared when both drug doses were reduced.[5] A subsequent analysis of the enantiomers of methadone revealed that fluvoxamine increased the levels of both *R*- and *S*-methadone.[4] A report describes one patient who was unable to maintain adequate methadone levels, despite a daily dose of 200 mg, and experienced withdrawal symptoms until fluvoxamine was added.[6] Another patient taking methadone 70 mg daily and diazepam 2 mg twice daily was admitted to hospital with an acute exacerbation of asthma and intractable cough 3 weeks after starting fluvoxamine 100 mg daily. Blood gas measurements indicated severe hypoxaemia and hypercapnia. The symptoms resolved when the methadone dose was reduced to 50 mg daily and diazepam was gradually withdrawn, at which point methadone levels fell by about 23% (from 262 nanograms/mL to 202 nanograms/mL).[7]

(c) Paroxetine

Paroxetine 20 mg daily increased steady-state methadone levels by 35% in 10 patients taking maintenance doses of methadone. Both *R*- and *S*-methadone levels were increased in the 8 patients who were extensive metabolisers of the cytochrome P450 isoenzyme CYP2D6 (i.e those with normal levels of this isoenzyme), but in the 2 patients who were poor metabolisers (i.e. those lacking the isoenzyme) only the *S*-methadone levels were increased. Apart from one patient who reported feeling high during the first night after starting paroxetine, no symptoms of over-medication or toxicity were noted.[8]

(d) Sertraline

A placebo-controlled study in 31 methadone-maintained patients with depression found that sertraline increased the methadone plasma level/dose ratio by 26%, whereas patients taking placebo had a 16% decrease after 6 weeks of concurrent use, but by 12 weeks the ratios had shifted towards baseline values. Adverse effects were similar in both groups.[9] A 31-year-old woman taking methadone 230 mg daily was found to have a prolonged QT interval after sertraline 50 mg daily was added to her medications, although she was asymptomatic. The QT interval returned to normal when the methadone and sertraline were stopped and her methadone was replaced with morphine.[10]

Mechanism

Fluvoxamine, and to a lesser extent fluoxetine, paroxetine, and sertraline, can inhibit the liver metabolism of the methadone (possibly by the cytochrome P450 isoenzymes CYP3A4,[11] CYP2D6,[11,12] and/or CYP1A2[4]) thereby allowing it to accumulate in the body.

Importance and management

Information regarding an interaction between fluvoxamine and methadone is limited, but it indicates that the effects of starting or stopping fluvoxamine should be monitored in patients taking methadone, being alert for the need to adjust the methadone dosage. Although the increase in methadone levels with sertraline and paroxetine, and possibly also fluoxetine, is unlikely to have clinical effects in most patients, the possibility should be borne in mind, especially if high doses of methadone are being used. Note that methadone alone can prolong the QT-interval in high doses, see 'drugs that prolong the QT-interval', (p.290).

SSRIs + Opioids; Tramadol

Tramadol should be used with caution with SSRIs because of the increased risk of seizures and because of the risk of serotonin syndrome. One patient developed hallucinations when taking tramadol with paroxetine.

Clinical evidence

A. Seizures

The CSM in the UK has publicised 27 reports of convulsions and one of worsening epilepsy with tramadol, a reporting rate of 1 in 7000 patients. Some of the patients were given doses well in excess of those recommended, and some were taking SSRIs (5 patients), which are known to reduce the convulsive threshold.[1] Similarly, of 124 seizure cases associated with

tramadol reported to the FDA in the US, 20 included the concurrent use of SSRIs.[2]

B. Serotonin syndrome

The Australian Adverse Drug Reaction Advisory Committee has stated that tramadol may cause serotonin syndrome, particularly when it is used at high doses or in combination with other drugs increasing serotonin levels; of 20 reported cases of serotonin syndrome associated with tramadol, 16 were taking potentially interacting medicines including SSRIs.[3] Cases of serotonin syndrome with specific SSRIs are discussed below.

(a) Citalopram

A 70-year-old woman who had been taking citalopram 10 mg daily for 3 years developed tremors, restlessness, fever, confusion, and visual hallucinations after starting to take tramadol 50 mg daily for pain relief following an operation. Her symptoms stopped after tramadol was stopped. However, she continued to take citalopram and one year later she developed identical symptoms after taking tramadol 20 mg daily. Citalopram is metabolised by the cytochrome P450 enzyme CYP2C19 and tramadol is *O*-demethylated by CYP2D6 and the patient was found to be deficient in both CYP2C19 and CYP2D6, suggesting that her metabolising capacity of both pathways was reduced.[4]

(b) Fluoxetine

A woman who had been taking fluoxetine 20 mg daily for 3 years developed what was eventually diagnosed as serotonin syndrome. A month previously she had started to take tramadol 50 mg four times daily, increased after a fortnight to 100 mg four times daily. Ten days before hospitalisation she had developed a tremor of the right hand and face, and in hospital she became agitated, and developed marked facial blepharospasm, some sweating and pyrexia, and stuttering. The symptoms began to subside 7 days after both drugs were stopped, and after 2 months she had recovered fully.[5]

(c) Paroxetine

A man who had been taking paroxetine 20 mg daily for 4 months without problems developed shivering, diaphoresis and myoclonus and became subcomatose within 12 hours of taking tramadol 100 mg. This was diagnosed as serotonin syndrome. Tramadol was stopped, the paroxetine dosage halved and he became conscious within a day. The other symptoms gradually disappeared over the next week.[6] A 78-year-old woman taking paroxetine 20 mg daily developed nausea, diaphoresis and irritability 3 days after starting tramadol 50 mg three times a day. The next day she developed muscular weakness and confusion, and was found to have a temperature of about 38.2°C and a pulse rate of 110 bpm. She recovered when the drugs were withdrawn. Similar symptoms occurred in another elderly woman taking paroxetine 10 mg daily within 2 days of starting tramadol 50 mg four times daily. Both women were later able to continue taking paroxetine alone without problems.[7]

A tetraparetic patient with chronic pain developed nightmares and hallucinations 56 days after starting to take tramadol, paroxetine and dosulepin, which only stopped when the drugs were withdrawn.[8]

(d) Sertraline

A 42-year-old woman was admitted to intensive care with atypical chest pain, sinus tachycardia, confusion, psychosis, sundowning [increased agitation, activity and negative behaviours, which happen late in the day or evening], agitation, diaphoresis and tremor. She was taking a large number of drugs, including sertraline and tramadol. She was diagnosed as having serotonin syndrome, attributed to an increase in the dosage of tramadol (from 150 mg daily to 300 mg daily in increments of 50 mg every 2 to 3 days), and an increased sertraline dosage (original amounts not stated but 100 mg daily when the adverse events developed). The tramadol had been started 3 weeks previously and she had been taking the sertraline for a year.[9]

An 88-year-old woman taking sertraline 50 mg daily (later increased to 100 mg daily), as well as several other medications was given dextropropoxyphene with paracetamol, and tramadol 200 mg daily increased to 400 mg daily for pain relief after a fracture. Ten days after starting tramadol she became confused, with alterations in cognitive function, tremor, problems with co-ordination, and muscle weakness. Serotonin syndrome was suspected and therefore sertraline was withdrawn over a period of 2 days, the dose of tramadol was reduced from 400 to 200 mg daily, and the patient recovered over a period of about 2 weeks.[10]

In another report, serotonin syndrome occurred after the first dose of sertraline 50 mg in a 75-year-old woman who had been taking tramadol 50 mg daily for 3 days. The concentration of serotonin (5-hydroxytryptamine) in her CSF was found to be elevated to 38.5 nanograms/mL (reference value less than 10 picograms/mL).[11]

C. Pharmacokinetic effects

A placebo-controlled, crossover study in 16 healthy subjects found that pretreatment with **paroxetine** 20 mg daily for 3 days increased the AUC of tramadol by about 35%, and decreased the AUCs of the *O*-demethylated metabolites of tramadol by 40 to 67%. The analgesic effect of tramadol was reduced, but not abolished.[12]

Mechanism

Tramadol may rarely cause seizures and SSRIs can reduce the seizure threshold, thus if both are taken together the risk is increased. Serotonin syndrome seems to develop unpredictably in some patients given two or more serotonergic drugs (in this case, tramadol and SSRIs).

Paroxetine is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6 and inhibits the metabolism of tramadol by this isoenzyme, which results in reduced formation of its *O*-demethylated metabolites. The reduction in these metabolites may result in reduced analgesia as the opioid effect of tramadol is thought to be mediated mainly by (+)-*O*-desmethyltramadol.[12]

Importance and management

Because of the possible increased risk of seizures, tramadol should be used with caution in patients taking drugs such as the SSRIs, which can lower the seizure threshold. The concurrent use of tramadol and an SSRI may also lead to an increase in serotonin-associated effects, which can include serotonin syndrome. However, the relatively few reported cases of serotonin syndrome or other reactions due to an interaction between an SSRI and tramadol need to be set in the wider context of apparently uneventful and advantageous use in other patients,[12-14] although some workers have suggested that the incidence of serotonin syndrome may be underreported.[15] There would seem to be little reason for totally avoiding the concurrent use of the SSRIs and tramadol but it would clearly be prudent to monitor the outcome closely. For more information about serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

Tramadol analgesia may possibly be altered by paroxetine and potentially by other SSRIs that inhibit CYP2D6, such as fluoxetine (see 'Table 35.2', (p.1465), for information on the inhibitory effects of the SSRIs). Bear the potential for this interaction in mind should a patient taking these SSRIs have a reduced response to tramadol, and adjust the dose of tramadol as necessary.

SSRIs + Protease inhibitors

Ritonavir-boosted darunavir reduces paroxetine and sertraline levels. Ritonavir-boosted fosamprenavir reduces paroxetine lev-

els. Paroxetine does not appear to alter the levels of ritonavir-boosted darunavir or fosamprenavir and sertraline does not appear to alter darunavir levels, whereas fluoxetine slightly raised the levels of ritonavir in one study. Two cases of serotonin syndrome have been attributed to the use of fluoxetine and ritonavir.

Clinical evidence

(a) Darunavir

In a pharmacokinetic study, the AUC and minimum level of **paroxetine** were reduced by 39% and 37%, respectively, when **paroxetine** 20 mg daily and ritonavir-boosted darunavir 100/400 mg twice daily were given together. The darunavir AUC and minimum level were unaffected by concurrent use.[1,2]

In a very similar study using the same dose of ritonavir-boosted darunavir, the AUC and minimum level of **sertraline** 50 mg daily were reduced by 49% without any effect on darunavir levels.[1,2] Note that the dose of darunavir used in these studies (400 mg twice daily) is less than that recommended (600 mg twice daily).[1,2]

(b) Fosamprenavir

In a pharmacokinetic study in healthy subjects, the AUC and maximum level of **paroxetine** were reduced by 58% and 60%, respectively, when **paroxetine** 20 mg daily and ritonavir-boosted fosamprenavir 100/700 mg twice daily were given together for 10 days. The fosamprenavir and ritonavir pharmacokinetics did not differ from historical control values. No serious adverse events occurred.[3]

(c) Ritonavir

In a single-dose study involving 18 healthy subjects, no significant pharmacokinetic changes were seen when ritonavir 600 mg was given at the same time as **escitalopram** 20 mg.[4] These findings need confirmation with multiple doses, because the effects of ritonavir on drug metabolising enzymes would not have been maximal before **escitalopram** was given.

Ritonavir 600 mg was given to 16 healthy subjects before and after they took **fluoxetine** 30 mg twice daily for 8 days. The maximum plasma levels of ritonavir were unaffected, but its AUC rose by 19%. These changes were not considered large enough to warrant changing the dose of ritonavir.[5] The study was criticised for not achieving steady state before assessing the pharmacokinetics and thus possibly underestimating the interaction.[6] However, the authors point out that **fluoxetine** levels were equivalent to those seen at steady state, and multiple dosing of ritonavir is likely to induce its own metabolism, so if anything, the interaction would be lessened at steady state.[7]

Two cases of serotonin syndrome were attributed to adding ritonavir to established **fluoxetine** treatment. One of these patients later tolerated ritonavir-boosted saquinavir when the **fluoxetine** dose was halved, and in the other nelfinavir was substituted for ritonavir.[8] Another case of serotonin syndrome developed in a patient taking **fluoxetine** and trazodone when ritonavir was added, see 'Trazodone + Protease inhibitors', p.1496.

Mechanism

It has been assumed that ritonavir would raise the levels of SSRIs that are substrates for the cytochrome P450 isoenzyme CYP2D6 (e.g. fluoxetine, paroxetine, sertraline) due to the inhibitory effect of ritonavir on this isoenzyme.[9] However, ritonavir is generally used as a pharmacokinetic enhancer with other protease inhibitors, and the available data show that this actually decreases paroxetine and sertraline levels. The mechanism is not known.

Importance and management

The pharmacokinetic interaction showing a reduction in paroxetine and sertraline levels with ritonavir-boosted darunavir and fosamprenavir is established. Although the clinical relevance of these reductions is not certain, it would be prudent to anticipate some reduction in efficacy when starting these protease inhibitors, and to monitor the clinical effect and increase the SSRI dose as necessary. Whether other SSRIs would be affected similarly is unknown, but fluoxetine would be expected to be. Moreover, whether other ritonavir-boosted protease inhibitors interact similarly is unknown, but it would be prudent to expect that they might also reduce the levels of these SSRIs. However, the US manufacturer of **tipranavir**[10] predicts that ritonavir-boosted tipranavir will result in an *increase* in the levels of fluoxetine, paroxetine and sertraline, presumably because tipranavir, unlike some of the other protease inhibitors, may also inhibit CYP2D6.

Although there is a study suggesting escitalopram levels are not affected by ritonavir, the findings of this study are questionable as it used simultaneous single doses. The general relevance of the few cases of serotonin syndrome is also uncertain.

The available data for ritonavir alone and ritonavir-boosted darunavir and fosamprenavir suggest that the pharmacokinetics of these protease inhibitors are not affected to a clinically relevant extent by fluoxetine, sertraline or paroxetine. This suggests that there are no pharmacokinetic concerns regarding antiviral efficacy or adverse effects.

SSRIs + Rifampicin (Rifampin)

In two cases rifampicin decreased the efficacy of citalopram and sertraline. Paroxetine is predicted to interact similarly.

Clinical evidence

A 34-year-old man, with a long-standing history of anxiety disorder, taking **sertraline** 200 mg at bedtime, reported that the medication was no longer working well. He was experiencing a significant amount of anxiety, excessive worry, and poor energy. He additionally reported feeling "spaced out" and having dizziness exacerbated by movement, lethargy, and insomnia. He had started taking rifampicin 300 mg twice daily and co-trimoxazole 7 days earlier and it was found that his **sertraline** and *N*-desmethylsertraline levels were only 39% and 46%, respectively, of the levels achieved when he was not taking rifampicin and co-trimoxazole. He later experienced similar symptoms when the **sertraline** dose was tapered so that paroxetine could be substituted.[1] Similarly, a 55-year-old man taking **citalopram** 40 to 60 mg daily reported a decrease in therapeutic efficacy (increased crying and panic attacks) after starting rifampicin 600 mg twice daily. His condition improved when the rifampicin was stopped.[2]

Mechanism

Both sertraline and citalopram are metabolised by cytochrome P450 isoenzymes including CYP3A4, of which rifampicin is a potent inducer. It would therefore appear that rifampicin induced the metabolism of these two drugs resulting in decreased plasma levels.

Importance and management

There seem to be very few reports of this interaction, but rifampicin is a potent enzyme inducer and so clinicians should be aware that rifampicin may reduce citalopram or sertraline plasma levels leading to decreased efficacy or symptoms of SSRI withdrawal. In theory, rifampicin could affect other SSRIs metabolised by other cytochrome P450 isoenzymes, but there appear to be no reports of this. The UK manufacturer of **paroxetine** suggests that dosage adjustment on starting or stopping enzyme inducing drugs such as rifampicin should be guided by clinical effect (tolerability and efficacy), and they suggest that no initial anticipatory dose adjustment is necessary.[3] Until more is known this would seem to be a sensible approach with rifampicin and any SSRI.

SSRIs + Sibutramine

Two case reports suggest that the concurrent use of sertraline or citalopram with sibutramine may cause serotonin syndrome.

Clinical evidence, mechanism, importance and management

A 43-year-old woman taking **citalopram** 40 mg daily was also given sibutramine 10 mg daily. Within a few hours of taking the first dose of sibutramine she developed racing thoughts, hyperactivity, psychomotor agitation, shivering and diaphoresis, which continued for the 3 days that she continued to take sibutramine. The authors suggested that one of the reasons for the hypomania may have been serotonin syndrome, which could have been caused by the use of two drugs with serotonergic action.[1] A letter briefly mentions another possible case of serotonin syndrome, following the use of sibutramine and **sertraline**.[2] The manufacturers of sibutramine say that concurrent use of any other drug that has serotonergic actions should be avoided[3] where possible,[4] or only undertaken with appropriate monitoring.[4] For more information about serotonin syndrome, see under 'Additive or synergistic interactions', (p.9).

SSRIs + SSRIs

An isolated report describes an adverse reaction (hypertension, tachycardia, fever, auditory hallucinations and confusion) in a man when he started sertraline within a day of stopping fluoxetine. A small study found that the concurrent use of citalopram and fluvoxamine markedly increased citalopram plasma levels: escitalopram will be similarly affected. Note that combining more than one SSRI is unusual, and would be expected to increase the risk of adverse effects.

Clinical evidence

(a) Citalopram or Escitalopram with Fluvoxamine

A study in 7 patients with depression who had not responded to treatment with citalopram 40 mg daily for 3 weeks, found that the addition of fluvoxamine (50 mg increased to 100 mg daily for another 3 weeks) increased *R*-citalopram levels by almost twofold and *S*-citalopram levels threefold. Six of the 7 patients showed clinical improvement. None of the patients developed serotonin syndrome, and no changes in vital signs or ECGs were seen.[1] This study shows that the levels of escitalopram, the *S*-isomer of citalopram, will be raised by fluvoxamine.

(b) Fluoxetine with Sertraline

One of 16 healthy subjects who began to take sertraline 50 mg daily on the day after stopping a 2-week trial of fluoxetine 20 mg daily, rapidly developed hypertension, tachycardia, fever, auditory hallucinations and confusion. Most of these symptoms disappeared 48 hours after stopping the sertraline, but the confusion took a week to subside.[2] The other 15 subjects had no clinically significant adverse effects. This subject was later found to have a history of psychosis so that the picture is a little confused, but the rapid abatement of the symptoms when the sertraline was stopped suggests that they were due either to the sertraline alone, or to an interaction with the residual fluoxetine.

Mechanism

Fluvoxamine increases citalopram levels, with a more marked effect on *S*-citalopram (escitalopram), possibly by inhibiting the cytochrome P450 isoenzyme CYP2C19. Fluoxetine has a very long half-life, and might therefore have contributed to the adverse effects seen when switching to sertraline in the case described. Combining drugs with serotonergic actions such as two SSRIs are likely have additive effects.

Importance and management

There is very little information on combining SSRIs because this is not a usual therapeutic strategy. It is likely that combining two SSRIs will have additive effects, and some SSRI manufacturers include other SSRIs in the list of drugs that have serotonergic effects and would therefore increase the risk of serotonergic adverse effects including the rare 'serotonin syndrome', (p.9), on concurrent use. On this basis they advise caution or avoidance of concurrent use. Some caution would seem prudent. The one study with fluvoxamine and citalopram highlights the fact that there might be a pharmacokinetic component to the interaction between some SSRIs, which would intensify any effects.

On the basis of the possible interaction, it is also not clear whether a washout period is needed if switching between two SSRIs, particularly when the first has a long half-life, such as fluoxetine. A decision on this will depend on the severity of the depression in the particular patient being treated. The manufacturers of sertraline imply caution when they say that the duration of a washout period when switching from one SSRI to another has not yet been established.[3,4]

4. Zoloft (Sertraline hydrochloride). Pfizer Inc. US Prescribing information, January 2009.

SSRIs + St John's wort (*Hypericum perforatum*)

Cases of severe sedation, mania and serotonin syndrome have been reported in patients taking St John's wort with SSRIs.

Clinical evidence

(a) Fluoxetine

For a report of hypomania when St John's wort, ginkgo biloba and melatonin were added to treatment with fluoxetine and buspirone, see 'Buspirone + St John's wort (*Hypericum perforatum*)', p.871.

For a report of serotonin syndrome when eletriptan, fluoxetine and St John's wort were used together, see 'Triptans + St John's wort (*Hypericum perforatum*)', p.691.

(b) Paroxetine

In one report, a woman stopped taking paroxetine 40 mg daily after 8 months, and 10 days later started to take 600 mg of St John's wort powder daily. No problems occurred until the next night when she took a single 20-mg dose of paroxetine because she thought it might help her sleep. The following day at noon she was found still to be in bed, rousable but incoherent, groggy and slow moving and almost unable to get out of bed. Two hours later she still complained of nausea, weakness and fatigue, but her vital signs and mental status were normal. Within 24 hours all symptoms had resolved.[1]

(c) Sertraline

Four elderly patients taking sertraline developed symptoms characteristic of serotonin syndrome within 2 to 4 days of also taking St John's wort 300 mg, either two or three times daily. The symptoms included dizziness, nausea, vomiting, headache, anxiety, confusion, restlessness, and irritability. Two of them were treated with oral cyproheptadine 4 mg either two or three times daily, and the symptoms of all of them resolved within a week. They later resumed treatment with sertraline without problems.[2] A search of Health Canada's database of spontaneous adverse reactions from 1998 to 2003 found 2 cases of suspected serotonin syndrome as a result of an interaction between sertraline and St John's wort.[3]

Mania developed in a 28-year-old man, who continued to take St John's wort against medical advice whilst also receiving sertraline 50 mg daily for depression; he was also receiving testosterone replacement post-orchidectomy.[4]

Mechanism

A pharmacodynamic interaction may occur between St John's wort and SSRIs because they can both inhibit the reuptake of 5-hydroxytryptamine (serotonin).[5] Serotonin syndrome has been seen with St John's wort alone,[6] and so additive serotonergic effects appear to be the explanation for what occurred in the cases described here.

Importance and management

Information appears to be limited to these reports, but interactions between SSRIs and St John's wort would seem to be established. The incidence is not known but it is probably small, nevertheless because of the potential severity of the reaction it would seem prudent to avoid concurrent use. The advice of the CSM in the UK is that St John's wort should be stopped if patients are taking any SSRI because of the risk of increased serotonergic effects and an increased incidence of adverse reactions.[7]

SSRIs + Terbinafine

Although terbinafine modestly increases paroxetine levels one study found no increase in paroxetine adverse effects. Some other SSRIs may interact similarly.

Clinical evidence

In a randomised study, 12 healthy subjects were given a single 20-mg dose of paroxetine, alone or after taking terbinafine 125 mg daily for 6 days. Terbinafine increased the AUC and maximum plasma concentration of paroxetine by 150% and 86%, respectively, and the half-life of paroxetine was also increased by 48% (from about 15 hours to 23 hours). There was no significant difference in the adverse effects reported between the two treatments.[1]

Mechanism

Terbinafine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, the isoenzyme by which paroxetine is metabolised. Concurrent use therefore decreases paroxetine metabolism and increases its levels.

Importance and management

Information appears to be limited to one study, but the results are in line with the way both drugs are known to interact. Be aware that paroxetine levels may be increased if terbinafine is also given, and consider a dose reduction if adverse effects become troublesome. Note that many of the SSRIs are metabolised, at least in part, by CYP2D6 (see 'Table 35.2', (p.1465)), and so may interact similarly, although the clinical relevance of these potential interactions is unknown.

SSRIs + Tobacco

Smoking has only modest effects on fluvoxamine pharmacokinetics. It is unclear whether smoking has any effect on citalopram pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Citalopram

In a pharmacokinetic study in adolescent patients (under 21 years of age), there was a clear dose-concentration relationship for citalopram and its metabolite, desmethylcitalopram, in the 9 non-smokers, whereas no such relationship was seen in the 10 smokers. The authors suggested that smoking might have had some effect on citalopram pharmacokinetics, but that this requires confirmation.[1] The clinical significance of any effect is unknown and more study is required.

(b) Fluvoxamine

A comparative study in 12 smokers and 12 non-smokers given single 50-mg oral doses of fluvoxamine found that smoking reduced the fluvoxamine AUC and maximum serum levels by about 30%.[2] However, a study in Japanese patients found no significant difference in the steady-state plasma levels of fluvoxamine and its metabolite (fluvoxamino acid) between 34 non-smokers and 15 smokers.[3] This suggests that the overall pharmacokinetic effect of smoking is probably minimal, although how a sudden withdrawal from heavy smoking would affect fluvoxamine pharmacokinetics has not been investigated.

Effects of the CYP 2D6 genotype and cigarette smoking on the steady-state plasma concentrations of fluvoxamine and its major metabolite fluvoxamino acid in Japanese depressed patients. *Ther Drug Monit* (2003) 25, 463–8.

SSRIs + Tryptophan

Central and peripheral toxicity developed in five patients taking high doses of fluoxetine when they were given tryptophan, which was attributed to serotonin syndrome. Adverse effects have occurred on combined use of paroxetine and tryptophan.

Clinical evidence

(a) Fluoxetine

Five patients taking fluoxetine 50 to 100 mg daily (high doses) for at least 3 months developed a number of reactions including central toxicity (agitation, restlessness, aggressive behaviour, worsening of obsessive-compulsive disorders) and peripheral toxicity (abdominal cramps, nausea, diarrhoea) within a few days of starting to take tryptophan 1 to 4 g daily. These symptoms disappeared when the tryptophan was stopped. Some of the patients had taken tryptophan in the absence of fluoxetine without problems.[1]

Conversely, in a placebo-controlled study involving 30 patients with depression, the use of tryptophan 1 g daily titrated to 4 g daily during the initial 8 weeks of treatment with fluoxetine 20 mg daily was beneficial and well-tolerated. No cases of serotonin syndrome occurred.[2]

(b) Paroxetine

The US manufacturer of paroxetine notes that adverse experiences, consisting primarily of headache, nausea, sweating, and dizziness, have been reported when paroxetine was taken with tryptophan.[3]

Mechanism

Tryptophan is a precursor of serotonin (5-hydroxytryptamine) and the authors of the fluoxetine cases point out that the symptoms resemble serotonin syndrome, which occurs when serotonin levels are increased.[1] The reaction appears to be dose related. It is likely to occur with any SSRI.

Importance and management

The cases with fluoxetine appear to be the only ones published, nevertheless, they demonstrate the potential for additive adverse effects. The authors recommended caution when tryptophan is used with fluoxetine or other serotonin reuptake inhibitors.[1] This caution (or advice to avoid concurrent use) is echoed by most of the manufacturers of the SSRIs; the UK manufacturer of paroxetine additionally mentions the serotonin precursor **oxitriptan** [L-5-hydroxytryptophan].[4] If tryptophan is used to augment the initial response to SSRIs, the SSRI should be started at a low dose,

with tryptophan gradually introduced, starting with a low dose. Patients should be closely monitored for adverse effects.[2]

SSRIs; Citalopram + Irinotecan

An isolated report attributes a case of rhabdomyolysis to the use of citalopram and irinotecan.

Clinical evidence, mechanism, importance and management

A 74-year-old man who had been taking citalopram for 2 months developed rhabdomyolysis after undergoing initial treatment for gastrointestinal cancer with irinotecan. All medications were discontinued, but the rhabdomyolysis was exacerbated upon restarting the citalopram for depression. The citalopram was discontinued and he improved over the next 5 days.[1]

The authors suggested that levels of citalopram might have increased because irinotecan might inhibit the cytochrome P450 isoenzyme CYP3A4, and the cytochrome system may also have been compromised by the malignancy.[1] However, the patient was also taking **simvastatin**, which is well known to be associated with a risk of rhabdomyolysis and which is also metabolised by CYP3A4, but the authors make no mention of this. An interaction between citalopram and irinotecan is therefore not established, and speculatively, this seems more likely to be an interaction between irinotecan and simvastatin, which was exacerbated by citalopram.

SSRIs; Fluoxetine + Aminoglutethimide

Evidence from one case suggests that the effects of fluoxetine are increased by aminoglutethimide.

Clinical evidence, mechanism, importance and management

A patient with severe obsessive-compulsive disorder, resistant to clomipramine combined with SSRIs, improved when given fluoxetine 40 mg daily and aminoglutethimide 250 mg four times daily. Over a four-and-a-half year period, whenever attempts were made to reduce the dosage of either drug, the patient started to relapse.[1] The evidence suggests that aminoglutethimide has a potentiating effect on fluoxetine. However, more study is needed to confirm the efficacy and safety of this drug combination in other patients.

SSRIs; Fluoxetine + Cannabis

An isolated report describes mania when a patient taking fluoxetine smoked cannabis.

Clinical evidence, mechanism, importance and management

A 21-year-old woman with a 9-year history of bulimia and depression started taking fluoxetine 20 mg daily. A month later, about 2 days after smoking two 'joints' of cannabis (**marijuana**), she experienced a persistent sense of well-being, increased energy, hypersexuality and pressured speech. These symptoms progressed into grandiose delusions, for which she was hospitalised. Her mania and excitement were controlled with lorazepam and perphenazine, and she largely recovered after about 8 days. The reasons for this reaction are not understood but the authors of the report point out that one of the active components of cannabis, **dronabinol** (Δ^9**-tetrahydrocannabinol**) is, like fluoxetine, a potent inhibitor of serotonin uptake. Thus a synergistic effect on central serotonergic neurones might have occurred.[1] This seems to be the first and only report of an apparent adverse interaction between cannabis and fluoxetine. The patient had only started fluoxetine 4 weeks before the manic episode, and was still suffering 'hyper' feelings over a month after smoking the cannabis. The symptoms only resolved when the fluoxetine was withdrawn, and so an interaction is by no means established.

SSRIs; Fluoxetine + Orlistat

The pharmacokinetics of a single 40-mg oral dose of fluoxetine (a lipophilic drug) were not affected by orlistat 120 mg three times daily in healthy subjects.[1] Therefore, no fluoxetine dose adjustments appear to be needed on the concurrent use of orlistat.

1. Zhi J, Moore R, Kanitra L, Mulligan TE. Effects of orlistat, a lipase inhibitor, on the pharmacokinetics of three highly lipophilic drugs (amiodarone, fluoxetine, and simvastatin) in healthy volunteers. *J Clin Pharmacol* (2003) 43, 428–35.

SSRIs; Fluvoxamine + Clindamycin

A man taking fluvoxamine developed severe orofacial dyskinesia two days after starting to take clindamycin.

Clinical evidence, mechanism, importance and management

A 32-year-old man with a major depressive episode was admitted to hospital 10 days after starting fluvoxamine 100 mg daily for 10 days. The fluvoxamine dose was increased to 200 mg daily, and after 4 weeks his mood was stabilised. Two days after starting clindamycin 300 mg daily for a furuncle, severe orofacial dyskinesia developed, which disappeared after he was given intravenous biperiden. A blood level of fluvoxamine taken at this time was actually lower than usual therapeutic levels.[1]

The authors speculated that the time course of events suggests that clindamycin might have contributed to the dyskinesia. However, there is no known mechanism for an interaction. Clindamycin would not be expected to alter the pharmacokinetics of fluvoxamine, and the fluvoxamine blood level appears to confirm this. Clindamycin is also not known to cause extrapyramidal adverse effects.

Based on this single case, no general advice can be given, but bear it in mind in case of a similar unexpected reaction.

1. Jakob F, Wolf J. EPMS under antidepressive therapy with fluvoxamine and concomitant antibiotic therapy with clindamycin. *Pharmacopsychiatry* (2007) 40, 129.

SSRIs; Fluvoxamine + Enoxacin

A study in healthy subjects suggested that enoxacin might slightly increase fluvoxamine levels.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study in 10 healthy subjects given enoxacin 100 mg twice daily for 11 days, with a single 50-mg dose of fluvoxamine on the eighth day. Enoxacin slightly increased the plasma levels of fluvoxamine at 2 and 3 hours, with a 14% increase in the maximum plasma level. There was no change in the AUC or elimination half-life of fluvoxamine or in the pharmacokinetics of the active metabolite of fluvoxamine, fluvoxamino acid. Sleepiness was increased from 30 minutes to 4 hours, but there was no change in the digit symbol substitution test or adverse effects.[1]

It was suggested that enoxacin slightly inhibits the metabolism of fluvoxamine by the cytochrome P450 isoenzyme CYP1A2; however fluvoxamine is not know to be metabolised by this route, so the exact mechanism is not clear.

The interpretation of this study is difficult. The minor change in just the maximum level of fluvoxamine would be very unlikely to be clinically relevant, and is unlikely to explain an increase in sleepiness. Further study is necessary, with multiple doses of fluvoxamine. Until more is known, bear

the possibility of an interaction in mind the event of increased sleepiness with enoxacin.

1. Kunii T, Fukasawa T, Yasui-Furukori N, Aoshima T, Suzuki A, Tateishi T, Inoue Y, Otani K. Interaction study between enoxacin and fluvoxamine. *Ther Drug Monit* (2005) 27, 349–53.

SSRIs; Paroxetine + Miscellaneous

Aluminium hydroxide and food do not appear to cause a clinically relevant change in paroxetine absorption, although absorption may be reduced by large quantities of milk. The concurrent use of paroxetine and aprepitant may slightly reduce the plasma levels of both drugs, but this is probably not clinically significant.

Clinical evidence, mechanism, importance and management

(a) Aluminium hydroxide

In a study in healthy subjects, *Aludrox* (aluminium hydroxide) 15 mL twice daily increased the absorption of a single 30-mg dose of paroxetine by about 12%, and increased its maximum plasma concentration by 14%.[1] These changes are unlikely to be clinically important. No particular precautions would seem to be necessary on concurrent use.

(b) Aprepitant

The US manufacturer of aprepitant notes that the concurrent use of paroxetine 20 mg daily and aprepitant 85 or 170 mg daily reduced the AUC of both drugs by about 25%, and reduced the maximum serum levels by about 20%.[2] These changes are unlikely to be clinically important. An interaction with **fosaprepitant** (which is rapidly metabolised to aprepitant) seems unlikely.

(c) Foods

A study in healthy subjects found that the absorption of paroxetine was not markedly changed by food. A 40% reduction in absorption was seen when paroxetine was taken with one litre of **milk**,[1] but it would seem unlikely that many people would drink such a large amount regularly, at the same time as taking paroxetine, and so this interaction is unlikely to be generally significant.

2. Emend (Aprepitant). Merck & Co., Inc. US Prescribing information, July 2009.

Tianeptine + Oxazepam

A study in healthy subjects given tianeptine 12.5 mg and oxazepam 10 mg both three times daily found no significant changes in the pharmacokinetics of either drug.[1]

1. Toon S, Holt BL, Langley SJ, Mullins FGP, Rowland M, Halliday MS, Salvadori C, Delalleau B. Pharmacokinetic and pharmacodynamic interaction between the antidepressant tianeptine and oxazepam at steady-state. *Psychopharmacology (Berl)* (1990) 101, 226–32.

Trazodone + Azoles

Ketoconazole or itraconazole may inhibit the metabolism of trazodone.

Clinical evidence, mechanism, importance and management

An *in vitro* study found that **ketoconazole** inhibited the metabolism of trazodone to its principal active metabolite, meta-chlorophenylpiperazine, and was of similar potency to ritonavir in this regard.[1]

Trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this enzyme such as **ketoconazole** and **itraconazole** may inhibit its metabolism, leading to substantial increases in trazodone plasma concentrations with the potential for adverse effects,[2-4] as has been shown for ritonavir, see 'Trazodone + Protease inhibitors', p.1496.

On the basis of the available data, the FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with a potent CYP3A4 inhibitor such as **ketoconazole** or **itraconazole**.[2-4] However, the UK manufacturer also suggests that the combination should be avoided, where possible.[4]

4. Molipaxin Capsules (Trazodone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, August 2009.

Trazodone + Ginkgo (*Ginkgo biloba*)

Coma developed in an elderly patient with Alzheimer's disease after she took trazodone with ginkgo.

Clinical evidence

An 80-year-old woman with Alzheimer's disease became comatose a few days after starting low-dose trazodone 20 mg twice daily and ginkgo biloba. The patient woke immediately after being given flumazenil 1 mg intravenously.[1]

Mechanism

It was suggested that the flavonoids in the ginkgo had a subclinical direct effect on the benzodiazepine receptor. In addition, it was suggested that ginkgo increased the metabolism of trazodone to its active metabolite, 1-(m-chlorophenyl)piperazine (mCPP) by the cytochrome P450 isoenzyme CYP3A4. The increased levels of the metabolite were thought to have enhanced the release of GABA (gamma-amino butyric acid). Flumazenil may have blocked the direct effect of the flavonoids, thus causing the GABA activity to fall below the level required to have a clinical effect. However, note that clinically relevant CYP3A4 induction has not been seen with the conventional CYP3A4 probe substrate midazolam.

Importance and management

Evidence for an interaction between ginkgo and trazodone appears to be limited to this isolated case, from which no general conclusions can be drawn. Bear this interaction in mind in case of an unexpected response to concurrent use.

1. Galluzzi S, Zanetti O, Binetti G, Trabucchi M, Frisoni GB. Coma in a patient with Alzheimer's disease taking low dose trazodone and ginkgo biloba. *J Neurol Neurosurg Psychiatry* (2000) 68, 679–80.

Trazodone + Haloperidol

Low-dose haloperidol does not alter the pharmacokinetics of trazodone to a clinically relevant extent.

Clinical evidence, mechanism, importance and management

Nine depressed patients who had been taking trazodone 150 to 300 mg at bedtime for 2 to 19 weeks were given haloperidol 4 mg daily for a week. Plasma trazodone levels were not significantly changed but levels of its metabolite (*m*-chlorophenylpiperazine) were slightly raised by 18% (from 78 to 92 nanograms/mL). This study[1] was carried out to investigate the way trazodone is metabolised, but it also demonstrated that no clinically relevant pharmacokinetic interaction occurs between these two drugs at these dosages.

1. Mihara K, Otani K, Ishida M, Yasui N, Suzuki A, Ohkubo T, Osanai T, Kaneko S, Sugawara K. Increases in plasma concentration of m-chlorophenylpiperazine, but not trazodone, with low-dose haloperidol. *Ther Drug Monit* (1997) 19, 43–5.

Trazodone + Lysergide (LSD)

A retrospective study found that 28 of 32 subjects (88%) who took LSD and who had taken an SSRI or trazodone for more than 3 weeks had a subjective decrease or virtual elimination of their responses to LSD.[1] The reasons for this effects are not understood. Lysergide increases serotonin in the brain, and one sugges-

tion is that when the serotonin re-uptake is blocked in the brain, there is an increased stimulation of 5-HT_1 and 5-HT_2 receptors.

1. Bonson KR, Buckholtz JW, Murphy DL. Chronic administration of serotonergic antidepressants attenuates the subjective effects of LSD in humans. *Neuropsychopharmacology* (1996) 14, 425–36.

Trazodone + Macrolides

Clarithromycin markedly impaired the clearance of trazodone and enhanced its sedative effects in one study. Erythromycin is also likely to increase trazodone plasma levels.

Clinical evidence, mechanism, importance and management

In a preliminary report of a placebo-controlled study in healthy subjects, **clarithromycin** (dose and duration not given) markedly reduced the clearance of a 50-mg dose of trazodone by almost 90%, almost doubled its elimination half-life, and increased its maximum level by 36%. Clarithromycin enhanced the sedation and performance impairment seen with trazodone.[1]

The manufacturers comment that trazodone is a substrate for the cytochrome P450 isoenzyme CYP3A4 and inhibitors of this isoenzyme may inhibit its metabolism leading to substantial increases in trazodone plasma levels, with the potential for adverse effects.[2,3] Clarithromycin is a known inhibitor of this isoenzyme and may therefore interact in this way, although other mechanisms might also be involved.

On the basis of the available data, caution is required when clarithromycin is given to a patient taking trazodone. Based on data with ritonavir (see 'Trazodone + Protease inhibitors', below), the UK manufacturer of trazodone recommends that a lower dose of trazodone should be considered if it is given with potent CYP3A4 inhibitors (they name **erythromycin**), but that concurrent use should be avoided where possible.[3] If CYP3A4 inhibition is the mechanism for this interaction, it seems likely that all macrolides that inhibit CYP3A4 will interact to some extent. See 'Ergot derivatives + Macrolides', p.683, for a general guide to the relative inhibitory potencies of the macrolides on CYP3A4.

2. Desyrel (Trazodone hydrochloride). Bristol-Myers Squibb Company. US Prescribing information, February 2009.
3. Molipaxin Capsules (Trazodone hydrochloride). Sanofi-Aventis. UK Summary of product characteristics, August 2009.

Trazodone + Protease inhibitors

Ritonavir markedly impairs the clearance of trazodone. Other protease inhibitors may interact similarly. A possible case of serotonin syndrome has been seen in a patient taking multiple serotonergic drugs, including trazodone, and ritonavir.

Clinical evidence

A randomised, placebo-controlled study in 10 healthy subjects found that short-term exposure to low-dose **ritonavir** (200 mg twice daily for 2 days) impaired the clearance of a single 50-mg dose of trazodone by 52%. The AUC of trazodone increased by 2.4-fold, whereas its mean peak plasma levels were increased by just 34%. In addition, **ritonavir** enhanced the adverse effects of trazodone with increased sedation, fatigue and performance impairment.[1] Symptoms of serotonin syndrome occurred in an HIV-positive patient taking antiretrovirals and other drugs, including fluoxetine, lithium and trazodone, when **ritonavir** was added. The symptoms resolved on discontinuing the trazodone and halving the **ritonavir** dose.[2] Serotonin syndrome has also been seen in a patient taking trazodone, fluoxetine, **indinavir** and excessive amounts of grapefruit, see 'SSRIs + Grapefruit juice', p.1484.

Mechanism

An *in vitro* study demonstrated that the metabolism of trazodone to its principal active metabolite, meta-chlorophenylpiperazine (mCPP), was inhibited by ritonavir, which is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4. Indinavir was also a strong inhibitor of mCPP formation, whereas **saquinavir** and **nelfinavir** were considerably less potent inhibitors.[3] The clinical study shows that this leads to an increase in adverse effects.[1]

Importance and management

Although data are limited, what is available suggests that the pharmacokinetic interaction between ritonavir and trazodone is likely to be clinically important. The FDA in the US and the manufacturers of trazodone recommend that a lower dose of trazodone should be considered if it is given with potent CYP3A4 inhibitors such as the protease inhibitors ritonavir and indinavir.[4-6] However, the UK manufacturer also suggests that the combination should be avoided where possible.[5]

Trazodone + Pseudoephedrine

A single report describes a woman taking trazodone who developed a toxic reaction when she took pseudoephedrine.

Clinical evidence, mechanism, importance and management

An isolated report describes a woman who had been taking trazodone 250 mg daily for 2 years who took two doses of a non-prescription medicine containing pseudoephedrine. Within 6 hours she experienced dread, anxiety, panic, confusion, depersonalisation and the sensation that parts of her body were separating. None of these symptoms had been experienced in the past when she was taking either preparation alone.[1] The reasons for this reaction are not understood. This appears to be an isolated case, and therefore no general conclusions can be drawn.

Trazodone + SSRIs

Trazodone and fluoxetine have been used concurrently with advantage, but some patients have developed increased adverse effects. Fluoxetine might modestly increase trazodone levels, whereas citalopram has little effect on trazodone levels.

Clinical evidence

(a) Citalopram

In a study using data from trazodone therapeutic drug monitoring, the trazodone concentration/dose ratio was 28% higher in 41 patients taking trazodone with citalopram than in 40 patients taking trazodone alone, but this difference was not statistically significant.[1]

(b) Fluoxetine

In a controlled study, 27 patients were given trazodone 100 mg daily alone for one week, and then randomised to receive fluoxetine 20 mg daily, pindolol 7.5 mg daily or placebo for 4 weeks. Fluoxetine increased trazodone levels by 43% at 2 weeks and 65% at 4 weeks compared with baseline values, whereas pindolol and placebo had no effect.[2] Similarly, a patient taking trazodone had a 31% increase in the trazodone plasma level corrected for dose (suggesting increased trazodone levels) when fluoxetine 40 mg daily was added. She became sedated and developed an unstable gait.[3] In another study, the trazodone concentration/dose ratio was 28% higher in 16 patients taking trazodone with fluoxetine than in 40 patients taking trazodone alone, but this difference was not statistically significant.[1]

A man with traumatic brain injury showed new-onset dysarthria and speech blocking when fluoxetine was added to trazodone. His speech returned to normal when the fluoxetine was stopped.[4] A 39-year-old HIV-

positive man taking multiple antiviral and antibacterial drugs experienced bilateral hand tremor while receiving trazodone 50 mg at bedtime, which worsened when the dose of trazodone was increased to 100 mg and fluoxetine 20 mg daily was added. The trazodone and fluoxetine were discontinued and the tremor completely disappeared after 7 days without specific treatment for myoclonus.[5]

Five out of 16 patients receiving fluoxetine stopped taking trazodone 25 to 75 mg, which was given for insomnia, because of excessive sedation the next day.[6] Three out of 8 patients had improvement in sleep and depression when given both drugs but the other 5 were either unaffected or had intolerable adverse effects (headaches, dizziness, daytime sedation, fatigue).[7] However, another report described advantageous concurrent use in 6 patients without an increase in adverse effects.[8]

For a case describing serotonin syndrome, which developed in a patient taking fluoxetine, trazodone and buspirone when venlafaxine was added, see 'SNRIs; Venlafaxine + Trazodone', p.1480.

Mechanism

It appears that the plasma levels of trazodone may be increased by fluoxetine due to inhibition of its metabolism by cytochrome P450 isoenzymes by fluoxetine and/or norfluoxetine.[2] Trazodone is a substrate for CYP3A4 and, although fluoxetine is a weak inhibitor of this isoenzyme, its metabolite norfluoxetine is a moderate inhibitor.[5] *In vitro* data suggest that citalopram has little inhibitory effect on CYP3A4.[1]

Importance and management

These cases and studies suggest that the concurrent use of trazodone and fluoxetine can be useful and uneventful but it would seem prudent to monitor the outcome for any evidence of increased adverse effects. Citalopram would not be expected to have a pharmacokinetic interaction. However, the cases with fluoxetine suggest that a pharmacodynamic interaction (leading to adverse effects such as dysarthria, tremor and sedation) may be possible, and therefore a degree of caution would be prudent if trazodone is given with any SSRI.

Trazodone + Tryptophan

A single case report describes the development of anorexia, psychosis and hypomania in a patient taking trazodone and tryptophan.

Clinical evidence, mechanism, importance and management

A single report describes the effective use of trazodone 100 mg and tryptophan 500 mg, both three times weekly, with daily clonazepam, in a woman with schizophrenia and congenital defects. However, the patient stopped eating, lost 4.5 kg in weight over 3 weeks, developed signs of psychosis or hypomania, and soon afterwards became drowsy and withdrawn. When the drugs were withdrawn the aggressive behaviour restarted, but she responded again to lower doses of trazodone and tryptophan, although the signs of psychosis re-emerged.[1] This appears to be an isolated report, and, as such, probably has little general relevance.

1. Patterson BD, Srisopark MM. Severe anorexia and possible psychosis or hypomania after trazodone-tryptophan treatment of aggression. *Lancet* (1989) i, 1017.

Tricyclic antidepressants + ACE inhibitors

Limited evidence from two patients suggests that enalapril may increase the effects of clomipramine, resulting in adverse effects. The concurrent use of tricyclic antidepressants and ACE inhibitors may possibly enhance the risk of postural hypotension.

Clinical evidence

Two patients taking **enalapril** (one taking 20 mg daily and the other taking 20 mg five times weekly) were given **clomipramine** for depression. The **clomipramine** dose of one of them was increased from 25 to 50 mg, and 10 days later he became euphoric and exalted. The problem resolved when the **clomipramine** dose was reduced to 25 mg again. The other patient had been stable taking **enalapril** for over a year when **clomipramine** and disulfiram 400 mg daily were added. Within 2 weeks he developed confusion, irritability and insomnia. These adverse effects diminished when the **clomipramine** dosage was reduced to 50 mg daily.[1]

Mechanism

The ratio of clomipramine to its metabolite (desmethylclomipramine) is normally less than 1, but both of these patients demonstrated a ratio of more than 1. This suggests that the normal metabolism (demethylation) of the clomipramine was inhibited, thus allowing the clomipramine to accumulate and its toxic effects to manifest themselves. In the second patient the disulfiram may also have had a minor additional enzyme inhibitory effect.[1]

Importance and management

Information regarding an interaction between clomipramine and enalapril is limited to these two cases and the interaction is not firmly established. More study is needed. There seems to be nothing documented about adverse effects from the concurrent use of the other ACE inhibitors and tricyclic antidepressants, although tricyclic antidepressants may cause postural hypotension, which could be more severe in the presence of ACE inhibitors.

1. Toutoungi M. Potential effect of enalapril on clomipramine metabolism. *Hum Psychopharmacol* (1992) 7, 347–9.

Tricyclic antidepressants + Ademetionine

A severe reaction, diagnosed as serotonin syndrome, developed in a woman taking ademetionine shortly after her clomipramine dosage was raised.

Clinical evidence, mechanism, importance and management

An elderly woman with a major affective disorder was given intramuscular ademetionine 100 mg daily and **clomipramine** 25 mg daily for 10 days. The **clomipramine** dose was then raised to 75 mg daily and, about 2 to 3 days later, she became progressively agitated, anxious and confused. On admission to hospital she was stuporous, with a pulse rate of 130 bpm, a respiratory rate of 30 breaths per minute, and she had diarrhoea, myoclonus, generalised tremors, rigidity, hyperreflexia, shivering, profound diaphoresis and dehydration. Her temperature rose from 40.5°C to 43°C. She had no infection, and was diagnosed with serotonin syndrome. The drugs were withdrawn and she was given dantrolene 50 mg intravenously every 6 hours for 48 hours. She made a complete recovery.[1] The reason for this severe adverse reaction is not understood, although there appears to be a connection between ademetionine and serotonin in the brain.[1,2] Another possibility is that serotonin syndrome was simply triggered by the large increase in the clomipramine dose.

An interaction is therefore not established; however, as both ademetionine and the tricyclics can affect serotonin some caution would be prudent if they are used together. See 'serotonin syndrome', (p.9), for more information about this reaction.

Tricyclic antidepressants + Amfetamines

No pharmacokinetic interaction was reported in children receiving dexamfetamine and desipramine, but concurrent use of amfetamines and tricyclics may increase the risk of cardiovascular adverse effects.

Clinical evidence, mechanism, importance and management

A retrospective review in children and adolescents taking either **desipramine** alone, or with a stimulant, indicated the absence of a clinically significant interaction between **desipramine** and **dexamfetamine** in 4 children who received both drugs; pharmacokinetic parameters for desipramine were similar in each group.[1]

The US manufacturer of **dexamfetamine** says that amfetamines may enhance the activity of the tricyclics. Further, they say that **dexamfetamine** with **desipramine** or **protriptyline** and possibly other tricyclics causes striking and sustained increases in the concentrations of **dexamfetamine** in the brain, and that cardiovascular effects can be potentiated.[2] The UK manufacturers give a similar warning.[3]

The clinical relevance of these warnings is unclear. It may be prudent to carefully consider the risks of using the combination of an amfetamine and a tricyclic in patients with pre-exiting cardiovascular disorders.

Tricyclic antidepressants + Aspirin

In one study the incidence and severity of adverse effects increased when aspirin was given with imipramine.

Clinical evidence, mechanism, importance and management

A study in 20 patients with depression, given **imipramine** in their usual dose of 75 mg twice daily for 5 days, found that when aspirin 500 mg twice daily was added for a further 2 days, the incidence and range of adverse effects rose by 52% and 56%, respectively, with adverse effects described as severe increasing 2.5-fold. The degree of binding of **imipramine** to plasma proteins decreased by 12% when aspirin was given, and it was suggested that the rise in the amount of 'free' (and pharmacologically active) **imipramine** in the plasma manifested as an increase in adverse effects.[1]

Information about this interaction seems to be limited to this report, which was only short-term, so the effects of long-term concurrent use are unclear.

Note that it has been suggested that tricyclic antidepressants may increase the risk of gastrointestinal bleeding with aspirin or NSAIDs,[2] similar to the SSRIs (see 'Antiplatelet drugs + SSRIs', p.817), but information on this appears to be limited. More study is needed.

Tricyclic and related antidepressants + Azoles; Fluconazole

Fluconazole has increased amitriptyline and nortriptyline levels in a number of cases. Mental changes, syncope, and a prolonged QTc interval have also been seen when fluconazole was given with a tricyclic.

Clinical evidence

(a) Amitriptyline

A man with AIDS given fluconazole 200 mg daily and amitriptyline 25 mg then 50 mg three times daily developed mental changes and visual hallucinations within 3 days of concurrent use. His serum amitriptyline level was found to be 724 nanograms/mL (reference range 150 to 250 nanograms/mL). His confusion resolved within 4 days of stopping the amitriptyline, at which point the levels had fallen to 270 nanograms/mL. Two similar cases were described in this report, in one case in a patient with renal impairment.[1]

A woman taking amitriptyline 100 mg twice daily, isosorbide mononitrate and metoprolol became lethargic, drowsy and confused 4 days after starting fluconazole 100 mg daily. She was found to have elevated serum levels of amitriptyline plus its metabolite nortriptyline of 956 nanograms/mL (patient's usual range 150 to 250 nanograms/mL) and a prolonged QTc interval. At first, an amitriptyline overdose was suspected. The patient was intubated, but she became delirious, agitated and disorientated. She recovered over the next 24 hours and the amitriptyline level had fallen to 190 nanograms/mL after 4 days. It was concluded that the amitriptyline toxicity was due to an interaction with fluconazole.[2]

Other reports similarly describe increased amitriptyline levels when fluconazole was given; in a child who developed syncope as a result[3] and in a 57-year-old woman who developed QT prolongation (although hypokalaemia and the use of sertraline, which can increase serum tricyclic levels, may have contributed to this effect).[4]

(b) Nortriptyline

An elderly woman taking nortriptyline 75 mg daily and other drugs (ciclosporin, morphine, metoclopramide, bumetanide as well as an unnamed antibacterial) was given fluconazole (loading dose of 200 mg, followed by 100 mg daily). After concurrent use for 13 days her trough serum nortriptyline levels had risen by 70% (from 149 nanograms/mL to 252 nanograms/mL).[5]

Mechanism

Not understood, but it has been suggested that the fluconazole inhibits the cytochrome P450 isoenzymes CYP2C9, CYP2C19, CYP3A4 and possibly CYP2D6, some of which are concerned with the metabolism of these tricyclics.[1,3] Concurrent use therefore decreases the metabolism of the tricyclic and its level rises. However, note that fluconazole does not inhibit CYP2D6 to a clinically relevant extent, and only tends to inhibit CYP3A4 in doses of 200 mg daily or more. Therefore other conditions must be necessary for an interaction to occur.

Importance and management

Information about an interaction between the tricyclics and fluconazole seems to be limited to these case reports, which, bearing in mind the widespread use of these drugs, would suggest that clinically relevant interactions are uncommon. The evidence suggests that other factors (such as renal impairment and other potentially interacting medications) may be necessary before this interaction occurs. Bear this possible interaction in mind if tricyclic adverse effects become troublesome.

Tricyclic antidepressants + Azoles; Ketoconazole

Ketoconazole does not affect the pharmacokinetics of desipramine, and has only modest effects on the pharmacokinetics of amitriptyline and imipramine.

Clinical evidence, mechanism, importance and management

A placebo-controlled study in 8 healthy subjects found that ketoconazole 200 mg every 12 hours for 3 doses decreased the mean apparent oral clearance of **amitriptyline** 50 mg by 26% and increased its AUC by about 24%.[1] Similarly, two groups of 6 healthy subjects were given a single 100-mg dose of either **imipramine** or **desipramine** alone, and then again on day 10 of a 14-day course of ketoconazole 200 mg daily. It was found that ketoconazole caused the oral clearance of **imipramine** to fall by 17%, its half-life to rise by 15% and the AUC of the desipramine metabolite to fall by 9%. No significant changes in the pharmacokinetics of **desipramine** were seen.[2]

Ketoconazole inhibits the metabolism of the cytochrome P450 isoenzyme CYP3A4, which has only a minor role in the metabolism of amitriptyline and imipramine, and hence the changes seen are small. Desipramine is not metabolised by CYP3A4 and is therefore unaffected by ketoconazole.

These modest changes would not be expected to be clinically significant and therefore no dose adjustments would appear necessary if ketoconazole is used with these drugs. Information about other tricyclics seems to be lacking, but as they share similar metabolic routes to the tricyclics studied, no clinically relevant interaction would be expected.

Tricyclic antidepressants + Baclofen

An isolated report describes a patient with multiple sclerosis taking baclofen, who was unable to stand within a few days of starting to take nortriptyline, and later imipramine.

Clinical evidence, mechanism, importance and management

A man with multiple sclerosis, who was taking baclofen 10 mg four times a day to relieve spasticity, complained of leg weakness and was unable to stand within 6 days of starting to take **nortriptyline** 50 mg at bedtime. His muscle tone returned 48 hours after stopping the **nortriptyline**. Two weeks later he was given **imipramine** 75 mg daily and once again his muscle tone was lost.[1]

The reason for this reaction is not understood, although it has been suggested that effects on GABA-receptors may be involved.[2]

The UK manufacturer of baclofen warns that the effect of baclofen may be potentiated by tricyclic antidepressants, resulting in pronounced muscular hypotonia.[2] However, this case report appears to be the only documentation to suggest that a clinically relevant interaction occurs.

2. Lioresal Tablets (Baclofen). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, July 2009.

Tricyclic and related antidepressants + Barbiturates or Phenytoin

The plasma levels of amitriptyline, imipramine, nortriptyline and mianserin can be reduced by the barbiturates. A reduced therapeutic response would be expected. The tricyclics also lower the convulsive threshold and may be inappropriate for patients with convulsive disorders.

Clinical evidence

A comparative study in 5 pairs of twins given **nortriptyline** found that the twins also taking unnamed barbiturates had considerably lower steady-state plasma **nortriptyline** levels.[1]

Similar observations have been made in patients and healthy subjects taking **nortriptyline** with **amobarbital**[2,3] or **pentobarbital**,[4] and **protriptyline** with **amobarbital sodium**.[5] Another patient had a reduction in blood **imipramine** levels of about 50% (and loss of antidepressant control) within 2 weeks of starting to take about 400 mg of **butalbital** daily.[6]

A comparative study in 6 epileptics and 6 healthy subjects found that **phenytoin** with either **phenobarbital** or carbamazepine markedly reduced the AUC of a single 30-mg dose of **mianserin**.[7,8]

Mechanism

The barbiturates are potent liver enzyme inducers and may therefore increase the metabolism and clearance of the tricyclic antidepressants and mianserin from the body.

Importance and management

The interaction between tricyclic antidepressants or mianserin and barbiturates is established. By no means has every drug pair been studied but as the barbiturates as a whole are potent liver enzyme inducers one should be alert for this interaction with any of them. Some reduction in the effects of the antidepressant would be expected, but the general clinical importance is uncertain. Note that the tricyclics and mianserin lower the convulsive threshold and may therefore be inappropriate for patients with epilepsy.

Tricyclic antidepressants may increase the duration of barbiturate anaesthesia, see 'Anaesthetics, general and/or Neuromuscular blockers + Tricyclic and related antidepressants', p.119.

Tricyclic antidepressants + Benzodiazepines and related drugs

The concurrent use of tricyclic antidepressants and benzodiazepines is not uncommon and normally appears to be uneventful. However, concurrent use has led to adverse effects (e.g. drowsiness, incoordination). One study found that diazepam may increase the risks of carrying out complex tasks (e.g. driving) if added to amitriptyline, and this seems possible with any benzodiazepine and tricyclic.

Clinical evidence

(a) Amitriptyline

1. Chlordiazepoxide. Clinical studies in large numbers of patients have found that the incidence of adverse reactions while taking amitriptyline and chlordiazepoxide was no greater than might have been expected with either of the drugs used alone,[1-3] but a few adverse reports have been documented. A depressed patient taking amitriptyline 150 mg and chlordiazepoxide 40 mg daily became confused, forgetful and uncoordinated. He acted as though he was drunk.[4] Two other patients taking amitriptyline and chlordiazepoxide experienced drowsiness, memory impairment, slurring of the speech and an inability to concentrate. Both were unable to work and one described himself as feeling drunk.[5] Four patients taking *Limbitrol* (a combination preparation containing chlordiazepoxide and amitriptyline) are reported to have experienced some manifestations of toxicity (delusions, confusion, agitation, disorientation, dry mouth, blurred vision).[6] Some of these effects seem to arise from increased CNS depression (possibly additive) and/or an increase in the antimuscarinic adverse effects of the tricyclic.

2. Diazepam. A study found an increase in amitriptyline levels when diazepam was given.[7] In contrast, two studies suggested that diazepam did not affect amitriptyline levels.[3,8] However, other studies found that the addition of diazepam to amitriptyline 50 to 75 mg further reduced attention and the performance of a number of psychomotor tests.[9,10]

3. Nitrazepam or Oxazepam. A study of the effects of nitrazepam and oxazepam on the steady-state plasma levels of amitriptyline did not find any interactions.[3]

(b) Clomipramine

One study suggested that **alprazolam** does not affect clomipramine levels.[11]

(c) Desipramine

1. Clonazepam. An isolated report describes a patient taking desipramine 300 mg daily whose serum desipramine levels were halved when he was given clonazepam 3 mg daily and rose again when the clonazepam was withdrawn.[12]

2. Zolpidem. Visual hallucinations have been seen in one patient given zolpidem and desipramine.[13]

(d) Imipramine

1. Alprazolam. Population pharmacokinetic data suggests that alprazolam raises imipramine levels by about 20 to 30%.[14]

2. Zaleplon. A single 75-mg dose of imipramine had no effect on the pharmacokinetics of zaleplon 20 mg, and psychomotor tests showed only short term additive effects lasting 1 to 2 hours.[15]

3. Zolpidem. A single-dose study using zolpidem 20 mg and imipramine 75 mg found no effect on the pharmacokinetics of either drug. However, imipramine increased the sedative effects of zolpidem, and anterograde amnesia was seen.[16]

(e) Nortriptyline

Studies on the effects of **alprazolam**, **chlordiazepoxide**, **diazepam**, **nitrazepam** and **oxazepam** on the steady-state plasma levels of nortriptyline have found no interactions.[3,17,18]

(f) Trimipramine

In a study, when 10 healthy subjects were given **zopiclone** and trimipramine for a week there was no statistically significant change in the bioavailability of either drug.[19]

Mechanism

Uncertain. Additive CNS depression and increased antimuscarinic effects are a possibility with some combinations.

Importance and management

There seems to be no reason for avoiding the concurrent use of benzodiazepines and tricyclics although the advantages and disadvantages of such use remain the subject of debate. Other combinations of tricyclic antidepressants and benzodiazepines would be expected to behave in the same way as those described here. Some patients will possibly experience increased drowsiness and inattention, particularly with the more sedative antidepressants such as amitriptyline, especially during the first few days, and this may be exaggerated by benzodiazepines. Driving risks may therefore be increased: patients should be warned.

Tricyclic and related antidepressants + Beta blockers

Propranolol increased imipramine levels in two children and maprotiline levels in isolated cases. Labetalol has been found to increase imipramine levels in adults. Amitriptyline does not appear to affect the pharmacokinetics of atenolol or metoprolol.

Clinical evidence

(a) Amitriptyline

A placebo-controlled study in 6 healthy subjects found that amitriptyline 75 mg daily did not affect the pharmacokinetics of **atenolol** 100 mg daily or **metoprolol** 100 mg twice daily, given for 2 weeks.[1]

(b) Imipramine

1. Labetalol. In a study in 13 healthy subjects, labetalol 200 mg every 12 hours for 4 days, increased the AUC of a single 100-mg dose of imipramine by 53%, when compared with a placebo. The maximum plasma level of imipramine increased by 28%.[2]

2. Propranolol. A 9-year-old boy was given propranolol for the control of anger and aggression, and imipramine for stress and depression. When his imipramine dose was raised from 60 to 80 mg daily and his propranolol dose was also raised, from 360 to 400 mg daily, his levels of imipramine plus its metabolite, desipramine rose sharply, from a total of 139 nanograms/mL to 469 nanograms/mL. Reducing the imipramine dose to 60 mg and raising the propranolol dose to 440 mg daily only reduced the total imipramine/desipramine levels to 426 nanograms/mL. Another imipramine dose reduction, to 40 mg, and an increase in the propranolol dose to 480 mg daily resulted in a final total imipramine/desipramine level of 207 nanograms/mL. No significant adverse effects or heart block occurred.[3]

A 9-year-old girl taking imipramine 75 mg daily with a total imipramine/desipramine level of 260 nanograms/mL, had a marked rise to 408 nanograms/mL within 3 days of starting to take propranolol 10 mg three times daily. Two days after stopping the imipramine, her desipramine level (imipramine not measured) had fallen from 382 nanograms/mL to 222 nanograms/mL.[3]

(c) Maprotiline

A patient experienced maprotiline toxicity (dizziness, hypotension, dry mouth, blurred vision, etc.) after taking **propranolol** 120 mg daily for 2 weeks. His trough maprotiline levels had risen by 40%. The levels fell and the adverse effects disappeared when the **propranolol** was withdrawn.[4] Another patient taking **propranolol** 120 mg daily began to experience visual hallucinations and psychomotor agitation within a few days of starting to take maprotiline 200 mg daily.[5] A further patient taking haloperidol, benzatropine, triamterene, hydrochlorothiazide and **propranolol** became disorientated, agitated and uncooperative, with visual hallucinations and incoherent speech, within a week of starting to take maprotiline 150 mg daily. These symptoms disappeared when all the drugs were withdrawn. Reintroduction of the antihypertensive drugs with haloperidol and desipramine proved effective and uneventful.[6]

Mechanism

Uncertain. The suggestion is that the affected drugs compete for metabolism (hydroxylation) by the same cytochrome P450 isoenzymes (particularly CYP2D6) in the liver.[2,3] Atenolol is mainly renally excreted and would therefore not be affected in this way. It has also been suggested that propranolol (and therefore possibly other beta blockers) reduces the blood flow to the liver so that the metabolism of maprotiline is reduced, leading to its accumulation in the body.

Importance and management

Information about an interaction between the beta blockers and tricyclic antidepressants or maprotiline seems to be limited to these studies and case reports. The authors of one of the reports[5] say that simultaneous use is inadvisable, but on the basis of these few cases, and with no further information, this seems over-cautious. In general it would seem that any interaction does not lead to adverse effects in most patients (the studies suggest the increase in tricyclic levels is modest). However, if adverse effects (e.g. dry mouth, blurred vision and urinary retention) occur it would seem prudent to consider an interaction as a possible cause, decreasing the antidepressant dose as appropriate.

Tricyclic antidepressants + Bupropion

Bupropion may increase the levels of the tricyclic antidepressants, including desipramine, imipramine, and nortriptyline. Adverse effects including confusion, lethargy and unsteadiness have been reported with nortriptyline and bupropion. Seizures occurred in two patients given clomipramine or trimipramine and bupropion.

Clinical evidence

A pharmacokinetic study in healthy subjects found that bupropion doubled the maximum plasma levels of **desipramine** and increased its AUC fivefold. The effect was present for at least 7 days after the last dose of bupropion.[1,2] Another study in a 64-year-old woman taking **imipramine** 150 to 200 mg daily found that when bupropion 225 mg daily was added, there was a fourfold rise in the plasma levels of imipramine and its metabolite desipramine, but no problems were reported. A comparison of the estimated clearances of imipramine and its main metabolite desipramine were: **imipramine** 1.7 mL/minute and desipramine 1.7 mL/minute without bupropion; and imipramine 0.73 mL/minute and desipramine 0.31 mL/minute with bupropion.[3]

An 83-year-old woman taking **nortriptyline** 75 mg at night had a plasma **nortriptyline** level of 96 nanograms/mL, but when sustained-release bupropion 150 mg twice daily was added she became unsteady, confused and lethargic and her plasma nortriptyline level increased by about 200% (to 274 nanograms/mL). The increased plasma **nortriptyline** level and toxicity occurred again when she was rechallenged with bupropion.[4]

A report describes a seizure when **trimipramine** 100 mg daily was taken with bupropion 150 mg twice daily. The addition of bupropion resulted in a substantial increase in the plasma levels of **trimipramine** into the 'toxic' range. The patient was later successfully treated with lower doses of both drugs (**trimipramine** 50 mg at night and bupropion 150 mg daily).[5] Another case report describes prolonged seizure activity after the concurrent use of bupropion 300 mg daily and **clomipramine** 25 mg daily, which persisted even after discontinuation of both drugs.[6]

Mechanism

In vitro studies[1,2] have shown that both bupropion and its active metabolite, hydroxybupropion, are inhibitors of CYP2D6, the isoenzyme involved in the metabolism of these tricyclics. Therefore concurrent use decreases the metabolism of the tricyclics and their levels rise.

Importance and management

Although clinical evidence for an interaction between the tricyclics and bupropion is limited, the rise in tricyclic levels is in line with the way both drugs are known to interact, and therefore an interaction would seem to be established. It would be prudent to be alert for increased tricyclic adverse effects if bupropion is also given, reducing the tricyclic dose as necessary.

Note that bupropion is predicted to increase the risk of seizures with tricyclics, and this effect is dose-related. See 'Bupropion + Miscellaneous', p.1468.

Tricyclic antidepressants + Calcium-channel blockers

Diltiazem and verapamil can increase plasma imipramine levels, possibly accompanied by undesirable ECG changes. Two isolated reports describe increased nortriptyline and trimipramine levels in two patients given diltiazem.

Clinical evidence

(a) Imipramine

In a study, 12 healthy subjects were given a 7-day course of **verapamil** 120 mg every 8 hours and 13 healthy subjects were given a 7-day course of **diltiazem** 90 mg every 8 hours. The AUCs of a single 100-mg dose of imipramine given on day 4 were increased by 15% by **verapamil**, and by 30% by **diltiazem**. One hour after taking imipramine (2 hours after taking the calcium-channel blockers), the average PR interval was greater than 200 milliseconds, which represented first-degree heart block. Two subjects developed second-degree heart block after taking imipramine with **verapamil**.[1]

(b) Nortriptyline

A diabetic patient taking **nifedipine**, glipizide and aspirin started taking nortriptyline, and, at the same time, the **nifedipine** was replaced by **diltiazem**, initially 180 mg daily, then raised to 240 mg daily after a week. Several changes in the nortriptyline dosage were made over a 4-week period because its plasma levels became unexpectedly high (the ratio of plasma nortriptyline to its dosage were approximately doubled), which was attributed to the use of **diltiazem**.[2]

(c) Trimipramine

A depressed woman taking trimipramine 125 mg daily developed high plasma trimipramine levels of 546 micrograms/L while taking **diltiazem** 60 mg three times daily. Two weeks later the trimipramine levels reached 708 micrograms/L, despite a reduction in the trimipramine dose to 75 mg daily. She showed no toxicity and her ECG was normal.[3]

Mechanism

It has been suggested that diltiazem and verapamil increase the bioavailability of imipramine by decreasing its clearance. The ECG changes appear to result from the increased imipramine levels and the additive effects of both drugs on the atrioventricular conduction time. Diltiazem may similarly affect nortriptyline and trimipramine.

Importance and management

Information appears to be limited to these reports so that the general clinical importance of each of these interactions is uncertain. However it would seem prudent to be alert for evidence of increases in the adverse effects of the tricyclic antidepressants if diltiazem or verapamil is added. The evidence of heart block with imipramine and verapamil is of particular concern. Note that it has also been suggested that the postural hypotension that may occur in patients taking tricyclics could be exacerbated by the use of antihypertensives. Patients should be warned.

Tricyclic antidepressants + Cannabis

Case reports describe tachycardia when patients taking tricyclic antidepressants smoked cannabis. Hypertension and drowsiness may occur when cannabinoids are used with tricyclics.

Clinical evidence

A 21-year-old woman taking **nortriptyline** 30 mg daily experienced marked tachycardia (an increase from 90 to 160 bpm) after smoking a cannabis cigarette. It was controlled with propranolol.[1] A 26-year-old man complained of restlessness, dizziness and tachycardia (120 bpm) after smoking cannabis while taking **imipramine** 25 mg twice daily.[2] Four adolescents aged 15 to 18 years, taking tricyclic antidepressants for attention-deficit hyperactivity disorder, experienced transient cognitive changes, delirium and tachycardia after smoking cannabis.[3]

Mechanism

Increased heart rates are well-documented adverse effects of both the tricyclic antidepressants and cannabis, and what occurred was probably due to the additive beta-adrenergic and antimuscarinic effects of the tricyclics, in combination with the beta-adrenergic effect of the cannabis.

Importance and management

Evidence for an interaction between cannabis and tricyclics appears to be limited. The manufacturer of **dronabinol**, a cannabinoid, notes that hypertension and drowsiness as well as tachycardia have been reported when cannabinoids have been used with tricyclics.[4] It would therefore seem that an interaction is established.

If concurrent use is undertaken, it would be prudent to be alert for these adverse effects, taking particular caution in those with underlying cardiac disease, which may make these effects more problematic.

Tricyclic and related antidepressants + Carbamazepine

The serum levels of amitriptyline, desipramine, doxepin, imipramine, nortriptyline and mianserin can be reduced (halved or more) by carbamazepine. In contrast, raised clomipramine levels have been seen in patients taking carbamazepine. An isolated report describes carbamazepine toxicity in a patient shortly after she started to take desipramine.

Clinical evidence

(a) Carbamazepine levels increased

A woman receiving long-term treatment with carbamazepine developed toxicity (nausea, vomiting, blurred vision with visual hallucinations, slurred speech, ataxia) within 6 days of starting to take **desipramine** daily (3 days at 150 mg daily). Her carbamazepine levels were found to have doubled from 7.7 micrograms/mL to 15 micrograms/mL.[1]

(b) Tricyclic levels increased

A study confirming the value of carbamazepine and **clomipramine** in the treatment of post-herpetic neuralgia found that carbamazepine appeared to raise both clomipramine plasma levels and those of its major metabolite (desmethylclomipramine).[2]

(c) Tricyclic levels reduced

A study found that carbamazepine reduced the serum levels of **nortriptyline** by 58% and of **amitriptyline** plus its metabolite, nortriptyline, by 60% in 8 psychiatric patients. In 17 other patients carbamazepine reduced serum **doxepin** levels by 54% and reduced the levels of doxepin plus its metabolite, nordoxepin, by 55%.[3] A retrospective study of very large numbers of patients confirmed that carbamazepine approximately halves the serum levels of **amitriptyline** and **nortriptyline**.[4] An elderly woman needed her **nortriptyline** dosage to be increased from 75 to 150 mg daily to achieve effective antidepressant serum levels when carbamazepine 500 to 600 mg daily was added.[5]

A study in 36 children (aged 5 to 16 years) with attention-deficit disorder taking **imipramine**, or **imipramine** and carbamazepine for 1 to 6 months, found that even though the **imipramine** dosage was significantly higher in the combined treatment group, the plasma levels were significantly lower; and the total plasma antidepressant levels were about half of those found in the children not taking carbamazepine.[6] A study[7] in 6 healthy subjects found that carbamazepine 200 mg twice daily for a month increased the apparent oral clearance of a single 100-mg dose of **desipramine** (given on day 24) by 31% and shortened its half-life from 22.1 hours to 17.8 hours. A patient given **desipramine** and carbamazepine is reported to have had exceptionally low serum desipramine levels and cardiac complaints, which may have been due to the presence of increased levels of the hydroxy metabolite of desipramine.[8]

A study in 13 patients with endogenous depression (DSM-III-R) taking **imipramine**, which confirmed that carbamazepine reduced the total serum levels of imipramine and desipramine, found that levels of the pharmacologically active free drugs remained unchanged.[9,10] Moreover 10 of the patients demonstrated a positive therapeutic response (greater than a 50% decrease in the Hamilton Depression Rating Scale) and a reduction in adverse drug reactions.[9]

A comparative study in 6 epileptics and 6 healthy subjects showed that phenytoin with either phenobarbital or carbamazepine markedly reduced the plasma levels of a single dose of **mianserin**.[11,12] The mean half-life of **mianserin** was reduced by 75% (from 16.9 hours to 4.8 hours) and the AUC was reduced by 86%. Another study in 4 patients found that carbamazepine reduced serum **mianserin** levels by 70%.[13] In another study 12 patients taking **mianserin** 60 mg daily were also given carbamazepine 400 mg daily for 4 weeks. Average plasma levels of total *S*-mianserin (the more potent enantiomer) and total *R*-mianserin were reduced by about 45% in the presence of carbamazepine.[14]

Mechanism

It seems likely that the carbamazepine (a recognised enzyme-inducing drug) increases the metabolism and loss of these tricyclics and mianserin from the body, thereby reducing their serum levels. The reason for the increased serum carbamazepine and clomipramine levels is not understood, although it has been suggested that both drugs may compete for hydroxylation by the hepatic microsomal enzyme system.[1,2] In addition, they both share a similar 3-ringed structure, and carbamazepine has been reported to interfere with an assay (serum fluorescence-polarised immunoassay) for tricyclic antidepressants, resulting in false positive results.[15]

Importance and management

The reduction in the serum levels of amitriptyline, desipramine, doxepin, imipramine, nortriptyline and mianserin caused by the interaction with carbamazepine appears to be established but the clinical importance is very much less certain. Evidence from one study,[9] that achieved a beneficial response in patients taking tricyclics and carbamazepine, suggests that it is possibly not necessary to increase the tricyclic dosage to accommodate this interaction. The fact that a retrospective study found that increased imipramine doses were being given to those taking carbamazepine suggests that this interaction will be naturally accounted for. If carbamazepine is added to treatment with any of these tricyclics or mianserin, be aware that the dose of the tricyclic may need to be titrated up to achieve the desired therapeutic response. One study suggests that the dose of mianserin may need to be approximately doubled if carbamazepine 400 mg daily is added.[14]

Remember too that the tricyclics and mianserin can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants + Cinacalcet

Cinacalcet causes a large increase in the levels of the tricyclic antidepressants.

Clinical evidence

A study in 14 healthy subjects found that cinacalcet 90 mg daily significantly increased the AUC and maximum plasma concentration of a single 50-mg dose of **desipramine** 3.6-fold and 1.8-fold, respectively, and the half-life of **desipramine** was approximately doubled.[1]

Mechanism

Cinacalcet is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6, by which desipramine is predominantly metabolised. Concurrent use therefore decreases desipramine metabolism, resulting in the raised levels seen.

Importance and management

An interaction between cinacalcet and desipramine is established, and would be expected to be clinically significant. Dose reductions of desipramine are likely to be needed if cinacalcet is also given. If starting desipramine in a patient taking cinacalcet it would seem prudent to start at the lowest dose and titrate upwards carefully. If both drugs are given, monitor closely for adverse effects such as dry mouth, urinary retention and constipation.

There seems to be no evidence regarding other tricyclics, but as they are, in general, predominantly metabolised by CYP2D6, they would be expected to interact similarly. Therefore the same precautions suggested for desipramine would be advisable.

Note that, the tricyclics have been associated with QT prolongation, most usually when their levels are high, and this interaction may therefore increase the risk of this effect. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further discussion on QT prolongation.

1. Harris RZ, Salfi M, Posvar E, Hoelscher D, Padhi D. Pharmacokinetics of desipramine HCl when administered with cinacalcet HCl. *Eur J Clin Pharmacol* (2007) 63, 159–63.

Tricyclic antidepressants + Colestyramine

Colestyramine causes a modest reduction in the plasma levels of imipramine. A case report suggests that doxepin may be similarly affected, and *in vitro* evidence suggests that amitriptyline, desipramine and nortriptyline are also likely to be similarly affected.

Clinical evidence

Six patients with depression taking **imipramine** 75 to 150 mg, usually twice daily, were given colestyramine 4 g three times daily for 5 days. The plasma levels of **imipramine** fell by an average of 23% (range 11 to 30%) and the plasma levels of desipramine (the major metabolite) were reduced, although this was less consistent and said not to be statistically significant. The effect of these reduced levels on the control of the depression was not assessed.[1]

A man whose depression was controlled with **doxepin** relapsed within a week of starting to take colestyramine 6 g twice daily. Within 3 weeks of increasing the dosage separation of the two drugs from 4 to 6 hours his combined serum antidepressant levels (i.e. **doxepin** plus the metabolite *n*-desmethyldoxepin) had risen from 39 nanograms/mL to 81 nanograms/mL and his depression had improved. Reducing the colestyramine to a single 6-g dose daily, separated from the **doxepin** by 15 hours, resulted in a further rise in his serum antidepressant levels, to 117 nanograms/mL, which was accompanied by relief of his depression.[2]

Mechanism

It seems almost certain that these tricyclics become bound to the colestyramine (an anion-exchange resin) within the gut, thereby reducing their absorption. An *in vitro* study[3] with simulated gastric fluid found that, at pH 1, **amitriptyline**, **desipramine**, doxepin, imipramine and **nortriptyline** were approximately 79 to 90% bound by colestyramine: at pH 4 they were 36 to 48% bound and at pH 6.5 they were 62 to 76% bound. In an earlier study,[4] binding of these tricyclics at pH 1 had ranged from 76 to 100%.

Importance and management

The interaction between imipramine and colestyramine is established, but of uncertain clinical importance because the fall in the plasma imipramine levels quoted above was only modest (23%) and the effects were not measured. The single case involving doxepin[2] was unusual because the patient had an abnormal gastrointestinal tract (hemigastrectomy with pyloroplasty and chronic diarrhoea). Nevertheless, given the way colestyramine is generally known to interact, it would seem prudent to be alert for any evidence of a reduced antidepressant response if colestyramine is given with any tricyclic. A simple way of minimising any interaction is to separate administration, and it is usually suggested that other drugs should be given one hour before or 4 to 6 hours after colestyramine.

Tricyclic and related antidepressants + Co-trimoxazole

In isolated cases the efficacy of tricyclic antidepressants and viloxazine appears to have been reduced by co-trimoxazole.

Clinical evidence, mechanism, importance and management

Four patients taking tricyclic antidepressants (**imipramine**, **clomipramine**, **dibenzepin**) and one taking **viloxazine** relapsed into depression when they took co-trimoxazole (trimethoprim with sulfamethoxazole) for 2 to 9 days.[1] Another patient taking alprazolam and **imipramine** for 5 years for panic disorder, and who had not had panic attacks for several months, developed insomnia, anxiety and panic attacks within 6 days of starting to take co-trimoxazole. The panic attacks stopped when she stopped taking co-trimoxazole.[2]

The reason for the reduction in the efficacy of treatment is not known. In the second case, one possibility was that co-trimoxazole, which may cause nervousness, had exacerbated the panic disorder.[2] These seem to be the only reports of a possible interaction between these drugs so that the general importance is uncertain. It seems likely to be small.

Tricyclic antidepressants + Cyclobenzaprine

Episodes of fainting in a patient may have been due to raised levels of nortriptyline, which were thought to have been caused by cyclobenzaprine.

Clinical evidence, mechanism, importance and management

A patient taking multiple medications, including citalopram, **nortriptyline** 100 mg at bedtime for pain and insomnia, and cyclobenzaprine 60 to 80 mg daily for pain, reported light-headedness and fainting episodes. Toxicology screens also found he had taken cocaine. **Nortriptyline** levels of 406 nanograms/mL (above the therapeutic range of 50 to 150 nanograms/mL) were found. The **nortriptyline** dose was halved to 50 mg daily and then discontinued; levels of 631 nanograms/mL and 400 nanograms/mL were found after 3 and 4 weeks, respectively. The episodes of syncope/presyncope only stopped when cyclobenzaprine was also discontinued.

Due to the complexities of the case, various causes including arrhythmias, cardiac ischaemia, seizures, orthostasis and anxiety were considered. The patient had previously experienced syncopal episodes attributed to misuse of prescription drugs, apparently including **nortriptyline**. It was considered that the symptoms could have been due to increased levels of **nortriptyline** in the presence of cyclobenzaprine, as well as to effects of cyclobenzaprine.[1]

While taking both drugs the patient experienced considerable fluctuations in his **nortriptyline** levels, which may have been due to an interaction with cyclobenzaprine. However, cyclobenzaprine is structurally related to the tricyclic antidepressants and may interfere with assays for tricyclics; indeed, as a serum **nortriptyline** level was reported as 378 nanograms/mL, several months after nortriptyline had been discontinued, and a re-evaluation using a high-performance liquid chromatographic (HPLC) assay revealed the patient's nortriptyline level to be 0, an interference of cyclobenzaprine with the assay method is possible in this case.[1]

This is an isolated case, with many complicating factors, so an interaction is by no means established.

Tricyclic antidepressants + Disulfiram

Disulfiram reduces the clearance of imipramine and desipramine. The concurrent use of amitriptyline and disulfiram has been reported to cause a therapeutically useful increase in the effects of disulfiram but 'organic brain syndrome' has been seen in two patients.

Clinical evidence, mechanism, importance and management

It has been noted that **amitriptyline** increases the effects of both disulfiram and citrated **calcium carbimide** without any increase in adverse effects.[1] A study in two men found that disulfiram 500 mg daily increased the AUC of **imipramine** (12.5 mg given intravenously after an overnight fast) by about 30%, and of **desipramine** 12.5 mg given intravenously in one subject by a similar amount.[2] Peak plasma levels were also increased.

The suggested reason for this increase in tricyclic levels is that disulfiram inhibits the metabolism of the antidepressants by the liver. The increase in tricyclic levels is modest and would not normally be expected to lead to an increase in adverse effects. However, a case report describes a man taking disulfiram who, when given **amitriptyline**, complained of dizziness, visual and auditory hallucinations, and who became disorientated to person, place and time. A similar reaction was seen in another patient.[3]

It seems unlikely that most patients will experience a clinically relevant interaction. Nevertheless, the case reports introduce a note of caution. If tricyclic adverse effects (e.g. dry mouth, urinary retention, constipation) become troublesome, it would seem worth considering this interaction as a possible cause.

Tricyclic antidepressants + Fenfluramine

It has been said that the concurrent use of tricyclics and fenfluramine is safe and effective; however, others have suggested that, as fenfluramine can cause depression, it should be avoided in patients with a history of depression.

Clinical evidence, mechanism, importance and management

Exacerbation of depression has been seen in some patients given fenfluramine[1] and several cases of withdrawal depression have been seen in patients taking amitriptyline and fenfluramine, following episodes of severe depression.[2] The manufacturers did advise that fenfluramine should not be used in patients with a history of depression or in those being treated with antidepressants.[3] On the other hand it has been also claimed that fenfluramine could be used safely and effectively with tricyclic antidepressants.[4,5] One report described a rise in the plasma levels of amitriptyline when fenfluramine 60 mg daily was given to patients taking amitriptyline 150 mg daily.[6]

Note that fenfluramine was widely withdrawn in 1997 because its use was found to be associated with a high incidence of abnormal echocardiograms indicating abnormal functioning of heart valves.

Tricyclic antidepressants + Flupentixol and related drugs

Flupentixol did not appear to inhibit the metabolism of imipramine in two patients but high levels of imipramine and its metabolite, desipramine, were found in another patient. In a retrospective study, zuclopenthixol did not seem to affect serum concentrations of tricyclic antidepressants.

Clinical evidence

A study using oral ^{14}C-**imipramine** found that flupentixol 3 to 6 mg daily did not decrease the total urinary excretion of radioactivity in 2 patients, suggesting that the metabolism of **imipramine** was not affected by flupentixol.[1] However, there is an isolated report of very high plasma levels of **imipramine** and its metabolite desipramine in a patient with schizophrenia who was given flupentixol decanoate 40 mg intramuscularly every 2 weeks and **imipramine** 150 mg daily. It was suggested that this may have resulted from competitive inhibition of liver enzymes.[2]

Using data from a drug monitoring database, the steady-state concentration/dose ratios for **amitriptyline** and/or **nortriptyline** in 50 patients also taking zuclopenthixol were compared with 206 patients taking amitriptyline and 444 patients taking nortriptyline but not taking potentially interacting drugs. Zuclopenthixol did not appear to affect **amitriptyline** or **nortriptyline** serum concentrations under routine therapeutic drug monitoring.[3]

Mechanism

Zuclopenthixol and flupentixol are partly metabolised by the cytochrome P450 isoenzyme CYP2D6. Many of the tricyclics are also metabolised by this isoenzyme, but this does not appear to lead to an interaction.

Importance and management

The interaction between flupentixol and imipramine is an isolated case and its general significance is unknown. The studies with flupentixol and zuclopenthixol suggest that, in general, a clinically significant pharmacokinetic interaction does not occur with the tricyclics. Nevertheless, the manufacturer of both flupentixol and zuclopenthixol has suggested that the metabolism of tricyclic antidepressants may be inhibited by these drugs.[4,5] Note that zuclopenthixol, flupentixol and the tricyclic antidepressants

have some antimuscarinic activity, which may lead to a pharmacological interaction, see 'Antipsychotics + Antimuscarinics', p.833.

Tricyclic antidepressants + Food

Limited evidence suggests that very high-fibre diets can reduce the serum levels of doxepin and desipramine, and therefore decrease their effects. The bioavailability of amitriptyline may be affected by food. An isolated report describes urticaria attributed to a possible drug-food interaction between clomipramine and cod.

Clinical evidence, mechanism, importance and management

Three patients had no response to **doxepin** or **desipramine** and had reduced serum tricyclic antidepressant levels while taking very high-fibre diets (wheat bran, wheat germ, oat bran, rolled oats, sunflower seeds, coconut shreds, raisins, bran muffins). When the diet was changed or stopped, the serum tricyclic antidepressant levels rose and the depression was relieved.[1] The reasons for this effect are not known. This interaction may possibly provide an explanation for otherwise unaccountable relapses or inadequate responses to tricyclic antidepressant treatment.

Another study in 12 healthy subjects found that breakfast had no effect on the bioavailability of a 50-mg dose of **imipramine**, or on its peak levels or the time to peak levels.[2] A study in 9 healthy subjects given a single 25-mg dose of **amitriptyline** in the fasting state and with a standardised breakfast found that there were no consistent changes in the bioavailability of **amitriptyline** or its main metabolite nortriptyline. Similar results were found in a parallel study in which the same subjects were given a single 25-mg dose of **nortriptyline**. However, there were large interindividual changes in the AUC of **amitriptyline** after food, ranging from an increase of 94% to a decrease of about 40%. The largest food-related **amitriptyline** AUC *increases* occurred among the subjects with the lowest fasting AUC values and the only major food-related *decrease* occurred in the subject with the largest fasting AUC. It was concluded that for an individual patient, the timing of **amitriptyline** administration in relation to food intake should be standardised to avoid large variations in drug levels.[3]

An isolated report describes a severe generalised urticaria that occurred after the ingestion of **cod** by a 33-year-old woman treated with **clomipramine** 100 mg daily. Clomipramine was gradually discontinued and the rash improved. Her antidepressant was changed to paroxetine and she then ate cod without developing any adverse effects. Furthermore, rechallenge with **clomipramine** did not induce any adverse events, but when she was rechallenged with **clomipramine** and cod, the urticaria was again observed. Ingestion of other fish during **clomipramine** treatment did not induce an effect.[4] This appears to be an isolated report. Its general relevance is therefore probably small.

Tricyclic antidepressants + Furazolidone

An isolated report describes the development of toxic psychosis, hyperactivity, sweating and hot and cold flushes when a woman taking amitriptyline also took furazolidone and diphenoxylate with atropine.

Clinical evidence, mechanism, importance and management

A depressed woman taking conjugated oestrogens 1.25 mg daily and **amitriptyline** 75 mg daily, was also given furazolidone 300 mg daily and diphenoxylate with atropine sulfate. Two days later she began to experience blurred vision, profuse perspiration followed by alternate chills and hot flushes, restlessness, motor activity, persecutory delusions, auditory hallucinations and visual illusions. The symptoms cleared within a day of stopping the furazolidone.[1] The reasons for this reaction are not understood but the authors point out that furazolidone has MAO-inhibitory properties and that the symptoms were similar to those seen when the tricyclic antidepressants and MAOIs interact. However the MAO-inhibitory activity of furazolidone normally develops over several days. Whether the concurrent use of atropine and **amitriptyline** (both of which have antimuscarinic activity) had some part to play in the reaction is uncertain. No firm conclusions can be drawn from this slim evidence, but clinicians should be aware of this case when considering the concurrent use of any tricyclic antidepressant and furazolidone.

Tricyclic antidepressants + Grapefruit juice

Grapefruit juice did not appear to have a clinically significant effect on amitriptyline or clomipramine levels in one study. However, an isolated report describes increased clomipramine levels when two children were also given grapefruit juice.

Clinical evidence, mechanism, importance and management

A study in 6 patients given **clomipramine** 112.5 to 225 mg daily found that grapefruit juice 250 mL increased the mean plasma levels of **clomipramine** and its metabolite, desmethylclomipramine, by 4.5% and 10.5%, respectively. In another 7 patients taking **amitriptyline** 100 to 150 mg daily grapefruit juice did not affect the plasma levels of the tricyclic.[1] However, an isolated report describes an 8-year-old boy with Tourette's syndrome and obsessive-compulsive disorder who had minimal improvement when taking **clomipramine** 25 mg three times daily for 3 months. He was additionally given 250 mL of frozen concentrate grapefruit juice with each dose of **clomipramine** and, after 3 days, his trough blood levels of clomipramine had risen from 73 nanograms/mL to 198 nanograms/mL and those of the desmethylclomipramine had risen from 144 nanograms/mL to 233 nanograms/mL, and a clinical improvement was seen. **Clomipramine** levels were also increased in a 13-year-old girl, with an autistic spectrum disorder, when grapefruit juice was added to each dose of clomipramine, but no clinical improvement was seen.[2]

The studies (and the known metabolic pathways of the tricyclics, see 'Table 35.2', (p.1465)) suggest that an interaction with grapefruit juice is unlikely. Just why the levels were raised in the children is unclear. Dose adjustments of the tricyclics would generally not be expected to be necessary in those who drink grapefruit juice.

Tricyclic antidepressants + Haloperidol and related drugs

Serum desipramine levels can be increased by haloperidol. This may have caused a grand mal seizure in one case but toxic reactions appear to be uncommon. Desipramine and bromperidol appear not to interact.

Clinical evidence

(a) Bromperidol

When 13 patients with schizophrenia taking bromperidol 12 to 24 mg daily for 1 to 20 weeks were also given **desipramine** 50 mg daily for a week, bromperidol plasma levels remained unchanged and no adverse clinical events were seen.[1]

(b) Haloperidol

1. Desipramine. A comparative study in patients taking similar doses of desipramine (2.5 to 2.55 mg/kg) found that the two patients also taking haloperidol had steady-state plasma desipramine levels that were more than double those of 15 other patients not taking haloperidol (255 nanograms/mL compared with 110 nanograms/mL).[2]

A case report describes a patient who had a grand mal seizure when taking desipramine with haloperidol. Her serum desipramine levels were unusually high, at 610 nanograms/mL.[3]

2. Imipramine. The urinary excretion of a test dose of ^{14}C-imipramine given to two patients with schizophrenia patients was reduced by about 35 to 40% when they took haloperidol 12 to 20 mg daily.[4] The plasma metabolite levels of ^{14}C-nortriptyline of another patient with schizophrenia fell when haloperidol 16 mg daily was taken, whereas the plasma levels of unchanged nortriptyline rose.[5]

Mechanism

Haloperidol reduces the metabolism of the tricyclic antidepressants, thereby reducing their clearance, which results in a rise in their plasma levels.

Importance and management

The interaction between the tricyclic antidepressants and haloperidol is established though its documentation is sparse. Concurrent use is common whereas adverse reactions are not, but be aware that serum desipramine levels may be elevated. This may have been the cause of the grand mal seizure in the case cited.[3] Imipramine appears to interact similarly. Monitor the outcome if haloperidol is added to established treatment with tricyclic antidepressants.

Note that bromperidol and haloperidol prolong the QT-interval, and this effect has been seen with tricyclics, usually in overdose, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290. Also, the concurrent use of antipsychotics and drugs with antimuscarinic effects, including tricyclic antidepressants, has led to severe adverse effects, see also, 'Antipsychotics + Antimuscarinics', p.833.

Tricyclic antidepressants + H_2-receptor antagonists

Cimetidine can raise the plasma levels of amitriptyline, desipramine, doxepin, imipramine and nortriptyline. Other tricyclic antidepressants are expected to interact similarly. Ranitidine does not appear to interact with the tricyclics.

Clinical evidence

(a) Amitriptyline

A group of healthy subjects took **cimetidine** 300 mg every 6 hours for 4 days, with a single 25-mg dose of amitriptyline on day 3. The peak plasma levels and the AUC of amitriptyline were raised by 37% and 80%, respectively, but the levels of nortriptyline (a metabolite of amitriptyline) were reduced.[1]

Another study by the same authors found that **ranitidine** does not interact with amitriptyline.[2]

(b) Desipramine

In a study in 8 patients, **cimetidine** 1 g daily for 4 days raised the plasma levels of desipramine 100 to 250 mg daily by 51%, and raised the levels of its hydroxylated metabolite (2-hydroxydesipramine) by 46%.[3] Another study suggests that this interaction does not occur in those individuals who have low levels or are completely lacking CYP2D6.[4]

(c) Doxepin

A study in 10 healthy subjects given a single 100-mg oral dose of doxepin 12 hours after starting to take **cimetidine** 300 mg every 6 hours found that the peak plasma level and AUC of doxepin were raised by 28% and 31%, respectively.[5]

In another study, **cimetidine** 600 mg twice daily was found to double the steady-state plasma levels of doxepin 50 mg daily, whereas **ranitidine** 300 mg daily had no effect on doxepin levels.[6] A patient taking doxepin complained that the normally mild adverse effects (urinary hesitancy, dry mouth and decreased visual acuity) became incapacitating when he also took **cimetidine**. His serum doxepin levels were found to be elevated in the presence of cimetidine.[7]

(d) Imipramine

In 12 healthy subjects, **cimetidine** 300 mg every 6 hours for 3 days raised the peak plasma levels and the AUC of a single 100-mg dose of imipramine by 65% and 172%, respectively. After taking **ranitidine** 150 mg twice daily for 3 days the pharmacokinetics of imipramine were unaltered.[8] These findings with **cimetidine** confirm those of previous studies.[9,10]

There are case reports of patients taking imipramine who developed severe antimuscarinic adverse effects (dry mouth, urine retention, blurred vision), associated with very marked rises in serum imipramine levels, when they also took **cimetidine**.[11,12]

(e) Nortriptyline

In a study in 6 healthy subjects, **cimetidine** 300 mg four times daily for 2 days did not affect the peak plasma levels of nortriptyline, but its AUC was increased by 20%.[9]

A case report describes a patient whose serum nortriptyline levels were raised about one-third while taking **cimetidine**.[13] Another patient complained of abdominal pain and distension (but no other antimuscarinic adverse effects) when taking nortriptyline and **cimetidine**.[14]

Mechanism

Cimetidine is a non-specific enzyme inhibitor, which reduces the metabolism of the tricyclic antidepressants, and may also reduce the hepatic clearance of these drugs. This results in a rise in their plasma levels. Ranitidine does not interact because it is not an enzyme inhibitor.

Importance and management

The interactions of the tricyclics with cimetidine are well established, well documented and of clinical importance. The incidence is uncertain but most patients could be affected. Those taking amitriptyline, desipramine, doxepin, imipramine or nortriptyline who are given cimetidine should be warned that adverse effects such as dry mouth, urinary retention, blurred vision, constipation, tachycardia, and postural hypotension may be more likely to occur. Other tricyclic antidepressants would be expected to be similarly affected. If symptoms are troublesome reduce the dosage of the antidepressant (33 to 50% has been suggested) or replace the cimetidine with ranitidine, which does not appear to interact. Other H_2-receptor antagonists that do not cause enzyme inhibition (e.g. **famotidine** and **nizatidine**) would also not be expected to interact. Note that if cimetidine is discontinued, decreases in plasma levels of the tricyclic antidepressants may occur, which could result in loss of therapeutic efficacy.

Note that, the tricyclics have been associated with QT prolongation, most usually when their levels are high, and this interaction may therefore increase the risk of this effect. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further discussion on QT prolongation.

Tricyclic and related antidepressants + Inotropes and Vasopressors

Patients taking tricyclic antidepressants show a grossly exaggerated response (hypertension, cardiac arrhythmias, etc.) to parenteral noradrenaline (norepinephrine), adrenaline (epinephrine) and to a lesser extent to phenylephrine. Case reports suggest that this interaction only occurs rarely with local anaesthetics containing these vasoconstrictors. Evidence for or against a similar interaction with mianserin and maprotiline is sparse.
Case reports describe reduced action of ephedrine in patients taking tricyclic antidepressants or mianserin.

Clinical evidence

(a) Adrenaline (Epinephrine) or Noradrenaline (Norepinephrine)

The effects of intravenous infusions of noradrenaline were increased about ninefold, and of adrenaline about threefold, in 6 healthy subjects who had been taking **protriptyline** 60 mg daily for 4 days.[1,2]

Similarly, the pressor effects of intravenous infusions of noradrenaline were increased four to eightfold, and of adrenaline two to fourfold in 4 healthy subjects who had been taking **imipramine** 75 mg daily for 5 days. Some potentiation of adrenaline-induced tachycardia occurred in one subject and striking changes in heart rhythm occurred in all 4 subjects.[3]

Five patients taking **nortriptyline**, **desipramine** or other unnamed tricyclic antidepressants experienced adverse reactions, some of them severe (throbbing headache, chest pain) following the injection of *Xylestesin* (lidocaine with 1:25 000 noradrenaline) during dental treatment.[4] Several episodes of marked increases in blood pressure, dilated pupils, intense malaise, violent but transitory tremor, and palpitations have been reported in patients taking unnamed tricyclic antidepressants when they were given local anaesthetics containing adrenaline or noradrenaline for dental treatment.[5]

There are other reports describing this interaction between:

- adrenaline with **amitriptyline**[6] and **nortriptyline**[7]
- noradrenaline with **amitriptyline**,[8,9] **clomipramine**,[10] **desipramine**,[8,9] **imipramine**[8,10,11] and **protriptyline**[9]

In contrast, in 5 healthy subjects taking **maprotiline**[12] and 5 patients with depression taking **mianserin**,[13] the pressor response to noradrenaline remained largely unchanged. However, a case report describes a 71-year-old woman who had been taking **mianserin** long-term who developed hypotension, following spinal anaesthesia and general anaesthesia, which was refractory to multiple boluses of ephedrine. However, her blood pressure increased excessively following a small dose of adrenaline.[14]

(b) Ephedrine

An elderly woman taking **amitriptyline** 75 mg daily developed hypotension (70 mmHg systolic) during subarachnoid anaesthesia, but her blood pressure rose only minimally when she was given intravenous boluses of ephedrine totalling 90 mg.[15] Similarly, in another patient receiving long-term **amitriptyline**, hypotension occurred during combined general and epidural anaesthesia, which was refractory to high doses of ephedrine, but control was achieved with noradrenaline.[16] Other reports describe hypotension refractory to ephedrine in patients receiving long-term **imipramine** and **lofepramine**,[17] or **mianserin**.[14]

(c) Isoprenaline (Isoproterenol)

In a study in 4 healthy subjects who had been taking **imipramine** 75 mg daily for 5 days, there were no noticeable or consistent changes in the response of blood pressure to isoprenaline and no abnormalities of heart rhythm were seen, but in one of the subjects there was a potentiation of isoprenaline-induced tachycardia.[3]

A case report describes a 30-year old woman with asthma who died due to aspiration of gastric contents in response to a cardiac arrhythmia following the use of an isoprenaline aerosol whilst taking **amitriptyline**; she was also taking other drugs including theophylline, ephedrine and phenobarbital.[18]

(d) Phenylephrine

The pressor effects of intravenous infusions of phenylephrine were increased two to threefold in 4 healthy subjects who had been taking **imipramine** 75 mg daily for 5 days.[3]

(e) Tyramine

The pressor response to tyramine was inhibited in 20 patients taking **clomipramine**,[19] and in patients (number not stated) taking **amitriptyline** 150 mg.[20] In 5 healthy subjects taking **maprotiline**, the pressor response to tyramine was reduced threefold.[12] The tyramine-response was unchanged by **mianserin**.[20-22]

Mechanism

The tricyclics and some related antidepressants block or inhibit the uptake of noradrenaline into adrenergic neurones. Thus the most important means by which noradrenaline is removed from the adrenoceptor area is inactivated and the concentration of noradrenaline outside the neurone can rise. If more noradrenaline (or one of the other directly-acting alpha or alpha/beta agonists i.e. adrenaline, phenylephrine) is then given, the adrenoceptors of the cardiovascular system concerned with raising blood pressure and/or cardiac rate and rhythm become grossly stimulated by this superabundance of amines, and the normal response becomes exaggerated. Mianserin, unlike the tricyclics, does not prevent the peripheral uptake of noradrenaline, and this may explain why it appears to interact somewhat differently in some cases.

Tyramine, and to some extent ephedrine, exerts its effects on blood pressure by causing the release of noradrenaline from adrenergic neurones. In the presence of a tricyclic antidepressant, the uptake of these amines into adrenergic neurones is partially or totally prevented and the noradrenaline-releasing effects are therefore blocked.[19] Consequently the effects of these drugs (and therefore probably other indirectly-acting sympathomimetics) might be expected to be reduced by tricyclic antidepressants.

For a categorisation of sympathomimetic drugs, see 'Table 24.1', (p.1048).

Importance and management

A well documented, well established and potentially serious interaction. The parenteral use of noradrenaline, adrenaline, phenylephrine or any other sympathomimetic amines with predominantly direct activity should be avoided in patients taking tricyclic antidepressants. If these inotropes must be used, the rate and amount injected must be very much reduced to accommodate the exaggerated responses that will occur. Evidence for a similar interaction with maprotiline and mianserin is sparse, but maprotiline is known to have the same effects on noradrenaline as the tricyclics, and a case report describes a similar interaction between adrenaline and mianserin, so some caution seems prudent.

The situation where adrenaline or noradrenaline are used with a local anaesthetic for surface or infiltration anaesthesia, or nerve block is less clear. The cases cited are all from the 1960s or 1970s, and the preparations concerned contained concentrations of adrenaline or noradrenaline several times greater than those used currently. However, it should be noted that preparations such as *Xylocaine* with adrenaline still carry a caution about their use with tricyclic antidepressants.[23] Anecdotal evidence suggests that local anaesthetics containing sympathomimetics are, in practice, commonly used in patients receiving tricyclic antidepressants,[24] so the scarcity of reports, especially recent ones, would add weight to the argument that the interaction is only rarely significant. However, it would still seem advisable to be aware of the potential for interaction. Aspiration has been recommended to avoid inadvertent intravenous administration. **Felypressin** has been shown to be a safe alternative.[25-27] If an adverse interaction occurs it can be controlled by the use of an alpha-receptor blocker, such as phentolamine.

Phenylephrine can be absorbed systemically from the eye and one manufacturer has contraindicated the use of phenylephrine eye drops in patients receiving tricyclic antidepressants, or within several days or their discontinuation, because the pressor response to adrenergic agents and the risk of cardiac arrhythmia may be potentiated.[28] However, it does not seem to have been established whether the response to oral doses or nasal

drops containing phenylephrine is enhanced by the presence of a tricyclic. Nevertheless, some caution seems prudent.

The effects of indirectly-acting sympathomimetics are expected to be reduced by tricyclic antidepressants, but there appear to be only a few reports of reduced efficacy of ephedrine, which has mixed indirect and direct sympathomimetic actions.

Tricyclic antidepressants + Macrolides

Troleandomycin increases the plasma levels of imipramine, and an isolated report suggests that josamycin may possibly increase amitriptyline levels. Erythromycin may possibly raise clomipramine levels, but was not found to interact with other tricyclic antidepressants in one study.

Clinical evidence, mechanism, importance and management

(a) Erythromycin

Erythromycin 250 mg four times daily for 6 days was found not to affect the tricyclic antidepressant levels of 8 patients taking **desipramine**, **imipramine**, **doxepin**, or **nortriptyline**.[1] Behavioural changes have been reported in a 15-year-old patient when erythromycin was added to a regimen of **clomipramine** and risperidone,[2] resulting in symptoms compatible with serotonin syndrome, although mental confusion and autonomic instability were absent.[3] It was suggested that erythromycin increased **clomipramine** levels by inhibiting its metabolism by the cytochrome P450 isoenzyme CYP3A4.[4] **Clomipramine** levels may also have been raised by competition with risperidone for metabolism by CYP2D6.

In general, no interaction would be expected between the tricyclics and erythromycin; the isolated report seems unlikely to be of general significance.

(b) Josamycin

A patient taking **amitriptyline** had a marked increase in the total serum levels of **amitriptyline** and its metabolite, nortriptyline, after taking josamycin but no toxicity was reported. It was suggested that josamycin had inhibited **amitriptyline** metabolism.[5] This is an isolated case and although its general significance is unknown, it seems likely to be small.

(c) Troleandomycin

A study in 9 healthy Chinese men found that when they were given troleandomycin 250 mg daily for 2 days before a single 100-mg oral dose of **imipramine**, the AUC of the **imipramine** was increased by 59% and its oral clearance was reduced by 30%. It is thought that troleandomycin inhibits the *N*-demethylation of **imipramine** by inhibiting the cytochrome P450 isoenzyme subfamily CYP3A.[6] The clinical importance of this interaction is uncertain, but it may be prudent to be alert for increased antimuscarinic adverse effects (e.g. dry mouth, blurred vision, urinary retention) if troleandomycin is given to a patient taking imipramine.

Tricyclic antidepressants + Maprotiline

An isolated case describes severe, reversible hepatitis associated with the concurrent use of maprotiline and opipramol.

Clinical evidence, mechanism, importance and management

A patient who had been taking opipramol 150 mg daily for 2 months developed a progressive fatigue syndrome while taking opipramol 100 mg daily and maprotiline 75 mg daily for a further 2 months. Six weeks later he was found to have a marked elevation of liver enzymes and jaundice. Liver enzymes decreased upon cessation of the antidepressants, and normalised completely within 2 months.[1]

It was thought that the concurrent use of both drugs had led to the hepatotoxicity seen: both maprotiline and the tricyclic antidepressants have been associated with hepatotoxicity.

The general relevance of this isolated case is unclear, but it serves as a reminder of the risks of using two potentially hepatotoxic drugs at the same time.

Tricyclic antidepressants + Methylphenidate

Methylphenidate can increase the levels and rate of response to imipramine and other tricyclic antidepressants. This has led to both increased beneficial and adverse effects. No significant pharmacokinetic interaction has been reported between desipramine and methylphenidate. An isolated report describes a blood dyscrasia in a child given methylphenidate and imipramine.

Clinical evidence

A study in 'several patients' found a dramatic increase in the plasma levels of **imipramine** and its active metabolite, desipramine, when they took

methylphenidate. In one patient taking **imipramine** 150 mg daily, the use of methylphenidate 20 mg daily increased the plasma levels of imipramine from 100 nanograms/mL to 700 nanograms/mL and increased the plasma levels of desipramine from 200 nanograms/mL to 850 nanograms/mL over a period of 16 days. Clinical improvement occurred in several of the patients.[1] Similar effects have been described in other reports.[2-5] It seems that elevation of drug levels takes several days to occur, and several days to wear off.[3]

In contrast, a retrospective review in children and adolescents taking either **desipramine** alone, or with a stimulant, indicated the absence of a clinically significant interaction between **desipramine** and methylphenidate in 25 children who received both drugs; pharmacokinetic parameters for desipramine were similar in each group.[6] In one patient taking **desipramine** 250 mg daily, the concurrent use of methylphenidate 40 mg daily resulted in a small decrease in serum **desipramine** levels, but a marked improvement in mood.[7] However, a further report describes more frequent adverse effects in 10 paediatric patients taking methylphenidate with **desipramine** than with methylphenidate alone, but desipramine levels were not particularly increased.[8]

A study of the combined use of tricyclic antidepressants (**desipramine**, **imipramine**, **nortriptyline**, **doxepin**) with methylphenidate 5 to 15 mg twice daily was undertaken in 20 of 41 patients with depression who responded to a test dose of methylphenidate. Combined use accelerated the antidepressant response to tricyclics with 6 of 20 patients responding after one week and 10 of 16 patients responding after 2 weeks. Adverse effects included insomnia, dizziness, hypotension and dry mouth. Methylphenidate was discontinued after less than 2 weeks concurrent use in 3 patients because of increased anxiety, irritability and hypomania.[9]

A report describes a 9-year-old boy and a 15-year-old boy who exhibited severe behavioural problems until the **imipramine** and methylphenidate that they were taking were stopped.[10] Another case report describes the development of oculogyric crisis in a 10-year-old girl after the addition of **imipramine** to treatment with methylphenidate and valproic acid.[11] Three patients taking tricyclic antidepressants and with labile blood pressure experienced hypertensive episodes when methylphenidate was also given. They responded to withdrawal of methylphenidate and two patients had further hypertensive episodes when rechallenged with methylphenidate.[12] An isolated report describes leucopenia, anaemia, eosinophilia and thrombocytosis in a 10-year-old child when **imipramine** and methylphenidate were given.[13]

Mechanism

In vitro experiments with human liver slices indicate that methylphenidate inhibits the metabolism of imipramine, resulting in raised blood levels.[3] The accelerated response to tricyclic antidepressants may also be partly due to increased serum levels in the presence of methylphenidate, although the adverse effects observed were not entirely consistent with elevated levels of tricyclics.[9] The blood dyscrasia may have been due to the rare additive effects of both drugs.[13]

Importance and management

Evidence is somewhat conflicting, but in general, the combination of methylphenidate and tricyclic antidepressants may result in some therapeutic improvement including, in some patients, an accelerated response. This may be partially because of the very marked rise in the blood levels of the antidepressant due to methylphenidate, but may also be due to an additional effect on mood attributable to methylphenidate. Concurrent use may cause adverse effects sufficiently severe to necessitate withdrawal of methylphenidate, but it is not certain whether this can solely be attributed to increases in serum levels of tricyclic antidepressants. It has been suggested that the concurrent use of methylphenidate and tricyclics in children and adolescents may be undesirable, due to case reports of adverse behavioural effects.[10] If concurrent use is deemed necessary it would seem prudent to monitor for adverse tricyclic effects (e.g. dry mouth, blurred vision, urinary retention) and adjust the dose of the tricyclic as necessary. If this is not effective it may be necessary to withdraw one or both drugs.

Tricyclic antidepressants + Modafinil

Clomipramine blood levels were reported to be increased by modafinil in one patient. However, a study found that the concurrent use of modafinil and clomipramine did not affect the pharmacokinetics of either drug.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study, 18 patients were given a single 50-mg dose of **clomipramine** on day 1 and modafinil 200 mg daily on days 1 to 3. No pharmacokinetic changes were found to have occurred with either of the two drugs.[1] However, a single case report describes a patient taking **clomipramine** 75 mg daily who had a rise in her blood levels of **clomipramine** and its metabolite desmethylclomipramine when modafinil 200 mg was added.[2] It was suggested that she had low levels of the cytochrome P450 isoenzyme CYP2D6 (a 'poor metaboliser') so that the additional inhibition of CYP2C19 by modafinil resulted in elevated **clomipramine** levels.

Information about other tricyclic antidepressants is lacking, but the manufacturers of modafinil point out that other poor metabolisers (about 7 to 10% of the Caucasian population) may possibly also show increased tricyclic antidepressant levels in the presence of modafinil.[3,4] Therefore monitoring concurrent use would seem to be a prudent precaution; lower doses of tricyclic antidepressants may be required in those patients deficient in CYP2D6.[3,4] However, note that not all tricyclic antidepressants are metabolised in the same way, and only those affected by CYP2C19 would be expected to be affected, see 'Table 35.2', (p.1465), for more information on the metabolism of the tricyclics.

Tricyclic antidepressants + Nasal decongestants

The effects of pseudoephedrine and other related drugs are predicted to be altered by the tricyclic antidepressants; however, there appears to be a lack of reported cases.

Clinical evidence, mechanism, importance and management

Some manufacturers of pseudoephedrine-containing products suggest that its activity might be diminished or enhanced by tricyclic antidepressants. There is some concern that concurrent use may lead to a rise in blood pressure.[1,2] In practice, the efficacy of ephedrine (which has similar effects mixed indirect and direct action on adrenergic neurones to pseudoephedrine) is diminished by tricyclics, when it is given as a vasopressor, see 'Tricyclic and related antidepressants + Inotropes and Vasopressors', p.1507. Therefore a similar reduction in effect would be expected when these drugs are given as nasal decongestants.

Furthermore, one manufacturer[2] warns of an increased risk of arrhyth-

mias on concurrent use, but this effect only appears to have been seen with intravenous adrenaline, and even then, rarely.

Tricyclic and related antidepressants + Oestrogens

There is limited evidence suggesting that oestrogens can sometimes affect the therapeutic response to imipramine, and also cause imipramine toxicity. Tricyclic-induced akathisia was attributed to the concurrent use of conjugated oestrogens in three patients. Maprotiline levels are not affected by hormonal contraceptives

Clinical evidence

A study in women taking **imipramine** 150 mg daily for primary depression found that those given **ethinylestradiol** 25 or 50 micrograms [daily] for one week had a greater improvement than those given **imipramine** alone. However, after 2 weeks, those given **ethinylestradiol** 50 micrograms daily had less improvement than other women given only 25 micrograms of **ethinylestradiol** [daily] or a placebo.[1] In an earlier associated study 5 patients taking **imipramine** 150 mg and **ethinylestradiol** 50 micrograms daily developed signs of **imipramine** toxicity (severe lethargy (4 patients), hypotension (4), coarse tremor (2), mild depersonalisation (2)) that was dealt with by halving the **imipramine** dose.[1] Similarly, in a case report, long-standing **imipramine** toxicity was relieved in a woman taking **imipramine** 100 mg daily when her dose of **conjugated oestrogens**, which she had increased to 7.5 mg daily, was reduced to 625 micrograms daily.[2] In another report, akathisia in 3 patients was attributed to an interaction between **conjugated oestrogens** in usual doses of 1.25 mg daily and **amitriptyline**, **clomipramine** or **doxepin**.[3]

A study found that oral contraceptives increased the absolute bioavailability of **imipramine** by 60%.[4] Several studies have shown that plasma **clomipramine** levels were raised or remained unaffected by the concurrent use of oestrogen-containing contraceptives; however, they were unable to confirm that tricyclic antidepressant toxicity occurs more often in those taking oral contraceptives than those who are not.[5-8]

A study in women found that, over a 28-day period, the use of oral hormonal contraceptives did not significantly affect the steady-state blood levels of **maprotiline** 75 mg given at night, nor was its therapeutic effectiveness changed.[9]

Mechanism

Among the possible reasons for these effects are that the oestrogens increase the bioavailability of imipramine,[4] by inhibiting its metabolism.[10] Other tricyclic antidepressants might be similarly affected.

Importance and management

These interactions are inadequately established. There is no obvious reason for avoiding concurrent use, but it would seem reasonable to be alert for any evidence of toxicity and/or lack of response to tricyclic antidepressant treatment in those taking oestrogens in any form. One study suggested that the imipramine dosage should be reduced by about one-third,[4] but given the lack of confirmatory data it would seem prudent to only adjust tricyclic doses according to response.

Tricyclic antidepressants + Orlistat

Orlistat does not appear to affect the plasma levels of clomipramine or desipramine in patients, or the pharmacokinetics of amitriptyline in healthy subjects.

Clinical evidence, mechanism, importance and management

A preliminary study in patients who had been taking psychotropic drugs long-term found no clinically relevant changes in plasma levels of **clomipramine** (3 patients) or **desipramine** (1 patient) when they were given orlistat over an 8-week period.[1] A study in 20 healthy subjects found that orlistat 120 mg three times daily for 6 days did not affect the pharmacokinetics of **amitriptyline** 25 mg three times daily.[2]

Although evidence is limited no particular precautions seem likely to be necessary on concurrent use.

Tricyclic antidepressants + Oxybutynin

Oxybutynin reduced the blood levels of clomipramine in one patient. Both tricyclics and oxybutynin have antimuscarinic effects, which would be expected to be additive on concurrent use.

Clinical evidence, mechanism, importance and management

An elderly woman had **clomipramine** and desmethylclomipramine blood levels of 405 and 50 nanograms/mL, respectively, after taking clomipramine 25 mg daily and fluvoxamine 100 mg daily for 18 days. Within one week of starting oxybutynin 5 mg daily, the levels of **clomipramine** and desmethylclomipramine had fallen to 133 nanograms/mL and less than 25 nanograms/mL, respectively, and remained low during a further week of concurrent treatment.[1]

It has been suggested that **clomipramine** levels may be reduced because oxybutynin is an inducer of cytochrome P450 isoenzymes, which could increase the metabolism of clomipramine, and therefore reduce it levels.[1] However, oxybutynin does not usually act in this way.

This appears to be the only report of an interaction, the mechanism of which is not fully clear. It is therefore of unknown general significance. However, note that both tricyclic antidepressants and oxybutynin have antimuscarinic effects, which may be additive on concurrent use. Consider 'Antimuscarinics + Antimuscarinics', p.786, for more on this potential interaction.

Tricyclic antidepressants + Propafenone

An isolated report describes markedly raised serum desipramine levels in a patient who also took propafenone.

Clinical evidence

A man with major depression responded well to **desipramine** 175 mg daily with serum desipramine levels in the range of 500 to 1000 nanomol/L. When he was treated for paroxysmal atrial fibrillation with digoxin 250 micrograms daily, and propafenone 150 mg twice daily and 300 mg at night, he developed markedly elevated serum **desipramine** levels (2092 nanomol/L) and toxicity (dry mouth, sedation, shakiness) while tak-

ing desipramine 150 mg daily. The adverse effects resolved when the **desipramine** was stopped for 5 days, but when it was restarted at 75 mg daily his serum desipramine levels were still raised, at 1130 nanomol/L.[1]

Mechanism

Propafenone is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, by which desipramine is predominantly metabolised. Concurrent use therefore decreases desipramine metabolism and results in an increase in its levels.

Importance and management

This appears to be the only report of an interaction between desipramine and propafenone, but it is in line with the way both drugs are known to interact. An interaction would therefore seem to be established, although its general importance is uncertain. It would seem prudent to be alert for signs of desipramine toxicity in any patient also given propafenone. Reduce the desipramine dosage appropriately. Other tricyclic antidepressants might be expected to be similarly affected as they are also metabolised, at least in part, by CYP2D6.

Note that, the tricyclics have been associated with QT prolongation, most usually when their levels are high, and this interaction may therefore increase the risk of this effect. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further discussion on QT prolongation.

1. Katz MR. Raised serum levels of desipramine with the antiarrhythmic propafenone. *J Clin Psychiatry* (1991) 52, 432–3.

Tricyclic and related antidepressants + Protease inhibitors

Ritonavir raises desipramine levels and is predicted to also raise the levels of other tricyclic antidepressants. A case report describes potentially life-threatening cardiac conduction problems and antimuscarinic effects when ritonavir and other protease inhibitors were given with maprotiline.

Clinical evidence

(a) Desipramine

A study in 15 healthy subjects found that **lopinavir**/**ritonavir** 400/100 mg twice daily modestly reduced the maximum plasma concentration of a single 100-mg dose of desipramine by 23%, but the AUC was unaffected. These results were not statistically significant.[1]

In a study, 14 healthy subjects were given a single 100-mg dose of desipramine before and after they took **ritonavir** 500 mg twice daily for 10 days. **Ritonavir** increased the AUC and half-life of desipramine nearly 2.5-fold and 2-fold, respectively. The maximum plasma levels were also increased by about 22%.[2] Another study in 13 healthy subjects, found that **ritonavir** 100 mg twice daily modestly increased the AUC of a single 50-mg dose of desipramine by 26% and prolonged the half-life by 30%. However, there was marked interindividual variability in desipramine pharmacokinetic parameters, both with and without ritonavir; in the presence of ritonavir 12 of 13 subjects had an increase in the AUC of desipramine ranging from 4 to 71%.[3]

(b) Maprotiline

A report describes a 32-year-old man with AIDS taking low-dose maprotiline 50 mg daily and fluconazole 200 mg daily, who experienced severe hypotension, cardiac conduction problems and other symptoms such as dry mouth, constipation and dysuria, 8 weeks after starting a combination of antiretroviral drugs including **ritonavir** 400 mg twice daily, **saquinavir**, **indinavir**, **amprenavir** and stavudine. The serum levels of maprotiline reached 1.5 mmol/L (reference range 0.3 to 1 mmol/L). Clinical and electrical abnormalities disappeared within 72 hours of stopping the maprotiline, antiretroviral drugs and fluconazole.[4]

Mechanism

The tricyclic antidepressants and maprotiline are metabolised, at least in part by the cytochrome P450 isoenzyme CYP2D6. Ritonavir is a known inhibitor of this isoenzyme, and therefore concurrent use decreases the metabolism of the tricyclics, leading to an increase in their levels. **Tipranavir** appears to be the only other protease inhibitor that also affects this isoenzyme to a clinically relevant extent, see 'Table 21.2', (p.914).

Importance and management

An interaction between desipramine and ritonavir appears to be established. However, its clinical relevance appears to depend on the dose of ritonavir used, with the studies suggesting that higher doses of ritonavir (500 mg twice daily) have a large effect on desipramine levels, which may require a dose reduction. In contrast, when ritonavir is given as a pharmacokinetic enhancer (i.e. at a dose of 100 mg twice daily), the effects are modest and unlikely to require dose adjustments of the tricyclic. Because of the increased levels seen, it would seem prudent to monitor for increased tricyclic adverse effects (e.g. dry mouth, urinary retention, constipation) in any patient given ritonavir (regardless of dose). It may be prudent to consider starting desipramine at a low dose in patients taking ritonavir 500 mg twice daily, increasing the dose slowly.

There seems to be little information regarding other tricyclics, but as they are all metabolised, at least in part, by CYP2D6, similar precautions to those suggested for desipramine would seem prudent.

Other protease inhibitors, with the exception of tipranavir, would not be expected to interact by this mechanism. However, the manufacturer of nelfinavir suggests that, as it is primarily metabolised by CYP3A4 and CYP2C19 drugs that could inhibit CYP2C19 (including amitriptyline and imipramine) might be expected to reduce the conversion of nelfinavir to its major active metabolite M8, and increase plasma nelfinavir levels. However, limited clinical data suggests this is unlikely to be clinically significant.[5] Furthermore, these tricyclics are not usually considered to be inhibitors of these isoenzymes. A clinically relevant interaction therefore seems unlikely.

Tricyclic antidepressants + Quinidine or Quinine

Quinidine can reduce the clearance of desipramine, imipramine, nortriptyline and trimipramine, and quinine can reduce the clearance of desipramine, thereby increasing their plasma levels.

Clinical evidence

(a) Quinidine

In a study in 5 healthy subjects quinidine 50 mg given one hour before a single 50-mg dose of **nortriptyline** increased the **nortriptyline** AUC fourfold, and increased the half-life from 14.2 hours to 44.7 hours.[1] The clearance fell by 65%. A single-dose study in healthy subjects found that quinidine 200 mg daily reduced the clearance of **imipramine** 100 mg and **desipramine** 100 mg by 30% and 85%, respectively.[2] A further study in 2 healthy subjects similarly found that quinidine 50 mg almost doubled the half-life of a single 75-mg dose of **trimipramine**, which was reflected in some waking EEG changes.[3]

In healthy subjects given quinidine 800 mg daily for 2 days, the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of **desipramine** was reduced by 97% and 68%, respectively in subjects with normal levels and low levels of [CYP2D6].[4]

(b) Quinine

Quinine 750 mg daily for 2 days reduced the urinary excretion of 2-hydroxydesipramine from a single 25-mg dose of **desipramine** in those with normal levels of [CYP2D6] by 56% but had no significant effect on the clearance in those with low levels of [CYP2D6].[4]

Mechanism

Quinidine reduces the metabolism (hydroxylation) of these tricyclic antidepressants, by inhibiting the cytochrome P450 isoenzyme CYP2D6, and thereby reduces their loss from the body.[5,6] Quinine inhibits the metabolism of desipramine to a lesser extent than quinidine, as it is a less potent inhibitor of CYP2D6.

Importance and management

An interaction between quinidine and the tricyclics appears to be established. It would be expected to be clinically relevant with nortriptyline, and possibly desipramine, but probably not with imipramine. This is due to differences in the way the tricyclics are metabolised (see 'Table 35.2' (p.1465)). There seems to be no information about the effect of quinidine on other tricyclics, but increased toxicity is possible (given that they are all metabolised, at least in part, by CYP2D6) and doses may need to be reduced. If quinidine is given with a tricyclic, particularly one metabolised solely by CYP2D6, be alert for tricyclic adverse effects (dry mouth, urinary retention, constipation), and decrease the tricyclic dose accordingly. Note that, the tricyclics have been associated with QT prolongation, most usually when their levels are high, and this interaction may therefore increase the risk of this effect, particularly as quinidine has effects on the QT interval. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further discussion on QT prolongation.

Information about the effect of quinine on tricyclics is very limited, but the effects are smaller than those of quinidine and therefore less likely to result in clinically significant adverse effects.

Tricyclic antidepressants + Rifampicin (Rifampin)

In three patients a marked reduction in nortriptyline and amitriptyline levels occurred when rifampicin was given.

Clinical evidence

A man with tuberculosis needed to take 175-mg doses of **nortriptyline** to achieve therapeutic serum levels while taking isoniazid 300 mg, rifampicin 600 mg, pyrazinamide 1.5 g and pyridoxine 25 mg daily. Three weeks after stopping the antitubercular drugs, the patient suddenly became drowsy and his **nortriptyline** serum levels were found to have risen from 193 nanomol/L to 562 nanomol/L, and later to 671 nanomol/L. It was then found possible to maintain his **nortriptyline** serum levels in the range of 150 to 500 nanomol/L with only 75 mg of **nortriptyline** daily.[1]

A woman taking **amitriptyline** and fluoxetine had a marked fall in her plasma **amitriptyline** levels when she took rifampicin 600 mg, isoniazid 200 mg and ethambutol 1.2 g daily. When these antitubercular drugs were stopped, her **amitriptyline** plasma levels rose.[2] In a further case, in a 43-year-old woman, the serum levels of **nortriptyline** 50 mg daily were not detectable when rifampicin 600 mg daily was given. Increasing the dose of **nortriptyline** to 75 mg daily failed to produce detectable serum levels. Two weeks after discontinuation of rifampicin, **nortriptyline** levels increased.[3]

Mechanism

It seems highly probable that rifampicin (a well recognised and potent enzyme inducer) increased the metabolism of nortriptyline and amitriptyline by the liver thereby reducing their levels.

Importance and management

Information about the interaction between tricyclic antidepressants and rifampicin seems to be limited to just these three reports, which is a little surprising since both have been widely used for a considerable time. This suggests that generally this interaction may have limited clinical importance. However, bear this interaction in mind if patients taking rifampicin seem unresponsive to treatment with tricyclics. Increase the tricyclic dosage if necessary, and remember to readjust the dose if rifampicin is stopped.

Tricyclic antidepressants + SNRIs

The use of duloxetine or venlafaxine with the tricyclics is expected to increase the risk of serotonin syndrome: cases have been seen with venlafaxine. Increased antimuscarinic adverse effects, movement disorders and seizures have also been reported. Venlafaxine and duloxetine appear to increase the levels of desipramine or its 2-hydroxydesipramine metabolite. Other tricyclics are expected to interact similarly.

Clinical evidence

(a) Duloxetine

In a study in healthy subjects, duloxetine 60 mg twice daily increased the AUC of a single 50-mg dose of **desipramine** by 2.9-fold.[1]

(b) Venlafaxine

A 74-year-old man taking venlafaxine 150 mg daily and thioridazine had his treatment changed to daily doses of venlafaxine 75 mg, **desipramine** 50 mg, haloperidol 500 micrograms and alprazolam 250 micrograms. Within 5 days he exhibited severe antimuscarinic adverse effects (acute confusion, delirium, stupor, urinary retention and paralytic ileus). This was attributed to an interaction between the venlafaxine and **desipramine**.[2] Similarly, a 75-year-old man taking haloperidol, alprazolam and venlafaxine developed urinary retention and became delirious when he also took **desipramine**.[3] Similar effects have been seen in other cases involving **nortriptyline** 20 mg daily[4] and **clomipramine** 150 mg daily.[3]

A 69-year-old man with bipolar disorder, who had been taking venlafaxine up to 337.5 mg daily, thioridazine 25 mg at night, and sodium valproate 1.2 g daily for several months with no adverse motor symptoms, experienced extrapyramidal effects 3 to 4 days after the venlafaxine was gradually replaced by **nortriptyline** 50 mg daily. Symptoms persisted despite withdrawal of thioridazine, but improved on reduction of the **nortriptyline** dosage to 20 mg daily.[5]

A 25-year-old woman taking venlafaxine 150 mg daily and **trimipramine** 50 mg daily for depression developed seizures within 11 days of the **trimipramine** dose being increased to 100 mg daily. Both drugs were stopped and the patient had no further seizures.[6]

There is also a report of the serotonin syndrome occurring in a 21-year-old patient when **amitriptyline** 10 mg at night was added to the range of medications she was receiving, which included venlafaxine 37.5 mg daily, pethidine (meperidine) 400 mg daily and fluconazole 200 mg daily.[7] There are two other reports of the serotonin syndrome in patients who had discontinued venlafaxine 3 days and 2 weeks, respectively, before starting **amitriptyline**.[8,9]

Venlafaxine has only modest effects on the metabolism of **imipramine** to desipramine (AUC and maximum levels increased by 35%),[10,11] but the AUC of another metabolite, 2-hydroxydesipramine, is increased 4.5-fold by venlafaxine 75 mg twice daily.[11]

Mechanism

Not fully established. It has been suggested that venlafaxine can inhibit the metabolism of these tricyclics by the cytochrome P450 isoenzyme CYP2D6, leading to an increase in their serum levels and a marked increase in their antimuscarinic adverse effects.[3] However, studies indicate that venlafaxine is a relatively weak inhibitor of CYP2D6.[10]

Nevertheless, it does appear to have some effect on the metabolism of desipramine.

The other effects (seizures, antimuscarinic effects, serotonin syndrome) seem likely to have occurred due to the additive effects of the venlafaxine and tricyclic.

Importance and management

Information regarding an interaction between the tricyclics and SNRIs appears to be sparse, mainly coming from case reports, although an interaction resulting in raised tricyclic levels appears to be established. It would therefore seem prudent to monitor for antimuscarinic adverse effects (dry mouth, urinary retention, constipation) in any patient given the combination and consider reducing the dose of the tricyclic if adverse effects become troublesome.

There only appears to be one case report describing serotonin syndrome with venlafaxine and amitriptyline, and this particular case is complicated by the presence of fluconazole, which can increase amitriptyline levels (see 'Tricyclic and related antidepressants + Azoles; Fluconazole', p.1498), and pethidine (meperidine), which has also been implicated in cases of serotonin syndrome. Nevertheless, both the tricyclics and the SNRIs have been associated with this effect, and so some caution would seem warranted. See, 'serotonin syndrome', (p.9), for guidance on managing this potential adverse reaction.

Tricyclic and related antidepressants + SSRIs

The levels of the tricyclic antidepressants can be raised by the SSRIs, but the extent varies greatly, from 20% to tenfold: fluvoxamine, fluoxetine and paroxetine appear to have the greatest effects. Tricyclic toxicity has been seen in a number of cases. Tricyclics may increase the levels of citalopram and possibly fluvoxamine, but the significance of this is unclear. There are several case reports of serotonin syndrome following concurrent, and even sequential, use of the SSRIs and tricyclics.

One study suggested that there was no clinically significant pharmacokinetic interaction between fluoxetine and mianserin.

Clinical evidence

(a) Citalopram

In one study[1] citalopram caused an increase of about 50% in the AUC of desipramine (the primary metabolite of **imipramine**), and a reduction in the levels of the subsequently formed metabolite of desipramine (2-hydroxydesipramine) after a single 100-mg oral dose of **imipramine**. In contrast, 5 patients taking **amitriptyline**, **clomipramine** or **maprotiline** had no changes in their plasma tricyclic antidepressant levels when citalopram 20 to 60 mg daily was also given.[2] In another general study, in which 18 patients were given citalopram and tricyclic antidepressants, the serum levels of citalopram were doubled in those receiving **clomipramine**; pooled results for all the tricyclics showed a 44% rise in serum citalopram levels.[3] An increase of this size is of doubtful clinical importance with citalopram. In 2 patients the plasma levels of **clomipramine** 100 mg daily remained stable when the dose was reduced to 75 mg daily and citalopram 40 mg daily was started.[4,5] One had elevated levels of desmethylclomipramine[4] and the other had elevated levels of the active metabolite, 8-hydroxydesmethylclomipramine.[5]

A case report describes elevated **desipramine** levels in a patient taking paroxetine that resolved when the patient was switched to citalopram.[6]

(b) Escitalopram

Escitalopram 20 mg daily for 21 days increased the maximum serum levels and AUC of a single 50-mg dose of **desipramine** by 40% and 100%, respectively.[7]

(c) Fluoxetine

Four patients given **desipramine** 300 mg, **imipramine** 150 mg or **nortriptyline** 100 mg, each daily, had two- to fourfold increases in plasma tricyclic antidepressant levels within 1 to 2 weeks of starting fluoxetine 10 to 60 mg daily. Two of them developed antimuscarinic adverse effects (constipation, urinary hesitancy).[8] A report describes extremely high levels and prolonged elimination of **imipramine** following overdose with "a handful" of **imipramine** tablets in a patient taking fluoxetine 20 mg daily.[9]

A number of other reports and studies clearly confirm that marked increases occur in the levels of **amitriptyline**,[10-13] **clomipramine**,[11,14] **desipramine**,[15-24] **imipramine**,[11,19-21,25,26] **nortriptyline**[17,18,27-29] and possibly **protriptyline**,[30] accompanied by toxicity, if fluoxetine is added without reducing the dosage of the tricyclic antidepressant. Delirium and seizures have also been described,[20,31] and a death has been attributed to chronic **amitriptyline** toxicity caused by fluoxetine.[32] The pharmacokinetics of fluoxetine appear not to be affected by **amitriptyline**.[13]

A migraine-like stroke developed in a woman 48 hours after her long-standing treatment with fluoxetine 100 mg daily was abruptly changed to **clomipramine** 200 mg daily.[33]

A study involving 34 patients found that the combination of fluoxetine 20 mg daily and **mianserin** 30 mg daily was superior to fluoxetine and placebo in the acute treatment of major depression, and no major adverse effects were reported. However, 12 patients did not complete 6 weeks of treatment, and of these, 2 dropped out because of adverse effects (dizziness and sedation) after one and 3 weeks, respectively. After 4 weeks of treatment, headache and increased body weight occurred more frequently in those taking both drugs than in those taking fluoxetine alone. **Mianserin** had no effect on fluoxetine plasma levels and the plasma concentration of mianserin was similar to that previously reported.[34]

(d) Fluvoxamine

The **amitriptyline** plasma levels of 8 patients rose (range 15 to 233%) when they were also given fluvoxamine 100 to 300 mg daily. Even larger rises in plasma **clomipramine** levels occurred (up to eightfold) in four other patients given fluvoxamine 100 to 300 mg daily. The tricyclic dosages remained the same or were slightly lower. No toxicity was seen.[35-37]

A number of other reports and studies confirm that increases occur in the levels of **amitriptyline**,[38-41] **clomipramine**,[38-43] **desipramine**,[44-47] **imipramine**,[38,39,44-48] **maprotiline**[38] and **trimipramine**[49] in the presence of fluvoxamine. This interaction seems severe with **clomipramine** (a 10-fold rise in one case)[43] and mild with **desipramine**.[46,47] One study also suggested that fluvoxamine levels may be raised by tricyclics.[38] An isolated report describes worsening depression in a patient taking **dosulepin** 75 mg daily and **mianserin** within 24 hours of replacing the **dosulepin** with fluvoxamine 75 mg daily. The symptoms continued during the next day but were reversed within a day of fluvoxamine being replaced with **dosulepin**.[50]

(e) Paroxetine

A study in 17 healthy subjects taking **desipramine** 50 mg daily found that when they were also given paroxetine 20 mg daily for 10 days the maximum plasma levels of the **desipramine** rose by 358%, the trough plasma levels rose by 511% and the AUC rose by 421%. An approximately tenfold increase in the maximum plasma levels and the AUC of the paroxetine also occurred.[51] Another study found a fivefold decrease in **desipramine** clearance in the presence of paroxetine 20 mg daily.[52] Paroxetine has also been shown to increase the levels of **clomipramine**,[53] **desipramine**,[6] **imipramine**,[54,55] and **trimipramine**.[56] This resulted in a variety of adverse effects including dizziness,[53] confusion,[6] sedation[56] and memory impairment.[56]

A 21-year-old man developed serotonin syndrome when he took one tablet of paroxetine only one day after stopping **desipramine**, which he had taken for 5 days. He recovered after treatment with cyproheptadine.[57] A woman taking paroxetine 30 mg daily developed serotonin syndrome (tachycardia, delirium, bizarre movements, myoclonus) within 2 hours of

taking a single 50-mg dose of **imipramine**. She recovered when treated with intravenous fluids, sedation and cyproheptadine.[58]

(f) Sertraline

In 9 healthy subjects, sertraline 50 mg daily increased the maximum plasma levels of **desipramine** 50 mg daily by 31% at steady-state, and increased the AUC by 23%.[24] A later related study in 17 healthy subjects by the same group of workers found that, using the same drug dosages, sertraline increased the **desipramine** maximum plasma levels by 44%, the minimum levels by 19% and the AUC by 37%. The maximum plasma levels and AUC of the sertraline were increased about twofold.[51] Other studies have found that sertraline increases **desipramine**,[59-62] **imipramine**,[59] and **nortriptyline**[63] levels, but it has also been suggested that sertraline has no effect on **imipramine** levels.[64,65]

A woman who had been taking sertraline 50 mg daily (as well as morphine sulfate and pericyazine) developed serotonin syndrome within 3 days of starting to take **amitriptyline** 75 mg daily. She recovered when all of the psychotropic drugs were withdrawn.[66]

Mechanism

Fluoxetine, paroxetine, and to a lesser extent sertraline and citalopram, inhibit the cytochrome P450 isoenzyme CYP2D6, which is involved in the metabolism of the tricyclic antidepressants. Hence these SSRIs cause tricyclic levels to rise. Fluvoxamine causes a similar effect, probably by inhibiting metabolism through CYP1A2 and possibly other isoenzymes. The elevated levels of 8-hydroxydesmethylclomipramine during concurrent clomipramine and citalopram administration in one patient may have been due to the inhibition of glucuronidation by citalopram.[5] The interaction is likely to vary depending on the various routes of metabolism of the tricyclics, and the various cytochrome P450 isoenzymes inhibited by the SSRIs. See 'Table 35.2', (p.1465), for information on the metabolic routes of the tricyclics and the inhibitory potential of the SSRIs.

Serotonin syndrome possibly develops because both the tricyclics and SSRIs affect serotonin transmission, which may result in increased serotonin levels. For more on serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Importance and management

The interactions of the SSRIs and tricyclic antidepressants are established and of clinical significance. The SSRIs increase tricyclic levels, with fluvoxamine, fluoxetine and paroxetine apparently having the greatest effects. The increased tricyclic levels can be beneficial.[38,41,67] However, it has been suggested that patients given fluoxetine should have their tricyclic dose reduced to one-quarter.[19] Similar recommendations have been made with fluvoxamine (reduction in tricyclic dose to one-third)[44] and sertraline.[68] It would also seem prudent to consider a dosage reduction of the tricyclic if paroxetine is added. Some suggest that a small initial dose of the SSRI should also be used.[68]

Patients taking any combination of tricyclic and SSRI should be monitored for adverse effects (e.g. dry mouth, sedation, confusion) with tricyclic levels monitored where possible. Remember that the active metabolite of fluoxetine has a half-life of 7 to 15 days, and so any interaction may persist for some time after the fluoxetine is withdrawn,[69-71] and may occur on sequential use. The manufacturer of clomipramine also recommends avoidance of drugs that can cause an accumulation of clomipramine and they advise a washout period of 2 to 3 weeks before and after treatment with fluoxetine.[72]

Serotonin syndrome seems to occur rarely but patients and prescribers should be aware of the symptoms so that prompt action can be taken if problems occur. For more about the serotonin syndrome, see 'Additive or synergistic interactions', (p.9).

Tricyclic antidepressants + St John's wort (*Hypericum perforatum*)

The plasma levels of amitriptyline, and its active metabolite, nortriptyline, are modestly reduced by St John's wort.

Clinical evidence

Twelve depressed patients were given **amitriptyline** 75 mg twice daily and St John's wort extract (*Lichtwer Pharma, Berlin*) 900 mg daily for at least 14 days. The $AUC_{0\text{-}12}$ of the **amitriptyline** was reduced by about 22% and the AUC of nortriptyline (its metabolite) was reduced by about 41%.[1]

Mechanism

Not fully understood. St John's wort is known to induce the activity of the cytochrome P450 isoenzyme CYP3A4, which is a minor route of metabolism of the tricyclic antidepressants. However, the tricyclics are predominantly metabolised by CYP2D6, so an effect on CYP3A4 is unlikely to lead to a clinically relevant reduction in their levels. Induction of P-glycoprotein by St John's wort may also contribute; however, the extent of its involvement in the transport of the tricyclics is unclear.

Importance and management

The evidence for an interaction is limited to this study, and based on the minor reduction in amitriptyline levels seen, it seems unlikely that a clinically significant reduction in efficacy would occur. Other tricyclics would be expected to interact similarly.

Both the tricyclics and St John's wort are antidepressants, but whether concurrent use is beneficial or safe is not known, and it was not assessed in this study. Further study is needed.

Tricyclic antidepressants + Sucralfate

Sucralfate causes a marked reduction in the absorption of amitriptyline.

Clinical evidence, mechanism, importance and management

When 6 healthy subjects took a single 75-mg dose of **amitriptyline** with a single 1-g dose of sucralfate, the AUC of the amitriptyline was reduced by 50%.[1] This reduction probably occurred because sucralfate reduced the absorption of amitriptyline from the gut. There seems to be nothing documented about other tricyclics, but they would be expected to interact similarly.

If sucralfate is given to a patient taking any tricyclic antidepressant it would seem prudent to monitor to confirm that the therapeutic effects of the antidepressant are not lost. It is generally recommended that other drugs should be given at least 2 hours before or after sucralfate to avoid a reduction in bioavailability.[2]

Tricyclic antidepressants + Temsirolimus

Temsirolimus did not alter desipramine pharmacokinetics in a single-dose study.

Clinical evidence, mechanism, importance and management

In a single-dose study in healthy subjects, the pharmacokinetics of oral desipramine 50 mg were unaffected by intravenous temsirolimus 25 mg given at the same time.[1] On the basis of this study, the manufacturer does not anticipate that a pharmacokinetic interaction will occur when temsirolimus is given at this dose with drugs that are substrates of the cytochrome P450 isoenzyme CYP2D6.[2,3] For a list of CYP2D6 substrates, see 'Table 1.3', (p.6). However, simultaneous dosing of these two drugs would not have allowed for maximal hepatic enzyme inhibition, so a multiple-dose study or single-dose study where desipramine was given on day 2 or 3 after intravenous temsirolimus would provide more proof of a lack of interaction.

Tricyclic antidepressants + Terbinafine

Terbinafine markedly increases the AUC of desipramine. Case reports describe increases in the serum levels of amitriptyline, desipramine, imipramine and nortriptyline, with associated toxicity, in patients additionally given oral terbinafine.

Clinical evidence

(a) Amitriptyline

A 37-year-old woman who had been taking amitriptyline 75 mg daily, valproate and olanzapine for 3 years, developed extreme dryness of the mouth, nausea and dizziness shortly after starting to take terbinafine 250 mg daily. Serum levels of amitriptyline and its metabolite nortriptyline rose from just under 400 nanomol/L to over 1800 nanomol/L. Terbinafine was stopped, and the amitriptyline dose reduced to 25 mg daily, but

the amitriptyline and nortriptyline levels did not return to baseline for several months. The patient had normal levels of CYP2D6.[1]

(b) Desipramine

In a pharmacokinetic study, terbinafine 250 mg daily for 21 days caused a marked fivefold increase in the AUC of a single 50-mg dose of desipramine, and increased its maximum levels twofold. The AUC of desipramine was still more than double the baseline level 4 weeks after stopping desipramine. The healthy subjects used in this study were extensive CYP2D6 metabolisers, which is the most common phenotype.[2]

A case report describes a 3.5-fold increase in desipramine levels, with associated toxicity (dizziness, ataxia, incoordination, and difficulty swallowing), in a 52-year-old man taking desipramine 350 mg daily, which occurred within 2 to 3 weeks of him starting to take terbinafine. The desipramine was stopped for a few days and restarted at a dose of just 50 mg daily, which gave similar serum levels to those seen before terbinafine was started. When the terbinafine was stopped, the dose of desipramine needed to be gradually titrated up to the initial amount.[3]

(c) Imipramine

A 51-year-old man who had been taking lithium carbonate and varying doses of imipramine 150 to 200 mg daily for 10 years was also given oral terbinafine 250 mg daily for onychomycosis. About a week later he complained of dizziness, muscle twitching and excessive mouth dryness. His serum imipramine levels, measured 5 days later, had risen from his usual range of 100 to 200 nanograms/mL up to 530 nanograms/mL. Within 10 days of reducing his daily imipramine dose from 200 to 75 mg daily, his serum levels had fallen to 229 nanograms/mL. His liver function was normal.[4]

(d) Nortriptyline

A report describes a marked increase in the serum levels of nortriptyline (about doubled) accompanied by evidence of toxicity (fatigue, vertigo, loss of energy and appetite, and falls) in a 74-year-old man taking nortriptyline 125 mg daily, roughly 14 days after he started to take terbinafine 250 mg daily. His symptoms responded to a dose reduction to 75 mg of nortriptyline daily. His serum levels were similarly elevated when he was later rechallenged with terbinafine. His liver function was normal.[5] The same authors reported a similar case in a woman who had been taking nortriptyline and terbinafine for one month before she showed signs of an interaction. A later rechallenge with terbinafine confirmed the interaction.[6]

Mechanism

Terbinafine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, which is the principal enzyme involved in the metabolism of many tricyclics. Terbinafine can have a very prolonged half-life, so an interaction may occur or continue for a number of weeks after stopping the drug.

Importance and management

Although there are only a few case reports an interaction appears to be confirmed, and the increase in the levels of tricyclic antidepressant in the presence of terbinafine appears to be clinically important. It would seem prudent to monitor for tricyclic adverse effects (such as dry mouth, blurred vision and urinary retention) if terbinafine is also given, and consider reducing the dose of the tricyclic if these become troublesome. Tricyclic levels may return to normal only slowly after discontinuation of terbinafine.[1,2,6] It is also suggested that there may be a risk of clinically significant interactions if these drugs are given within 3 months of stopping terbinafine.[1]

Note that, the tricyclics have been associated with QT prolongation, most usually when their levels are high, and this interaction may therefore increase the risk of this effect. See 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, for further discussion on QT prolongation.

Tricyclic antidepressants + Thyroid hormones

The antidepressant response to imipramine, amitriptyline and possibly other tricyclics can be accelerated by the use of thyroid hormones. However, isolated cases of paroxysmal atrial tachycardia, thyrotoxicosis and hypothyroidism have occurred on concurrent use.

Clinical evidence, mechanism, importance and management

The addition of **liothyronine** 25 micrograms daily was found to increase the speed and efficacy of **imipramine** in relieving depression.[1] Similar results have been described in other studies with **desipramine**[2] or **amitriptyline**[3] but the reasons are not understood. One possible explanation is that the patients had overt or subclinical hypothyroidism, which after correction with **liothyronine** allowed them to overcome an impaired response to tricyclic antidepressants.[4] Other suggestions are that small alterations in thyroid hormone levels may result in alterations in cerebral function[5] and that thyroid hormones may increase receptor sensitivity to neurotransmitters such as serotonin (5-hydroxytryptamine, 5-HT).[6]

However, adverse reactions have also been seen when thyroid hormones were given with tricyclics. A patient being treated for both hypothyroidism and depression with **thyroid** 60 mg and **imipramine** 150 mg daily complained of dizziness and nausea. She was found to have developed paroxysmal atrial tachycardia.[7] A 10-year-old girl with congenital hypothyroidism, well controlled with desiccated **thyroid** 150 mg daily, developed severe thyrotoxicosis after taking **imipramine** 25 mg daily for 5 months for enuresis. The problem disappeared when the **imipramine** was withdrawn.[8]

The interaction between thyroid hormones and tricyclics is normally advantageous,[6] in which **liothyronine** appears to have a significantly greater antidepressant-potentiating effect than **levothyroxine**.[5] There would seem to be no good reason, generally speaking, for avoiding concurrent use unless problems arise.

Tricyclic and related antidepressants + Tobacco

Smoking tobacco reduces the plasma levels of amitriptyline, clomipramine, desipramine, imipramine and nortriptyline, but this does not appear to result in a clinically significant interaction. Maprotiline levels are not affected by smoking tobacco.

Clinical evidence

Two studies found no difference between the steady-state **nortriptyline** plasma levels of tobacco smokers and non-smokers,[1,2] but others have found that smoking tobacco lowers the plasma levels of **amitriptyline**, **clomipramine**,[3] **desipramine**, **imipramine**[4] and **nortriptyline**.[5] For example a 25% reduction in plasma **nortriptyline** levels was found in one study,[5] and a 45% reduction in total levels of **imipramine** and its metabolite, desipramine, was found in another.[4] Smoking has no effect on **maprotiline** efficacy and blood levels.[6,7]

Mechanism

The probable reason for the reduced tricyclic levels is that some of the components of tobacco smoke are enzyme inducers, which increase the metabolism of these antidepressants by the liver.

Importance and management

The interactions between tobacco smoke and tricyclics are established but it might wrongly be concluded from the figures quoted that smokers need larger doses of the tricyclic to control their depression. Some evidence suggests that the plasma levels of free (and pharmacologically active) nortriptyline are greater in smokers than non-smokers (10.2% compared with 7.4%), which probably offsets the fall in total plasma levels.[5] Thus the apparently lower plasma levels in smokers may be as therapeutically effective as the higher levels in non-smokers, so that there is probably no need to raise the dosage to accommodate this interaction.

Tricyclic antidepressants + Valproate

Amitriptyline and nortriptyline plasma levels can be increased by sodium valproate and valpromide. Status epilepticus, tremulousness and/or sleep disturbances have been attributed to elevated clomipramine or nortriptyline levels in patients taking valproate or valproic acid. Valproate pharmacokinetics may be modestly affected by amitriptyline.

Clinical evidence

(a) Amitriptyline

In one study, 15 healthy subjects were given a single 50-mg dose of amitriptyline 2 hours after taking the ninth dose of valproate semisodium 500 mg every 12 hours. The maximum plasma levels and AUC of amitriptyline were raised by 19% and 30%, respectively. The corresponding values for the nortriptyline metabolite were 28% and 55%, respectively.[1] Similarly, in 10 patients taking amitriptyline 125 mg daily, the use of valpromide 600 mg daily for 10 days caused a 50% rise in the mean steady-state plasma levels of amitriptyline and a 65% rise in the levels of the nortriptyline metabolite, when compared with 10 similar patients taking amitriptyline alone.[2,3]

A study in 6 patients with depression found that amitriptyline 100 mg daily for 3 weeks produced a 43% increase in the volume of distribution and a 16% increase in the plasma half-life of a single 400-mg intravenous dose of sodium valproate. The AUC and total body clearance of valproate were not significantly changed.[4]

(b) Clomipramine

An epileptic patient who had been seizure-free for 3 years while taking valproic acid developed a prolonged episode of status epilepticus 12 days after starting to take clomipramine 75 mg daily. The clomipramine serum level 7 hours after the last dose was 342 nanograms/mL (usual levels 68 to 272 nanograms/mL). The seizure was attributed to the elevated clomipramine levels.[5] Similarly, a patient taking clomipramine 150 mg daily, suffered feelings of numbness and sleep disturbances attributed to elevated serum levels of clomipramine and desmethylclomipramine, caused by valproate 1 to 1.4 g daily. Halving the dose of clomipramine restored serum concentrations to therapeutic levels.[6]

(c) Desipramine

A woman taking valproic acid, tiotixene and desipramine developed elevated and potentially toxic serum desipramine levels (a rise from 259 nanograms/mL to 324 nanograms/mL) at the end of a 3-month period during which valproic acid was gradually withdrawn and replaced by clorazepate. The authors of the report attributed this reaction to the valproic acid withdrawal.[7]

(d) Nortriptyline

One patient developed grossly elevated nortriptyline plasma levels (393 nanograms/mL, about threefold higher than the therapeutic range) and evidence of toxicity (tremulousness of hands and fingers) about one week after starting to take valproate 750 mg to 1 g daily. The toxicity rapidly disappeared when both drugs were stopped. Another patient, with bipolar disorder, also developed elevated nortriptyline plasma levels, attributed to the addition of valproate, and his rate of mood cycling increased.[8]

Mechanism

Uncertain. Inhibition of the metabolism of these tricyclics by valproate has been suggested.[5,6,8]

Importance and management

Information seems to be limited to these reports, and an interaction is not established. However, if tricyclic adverse effects (e.g. dry mouth, urinary retention, constipation) develop in patients also taking valproate it would be prudent to consider an interaction as a possible cause.

The occurrence of status epilepticus in one patient reinforces the fact that the tricyclics can lower the convulsive threshold and should therefore be used with caution in patients with epilepsy.

Tricyclic antidepressants + Yohimbine

Low-dose yohimbine may reduce dry mouth and orthostatic hypotension associated with tricyclic antidepressants. Amitriptyline and clomipramine may increase yohimbine plasma concentrations.

Clinical evidence

In a study, 12 patients with orthostatic hypotension associated with **clomipramine** 150 mg daily for 2 to 7 days were given oral yohimbine 4 mg three times daily. Yohimbine appeared to decrease the orthostatic hypotension and induced a significant increase in blood pressure at a dose not usually associated with changes in blood pressure. However, yohimbine levels measured 2 hours after dosing were much greater than those seen in healthy subjects not taking **clomipramine** and the plasma levels of yohimbine appeared to correlate with the levels of desmethylclomipramine but not with those of **clomipramine**.[1]

Another study found that low-dose yohimbine 4 mg significantly increased the salivary volume for 3 hours in 10 patients with depression taking **amitriptyline** or **clomipramine**, but had no effect on salivary volume in healthy subjects not taking tricyclics. Plasma levels of yohimbine after 90 minutes were 72.7 nanograms/mL in the patients taking the tricyclics, compared with 18.7 nanograms/mL in healthy subjects not taking tricyclics.[2]

Mechanism

Not fully understood. A pharmacodynamic interaction may occur, involving α_2-adrenoceptor inhibition by yohimbine and inhibition of noradrenaline (norepinephrine) reuptake by the tricyclic antidepressant. A

pharmacokinetic interaction may occur as yohimbine and tricyclic antidepressants are both hydroxylated by hepatic enzymes. An interaction could also occur due to decreased first pass hepatic clearance of yohimbine.

Importance and management

The usefulness of this interaction in the treatment of antidepressant-associated dry mouth and hypotension is uncertain. Yohimbine is chemically similar to reserpine and may increase anxiety; the manufacturer of yohimbine warns that it should not be used in conjunction with mood-modifying drugs such as antidepressants.[3] If concurrent use is undertaken it would be prudent to be aware that yohimbine levels may be raised, and be alert for adverse effects that may occur as a result of this.

Tricyclic antidepressants; Amitriptyline + Ethchlorvynol

Transient delirium has been attributed to the concurrent use of amitriptyline and ethchlorvynol,[1] but no details were given and there appear to be no other reports confirming this alleged interaction. Its general relevance is therefore probably small.

1. Hussar DA. Tabular compilation of drug interactions. *Am J Pharm* (1969) 141, 109–56.

Tricyclic antidepressants; Desipramine + Febuxostat

Febuxostat does not affect the pharmacokinetics of desipramine.

Clinical evidence, mechanism, importance and management

A placebo-controlled crossover study in 18 subjects, febuxostat 120 mg daily modestly increased the total exposure to a single 25-mg oral dose of desipramine. The maximum plasma concentration and AUC of desipramine were increased by 14% and 12%, respectively.[1] The incidence of adverse events was similar for both treatment regimens.

The pharmacokinetic changes are too small to be clinically relevant and therefore no desipramine dosage adjustment is necessary in patients also given febuxostat.

1. Khosravan R, Erdman K, Vernillet L, Wu JT, Joseph-Ridge N, Umeda S, Mulford D. Effect of febuxostat on pharmacokinetics of desipramine, a CYP2D6 substrate, in healthy subjects. *Clin Pharmacol Ther* (2005) 77, P43.

Tricyclic antidepressants; Doxepin + Tamoxifen

An isolated report describes a reduction in doxepin serum levels, which was attributed to the use of tamoxifen.

Clinical evidence, mechanism, importance and management

A 79-year-old woman with a long history of bipolar disorder, which was stabilised with lithium carbonate and doxepin 200 mg at bedtime, was given tamoxifen 20 mg daily after a mastectomy for breast cancer. It was noted that her total blood levels of doxepin and its major metabolite were reduced by about 25% over the next 11 months. The control of her depression remained unchanged. The reasons for this apparent interaction are not known.[1] The manufacturer of tamoxifen has another undetailed and isolated report of a possible interaction.[2]

These appears to be the only reports of an interaction between a tricyclic antidepressant and tamoxifen so that their general importance is not known. The evidence is too sparse to warrant recommending any particular precautions.

2. Zeneca, Personal communication. November 1995.

Tricyclic antidepressants; Imipramine + Vinpocetine

Vinpocetine does not appear to affect imipramine levels.

Clinical evidence, mechanism, importance and management

In 18 healthy subjects the steady-state plasma levels of imipramine 25 mg three times daily were unaffected by vinpocetine 10 mg three times daily, when both drugs were taken together for 10 days.[1] No imipramine dose adjustments are therefore likely be necessary if vinpocetine is also given. There seems to be nothing documented about any of the other tricyclic antidepressants.

Thyroid hormones

This section covers the interactions where there is documented evidence that a drug alters the efficacy of thyroid hormones. The mechanism for this can be pharmacokinetic (altered absorption or metabolism) or pharmacodynamic (when the drug in question alters thyroid function).

Thyroid hormones + Amiodarone

Patients taking levothyroxine for hypothyroidism may develop elevated levels of thyroid-stimulating hormone or overt hypothyroidism if they are also given amiodarone.

Clinical evidence

A patient with hypothyroidism who was euthyroid while taking **levothyroxine** 75 micrograms daily had an increase in TSH, up to 20 to 30 mU/L within about 10 weeks of starting amiodarone (initially 800 mg daily, reduced to 200 mg daily).The thyroxine/T3 ratio decreased by 33%. She developed fatigue, weakness, cold intolerance and hyponatraemia. **Levothyroxine** was gradually increased to 112 micrograms daily, amiodarone was maintained at 200 mg daily. The TSH levels decreased to 4.2 mU/L and the symptoms of hypothyroidism resolved.[1] Similar increases in TSH were reported when two other patients receiving stable doses of **levothyroxine** started taking amiodarone.[1,2]

In a study investigating the effect of amiodarone and **levothyroxine** treatment, 5 patients were given **levothyroxine** 300 micrograms daily for 16 days, with amiodarone 400 mg daily from day 10 to day 16. When compared with a control group taking **levothyroxine** alone, there was a significant fall in serum T3 levels and a rise in reverse-T3 levels. This suggests that amiodarone interferes with thyroid hormone metabolism, possibly leading to hypothyroidism, even in the presence of **levothyroxine**.[3]

Mechanism

Amiodarone has complex effects on thyroid function and may cause hypothyroidism or hyperthyroidism in some euthyroid patients. Amiodarone has direct effects on the thyroid gland and also alters serum levels of thyroid hormones. Basal-serum TSH levels increase when amiodarone is started, but generally decrease to normal after about 3 months of treatment. Amiodarone reduces the peripheral conversion of thyroxine to T3 which results in an increase in thyroxine, a modest decrease in T3 and a decrease in reverse-T3 clearance.

Importance and management

Amiodarone is well-known to be a cause of hypothyroidism or hyperthyroidism, and thyroid function should be regularly assessed when it is used. Particular care is required in patients with thyroid dysfunction, in whom amiodarone use might not be appropriate. The UK manufacturer of amiodarone[4] contraindicates its use in patients with current or a history of thyroid dysfunction, although levothyroxine has been used to manage amiodarone-induced hypothyroidism in some patients.[4,5] It would be prudent for patients taking levothyroxine or **liothyronine** and amiodarone to have their thyroid function very closely monitored. Note that, if amiodarone is discontinued, its effects will persist for a very long time due to its prolonged half-life (mean of 53 days).

Thyroid hormones + Androgens

A study suggests that patients with hypothyroidism may require levothyroxine dose reductions if they are given fluoxymesterone. Liothyronine is expected to interact similarly.

Clinical evidence, mechanism, importance and management

In a study, 11 women with metastatic, hormone-dependent breast cancer were given **fluoxymesterone** 10 mg twice daily. After 4 weeks of treatment, 7 of the patients who had no evidence of thyroid disease had decreased serum levels of total thyroxine and thyroxine-binding globulin, but their calculated free thyroxine index and measured free hormone levels were unchanged. These patients remained asymptomatic 6 to 12 weeks after **fluoxymesterone** was discontinued, with serum levels returning to baseline. In contrast the other 4 patients, whose primary hypothyroidism of 5 to 20 years duration was stabilised with **levothyroxine**, developed hyperthyroidism after starting **fluoxymesterone** 10 mg twice daily. Their serum free thyroxine levels increased and their TSH levels decreased. **Levothyroxine** dose reductions of between 25 and 50% were required to maintain a euthyroid state.[1]

Other studies have reported a decrease in the binding capacity of thyroxine-binding globulin and an increase in the binding of thyroxine-binding prealbumin after the short-term use of androgens, but the exact mechanism is not known.[2,3]

Evidence for an interaction between fluoxymesterone and levothyroxine appears to be limited to this study. However, what is known suggests that patients with thyroid dysfunction who are receiving levothyroxine may need dosage adjustments to remain euthyroid if fluoxymesterone is started. Evidence regarding possible interactions of both **liothyronine** and other thyroid hormones appears to be lacking, but the available evidence suggests that they may interact in the same way. Therefore if any patient with thyroid dysfunction taking a thyroid hormone is given an androgen it would be prudent to be alert for symptoms of hypothyroidism. If such symptoms occur, monitor thyroid hormones, and adjust the dose of the thyroid hormone accordingly.

Thyroid hormones + Antacids

A few reports describe reduced levothyroxine effects in patients given aluminium or magnesium-containing antacids.

Clinical evidence, mechanism, importance and management

A man with hypothyroidism corrected with **levothyroxine** 150 micrograms daily developed high serum TSH levels (a rise from 1.1 mU/L up to 36 mU/L) while taking an **aluminium**/**magnesium hydroxide** antacid (*Silain-Gel*), and on two subsequent occasions when rechallenged. The reasons are not understood. Although he remained asymptomatic throughout,[1] the rise in the levels of TSH indicated that the dosage of **levothyroxine** had become insufficient in the presence of the antacid. Two similar cases have also been reported, where the presence of an **aluminium**/**magnesium** antacid or **magnesium oxide** reduced the response to **levothyroxine**. One patient required four times her normal dose of **levothyroxine**.[2]

The general importance of this interaction is not known, but be alert for the need to increase the **levothyroxine** dosage in any patient given antacids. More study is needed. Calcium-containing antacids may interact similarly, see 'Thyroid hormones + Calcium compounds', p.1521.

Thyroid hormones + Barbiturates

An isolated report describes thyrotoxicosis when a patient taking levothyroxine reduced her dose of secobarbital with amobarbital.

Clinical evidence, mechanism, importance and management

An elderly woman taking **levothyroxine** 300 micrograms daily for hypothyroidism complained of severe breathlessness within a week of reducing her nightly dose of *Tuinal* (**secobarbital** 100 mg with **amobarbital** 100 mg) from two capsules to one capsule. She was subsequently found to be thyrotoxic. She became symptom-free again when the dosage of the **levothyroxine** was halved.[1] The reason for this effect is not known, but **phenobarbital** has been shown to reduce the serum levels of endogenous

thyroid hormones in some studies,[2] and it seems possible that in this case these other two barbiturates acted in the same way. This effect has also been seen with other enzyme-inducing drugs, see 'Thyroid hormones + Carbamazepine or Phenytoin', p.1522.

The general importance of this interaction is almost certainly small, but be alert for any evidence of changes in thyroid status if barbiturates are added or withdrawn from patients taking **levothyroxine**. Monitor thyroid hormones levels if an interaction is suspected, and adjust the levothyroxine dose accordingly. Although the possibility of a similar interaction with **liothyronine** does not appear to have been studied, it would seem prudent to be alert for a similar reduction in its effect in the presence of barbiturates.

Thyroid hormones + Bile-acid binding resins

The absorption of thyroid extract, levothyroxine, and liothyronine from the gut is reduced by the concurrent use of colestyramine. Colesevelam also decreases levothyroxine absorption.

Clinical evidence

(a) Colestyramine

A patient with hypothyroidism, taking **levothyroxine**, had a fall in his basal metabolic rate when given colestyramine: this prompted a further study in two similar patients taking **thyroid extract** 60 mg daily or **levothyroxine** 100 micrograms daily, and 5 healthy subjects. Colestyramine 4 g four times daily reduced the absorption of **levothyroxine**^{131}, the amount recovered in the faeces being roughly doubled. One of the patients had a worsening of her hypothyroidism. Giving the **levothyroxine** 4 to 5 hours after the colestyramine reduced but did not completely prevent the interaction.[1] Another report describes a patient taking **levothyroxine** whose TSH levels rose when colestyramine was taken, and fell again when it was stopped, indicating an impairment of **levothyroxine** absorption.[2] Two case reports, describe the use of colestyramine to achieve a more rapid return to normal thyroid function in patients who have become hyperthyroid while taking levothyroxine,[3] and in a case of levothyroxine overdose.[4] A further case report describes a patient taking **levothyroxine** and colestyramine, who only became euthyroid when the **levothyroxine** was taken in the morning, and the colestyramine was taken at night.[5]

(b) Colesevelam

In a single-dose study, 6 healthy subjects were given a large dose of **levothyroxine** (1000 micrograms) at the same time as colesevelam 3.75 g. Colesevelam decreased the serum thyroxine $AUC_{0\text{-}6}$ by 96%.[6] A study by the manufacturer reported a smaller decrease in levothyroxine absorption: the same dose of colesevelam decreased the $AUC_{0\text{-}\infty}$ of a 600-microgram dose of **levothyroxine** by 22%.[7]

Mechanism

Colestyramine and colesevelam bind to levothyroxine in the gut, thereby reducing its absorption. Since levothyroxine probably also undergoes enterohepatic recirculation, continued contact with these bile-acid sequestrants is possible and separating administration may not entirely eliminate the interaction.

Importance and management

The interaction between levothyroxine and colestyramine appears to be established (although the documentation is very limited) and the reduced thyroxine levels that result are of clinical importance. *In vitro* tests show that **liothyronine** interacts with colestyramine similarly.[1] The interaction can be minimised by separating the dosages by 4 to 6 hours (but see *Mechanism*, above). Even so, the outcome should be monitored so that any necessary thyroid hormone dosage adjustments can be made.

Similarly, the interaction between colesevelam and levothyroxine is of clinical importance. Levothyroxine should be given 4 hours before colesevelam.[7]

Thyroid hormones + Calcium compounds

The efficacy of levothyroxine can be reduced by calcium carbonate, whereas calcium acetate might not interact.

Clinical evidence

(a) Calcium acetate

In a retrospective study, 67 patients were identified who were taking **levothyroxine** and a phosphate binder (calcium carbonate, calcium acetate or sevelamer). The TSH levels were significantly higher in patients taking calcium carbonate or sevelamer (both thought to reduce **levothyroxine** efficacy) than calcium acetate, and the effects became more pronounced over time, suggesting that calcium acetate had little effect on the efficacy of **levothyroxine**.[1]

(b) Calcium carbonate

In a study, 20 patients with hypothyroidism were given **levothyroxine**, to which calcium carbonate 1.2 g daily was then added for 3 months. While taking the calcium carbonate their mean free thyroxine levels fell from 16.7 picomol/L to 15.4 picomol/L and rose again to 18 picomol/L when it was stopped. The mean total thyroxine levels over the same period were about 118 nanomol/L, 111 nanomol/L and 120 nanomol/L, respectively, and the mean TSH levels were 1.6 mU/L, 2.7 mU/L and 1.4 mU/L, respectively.[2]

A woman with thyroid cancer taking **levothyroxine** 125 micrograms daily to suppress serum TSH levels had a reduced response (fatigue, weight gain) when she took *Tums* containing calcium carbonate for the prevention of osteoporosis. She often took the two together. Over a 5-month period her serum TSH levels rose from 0.08 mU/L to 13.3 mU/L. Within 3 weeks of stopping the calcium carbonate, her serum TSH levels had fallen to 0.68 mU/L.[3] Other reports have described 5 patients who had elevations in their TSH levels while taking calcium carbonate with **levothyroxine**. All levels returned to normal when administration was separated by about 4 hours,[3-5] or in one case when the calcium supplementation was stopped.[6]

Mechanism

In vitro studies indicate that levothyroxine is adsorbed onto calcium carbonate when the pH is low (as in the stomach), which would reduce the amount available for absorption.[2]

Importance and management

An established interaction, which seems to be of limited clinical significance. The study cited[2] shows that the mean reduction in the absorption of levothyroxine is quite small, but the case reports[3,4] show that some individuals can experience a reduction in the absorption that is clinically important. Since it is impossible to predict which patients are likely to be clinically affected, the cautious approach would be to advise all patients to separate the dosages of the two preparations by at least 4 hours to avoid admixture in the gut. This interaction would be expected to occur with calcium carbonate in any form but it is not known whether other thyroid hormone preparations interact in the same way as levothyroxine. Limited evidence suggests that calcium acetate might not interact. Other calcium compounds do not appear to have been studied.

Thyroid hormones + Carbamazepine or Phenytoin

Clinical hypothyroidism can occur in patients stable taking levothyroxine when they start carbamazepine or phenytoin. Correction of hypothyroidism with levothyroxine does not appear to affect the pharmacokinetics of phenytoin.

Clinical evidence

(a) Carbamazepine

In a study, when 10 patients, whose hypothyroidism was stabilised with **levothyroxine**, were given carbamazepine, there was a minor decrease of about 10 to 15% in free thyroxine, and a decrease of 15 to 25% in total thyroxine, with a consequent increase in TSH levels. In 3 of the 10 patients, the TSH level rose over 5 mU/L, requiring treatment adjustment. In a control group of 19 patients with no thyroid disorder, similar changes in thyroxine levels caused just a slight non-significant increase in TSH levels.[1] Similar findings were reported in another study when 5 children receiving stable doses of **levothyroxine** were given carbamazepine. In this study, 2 children had markedly increased TSH levels, and all 5 children had their **levothyroxine** dose increased to restore pre-treatment thyroid function.[2] Another study in 9 patients taking **levothyroxine** found that thyroxine and T3 levels were reduced after they had been taking carbamazepine for 3 weeks, but there was no change in TSH levels.[3]

(b) Phenytoin

A study in 7 patients found that the pharmacokinetics of phenytoin were unchanged by the addition of **levothyroxine**. The pharmacokinetics of phenytoin were assessed in the hypothyroid state and after the patients had been euthyroid for 4 to 11 months.[4]

In a study, 6 patients whose hypothyroidism was stabilised with **levothyroxine**, were given phenytoin 350 mg daily for 14 days. Phenytoin appeared to slightly reduce the intestinal absorption of **levothyroxine** and to increase the metabolism of thyroxine. Total and free serum levels of thyroxine and T3 were decreased and there was an associated increase in TSH.[5] A case report describes a patient with hypothyroidism that had been successfully managed with 150 micrograms of **levothyroxine** daily for 4 years, who developed hypothyroidism when given **phenytoin** 300 mg daily. Doubling the **levothyroxine** dosage proved to be effective. Later this interaction was confirmed when stopping and restarting the **phenytoin** produced the same effect.[6]

Mechanism

Both phenytoin and carbamazepine can increase the metabolism of endogenous thyroid hormones, thereby reducing their plasma levels, but this rarely results in hypothyroidism in euthyroid patients. However, in patients taking levothyroxine replacement therapy, the decrease appears more likely to be clinically relevant.[1]

Importance and management

Although the evidence is limited, this interaction is established. The available evidence suggests that some patients taking levothyroxine might require an increase in dose when they start carbamazepine or phenytoin. Be alert for this effect if both drugs are given, and monitor thyroid hormones levels if an interaction is suspected: adjust the levothyroxine dose accordingly. This effect has also been seen with other enzyme-inducing drugs. Consider also 'Thyroid hormones + Barbiturates', p.1520.

Given the proposed mechanism of the interaction with levothyroxine, it seems likely that **liothyronine** may be similarly affected by carbamazepine and phenytoin, but this does not appear to have been studied.

It has been suggested that the general increase in metabolism that occurs when hypothyroidism is corrected may cause an increase in the metabolism of phenytoin. However, one study suggests that this may not be the case.

Thyroid hormones + Chloroquine with Proguanil

An isolated case report describes a reduction in the control of hypothyroidism in a patient taking levothyroxine when chloroquine and proguanil antimalarial prophylaxis was given.

Clinical evidence, mechanism, importance and management

An isolated case report describes a woman with stable hypothyroidism taking levothyroxine 125 micrograms daily, who was given antimalarial prophylaxis with chloroquine 100 mg daily and proguanil 200 mg daily for 2 months. At a routine monitoring appointment 4 weeks later, she was noted to have a TSH level of 44.8 mU/L. No change was made to her levothyroxine dose and the increase in her TSH level resolved within one week of stopping both chloroquine and proguanil at the end of the required period of prophylaxis. A subsequent course of prophylaxis with the same antimalarial regimen produced a similar effect, with the TSH rising from 3.2 mU/L to 54.7 mU/L. This increase resolved within 4 weeks of stopping the antimalarials.[1]

This appears to be the only published report of an interaction between levothyroxine and the combination of chloroquine and proguanil, and its general significance is unclear, especially as no action appeared to be necessary to manage the effects of the interaction. This interaction may have more relevance to other indications for chloroquine, where it is used long-term, but more study is needed to establish this. However, until more is known, bear this case report in mind should a patient taking levothyroxine and either proguanil and/or chloroquine experiences an unexpected decrease in the control of their hypothyroidism.

Thyroid hormones + Chromium compounds

Chromium picolinate decreases levothyroxine absorption.

Clinical evidence, mechanism, importance and management

In a single-dose study in 7 healthy subjects, giving a large dose of **levothyroxine** (1000 micrograms) at the same time as chromium picolinate 1 mg resulted in a 17% decrease in the $AUC_{0\text{-}6}$ of thyroxine.[1] This preliminary evidence suggests that, until more is known, it would be prudent to be alert for symptoms of hypothyroidism. If such symptoms occur, monitor thyroid hormones, and adjust the dose of the **levothyroxine** accordingly. Separation of administration might minimise any interaction, but this needs confirmation.

Thyroid hormones + Ciprofloxacin

A case report describes unexplained hypothyroidism in two patients taking levothyroxine who had also been taking ciprofloxacin.

Clinical evidence, mechanism, importance and management

An 80-year-old patient with advanced thyroid cancer taking **levothyroxine** 125 micrograms daily was given oral ciprofloxacin 750 mg twice daily and intravenous dicloxacillin for osteomyelitis complicating a fracture. After 4 weeks of treatment she complained of increasing tiredness, and was found to have a markedly raised TSH level (10 times of the upper limit of the reference range). Increasing the **levothyroxine** dose to 200 micrograms daily did not have any effect on TSH, so the dose was returned to 125 micrograms. The ciprofloxacin was then stopped, and the thyroid function tests rapidly normalised.[1]

Another woman, with stable thyroid function, taking **levothyroxine** 150 micrograms daily, had a more than tenfold increase in TSH levels after taking ciprofloxacin 500 mg twice daily for 3 weeks.[1] When administration of **levothyroxine** and ciprofloxacin was separated by 6 hours, the thyroid function tests normalised, which suggests that concurrent dosing somehow reduces the absorption of **levothyroxine**.

This interaction is not established, but the two cases suggest that long-term ciprofloxacin should be considered as a possible cause of hypothyroidism in patients taking **levothyroxine**. Further study is needed.

1. Cooper JG, Harboe K, Frost SK, Skadberg Ø. Ciprofloxacin interacts with thyroid replacement therapy. *BMJ* (2005) 330, 1002.

Thyroid hormones + Ezetimibe

Ezetimibe does not appear to alter levothyroxine absorption.

Clinical evidence, mechanism, importance and management

In a single-dose study in 7 healthy subjects, giving a large dose of **levothyroxine** (1000 micrograms) at the same time as ezetimibe 10 mg did not alter the AUC_{0-6} of thyroxine.[1] Similarly, in another single-dose study, in 10 healthy subjects, **ezetimibe** 10 mg did not affect the AUC of serum thyroxine in response to a single 600-microgram dose of **levothyroxine**.[2]

These findings suggest that levothyroxine requirements are unlikely to change in patients taking ezetimibe.

2. Ananthakrishnan S, Braverman LE, Levin RM, Magnani B, Pearce EN. The effect of famotidine, esomeprazole, and ezetimibe on levothyroxine absorption. Thyroid (2008) 18, 493–8.

Thyroid hormones + Grapefruit juice

A case report describes hypothyroidism in a patient taking levothyroxine, which resolved when grapefruit juice consumption was reduced. However, a pharmacokinetic study suggests that generally an interaction is unlikely.

Clinical evidence, mechanism, importance and management

A 36-year-old woman with previously stable thyroid function taking **levothyroxine** 100 micrograms daily and with a marked consumption of grapefruit juice (specific volumes not stated) had a very high TSH level even after an increase in her **levothyroxine** dose to 150 micrograms daily. When she was advised to drink less grapefruit juice, her TSH fell to within the normal range.[1]

This case prompted a crossover study in 10 healthy subjects, which found that grapefruit juice caused only a slight 11% reduction in the maximal increase in thyroxine after a single 600-microgram dose of **levothyroxine**. In this study, normal-strength grapefruit juice 200 mL was taken 3 times a day for 2 days, then on the third day, grapefruit juice 200 mL was taken one hour before, simultaneously with, and one hour after, **levothyroxine**.[1]

The pharmacokinetic study established that grapefruit juice appears to have only small effects on thyroxine levels in those taking **levothyroxine**, which suggests that a clinically relevant interaction is unlikely. However, consider this case in the event of an unexpected decreased response to **levothyroxine**.

1. Lilja JJ, Laitinen K, Neuvonen PJ. Effects of grapefruit juice on the absorption of levothyroxine. *Br J Clin Pharmacol* (2005) 60, 337–41.

Thyroid hormones + H_2-receptor antagonists

Cimetidine, but not ranitidine or famotidine, causes a small reduction in the absorption of levothyroxine.

Clinical evidence, mechanism, importance and management

In a study in 10 women with simple goitre, **cimetidine** 400 mg, given 90 minutes before a single capsule of **levothyroxine**, reduced absorption of **levothyroxine** over the first 4 hours by about 21%. The reasons are not understood. A single 300-mg dose of **ranitidine** was found not to affect the absorption of **levothyroxine** in a matched group of 10 women.[1] Similarly, in a study in 10 healthy subjects, **famotidine** 20 mg twice daily for one week did not affect the AUC of serum thyroxine in response to a single 600-microgram dose of **levothyroxine**.[2]

The clinical importance of this interaction with **cimetidine** awaits assessment, but the magnitude of the effect is small, and therefore it seems unlikely to be generally significant.

Thyroid hormones + Imatinib and Sunitinib

Imatinib appears to cause hypothyroidism in thyroidectomy patients taking levothyroxine. A possible case has also occurred with sunitinib.

Clinical evidence

Retrospective analysis of 11 patients with thyroid cancer taking **levothyroxine** found that 8 patients who had previously undergone a total thyroidectomy developed markedly elevated TSH levels and were clinically hypothyroid after taking **imatinib**. Despite a mean threefold increase in the dose of **levothyroxine**, hypothyroidism was reversed in only 3 patients. Thyroid function tests normalised on discontinuing imatinib. Conversely, no effect on thyroid function was seen in the 3 patients who had not had their thyroid gland removed.[1]

In another report by the same authors, a woman is described who remained euthyroid when restarting **imatinib** when her **levothyroxine** dose was immediately increased from 175 micrograms daily to 300 micrograms daily. However, she was unable to tolerate the imatinib, and this was discontinued. Five months later she started taking **sunitinib** 50 mg daily for 4 weeks of a 6-week cycle. After 3 days her TSH levels rose, with normal free thyroxine and T3 levels, and the **levothyroxine** dose was increased to 300 micrograms daily. However, the TSH levels failed to return to normal, and, additionally, haematological toxicity occurred. When her blood counts recovered, she received a reduced dose of sunitinib 37.5 mg with **levothyroxine** 300 micrograms daily for the second cycle. On this cycle she remained euthyroid without serious haematological toxicity.[2]

Mechanism

The authors postulated that imatinib might increase the clearance of the thyroid hormones thyroxine and T3 by inducing glucuronosyltransferases (UGTs).[1] Patients who have undergone a thyroidectomy cannot respond to these changes and therefore become hypothyroid. Sunitinib alone commonly causes hypothyroidism.[3]

Importance and management

The findings appear to be established. TSH levels should be closely monitored in thyroidectomy patients taking levothyroxine if they are given imatinib, anticipating the need to increase the levothyroxine dose. The authors suggest that in thyroidectomy patients the dose of levothyroxine should be doubled before starting imatinib.[1] Note that toxicity of imatinib (fatigue and periorbital oedema) may be indistinguishable from symptoms of hypothyroidism.[2]

Patients receiving sunitinib should also have their thyroid function monitored.[3]

Thyroid hormones + Iron compounds

Ferrous sulfate causes a reduction in the effects of levothyroxine in patients with treated hypothyroidism.

Clinical evidence

In a study, 14 patients whose primary hypothyroidism was stabilised with **levothyroxine** had an increase in TSH levels from 1.6 to 5.4 mU/L when given **ferrous sulfate** 300 mg daily for 12 weeks. The symptoms of hypothyroidism in 9 patients worsened.[1] In another report, a woman whose hypothyroidism was stabilised with **levothyroxine**, had a very marked rise in TSH levels when she took **ferrous sulfate**. Her **levothyroxine** dosage needed to be raised from 175 micrograms daily to 200 micrograms daily.[2] Another similar report is described, in which a pregnant woman required an increase in her **levothyroxine** dose, from 150 to 250 micrograms daily, while taking **ferrous sulfate** 325 mg three times daily with meals and levothyroxine at bedtime. When the ferrous sulfate was stopped after delivery she had symptoms of hyperthyroidism, and required a reduction in her levothyroxine dose to the original level. When the ferrous sulfate was restarted 12 weeks postpartum, the same interaction occurred.[3]

Mechanism

The addition of iron to levothyroxine *in vitro* was found to produce a poorly soluble purple iron-levothyroxine complex. This might also occur in the gut.[1]

Importance and management

Information is limited to these reports but the interaction between ferrous sulfate and levothyroxine appears to be clinically important. Be alert for this effect if both drugs are given, and monitor thyroid hormone levels if an interaction is suspected: adjust the levothyroxine dose accordingly. Although it has been suggested that the doses of ferrous sulfate and levothyroxine should be separated by 2 hours or more, on the assumption that reduced absorption accounts for this interaction,[1] the later case report suggests that this might not prevent the interaction.[3] The same precautions would seem appropriate with any other iron compound.

Thyroid hormones + Lanthanum

Lanthanum carbonate decreases levothyroxine absorption.

Clinical evidence, mechanism, importance and management

In a single-dose study, 6 healthy subjects were given a large dose of **levothyroxine** (1000 micrograms) at the same time as lanthanum carbonate 500 mg. Lanthanum decreased the serum thyroxine AUC_{0-6} by about 40%.[1]

The interaction between levothyroxine and lanthanum appears to be established (although the documentation is very limited) and the reduced thyroxine levels that result seem likely to be of clinical importance.

Other absorption interactions of lanthanum can be minimised by separating the dosages by 2 hours, and it would seem prudent to apply this precaution to the interaction with **levothyroxine**. Even so, the outcome should be monitored so that any necessary thyroid hormone dosage adjustments can be made.

1. Weitzman SP, Ginsburg KC, Carlson HE. Colesevelam hydrochloride and lanthanum carbonate interfere with the absorption of levothyroxine. Thyroid (2009) 19, 77–79.

Thyroid hormones + Oestrogens

Oral HRT appears to increase the requirement for levothyroxine in some patients. This effect may therefore be expected with combined hormonal contraceptives, although no interaction has been reported.

Clinical evidence

In 25 postmenopausal women taking stable doses of **levothyroxine** (for hypothyroidism or TSH suppression), the addition of HRT (**conjugated oestrogens** 0.625 mg daily with or without **medroxyprogesterone acetate** 5 mg daily for 12 days each month) decreased serum free thyroxine levels and increased TSH levels. The changes in TSH were clinically important in 10 of the 25 women, requiring increased doses of **levothyroxine**, although only one woman had symptoms of hypothyroidism.[1]

Mechanism

Oestrogens increase thyroxine binding-globulin. In women with normal thyroid function this does not alter free thyroxine levels or TSH levels,[1] as the thyroxine secretion can increase to accommodate the changes. However, in women with hypothyroidism, who cannot compensate for the increased thyroxine binding, decreased free thyroxine and therefore increased TSH can result. One crossover study found that oral HRT (conjugated oestrogens) had a greater effect on thyroxine levels and thyroxine-binding globulin than transdermal HRT (**ethinylestradiol**), which had minimal effects on these markers of thyroid function. Thyroxine binding-globulin is synthesised in the liver, and it is suggested that oral oestrogens increase this synthesis more than transdermal oestrogens because higher concentrations of oestrogen are present in the liver following oral dosing: an oral dose of oestrogen undergoes first-pass metabolism in the liver whereas transdermal oestrogens do not.[2]

Importance and management

Although this study appears to be the only evidence of an interaction, it would be prudent to monitor thyroid function several months after starting or stopping HRT to check levothyroxine requirements. This potential interaction should not affect the management and dosing of patients already taking HRT and newly started on levothyroxine, as the levothyroxine dose is usually adjusted according to thyroid function tests and clinical improvement of symptoms. Theoretically, the interaction should not apply to transdermal HRT (see *Mechanism*, above), but this requires confirmation.

The interaction is predicted to occur in any patient taking oral oestrogens, including combined hormonal contraceptives (although there do not appear to be any published studies). Nevertheless, it has been suggested that all patients taking levothyroxine and oral oestrogens should have their thyroid function assessed within several months of either starting or stopping the oestrogen.[3] However, one could argue that if a clinically important interaction between levothyroxine and combined oral contraceptives were to occur, it would have come to light by now.

The effects on **liothyronine** do not appear to have been studied, but it would be expected to interact in the same way as levothyroxine, although it has a lower affinity for thyroxine-binding globulin. Nevertheless, it would be advisable to follow the same precautions as for levothyroxine.

3. Utiger RD. Estrogen, thyroxine binding in serum, and thyroxine therapy. *N Engl J Med* (2001) 344, 1784–85.

Thyroid hormones + Orlistat

A woman taking levothyroxine developed symptoms of hypothyroidism when she started to take orlistat.

Clinical evidence

A case report describes a woman taking stable doses of **levothyroxine** 250 micrograms daily after a thyroidectomy who started to take orlistat.

Within 2 weeks she had developed signs of hypothyroidism (tiredness, lethargy, cold intolerance): her free thyroxine level was found to be 7 picomol/L and her TSH level was 73.6 mU/L. Two weeks after stopping orlistat, and increasing the dose of **levothyroxine** to 300 [micrograms] daily, her symptoms improved, 4 weeks later her thyroxine and TSH levels had normalised.[1]

Mechanism

It is suggested that the orlistat may have bound to levothyroxine in the gastrointestinal tract, thus reducing its bioavailability.[1]

Importance and management

Evidence for an interaction between levothyroxine and orlistat is limited, but what happened is in line with the way both drugs are known to interact. One manufacturer of levothyroxine recommends that the administration of levothyroxine and orlistat should be separated by 4 hours.[2] It may be prudent to monitor the response to concurrent use, to ensure that this is effective.

Thyroid hormones + Polystyrene sulfonate

A woman taking levothyroxine for hypothyroidism relapsed when she took sodium polystyrene sulfonate. Calcium polystyrene sulfonate would be expected to interact similarly.

Clinical evidence

A woman taking **levothyroxine** 150 micrograms daily for hypothyroidism, following total thyroidectomy, later developed renal impairment and required dialysis. She was also taking digoxin, clofibrate, calcium carbonate, ferrous sulfate, nicotinic acid, folic acid, and magnesium sulfate. Because of persistent hyperkalaemia she started taking sodium polystyrene sulfonate 15 g daily. After 6 months, she developed lethargy, a hoarse voice, facial fullness and weight gain (all symptoms of hypothyroidism). These symptoms resolved within 6 weeks of raising the **levothyroxine** dosage to 200 micrograms daily and separating its administration from the sodium polystyrene sulfonate by 10 hours (previously taken at the same time as the **levothyroxine**).[1]

Mechanism

Sodium polystyrene sulfonate is a cation-exchange resin that is used to bind potassium ions in exchange for sodium. An *in vitro* study found that when levothyroxine 200 micrograms was dispersed in 100 mL water with 15 g sodium polystyrene sulfonate, the concentration of the levothyroxine at pH 2 fell by 93% and at pH 7 by 98%.[1] This drop in concentration would be expected to occur in the gut as well, thereby markedly reducing the amount of levothyroxine available for absorption. Calcium polystyrene sulfonate would be expected to interact similarly.

Importance and management

Information seems to be limited to this study, but the interaction would appear to be of general importance. Separate the dosages of levothyroxine and polystyrene sulfonates as much as possible (10 hours was effective in the case reported) and monitor thyroid hormone levels to confirm that this is effective.

Thyroid hormones + Protease inhibitors

A man needed to have his levothyroxine dosage doubled when he took ritonavir-boosted saquinavir, and hypothyroidism could not be corrected in another woman while she was taking ritonavir-boosted lopinavir and then nelfinavir. Another woman possibly had a similar reaction when given indinavir then nelfinavir. Conversely, another woman needed a markedly reduced dose of levothyroxine when given indinavir, and a further man was able to resume his usual levothyroxine dose when ritonavir-boosted saquinavir was changed to indinavir.

Clinical evidence

(a) Indinavir

A 36-year-old HIV-positive woman taking **levothyroxine** 750 micrograms daily (following partial thyroid gland destruction for Graves' disease) was given stavudine, lamivudine and indinavir. After about 7 weeks she presented with symptoms of hyperthyroidism (including nervousness, palpitations and weight loss). Her serum TSH was low and serum thyroxine was high. After stepped dose decreases she was finally restabilised taking **levothyroxine** 120 micrograms daily, with normal thyroid hormone levels.[1] In contrast to this case, a patient who needed a **levothyroxine** dose increase while taking ritonavir-boosted saquinavir was satisfactorily stabilised with their original dose of **levothyroxine** when given indinavir.[2] In yet another woman, a 4-week course of antiretroviral prophylaxis, including 2 weeks of **indinavir** then 2 weeks of **nelfinavir**, tended to *reduce* the efficacy of **levothyroxine** 125 micrograms daily. She was fatigued and had elevated TSH levels (6.2 mU/L at day 12 and 17.4 mU/L at day 27) and hypercholesterolaemia, which resolved after the antiretroviral drugs were stopped.[3]

(b) Nelfinavir

For a case where 2 weeks of nelfinavir prophylaxis reduced the efficacy of levothyroxine, see under *Indinavir*, above. For another case where hypothyroidism failed to improve on switching from ritonavir-boosted lopinavir to nelfinavir, see *Ritonavir-based regimens*, below.

(c) Ritonavir-based regimens

An HIV-positive man, taking **levothyroxine** for autoimmune thyroiditis, developed an enlarged thyroid gland and marked lethargy about a month after his antiretrovirals were changed to include stavudine, lamivudine, **saquinavir** 400 mg twice daily and ritonavir 600 mg twice daily. It became necessary to double his maintenance dose of **levothyroxine** to restabilise him. When the ritonavir and **saquinavir** were withdrawn and replaced by **indinavir**, the patient was able to go back to the original dose of **levothyroxine**.[2]

In another HIV-positive patient, taking zidovudine, lamivudine and ritonavir-boosted **lopinavir**, **levothyroxine** was started after a total thyroidectomy and post-surgical radioiodine therapy. However, abnormal thyroid function persisted despite an increase in the **levothyroxine** dose to 225 micrograms daily. The antiretrovirals were withdrawn and thyroid function normalised. However, when the same antiretroviral regimen was restarted 8 months later because of a reduced CD4 cell count, hypothyroidism recurred within a month. A switch to **nelfinavir** did not normalise thyroid function, and the patient was eventually stabilised on a combination of three NRTIs.[4]

Mechanism

Uncertain. Ritonavir *increases* the activity of the glucuronosyl transferases, which are concerned with the metabolism (conjugation) of levothyroxine, and might therefore reduce its effect. Conversely, indinavir might *reduce* the activity of glucuronosyl transferases.

Importance and management

Direct information about the interactions of protease inhibitors and thyroid hormones seems limited. Whether or not an interaction occurs seems to depend on the individual protease inhibitor, how it affects glucuronidation, and how much remaining thyroid function a patient has.[3] Until more is known about this interaction it would seem prudent to monitor thyroid function more closely if a protease inhibitor is given to a patient with pre-existing hypothyroidism.

Thyroid hormones + Proton pump inhibitors

The TSH levels of patients taking levothyroxine were slightly increased when they took omeprazole and lansoprazole. Pantoprazole and esomeprazole did not appear to interact in short-term studies.

Clinical evidence

In a randomised, crossover study in 20 healthy subjects, pre-treatment with **pantoprazole** 40 mg daily for one week had no effect on the AUCs of TSH or thyroxine after a single 4-micrograms/kg dose of **levothyroxine**.[1] Similarly, in a study in 10 healthy subjects, **esomeprazole** 40 mg daily for one week did not affect the AUC of serum thyroxine in response to a single 600-microgram dose of **levothyroxine**.[2]

In contrast, in a non-randomised study in 10 women with multinodular goitre and gastroesophageal reflux disease taking a stable dose of **levothyroxine** to suppress thyroid growth, the use of **omeprazole** 40 mg daily for at least 6 months caused a variable increase in TSH levels (median 1.7 mU/L versus 0.1 mU/L before treatment). At that time, the dose of **levothyroxine** was increased to suppress TSH levels: this required a median dose of **levothyroxine** of 2.16 micrograms/kg compared with 1.58 micrograms/kg before starting **omeprazole** (a 37% increase).[3] Similarly, in a retrospective analysis of 37 patients who had received stable doses of levothyroxine for at least 6 months and had then taken **lansoprazole** 30 mg daily for at least 2 months, the mean TSH levels slightly increased (by about 0.7 mU/L).[4]

Mechanism

A decrease in gastric acidity might decrease levothyroxine absorption. Supporting this is the finding that in patients with impaired gastric acid secretion the required dose of levothyroxine was 22 to 34% higher than in patients free of gastric disease.[3] However, this effect could be due to the disease rather than gastric acid *per se*.[5]

Importance and management

An interaction between levothyroxine and proton pump inhibitors is not established. The studies with pantoprazole and esomeprazole did not reveal a change in levothyroxine absorption, whereas the study in patients who had been taking omeprazole for 6 months suggested that patients may need a modest increase in levothyroxine dose, and the retrospective analysis with lansoprazole showed an even smaller increase in TSH. Bear in mind the possibility of an interaction if a patient starting a proton pump inhibitor shows signs of reduced levothyroxine efficacy. Any interaction may take several months to develop. Further study is needed.

Thyroid hormones + Raloxifene

There are two reports of patients who developed increased levothyroxine requirements after taking raloxifene for a number of months.

Clinical evidence

A 79-year-old woman taking **levothyroxine** 150 micrograms daily developed elevated TSH levels and symptoms of hypothyroidism within 2 to 3 months of starting to take raloxifene 60 mg daily. Over the next 6 months the **levothyroxine** dose was progressively increased to 300 micrograms daily without normalising TSH levels. This patient took the raloxifene early in the morning, at the same time as the **levothyroxine**. Subsequently, separating the dose of raloxifene and **levothyroxine** by 12 hours led to a drop in TSH levels. In a single-dose study in this patient, serum thyroxine levels were reduced when **levothyroxine** 1000 micrograms was given with raloxifene 60 mg, and separating the doses of raloxifene and **levothyroxine** by 12 hours was found to reduce TSH levels.[1] Another very similar case has been reported in a 47-year-old woman, which also resolved on separating administration of the **raloxifene** and **levothyroxine** by 12 hours.[2]

Mechanism

Raloxifene is known to increase levels of thyroxine binding globulin, which results in increased levels of total thyroxine without altering free thyroxine.[3] However, this is not likely to be the mechanism in the cases described, because separating the doses would not reduce any effect by this mechanism. It appears that raloxifene reduced the absorption of levothyroxine, but the mechanism for this is not known.

Importance and management

The interaction between levothyroxine and raloxifene is not established, but the similar outcomes in both case reports suggest that an interaction may occur. Further study is needed, but until then it would be prudent to monitor TSH levels in patients taking levothyroxine and starting raloxifene, especially if they develop symptoms of hypothyroidism. If TSH levels are raised, try separating administration by 12 hours before increasing the levothyroxine dose.

Thyroid hormones + Rifampicin (Rifampin)

Two case reports suggest that rifampicin might possibly reduce the effects of thyroid hormones.

Clinical evidence, mechanism, importance and management

A woman with Turner's syndrome, who had undergone a total thyroidectomy and who was taking **levothyroxine** 100 micrograms daily, had a marked fall in serum thyroxine levels and free thyroxine index with a dramatic rise in TSH levels when given rifampicin. However, no symptoms of clinical hypothyroidism developed, and the drop in serum thyroxine occurred before starting rifampicin, which may reflect the clinical picture of an acute infection.[1] Another case describes a *fall* in TSH levels when rifampicin was discontinued.[2]

A possible reason for the changes is that rifampicin, a potent enzyme inducer, can markedly increase the metabolism of many drugs and thereby reduce their effects. Rifampicin has been found to reduce endogenous serum thyroxine levels in healthy subjects[3] and possibly in patients.[2] Note that, other potent enzyme inducers have, rarely, also been seen to interact in this way, see 'Thyroid hormones + Carbamazepine or Phenytoin', p.1522.

There seem to be no reports of adverse effects in other patients given both drugs and the evidence for this interaction is by no means conclusive. Although rifampicin can affect thyroid hormones, it appears that healthy individuals can compensate for this. Since hypothyroid patients may not be able to compensate in the same way, bear this interaction in mind if rifampicin is given to a patient taking **levothyroxine**. If symptoms of hypothyroidism develop, monitor thyroid hormone levels, and adjust the dose of levothyroxine accordingly. It would seem prudent to take similar precautions in patients given **liothyronine** and rifampicin.

Thyroid hormones + Sertraline

Limited evidence suggests that the effects of levothyroxine can be opposed in some patients by sertraline.

Clinical evidence, mechanism, importance and management

Nine patients with hypothyroidism were noted to have elevated TSH levels (indicating a decrease in the efficacy of their treatment with **levothyroxine**), when they were also taking sertraline. Two other patients with thyroid cancer, whose TSH levels had been deliberately depressed, developed TSH levels in the normal range while taking sertraline. None of the patients showed any signs of hypothyroidism at the time, and all of them had been taking the same dose of **levothyroxine** for at least 6 months. TSH levels of up to almost 17 mU/L (reference range given as 0.3 to 5 mU/L) were seen in some patients. The **levothyroxine** dosages were increased by 11 to 50%, until the TSH levels were back to normal. The authors of this report say that they know of three other patients whose TSH levels were unaltered by sertraline.[1]

The manufacturers of sertraline say that their early-alert safety database to the end of July 1997 had identified 14 cases of hypothyroidism where a possible relation to sertraline could not be excluded. Seven of the patients were also taking **levothyroxine**.[2]

The mechanism of this interaction (if such it is) is not known, but these cases draw attention to the need to monitor the effects of giving sertraline to patients taking **levothyroxine**, the dosage of which may need to be increased. More study is needed.

Thyroid hormones + Sevelamer

Sevelamer decreases levothyroxine absorption, and appears to increase levothyroxine requirements.

Clinical evidence, mechanism, importance and management

In a single-dose study in 7 healthy subjects, giving a large dose of **levothyroxine** (1000 micrograms) at the same time as sevelamer 800 mg resulted in a decrease of about 50% in the AUC_{0-6} of thyroxine.[1] In a retrospective study, 67 patients were identified who were taking **levothyroxine** and a phosphate binder (calcium carbonate, calcium acetate or sevelamer). The TSH levels were significantly higher in patients taking sevelamer than calcium acetate, and the difference was greater over time. In addition, patients taking sevelamer required significantly higher **levothyroxine** doses than those taking either of the calcium compounds.[2]

The available evidence suggests that sevelamer decreases the absorption of **levothyroxine**, and that this could result in increased dose requirements. It would be prudent to monitor **levothyroxine** requirements in patients taking sevelamer. Whether separation of administration would minimise any interaction remains to be demonstrated. However, where there is a potential risk of decreased absorption, it is generally recommend that other drugs should be avoided for at least 1 hour before or 3 hours after sevelamer.

Thyroid hormones + Statins

Isolated cases describe both an increase and a decrease in the response to levothyroxine in patients taking lovastatin. Another report describes reduced efficacy of levothyroxine in two patients taking simvastatin. In one of these patients, the subsequent use of pravastatin did not affect thyroid function.

Clinical evidence, mechanism, importance and management

(a) Lovastatin

A 54-year-old diabetic man taking **levothyroxine** 150 micrograms daily for Hashimoto's thyroiditis, and a number of other drugs (gemfibrozil, clofibrate, propranolol, diltiazem, quinidine, aspirin, dipyridamole, insulin) started taking lovastatin 20 mg daily. Weakness and muscle aches (with a normal creatinine phosphokinase) developed within 2 to 3 days, and over a 27-day period he lost 10% of his body weight. His serum thyroxine levels rose from about 145 nanomol/L to 350 nanomol/L. The author of the report postulated that the lovastatin may have displaced the thyroid hormones from their binding sites, thereby increasing their effects and causing this acute thyrotoxic state. It was suggested that the patient did not have any cardiac symptoms because of his pre-existing drug regimen.[1]

In contrast, a woman with goitrous hypothyroidism due to Hashimoto's thyroiditis, which was being treated with **levothyroxine** 125 micrograms daily, developed evidence of hypothyroidism (elevated TSH) on two occasions while taking lovastatin 20 or 60 mg daily. No clinical signs of hypothyroidism developed, apart from some increased fatigue, and possibly an increased sensitivity to insulin. The author suggested that lovastatin may have influenced the absorption or clearance of **levothyroxine**.[2]

When the second report was published, the manufacturers of lovastatin reported that at that time (August 1989) more than 1 million patients had taken lovastatin, and hypothyroidism had only been reported in 3 patients.[3] It seems that any interaction is a very rare event and consequently unlikely to happen in most patients. No special precautions would therefore seem to be necessary.

(b) Simvastatin

A 75-year-old woman who had been stable taking **levothyroxine** 800 micrograms weekly for many years had a gradual increase in TSH levels and increasing tiredness after starting to take simvastatin 10 mg daily. After 4 months the **levothyroxine** dose was increased to 900 micrograms weekly, but the patient's symptoms had not improved in 2 weeks and the simvastatin was stopped. The patient's symptoms gradually resolved, and the dose of levothyroxine was reduced back to the previous level.[4]

Another patient, who had recently started taking **levothyroxine** 50 micrograms daily because of rising TSH levels, was also given simvastatin 10 mg daily. TSH levels continued to increase, so the simvastatin was stopped, and the TSH levels decreased to the normal range within 4 weeks without the need for an alteration in the **levothyroxine** dose. This patient was subsequently given **pravastatin** without a change in thyroid status.[4]

The authors conclude that any interaction must be extremely rare given the frequent use of simvastatin and **levothyroxine**.[4] No special precautions would appear to be required on concurrent use, but bear the possibility of this interaction in mind in the event of an unexpected response to treatment.

Thyroid hormones + Sucralfate

Sucralfate may reduce levothyroxine absorption, but not all studies have found this effect.

Clinical evidence, mechanism, importance and management

A woman with hypothyroidism did not respond to **levothyroxine**, despite taking 4.8 micrograms/kg daily, while taking sucralfate (dose not stated). Her response remained inadequate (TSH levels high, thyroxine levels low) even when the **levothyroxine** was taken 2.5 hours after the sucralfate, but when **levothyroxine** was taken 4.5 hours before the sucralfate, the thyroxine and TSH levels gradually became normal. A later *in vitro* study demonstrated that sucralfate binds strongly to **levothyroxine**, and it is

presumed that this can also occur in the gut, thereby reducing its absorption.[1]

Other studies have found similar effect. A single-dose study in healthy subjects found that giving a large dose of **levothyroxine** (1000 micrograms) with the last dose of sucralfate (five 1-g doses given every 6 hours), resulted in a 72% reduction in **levothyroxine** absorption, and a delay of 2 hours in reaching maximum absorption. Separating dosing by 8 hours avoided this effect.[2] Conversely, in 10 patients whose hypothyroidism was controlled by stable doses of **levothyroxine**, giving sucralfate 1 g daily for 6 weeks at the same time as **levothyroxine** did not alter the levels of thyroxine or TSH.[3] Another placebo-controlled study similarly found that sucralfate had little effect on the absorption of **levothyroxine**, with just a minor decrease in serum thyroxine levels seen (about 94 nanomol/L with sucralfate versus about 105 nanomol/L with placebo).[4]

An interaction is not established, and findings are somewhat contradictory. Nevertheless, it might be prudent not to take sucralfate until a few hours after **levothyroxine**. Patients should be advised accordingly and the response well monitored.

37

Urological drugs

The drug classes used for various genito-urinary disorders are summarised in 'Table 37.1', (below). The main groups of drugs included in this chapter are the urinary antimuscarinics and the phosphodiesterase type-5 inhibitors (PDE5 inhibitors), along with various individual miscellaneous drugs. Note that, where these drugs affect other drugs, the interaction is generally covered elsewhere.

Antimuscarinics

The main pharmacodynamic interaction of antimuscarinic drugs is an increased risk of antimuscarinic effects (e.g. dry mouth, constipation, confusion) when used with other drugs with antimuscarinic properties. Many drugs have antimuscarinic adverse effects, which may not be readily appreciated from their clinical uses, see 'Table 18.2', (p.786) for a list. Some of the newer antimuscarinics used for incontinence have greater selectivity for the M_3 muscarinic receptors of the bladder. However, it is not established whether this results in a clinically relevant difference in the incidence of antimuscarinic adverse effects or antimuscarinic drug interactions.

Some of the urinary antimuscarinics, including darifenacin, solifenacin and tolterodine, are principally metabolised by the cytochrome P450 isoenzyme system, or, in the case of fesoterodine, its main active metabolite is metabolised by these isoenzymes. Therefore clinically important pharmacokinetic drug interactions can occur with these drugs, due to altered metabolism.

Phosphodiesterase type-5 inhibitors (PDE5 inhibitors)

The main concern regarding the phosphodiesterase type-5 inhibitors has centred around their cardiovascular adverse effects. Therefore the possible risks of their use in patients with cardiovascular disease, and their drug interactions with drugs used in cardiovascular disease have been particularly studied. Important interactions occur with 'nitrates', (p.1537), and also 'alpha blockers', (p.1531). All the phosphodiesterase type-5 inhibitors are metabolised, to a greater or lesser extent, by the cytochrome P450 isoenzyme CYP3A4, and therefore clinically relevant drug interactions can occur with drugs that induce or inhibit this route of metabolism.

Table 37.1 Classification of urological drugs

Group	*Drugs*
Drugs for benign prostatic hyperplasia	
Alpha blockers	See Alpha blockers, p.92
Anti-androgens	Dutasteride, Finasteride
Drugs for urinary incontinence	
Antimuscarinics	Darifenacin, Flavoxate, Oxybutynin, Propiverine, Solifenacin, Tolterodine, Trospium
SNRIs	Duloxetine, covered under SSRIs, tricyclics and related antidepressants, p.1464
Drugs for nocturnal enuresis in children	
Tricyclic antidepressants	Imipramine, covered under SSRIs, tricyclics and related antidepressants, p.1464
Vasopressin analogues	Desmopressin
Drugs for erectile dysfunction	
Dopaminergic agonists	Apomorphine, covered under Antiparkinsonian and related drugs, p.784
Muscle relaxants	Papaverine
Phosphodiesterase type-5 inhibitors	Sildenafil, Tadalafil, Vardenafil
Prostaglandins	Alprostadil
Others	Phentolamine, Yohimbine

Alprostadil + Miscellaneous

Some manufacturers advise that intracavernosal alprostadil and other drugs used for erectile dysfunction should not be given concurrently. Concurrent use of alprostadil with antihypertensives, alpha blockers, and drugs causing vasodilation, such as the nitrates, may theoretically increase the risk of hypotension. Nasal decongestants and appetite suppressants might theoretically reduce the efficacy of alprostadil. Clinical experience suggests that an alprostadil infusion does not interact with penicillin, gentamicin, dopamine, isoprenaline (isoproterenol), furosemide, or digoxin.

Clinical evidence, mechanism, importance and management

A. Erectile dysfunction

(a) Appetite suppressants and decongestants

Some manufacturers say that, theoretically, sympathomimetics such as **nasal decongestants** and **anorectics** might diminish the effect of alprostadil for erectile dysfunction.[1,2]

(b) Other drugs for erectile dysfunction

Prolonged priapism occurred in a man who used an intracavernous injection of alprostadil 15 micrograms about one hour after taking a single 100-mg dose of **sildenafil** because of an inadequate response to the **sildenafil**.[3] Two other cases are described, one in a man who took **sildenafil** 100 mg and then, 90 minutes later, used 0.25 mL of intracavernosal *Trimix* (**papaverine**, **phentolamine** plus alprostadil), and another in a man who took **tadalafil** 20 mg and then used *Trimix* 18 hours later.[3] Note that tadalafil has a half-life of 17.5 hours.[3] Some manufacturers say that smooth muscle relaxants such as **papaverine** and other drugs used to induce erections such as **alpha-blocking drugs** [e.g. intracavernosal **phentolamine**] or the phosphodiesterase type-5 inhibitors such as **sildenafil** should not be used concurrently because of the risks of priapism.[2,4] This recommendation does not appear to have been made for alprostadil for urethral application.[1,5]

(c) Vasodilating drugs

Alprostadil can rarely cause hypotension.[1,2,4] Some manufacturers caution that there is a theoretical risk of hypotensive symptoms if alprostadil is used with vasodilating medications,[1,2,4] or antihypertensives,[5] and that this might be more common in the elderly.[1] Vasodilating medications would include **alpha blockers** and **nitrates**. One manufacturer advises against the combination.[6]

B. Neonatal congenital heart defects

The manufacturers of intravenous alprostadil note that there are no known drug interactions between alprostadil infusion and the drugs commonly given to neonates with congenital heart defects, including antibacterials such as **penicillin** or **gentamicin**, vasopressors, such as **dopamine** or **isoprenaline** (**isoproterenol**), diuretics such as **furosemide**, and **digoxin**.[7,8]

Desmopressin + Erythromycin

Erythromycin does not induce gastrointestinal motility sufficiently to affect desmopressin absorption.

Clinical evidence, mechanism, importance and management

In a study, 18 healthy subjects were given erythromycin 250 mg four times daily for 3 days, with a 400-microgram oral dose of desmopressin one hour after the final dose of erythromycin. When compared with desmopressin alone, the time to peak desmopressin levels was reduced from 1.3 to 0.9 hours by erythromycin, but other pharmacokinetic parameters were not affected, suggesting the erythromycin did not induce gastrointestinal motility sufficiently to affect total desmopressin absorption.[1]

This study suggests that no interaction of clinical significance would be expected if erythromycin is given to patients receiving oral desmopressin.

Desmopressin + Food

Food reduces the absorption of oral desmopressin.

Clinical evidence, mechanism, importance and management

In a study in healthy subjects, a standardised meal decreased the absorption (rate and extent) of a 400-microgram dose of desmopressin tablets by 40% when the tablets were given either at the same time as the meal or 1.5 hours after the meal, when compared with the fasting state. However, the meal did not significantly affect the pharmacodynamic effect of desmopressin (urine production and osmolality).[1] Nevertheless, the manufacturer of desmopressin considers that the effect of food could be clinically important, particularly with lower doses of desmopressin. They suggest that if a reduction in effect is noted, then the effect of food should be considered before increasing the dose.[2] If problems occur, it may be prudent to advise patients to take desmopressin consistently with respect to food.

Desmopressin + Loperamide

Loperamide may markedly increase oral desmopressin.

Clinical evidence

In a study, 18 healthy subjects were given a 400-microgram oral dose of desmopressin as immediate-release tablets, either alone or after three doses of loperamide 4 mg, given 24, 12 and 1 hour before the desmopressin. Loperamide increased the AUC and peak plasma levels of desmopressin 3.1-fold and 2.3-fold, respectively, and the time to peak desmopressin plasma levels was increased from 1.3 to 2 hours, whereas the elimination half-life was unaltered.[1]

Mechanism

It was suggested that loperamide increases the absorption of desmopressin by slowing gastrointestinal motility. Other mechanisms such as reduced pancreatic secretion or reduced enzymatic degradation of desmopressin in the intestine have been suggested, but are considered less likely as desmopressin clearance was not significantly affected.[1]

Importance and management

Evidence appears to be limited to one study. Increased desmopressin absorption could lead to a prolonged duration of action, and if fluid intake is not restricted in such a situation, there could be an increased risk of water intoxication and/or hyponatraemia.[1] It would therefore be prudent to increase the monitoring of the effects of oral desmopressin in any patient given loperamide, reducing the desmopressin dose or dose frequency as necessary. However, note that in primary nocturnal enuresis, the indication for loperamide (diarrhoea) is a reason to temporarily stop desmopressin.[2-4] The manufacturer suggests that other drugs that slow gastrointestinal transport might have the same effect.[2] Although the effect of loperamide on sublingual formulations of desmopressin has not been studied, the same precautions should be applied.

As the loperamide interacts by an effect on the gut, no interaction would be expected with intranasal or parenteral desmopressin.

Desmopressin + Miscellaneous

Any drug that can cause water retention or hyponatraemia (e.g. tricyclic antidepressants, SSRIs, chlorpromazine, carbamazepine, and NSAIDs) may have an additive effect with desmopressin. This may lead to avoid water overload and/or hyponatraemia.

Clinical evidence, mechanism, importance and management

In a retrospective analysis of 103 children with cranial diabetes insipidus, major complications (symptomatic water overload) or asymptomatic hyponatraemia were seen in 33 children. In patients taking desmopressin with **carbamazepine**, major complications were more common than in those not receiving **carbamazepine** (33% versus 10%).[1]

The severity of the potential adverse interaction between desmopressin and drugs that can cause water retention or hyponatraemia is demonstrated by the case report of a 10-year-old boy, who had been receiving intranasal desmopressin for 7 months for primary nocturnal enuresis. A few weeks after **imipramine** 25 mg at night was added, he had a hyponatraemic convulsion.[2]

Any drug that is known to induce the syndrome of inappropriate antidiuretic hormone secretion has the potential to have additive effects with desmopressin. This increases the risk of water retention and/or hyponatraemia. Examples are **carbamazepine**, **chlorpromazine**, **SSRIs** and **tricyclic antidepressants**, such as **imipramine**. Other drugs that can cause water retention such as the **NSAIDs** might also increase the risk of fluid overload and hyponatraemia. Caution is required on concurrent use,[3,4] with more frequent monitoring of serum sodium.

Dutasteride + Colestyramine

In a study in 12 healthy subjects the absorption of dutasteride 5 mg was not affected when it was given one hour before a single 12-g dose of colestyramine.[1,2] No precautions seem necessary if this dosing interval is observed. Note that, in general, it is recommended that other drugs are given one hour before or 4 to 6 hours after colestyramine.

Dutasteride + CYP3A4 inhibitors

Preliminary evidence suggests that diltiazem and verapamil, CYP3A4 inhibitors, cause moderate increases in dutasteride levels. More potent CYP3A4 inhibitors would be expected to have a greater effect. No clinically significant interaction appears to occur between dutasteride and amlodipine.

Clinical evidence, mechanism, importance and management

In a population pharmacokinetic analysis, it was found that **diltiazem** (5 subjects) and **verapamil** (6 subjects) were associated with a 44% and 37% decrease in dutasteride clearance,[1] and an 80% and 60% increase in serum levels,[2] respectively. In contrast, **amlodipine** (4 subjects) was not associated with any significant change in the clearance of dutasteride.[1] The changes were thought to be due to the inhibitory effect of **diltiazem** and **verapamil** on the cytochrome P450 isoenzyme CYP3A4, an effect that **amlodipine** lacks. Dutasteride has a wide safety margin, so these changes are not thought to be clinically significant.[1,2] However, in the UK, the manufacturers warn that potent CYP3A4 inhibitors (they name **indinavir**, **itraconazole**, **ketoconazole**, **nefazodone** and **ritonavir**) may cause a clinically significant increase in dutasteride levels, and so they suggest reducing the dosing frequency if increased dutasteride adverse effects occur in the presence of these drugs.[2] The US manufacturer similarly recommends caution with long-term use of potent CYP3A4 inhibitors, and they name **ritonavir** as an example.[1]

2. Avodart (Dutasteride). GlaxoSmithKline UK. UK Summary of product characteristics, August 2008.

Papaverine + Diazepam

Two men given normal test doses of papaverine for the investigation of impotence had prolonged erections, which were attributed to the concurrent use of diazepam.

Clinical evidence, mechanism, importance and management

Undesirably prolonged erections (duration of 5 and 6 hours) occurred in 2 patients who had been given 5 or 10 mg of diazepam intravenously for anxiety before a 60-mg intracavernosal injection of papaverine.[1] Papaverine acts by relaxing the arterioles that supply the corpora so that the pressure rises. The increased pressure in the corpora compresses the trabecular venules so that the pressure continues to maintain the erection. Diazepam also relaxes smooth muscle and it would seem that this effect can be additive with the effects of papaverine. The authors of the report say that caution should be exercised in the choice of papaverine dosage in patients taking anxiolytics (i.e. use less) although these two cases involving diazepam seem to be the only ones reported.[1]

Phosphodiesterase type-5 inhibitors + Alpha blockers

Postural hypotension may occur with higher doses of sildenafil, tadalafil or vardenafil given at the same time as doxazosin or terazosin. The effect may be less marked with tamsulosin.

Clinical evidence

(a) Sildenafil

Retrospective analysis of pooled data from various clinical studies that included patients taking non-nitrate antihypertensives such as the alpha blockers suggested that the adverse effect profile, blood pressure, and heart rate were not significantly different between sildenafil and placebo.[1] However, the manufacturer notes that when sildenafil 100 mg was given simultaneously with **doxazosin** 4 mg after at least 14 consecutive daily doses of **doxazosin**, severe postural hypotension (starting at 35 minutes and lasting 8 hours) occurred in one of 4 subjects with BPH, and 2 others had mild dizziness. Two of the subjects had a standing systolic BP of less than 85 mmHg. This did not occur in a further 17 subjects who, as a result of these effects, were given a lower dose of sildenafil 25 mg. In two other studies in men with BPH, 2 of 19 patients and 3 of 20 patients had a standing systolic BP of less than 85 mmHg after receiving 14 days of **doxazosin** then a single dose of sildenafil 50 mg or 100 mg given at the same time as **doxazosin**.[2]

A case report describes a patient with intermittent Wolff-Parkinson-White syndrome taking **doxazosin** 1 mg daily for mild hypertension who developed palpitations and chest pain one hour after taking sildenafil 50 mg and drinking 1.5 L of beer. He had atrial fibrillation (which failed to respond to DC conversion, and reverted spontaneously after 4 hours) and severe hypotension lasting 16 hours, for which he was given a dopamine infusion. The authors considered that the hypotension might have been caused by an interaction between the alcohol, **doxazosin** and the sildenafil.[3]

(b) Tadalafil

In a well-controlled study in 18 healthy subjects, a single 20-mg dose of tadalafil was given at the same time as **doxazosin** 8 mg following a minimum of 7 days of pretreatment with **doxazosin** 8 mg daily. The blood-pressure lowering effects of doxazosin were increased: the mean maximum systolic falls for the combination were 19.6 mmHg when lying and 27.8 mmHg when standing, which was 3.6 mmHg and 9.8 mmHg greater than doxazosin with placebo. Five of the subjects had a standing systolic BP of less than 85 mmHg. Some of the subjects felt dizzy, but none of them fainted.[4]

Conversely, only a small (3.2 mmHg and 1.7 mmHg) additional drop in blood pressure was seen when tadalafil 10 or 20 mg was given 2 hours after **tamsulosin** 400 micrograms. Note that the 2-hour difference was used so that the maximum plasma levels of each drug would coincide. None of the subjects had a standing systolic BP of less than 85 mmHg.[4] In a placebo-controlled study, 17 healthy subjects were given extended-release **alfuzosin** 10 mg daily, with a single 20-mg oral dose of tadalafil on day 7. The additional blood pressure-lowering effect of the tadalafil was small (2.1 mmHg systolic supine and 4.3 systolic standing). One of the subjects had a decrease in standing systolic BP to less than 85 mmHg. No syncope or severe adverse events were reported. Note that the doses were separated in such a way that the peak plasma levels of each drug would coincide.[5]

The above studies used single doses of tadalafil. In another two studies in healthy subjects, tadalafil 5 mg daily was given alone and then either **doxazosin** (titrated from 1 mg daily to 4 mg daily) or **tamsulosin** 400 micrograms daily were added. The mean maximum additional decrease in standing systolic BP on adding the alpha blocker was similar (0.5 mmHg with doxazosin 4 mg and 0.9 mmHg for tamsulosin). Standing systolic BP of less than 85 mmHg occurred in 1 of 37 subjects receiving doxazosin and none of 35 subjects receiving tamsulosin.[6]

(c) Vardenafil

The manufacturers of vardenafil have conducted several placebo-controlled, randomised, crossover studies, in patients with BPH and in healthy subjects taking alpha blockers, to assess the effects of the concurrent use of vardenafil on blood pressure. Vardenafil 5 mg was given to 21 patients taking **terazosin** 5 or 10 mg daily. Vardenafil given simultaneously caused significant hypotension in one patient (BP 80/60 mmHg) and 5 patients experienced postural hypotension of greater than 30 mmHg (compared with only 2 patients in the placebo group). When vardenafil was given 6 hours after the alpha blocker no adverse effects were reported.[7] Vardenafil 10 or 20 mg was also given to healthy subjects taking **terazosin** 10 mg daily, either simultaneously with the terazosin or separated by 6 hours. Due to significant hypotension in most of the subjects given the drugs simultaneously, this arm of the study was halted.[7]

Vardenafil 5 mg was given to 21 patients taking **tamsulosin** 400 micrograms daily. Vardenafil given simultaneously caused significant hypotension in 2 patients (systolic BP less than 85 mmHg) and 2 patients experienced postural hypotension of greater then 30 mmHg (compared with only one patient in the placebo group). When vardenafil was given 6 hours after the alpha blocker significant hypotension still occurred in 2 patients and one experienced postural hypotension of greater than 30 mmHg.[7] Larger doses of vardenafil (10 then 20 mg) given to 23 patients with BPH taking **tamsulosin** 400 or 800 micrograms resulted in mean additional decreases in supine systolic BP of 4.5 mmHg and 4 mmHg, respectively, when compared with placebo. A decrease in standing systolic BP of greater than 30 mmHg occurred in one patient, and 3 patients became dizzy, but no patient had a systolic BP of less than 85 mmHg.[7,8] When vardenafil 10 or 20 mg was given to 20 healthy subjects taking **tamsulosin** 400 micrograms daily, 7 subjects became dizzy.[7]

In a study of the effect of vardenafil on blood pressure in normotensive men with erectile dysfunction, three patients had fainting episodes after their first dose of vardenafil 10 mg. Two of these were taking **doxazosin** for benign prostatic hyperplasia.[9]

Mechanism

Phosphodiesterase type-5 inhibitors cause mild to moderate vasodilatation of vascular smooth muscle in veins and arteries, and so can lower blood pressure. The concern is that this could be additive or synergistic with the orthostatic hypotension that can occur with alpha blockers.

Importance and management

The interactions between the phosphodiesterase type-5 inhibitors and the alpha blockers are established, and concurrent use requires caution. The risk of symptomatic hypotension is reduced if the patient taking an alpha blocker is haemodynamically stable before the phosphodiesterase type-5 inhibitor is started, and if it is started at the lowest recommended dose. The risk may also be minimised if administration is separated so that the peak levels of the two drugs do not coincide. If an alpha blocker is required in a patient already using a phosphodiesterase type-5 inhibitor, extra caution is required, particularly with alpha blockers well-known to be associated with first-dose hypotension, such as immediate-release alfuzosin, prazosin and terazosin. This effect is seen less frequently with modified-release alfuzosin and tamsulosin. Patients should be warned of the risks and advised what to do in the event of postural hypotensive symptoms (i.e. lay down, raise the legs and, when recovered, get up slowly).

Note that the combination of sildenafil and doxazosin has been used for erectile dysfunction refractory to sildenafil monotherapy.[10]

Phosphodiesterase type-5 inhibitors + Antacids

No clinically significant interaction appears to occur between sildenafil, tadalafil or vardenafil and aluminium/magnesium hydroxide-containing antacids.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a single-dose study in 12 healthy subjects, the bioavailability of sildenafil was not affected by single 30-mL doses of an **aluminium/magnesium hydroxide** antacid.[1]

(b) Tadalafil

A randomised, crossover study in 12 healthy subjects found that 20 mL of *Maalox* (**aluminium/magnesium hydroxide**) reduced the mean maximum serum level of a single 10-mg dose of tadalafil by 30%. Although peak tadalafil levels were delayed by 2.5 hours, the total amount of tadalafil absorbed was unchanged. None of the changes caused were considered to be clinically relevant, and there would appear to be no reason for avoiding concurrent use.[2]

(c) Vardenafil

In a crossover study, 12 healthy subjects were given a single 20-mg dose of vardenafil with 10 mL of an **aluminium/magnesium hydroxide** antacid (*Maalox 70*). The bioavailability of vardenafil was not significantly altered by the antacid, therefore no additional precautions are needed if these drugs are used together.[3]

Phosphodiesterase type-5 inhibitors + Antihypertensives

For the potentially serious interactions of sildenafil, tadalafil and vardenafil with the alpha blockers and nitrates, see 'Alpha blockers', (p.1531) and 'Nitrates', (p.1537). No clinically relevant interactions appear to occur between sildenafil, tadalafil or vardenafil and most other antihypertensive drugs. The exceptions may be diltiazem and verapamil, which theoretically may inhibit the metabolism of phosphodiesterase type-5 inhibitors.

Clinical evidence

(a) Sildenafil

In a study in 8 hypertensive men taking one to five antihypertensives (**amlodipine** (5 patients), a **diuretic** (4), an **ACE inhibitor** (3), an **angiotensin II receptor antagonist** (2), **diltiazem** (1)), a single 50-mg dose of sildenafil reduced the systolic BP by a mean maximum of 24 mmHg, compared with only 6 mmHg for placebo. One patient had a blood pressure fall of 48/23 mmHg, but none complained of hypotensive symptoms.[1] Two retrospective analyses of pooled data from various clinical studies suggests that patients taking non-nitrate antihypertensives (**ACE inhibitors**, alpha blockers, **beta blockers**, **calcium-channel blockers**, **diuretics**) and sildenafil had no significant difference in blood pressure or heart rate, when compared with those taking antihypertensives and placebo,[2] and that the incidence of dizziness did not differ between the two groups.[2,3] In a placebo-controlled study in patients with hypertension stabilised with two or more antihypertensives (including **diuretics**, **calcium-channel blockers**, **ACE inhibitors**, **beta blockers**, alpha blockers, **angiotensin II receptor antagonists**), the occurrence of adverse events potentially related to hypotensive effects (dizziness, hypotension, labile BP, vertigo) was less than 4% in those given sildenafil.[4] Note that combined use with alpha blockers may be especially likely to induce hypotensive events, see 'Phosphodiesterase type-5 inhibitors + Alpha blockers', p.1531.

The manufacturers report that, in population pharmacokinetic analysis, there was no effect on sildenafil pharmacokinetics in those taking **ACE inhibitors**, **calcium-channel blockers** and **thiazide** and **related diuretics**[5,6] whereas the AUC of the less potent active metabolite of sildenafil is increased by 62% by **loop** and **potassium-sparing diuretics** and by 102% by **non-selective beta blockers**.[6]

When sildenafil 100 mg was given to hypertensive patients taking **amlodipine** the mean additional fall in blood pressure (8/7 mmHg) was of the same magnitude as that seen when sildenafil was given alone to healthy subjects.[5,6]

A case report describes a patient taking **diltiazem** 30 mg three times daily who underwent coronary angiography 48 hours after taking sildenafil 50 mg, and who developed profound and persistent hypotension (BP 90/60 mmHg) after receiving sublingual nitrate for pain related to angina during the procedure.[7] It was suggested that **diltiazem** may have inhibited the metabolism of sildenafil so that it interacted with the nitrate,[7,8] although the time scale for this interaction has been disputed.[9]

The manufacturer notes that in population pharmacokinetic analysis of patients with *pulmonary hypertension*, there appeared to be an increase in sildenafil exposure when it was taken with **beta blockers** (none named) in combination with CYP3A4 substrates (none named).[10,11] The clinical relevance of this finding is uncertain, and further study is needed.

(b) Tadalafil

Placebo-controlled studies in patients taking **enalapril**, **metoprolol** or **bendroflumethiazide**, found that a 10-mg dose of tadalafil did not affect blood pressure or heart rate.[12] Similar results were seen in a study in patients taking **amlodipine** and given tadalafil 20 mg.[12] In another study in patients taking unnamed **angiotensin II receptor antagonists** (alone or in combination with **thiazides**, **calcium-channel blockers** or **beta blockers**[13]), tadalafil 20 mg lowered the mean BP by 8/4 mmHg more than placebo.[14] About twice as many patients taking tadalafil had a potentially clinically relevant decrease in blood pressure, when compared to those taking the antihypertensives alone, although no potential hypotensive symptoms (e.g. dizziness) occurred.[12]

In phase III studies in patients taking antihypertensives (**ACE inhibitors**, **calcium-channel blockers**, **thiazide diuretics**, **beta blockers**, **angiotensin II receptor antagonists**, alpha blockers and **loop diuretics**) blood pressure was similar in those given tadalafil and those given placebo. There was no difference in the number of patients with a potentially clinically relevant reduction in systolic BP (greater than 30 mmHg), and there was a similar incidence of dizziness.[12]

(c) Vardenafil

In a randomised, crossover study, 22 patients with hypertension stabilised by slow-release **nifedipine** 30 or 60 mg daily, were given a single 20-mg dose of vardenafil, or placebo. Vardenafil slightly decreased the maximum plasma levels and relative bioavailability of **nifedipine**, as well as causing a further decrease in supine blood pressure of about 6/5 mmHg. Heart rate was increased by 4 bpm.[15] **Nifedipine** did not alter vardenafil levels.[16]

The UK manufacturer says that, although not specifically studied, population pharmacokinetic analysis has suggested that **ACE inhibitors**, **beta blockers**, and **diuretics** have no effect on vardenafil pharmacokinetics.[17]

Mechanism

Phosphodiesterase type-5 inhibitors cause mild to moderate vasodilatation of vascular smooth muscle in veins and arteries, and so can lower blood pressure. This might be additive with the effects of antihypertensive drugs.

It should be noted that some calcium-channel blockers (e.g. **diltiazem**, **verapamil**) are known to inhibit the cytochrome P450 isoenzyme CYP3A4, by which sildenafil, tadalafil and vardenafil are metabolised, and so these calcium-channel blockers have the potential to raise phosphodiesterase type-5 inhibitor levels.

Importance and management

A small, additional decrease in blood pressure might be anticipated when phosphodiesterase type-5 inhibitors are used in patients taking antihypertensives such as beta blockers, ACE inhibitors, calcium-channel blockers and diuretics. This effect rarely results in clinically important adverse effects,[18] but consider also whether the patient's underlying cardiovascular disease would make resumption of sexual activity high-risk: poorly controlled hypertension and unstable or refractory angina are categorised as high-risk.[18]

There are no established pharmacokinetic interactions between phosphodiesterase type-5 inhibitors and ACE inhibitors, beta blockers, and dihydropyridine calcium-channel blockers. In addition, there are no pharmacokinetic data on the effects of **diltiazem** or **verapamil**, but on the basis of the known effect of other moderate CYP3A4 inhibitors such as 'erythromycin', (p.1537), on the metabolism of sildenafil, tadalafil and vardenafil, increased effects might be predicted. A lower starting dose of these phosphodiesterase type-5 inhibitors might be appropriate in patients taking diltiazem or verapamil.

There are some preliminary data suggesting a small increase in exposure to sildenafil with loop and potassium-sparing diuretics and non-selective beta blockers, but the manufacturer does not consider this to be clinically relevant.[6]

Note that some consider that the precautions required for 'alpha blockers', (p.1531), should also be applied to the beta blockers that also have alpha blocker activity, such as **carvedilol** and **labetalol**.[18]

Phosphodiesterase type-5 inhibitors + Aspirin

Sildenafil, tadalafil and vardenafil do not potentiate the increased bleeding time seen with aspirin.

Clinical evidence

(a) Sildenafil

In a pharmacological study, sildenafil 50 mg did not potentiate the increase in bleeding time seen with aspirin 150 mg.[1]

(b) Tadalafil

A randomised, parallel-group study in a total of 28 subjects found that a single 10-mg dose of tadalafil did not increase the bleeding time after aspirin 300 mg daily was taken for 5 days.[2]

(c) Vardenafil

The manufacturers say that population pharmacokinetic analysis suggests that aspirin had no effect on vardenafil pharmacokinetics.[3] In addition, vardenafil 10 mg and 20 mg did not potentiate the bleeding time caused by aspirin 162 mg.[3,4]

Mechanism

Phosphodiesterase type-5 is found in platelets. *In vitro*, sildenafil potentiated the antiplatelet effect of nitroprusside. However, an antiplatelet effect has not been seen clinically.[1]

Importance and management

No additional precautions seem necessary if phosphodiesterase type-5 inhibitors are given with antiplatelet doses of aspirin.

Phosphodiesterase type-5 inhibitors + Azoles

Ketoconazole markedly raises the levels of tadalafil, very markedly raises the levels of vardenafil, and probably reduces sildenafil clearance. Itraconazole and other azole antifungals that are potent CYP3A4 inhibitors, such as posaconazole and voriconazole, are predicted to interact similarly.

Clinical evidence

(a) Sildenafil

Saquinavir increases the AUC of sildenafil twofold by inhibiting CYP3A4 (see 'Phosphodiesterase type-5 inhibitors + Protease inhibitors', p.1539). The manufacturers of sildenafil therefore predict that other more potent CYP3A4 inhibitors such as **itraconazole** and **ketoconazole** will have even greater effects.[1,2] They say that population data from clinical studies suggests that **ketoconazole** did reduce sildenafil clearance,[1,2] without increasing the incidence of adverse effects.[1] Similarly, a case report describes the apparently uneventful concurrent use of sildenafil 100 mg with **itraconazole** 400 mg daily for 7 days each month in a 56-year-old man.[3]

(b) Tadalafil

In a randomised study in 12 healthy subjects, **ketoconazole** 200 mg daily increased the AUC of a single 10-mg dose of tadalafil twofold,[4,5] and **ketoconazole** 400 mg daily increased the AUC fourfold.[4,5] The manufacturers predict that **itraconazole** will interact similarly.[4,5] This prediction has been borne out by a case report, which describes a 56-year-old man who was taking **itraconazole** 400 mg daily for 7 days each month. Within a few hours of his first 10-mg dose of tadalafil he developed priapism, which lasted for more than 4 hours. The same reaction occurred when he took tadalafil during the following month. He had seemingly previously taken sildenafil with **itraconazole** without adverse effect.[3]

(c) Vardenafil

Ketoconazole 200 mg daily increased the AUC of a 5-mg dose of vardenafil tenfold, and increased the maximum plasma levels fourfold. Although not specifically studied, **itraconazole** is expected to cause similar rises in vardenafil levels.[6,7]

Mechanism

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Ketoconazole and itraconazole are potent inhibitors of this isoenzyme, and therefore they inhibit sildenafil, tadalafil and vardenafil metabolism, which leads to an increase in their levels.

Importance and management

Information about the interaction between phosphodiesterase type-5 inhibitors and azoles is sparse, but what is known is in line with the predicted effects.

For **sildenafil**, when used for erectile dysfunction, the manufacturers recommend that a low starting dose of sildenafil (25 mg) should be considered if ketoconazole or itraconazole are used concurrently.[1,2] When used for pulmonary hypertension, the manufacturers say that concurrent use of sildenafil with ketoconazole or itraconazole is contraindicated in the UK,[8] or not recommended in the US.[9]

For **tadalafil**, the UK manufacturer advises caution[4] and the US manufacturer advises that the 'as needed' dose of tadalafil should not exceed 10 mg in a 72-hour period, and that the daily dose should not exceed 2.5 mg daily for patients taking potent CYP3A4 inhibitors such as ketoconazole.[5] However, note that the 10 mg dose has caused priapism in one patient taking itraconazole.

Vardenafil levels are greatly increased by ketoconazole and probably itraconazole so the UK manufacturer advises avoiding concurrent use in all patients. The use of ketoconazole or itraconazole in patients over 75 years of age is specifically contraindicated with vardenafil.[6] In contrast, the US manufacturer recommends that the dose of vardenafil should not exceed 5 mg in 24 hours when used with ketoconazole or itraconazole 200 mg daily, or 2.5-mg in 24 hours with ketoconazole or itraconazole 400 mg daily.[7]

For all three phosphodiesterase type-5 inhibitors, similar advice would apply to **posaconazole** and **voriconazole**, which are both also potent inhibitors of CYP3A4.

Phosphodiesterase type-5 inhibitors + CYP3A4 inducers

Rifampicin (rifampin) markedly reduces tadalafil levels by inducing CYP3A4, and is predicted to interact similarly with sildenafil and vardenafil. Other CYP3A4 inducers are likely to have a similar effect on these phosphodiesterase type-5 inhibitors.

Clinical evidence

(a) Sildenafil

On the basis of the 63% reduction in AUC seen with the moderate CYP3A4 inducer 'bosentan', (p.1535), the US manufacturer of sildenafil says that concurrent use with potent inducers of CYP3A4 such as **rifampicin** (**rifampin**) is predicted to cause a greater reduction in sildenafil levels.[1]

(b) Tadalafil

A study[2,3] in 12 healthy subjects found that **rifampicin** (**rifampin**) 600 mg daily for 13 days markedly reduced the AUC of a single 10-mg dose of tadalafil by 88%.

Mechanism

Rifampicin (rifampin) induces the activity of the cytochrome P450 isoenzyme CYP3A4, the principal enzyme concerned with the metabolism of sildenafil, tadalafil and **vardenafil**.

Importance and management

The pharmacokinetic interaction between rifampicin (rifampin) and tadalafil is established, and will almost certainly occur with sildenafil and vardenafil. It is unlikely that standard doses of these phosphodiesterase type-5 inhibitors would be as effective as usual in patients taking rifampicin. The manufacturers predict that other CYP3A4 inducers such as **carbamazepine**,[2-4] **phenobarbital**,[2-4] **phenytoin**,[2-4] and **St John's wort**[4] will interact similarly. Despite the marked interaction, the US manufacturer of tadalafil states that no dosage adjustment is warranted, although they do say that reduced efficacy of once-daily tadalafil is anticipated.[3] Conversely, the UK manufacturers of sildenafil state that efficacy should be closely monitored in patients taking CYP3A4 inducers.[4] If these phosphodiesterase type-5 inhibitors are not effective in a patients taking a CYP3A4 inducer, it would seem sensible to try a higher dose with close monitoring.

Although the manufacturer of **vardenafil** does not mention CYP3A4 inducers,[5,6] like tadalafil and sildenafil, vardenafil is principally metabolised by CYP3A4, and its levels are markedly raised by CYP3A4 inhibitors such as ketoconazole (see 'Phosphodiesterase type-5 inhibitors + Azoles', p.1534). It is therefore very likely that vardenafil levels will be reduced by potent CYP3A4 inducers such as rifampicin, and concurrent use should be monitored. For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

Phosphodiesterase type-5 inhibitors + Drugs that prolong the QT interval

Vardenafil caused a small increase in QTc interval, which was additive with that of gatifloxacin. This suggests that vardenafil may also have this effect with other drugs that prolong the QT interval. Tadalafil, and probably sildenafil, have no clinically relevant effect on the QT interval.

Clinical evidence

(a) Sildenafil

Sildenafil 50 mg caused a small 6 millisecond increase in the QTc interval in healthy subjects.[1] This increase was slightly smaller than that seen with a single 400-mg dose of moxifloxacin (8 milliseconds) used as a positive control.[1] No change in QT interval with sildenafil 50 mg was reported in other studies.[2,3]

(b) Tadalafil

In a well-designed study in healthy subjects, tadalafil 100 mg (five times the usual recommended dose) caused a 3.5 millisecond increase in the QTc. The positive control used in this study was intravenous ibutilide 2 micrograms/kg, which caused a 8.9 millisecond increase in QTc interval (individual) (9.5 milliseconds, Fridericia) compared with placebo. No subject had a QTc greater than 450 milliseconds and no subject had an increase in QTc of greater than 30 milliseconds.[4]

(c) Vardenafil

Vardenafil 10 mg and 80 mg caused small (8 millisecond and 10 millisecond, respectively) increases in the QTc interval in healthy subjects.[1] These increases were similar to that seen with a single 400-mg dose of moxifloxacin (8 milliseconds) used as a positive control.[1]

In another study in 44 healthy subjects, a single 10-mg dose of vardenafil caused a mean increase from baseline in QTc of 5 milliseconds when compared with placebo. A single 400-mg dose of gatifloxacin increased the QTc by 4 milliseconds. The effect of the combination of vardenafil and gatifloxacin was additive, resulting in a 9 millisecond increase in QTc.[5]

Mechanism

The effects of drugs that prolong the QT interval are expected to be additive, as was seen with vardenafil and gatifloxacin. Prolongation of the QT interval is associated with an increased risk of the potentially fatal torsade de pointes arrhythmia (see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290).

Importance and management

On the basis of what is currently known, the proarrhythmic risk of drugs that prolong the QTc interval by around 5 to less than 20 milliseconds is inconclusive. Vardenafil fits in this category. The manufacturers of vardenafil recommend that the possible increase in QT interval should be taken into account when prescribing vardenafil to patients with a known history of QT prolongation or using other drugs known to prolong the QT interval. Moreover, they say that vardenafil should not be used in those taking class Ia antiarrhythmics (e.g. **quinidine**, **procainamide**) or class III antiarrhythmics (e.g. **amiodarone**, **sotalol**), which are known to significantly prolong the QT interval.[5,6]

Regulatory guidance for the assessment of risk of a non-antiarrhythmic drug states that drugs causing an increase in mean QT/QTc interval of around 5 milliseconds or less do not appear to cause torsade de pointes. Tadalafil clearly fits in this category, and no special precautions are therefore required. Sildenafil probably also fits in this category.

There do not appear to be any published reports of torsade de pointes with any of these phosphodiesterase type-5 inhibitors.

For a full list of class Ia and class III antiarrhythmics, and for further information on regulatory guidance concerning QT prolongation, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Phosphodiesterase type-5 inhibitors + Endothelin receptor antagonists

Bosentan markedly reduces sildenafil levels and modestly reduces tadalafil levels. Bosentan levels are modestly reduced by sildenafil, and are not affected to a clinically relevant extent by tadalafil. No clinically significant pharmacokinetic interaction occurs between ambrisentan and sildenafil or tadalafil.

Clinical evidence

(a) Ambrisentan

1. Sildenafil. A crossover study in 19 healthy subjects found that sildenafil 20 mg three times daily for 7 days had no clinically significant effect on the pharmacokinetics of a single 10-mg dose of ambrisentan. Ambrisentan 10 mg daily for 7 days slightly increased the maximum concentration of a single 20-mg dose of sildenafil by 13%; however, this is not considered to be clinically relevant. Ambrisentan had no significant effects on other pharmacokinetic parameters of sildenafil. No serious adverse effects were reported, although headache was common and no additive or synergistic reduction in blood pressure was noted.[1]

2. Tadalafil. In a crossover study in 23 healthy subjects, tadalafil 40 mg daily for 8 days slightly decreased AUC of a single 10-mg dose of ambrisentan given on day 6, by about 12%. Peak plasma levels of ambrisentan were similar in the presence and absence of tadalafil. The pharmacokinetics of tadalafil were not affected by concurrent use with ambrisentan.[2]

(b) Bosentan

1. Sildenafil. In 10 patients with pulmonary hypertension, bosentan 62.5 mg twice daily for one month decreased the AUC of a single 100-mg dose of sildenafil by 53% and increased its clearance 2.3-fold. After a second month of bosentan at an increased dose of 125 mg twice daily, the AUC of a single 100-mg dose of sildenafil was reduced by 69%, and the clearance increased 3.4-fold. The AUC of the primary metabolite, desmethyl-sildenafil, was also decreased in a dose-dependent manner by bosentan.[3] In a further well-controlled study in healthy subjects, the concurrent use of bosentan 125 mg twice daily and sildenafil 80 mg three times daily for 6 days decreased the AUC of sildenafil by 63% and increased the AUC of bosentan by 50%, when compared with either drug given alone.[4]

2. Tadalafil. In a well-controlled study in healthy subjects, the concurrent use of tadalafil 40 mg once daily and bosentan 125 mg twice daily for 10 days decreased the AUC of tadalafil by 41% and increased the AUC of bosentan by just 13%, which was not statistically significant.[5]

(c) Sitaxentan

The AUC and maximum concentration of a single 100-mg dose of **sildenafil** were increased by 28% and 18%, respectively, by sitaxentan; these changes are not expected to be clinically relevant. Furthermore, sitaxentan did not alter the pharmacokinetics of the active metabolite of **sildenafil**.[3]

Mechanism

Bosentan induces the cytochrome P450 isoenzyme CYP3A4, by which sildenafil and tadalafil are principally metabolised. The mechanism by which sildenafil increases bosentan levels is unknown, but might, in part, involve inhibition of organic anion transporting polypeptides (OATP).[6]

Importance and management

These pharmacokinetic interactions are established and potentially clinically important. The efficacy of sildenafil and tadalafil might be reduced in patients taking bosentan, and should be closely monitored. Sildenafil might increase the effects of bosentan, therefore patients should be monitored for signs of bosentan adverse effects such as flushing, headache and oedema. Tadalafil is unlikely to have this effect.

No dose adjustment of either drug is required on the concurrent use of ambrisentan with either sildenafil or tadalafil, and the dose of sildenafil does not need to be adjusted if sitaxentan is also given.

Phosphodiesterase type-5 inhibitors + Grapefruit juice

Grapefruit juice slightly increases the absorption of sildenafil. Tadalafil and vardenafil are predicted to be similarly affected.

Clinical evidence, mechanism, importance and management

Grapefruit juice 250 mL was given to 24 healthy subjects, both one hour before and with a 50-mg dose of **sildenafil**. There was a minor 23% increase in the AUC of **sildenafil**, but the maximum plasma level was not significantly changed. Inter-individual variation in **sildenafil** pharmacokinetics was also increased by grapefruit juice. The authors suggest that, although the slight rise in AUC is unlikely to be clinically significant, the combination is best avoided due to the increased variability in **sildenafil** pharmacokinetics.[1] However, this seems over-cautious, especially because the manufacturer permits reduced doses of **sildenafil** with much more potent inhibitors of CYP3A4, such as itraconazole, see 'Phosphodiesterase type-5 inhibitors + Azoles', p.1534.

The manufacturers of **tadalafil** predict that grapefruit juice will increase its levels[2,3] and the UK manufacturer advises caution with concurrent use.[2]

The manufacturers of **vardenafil** also predict that grapefruit juice will modestly increase its levels[4,5] and the UK advice is to avoid the combination.[4]

Phosphodiesterase type-5 inhibitors + H_2-receptor antagonists

Sildenafil levels are modestly raised by cimetidine. No interaction appears to occur when nizatidine is given with tadalafil and when cimetidine or ranitidine is given with vardenafil.

Clinical evidence, mechanism, importance and management

(a) Sildenafil

In a study in 10 healthy subjects, **cimetidine** 800 mg daily for 4 days increased the AUC of a single 50-mg dose of sildenafil given on day 3 by 56%, when compared with 10 healthy subjects given sildenafil and placebo.[1] It has been suggested that these changes occur because **cimetidine** is a non-specific cytochrome P450 inhibitor.[2] The manufacturers say that population pharmacokinetic analysis revealed a reduced clearance of sildenafil in patients taking CYP3A4 inhibitors, including **cimetidine**.[2,3] The UK manufacturers say that, although no increase in adverse effects was seen, a starting dose of 25 mg of sildenafil should be considered.[3] However, the study suggests the effect is modest, and so this recommendation seems over-cautious. Furthermore, the US manufacturer dose not advise a sildenafil dose reduction in those taking **cimetidine**.[2]

(b) Tadalafil

A randomised, crossover study in 12 healthy subjects found that **nizatidine** 300 mg reduced the mean maximum serum levels of a single 10-mg dose of tadalafil by 14%, but other pharmacokinetic parameters, including the extent of absorption, were largely unchanged. None of the changes caused were considered to be clinically relevant and there would appear to be no reason for avoiding concurrent use.[4] This study also suggests that any alterations in the absorption of tadalafil are therefore unlikely to be caused by changes in gastric pH.[4]

(c) Vardenafil

In a crossover study, 10 healthy subjects were given a single 20-mg dose of vardenafil after they had taken **cimetidine** 400 mg twice daily for 3 days, **ranitidine** 150 mg twice daily for 3 days or with no pre-treatment. **Cimetidine** slightly increased the relative bioavailability of vardenafil (by

about 12%, not considered clinically relevant), while **ranitidine** had no effect. It was concluded that any alterations in the absorption of vardenafil are not caused by changes in gastric pH.[5] No special precautions appear to be necessary during concurrent use.

Phosphodiesterase type-5 inhibitors + Macrolides

Erythromycin raises sildenafil levels almost threefold, raises vardenafil levels fourfold, and is predicted to similarly affect tadalafil levels. Clarithromycin, but not azithromycin, raises sildenafil levels about twofold and is predicted to increase tadalafil and vardenafil levels.

Clinical evidence

(a) Sildenafil

In a study in 24 healthy subjects, **erythromycin** 500 mg twice daily for 5 days was found to increase the AUC of a single 100-mg dose of sildenafil almost threefold.[1] In the same study, **azithromycin** 500 mg once daily for 3 days had no effect on the pharmacokinetics of sildenafil.[1] In another study, in 12 healthy subjects, **clarithromycin** 500 mg increased the AUC of sildenafil 50 mg 2.3-fold, and increased its maximum level 2.4-fold.[2]

(b) Tadalafil

Ketoconazole doubles tadalafil levels by inhibiting CYP3A4 (see 'Phosphodiesterase type-5 inhibitors + Azoles', p.1534). The manufacturers therefore predict that other CYP3A4 inhibitors such as **erythromycin** and **clarithromycin**[3,4] will interact similarly.

(c) Vardenafil

Erythromycin 500 mg three times daily increased the AUC of a 5-mg dose of vardenafil fourfold, and increased its maximum plasma levels threefold in healthy subjects.[5,6]

Mechanism

Sildenafil, tadalafil and vardenafil are all metabolised by the cytochrome P450 isoenzyme CYP3A4. Many macrolides are moderate inhibitors of this isoenzyme and therefore inhibit sildenafil, tadalafil and vardenafil metabolism. This leads to increased levels of the phosphodiesterase inhibitors. Azithromycin does not usually act as a CYP3A4 inhibitor and therefore does not interact.

Importance and management

The pharmacokinetic interaction of the macrolides with the phosphodiesterase type-5 inhibitors is established, although most of the studies concern the use of sildenafil. These interactions are expected to result in both increased efficacy and an increased incidence of adverse effects.

For **sildenafil**, the manufacturers recommend that a low starting dose of sildenafil 25 mg should be considered in patients with erectile dysfunction taking CYP3A4 inhibitors such as erythromycin.[7,8] For pulmonary hypertension, the UK manufacturer says that a reduction of the sildenafil dose to 20 mg twice daily should be considered with erythromycin, and 20 mg daily with clarithromycin or **telithromycin**,[9] although note that erythromycin had a greater effect than clarithromycin in the studies above.

For **tadalafil**, the UK manufacturer advises caution if CYP3A4 inhibitors are also given as adverse effects may be increased in some patients. They specifically mention erythromycin and clarithromycin.[3]

For **vardenafil**, the UK manufacturer says that dosage adjustments might be necessary in patients taking erythromycin or clarithromycin, and recommend that the dose of vardenafil should not exceed 5 mg.[5] The US manufacturer similarly recommends that the dose of vardenafil should not exceed 5 mg in 24 hours for erythromycin, but further restricts the dose in the presence of clarithromycin, to 2.5 mg in 24 hours.[6]

Dosing guidance is not given for the other macrolides, but it would seem prudent to follow the advice given for erythromycin in patients taking any macrolide known to inhibit CYP3A4 (e.g. clarithromycin, **telithromycin**). Azithromycin seems unlikely to interact.

Phosphodiesterase type-5 inhibitors + Miscellaneous

No pharmacokinetic interaction appears to occur between sildenafil and an oral combined hormonal contraceptive, whereas tadalafil slightly increases the bioavailability of ethinylestradiol from an oral combined hormonal contraceptive. Sildenafil does not alter the pharmacokinetics of tolbutamide.

Clinical evidence, mechanism, importance and management

(a) Hormonal contraceptives

The pharmacokinetics of **sildenafil** were not altered by concurrent use of an oral combined hormonal contraceptive (**ethinylestradiol/levonorgestrel**), and the plasma levels of these contraceptive steroids were not altered by sildenafil.[1,2]

In contrast, use of **tadalafil** 10 mg with an oral combined hormonal contraceptive (**ethinylestradiol/levonorgestrel**) increased the steady-state AUC of **ethinylestradiol** by 18% and its maximum level by 53%, with no change in systemic clearance.[3,4] The mechanism for this is unknown.[4] The pharmacokinetics of **levonorgestrel** were not affected. There were no changes in levels of LH, FSH, and progesterone, which suggests that the pharmacokinetic changes with **ethinylestradiol** are unlikely to be clinically relevant.

(b) Tolbutamide

Sildenafil 50 mg did not alter the pharmacokinetics of tolbutamide 250 mg,[5,6] probably because sildenafil is only a weak inhibitor of the cytochrome P450 isoenzyme CYP2C9 by which tolbutamide is metabolised. This is in line with the way other CYP2C9 substrates behave, see *warfarin*, under 'Coumarins + Phosphodiesterase type-5 inhibitors', p.496.

Phosphodiesterase type-5 inhibitors + Nitrates

Phosphodiesterase type-5 inhibitors potentiate the hypotensive effects of nitrates in a proportion of patients, which might result in potentially serious hypotension or even precipitate myocardial infarction. Therefore, the concurrent use of sildenafil, tadalafil or vardenafil with organic nitrates (glyceryl trinitrate (nitroglycerin), isosorbide dinitrate, isosorbide mononitrate, sodium nitroprusside, etc.) is contraindicated. The concurrent use of nicorandil and all phosphodiesterase type-5 inhibitors is also contraindicated.

Clinical evidence

(a) Sildenafil

Two double-blind, placebo-controlled studies in groups of 15 or 16 men with angina found that the fall in blood pressure seen when taking nitrates

was approximately doubled by a single 50-mg dose of sildenafil. Those given sildenafil and **isosorbide dinitrate** 20 mg twice daily had a mean blood pressure fall of 44/26 mmHg, compared with 22/13 mmHg with placebo. Those who used 500 micrograms of sublingual **glyceryl trinitrate** (**nitroglycerin**) one hour before the sildenafil had a mean blood pressure fall of 36/21 mmHg compared with 26/11 mmHg with **glyceryl trinitrate** and placebo. Individual blood pressure falls as great as 84/52 mmHg were seen.[1]

A postmarketing report from the FDA in the US for the period late March to July 1998 briefly lists 69 fatalities in patients who had taken sildenafil. These were mostly in middle-aged and elderly men (average age 64 years), 12 of whom had also taken **glyceryl trinitrate** or a nitrate medication, but it is not clear what part (if any) the nitrates played in the deaths.[2]

In a limited and preliminary study it was reported that no blood pressure alteration was seen when a small dose of **glyceryl trinitrate** (amount not specified) was given as a dermal patch while subjects were taking 50 mg of sildenafil. In addition, the beneficial effects of the **glyceryl trinitrate** on the radial artery pressure waveform were approximately doubled, and persisted for up to 8 hours.[3]

A placebo-controlled, randomised study in 32 men with stable coronary artery disease suggested that, 45 minutes after a single 100-mg dose of sildenafil had been given, it was possible to cautiously give intravenous **glyceryl trinitrate**, starting at a low dose and slowly increasing to a maximum of 160 micrograms/minute. Sildenafil caused an additional reduction in blood pressure of about 4 to 6 mmHg, when compared with placebo. In general, when compared with placebo, the dose of nitrate tolerated was lower, and despite this, hypotension was more common, in the presence of sildenafil.[4]

(b) Tadalafil

In a randomised, placebo-controlled study, 51 patients with chronic stable angina were given tadalafil 5 mg, 10 mg or a placebo, followed 2 hours later by a single 400-microgram dose of sublingual **glyceryl trinitrate**. Although tadalafil caused little additional decrease in blood pressure to that seen with **glyceryl trinitrate**, a potentially clinically significant blood pressure reduction (standing systolic BP less than 85 mmHg) was seen in 13 and 11 of the patients when given tadalafil 5 and 10 mg, respectively, compared with one patient in the placebo group.[5,6] In a similar study in 45 patients taking long-term oral **isosorbide mononitrate**, tadalafil 5 or 10 mg had minimal effects on the decrease in blood pressure caused by the nitrate, but again, more patients had a standing systolic BP of less than 85 mmHg when receiving tadalafil 10 mg than placebo (6 versus 0).[5,6] Another similar study in 48 healthy subjects compared the effects of tadalafil 10 mg, sildenafil 50 mg, and placebo, in combination with sublingual **glyceryl trinitrate** 400 micrograms. Again, it was found that the presence of the tadalafil had minimal effects on the mean maximum decreases in blood pressure, but it was noted that 23 patients given tadalafil and 23 given sildenafil had a standing systolic blood pressure of 85 mmHg or less following the use of the nitrate, compared with 12 in the placebo group.[6,7] In a further study, a haemodynamic interaction between tadalafil 20 mg and sublingual **glyceryl trinitrate** was seen when the **glyceryl trinitrate** was given 4, 8 and 24 hours after the tadalafil, and was not seen at 48 hours and beyond. Note that no time points between 24 and 48 hours were examined.[8]

An analysis of the rates of serious cardiovascular adverse events (mortality, myocardial infarction, thrombotic strokes) in clinical studies involving tadalafil indicated that adverse events were no more frequent than in the general population of men with erectile dysfunction.[6]

(c) Vardenafil

A single 400-microgram dose of sublingual **glyceryl trinitrate** (**nitroglycerin**) given to 18 healthy subjects 1 to 24 hours after a single 10-mg dose of vardenafil was found to be no different to placebo in causing changes in seated heart rate and blood pressure.[9,10] However, a single 20-mg dose of vardenafil did potentiate the blood pressure-lowering effects and increases in heart rate (about an 8 mmHg additional drop in systolic BP compared with placebo) seen with **sublingual nitrates** (400 micrograms) taken 1 and 4 hours after the vardenafil. These effects were not seen when the nitrate was taken 24 hours after the vardenafil dose.[9,11]

Mechanism

Sexual stimulation causes the endothelium of the penis to release nitric oxide (NO), which in turn activates guanylate cyclase to increase the production of cyclic guanosine monophosphate (cGMP). This relaxes the blood vessel musculature of the corpus cavernosum thus allowing it to fill with blood and cause an erection. The erection ends when the guanosine monophosphate is removed by an enzyme (type 5 cGMP phosphodiesterase, or PDE5). Sildenafil, tadalafil and vardenafil inhibit this enzyme thereby increasing and prolonging the effects of the cyclic guanosine monophosphate. Because this vasodilation is usually fairly localised (these drugs are highly selective for PDE5) it normally only causes mild to moderate falls in blood pressure (on average about 10 mmHg) with mild headache or flushing. Nitrates (e.g. glyceryl trinitrate) increase the production of cyclic guanosine monophosphate, and when phosphodiesterase type-5 inhibitors (PDE5 inhibitors) are taken concurrently, cyclic guanosine monophosphate accumulates and high levels of nitric oxide enter the circulation. This markedly increases systemic vasodilation and hence causes the hypotensive effect.

Importance and management

The interaction between phosphodiesterase type-5 inhibitors and nitrates is established, clinically important, potentially serious and even possibly fatal. Sildenafil and organic nitrates of any form are contraindicated both for erectile dysfunction[12,13] (within 24 hours of each other[14]) and for pulmonary hypertension[15,16] because of the risk of precipitating serious hypotension, or even myocardial infarction.[17] The ACC/AHA Expert consensus document provides a useful list of many of the organic nitrates available, which include glyceryl trinitrate (nitroglycerin), isosorbide mononitrate, isosorbide dinitrate, '**sodium nitroprusside**', (p.1075), and illicit substances such as **amyl nitrite**.[14] However, the use of some nitrate donors may be beneficial, see 'Phosphodiesterase type-5 inhibitors; Sildenafil + Nitric oxide', p.1541.

The manufacturers of vardenafil[9,11] and tadalafil[18,19] say that their combination with nitrates (taken either regularly and/or intermittently) is contraindicated. Nitrates should not be given for at least 48 hours after the last dose of tadalafil because this has a long elimination half-life.[18,19]

If patients develop angina during sexual activity after taking a phosphodiesterase type-5 inhibitor they should discontinue sexual activity, relax for 5 to 10 minutes, and if the pain persists seek emergency care, informing medical personnel that they have taken a phosphodiesterase type-5 inhibitor. In the event of myocardial infarction, usual therapies can be given, with the exception of organic nitrates.[20] Note that, in the study where glyceryl trinitrate infusions were successfully given to patients who had taken sildenafil, the patients had stable heart disease, and the suggestion of this being a usable combination may not be applicable to patients experiencing episodes of acute cardiac disease.

There is no known antidote to the phosphodiesterase type-5 interaction with nitrates. Important hypotension should be managed by placing the patient in the Trendelenburg position (that is, laid flat on their back, with their feet higher than their head) and giving intravenous fluids and alpha agonists such as phenylephrine. It has also been suggested that, if hypotension is refractory, intra-aortic balloon counterpulsation should be used.[20]

It is not yet known whether **nicorandil** interacts with the phosphodiesterase inhibitors to a clinically relevant extent or not,[21] but because part of its vasodilatory actions are mediated by the release of nitric oxide (like conventional nitrates), the manufacturers of nicorandil contraindicate its use with all phosphodiesterase inhibitors.[22]

Phosphodiesterase type-5 inhibitors + Protease inhibitors

Indinavir, saquinavir and ritonavir can cause marked rises in serum sildenafil levels. A fatal heart attack occurred in a man taking ritonavir and saquinavir when he also took sildenafil. Even more marked rises in serum levels occur with vardenafil and indinavir or ritonavir, and are predicted to occur with vardenafil and other protease inhibitors. Ritonavir and ritonavir-boosted tipranavir cause less marked increases in tadalafil levels.

Clinical evidence

A. Sildenafil

(a) Indinavir

A study in 6 HIV-positive patients found that sildenafil 25 mg did not significantly alter the plasma levels of indinavir. However, the sildenafil AUC was about 4.4-fold higher than the AUC in historical control patients taking sildenafil (data normalised to a 25 mg dose) without indinavir.[1] A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of indinavir.[2]

(b) Nelfinavir

A study in 5 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of nelfinavir.[2]

(c) Ritonavir

In a randomised, placebo-controlled study, 28 healthy subjects were given sildenafil 100 mg before and after taking ritonavir for 7 days (300 mg, 400 mg and 500 mg twice daily on days 1, 2 and 3 to 7, respectively). It was found that the AUC of sildenafil was increased 11-fold and its maximum serum levels were increased 3.9-fold by ritonavir, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of ritonavir remained unchanged.[3] However, the clinical significance of this interaction is highlighted by a case report of a 47-year-old man, with no cardiovascular risk factors apart from smoking, who had a myocardial infarction when he took sildenafil 25 mg while he was also taking ritonavir 400 mg twice daily and **saquinavir** 400 mg twice daily. One hour after the ninth dose (used over the previous 12 weeks), he had an onset of severe chest pain, and died about one day later.[4]

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of ritonavir (given with saquinavir).[2]

(d) Saquinavir

In a randomised, placebo-controlled study, 28 healthy subjects were given sildenafil 100 mg before and after taking saquinavir 1.2 g three times daily for 7 days. It was found that the sildenafil AUC was increased 3.1-fold and its maximum serum levels were increased 2.4-fold, but the incidence and severity of the sildenafil adverse effects and the steady-state levels of saquinavir remained unchanged.[3] Also see *Ritonavir*, above for a case report of a fatal interaction involving sildenafil, ritonavir and saquinavir.

A study in 2 HIV-positive patients found that sildenafil 25 mg did not affect the pharmacokinetics of ritonavir-boosted saquinavir.[2]

B. Tadalafil

(a) Ritonavir

Ritonavir 200 mg twice daily increased the AUC of a single 20-mg dose of tadalafil twofold (124%), without affecting its maximum serum levels.[5,6]

(b) Tipranavir

In a study in healthy subjects, the first dose of ritonavir-boosted tipranavir initially increased the AUC of tadalafil from a single-dose by 2.3-fold. However steady-state levels of ritonavir-boosted tipranavir had no significant effect on tadalafil exposure.[7,8]

C. Vardenafil

When a single 10-mg dose of vardenafil was given with **indinavir** 800 mg three times daily, the AUC of vardenafil was increased 16-fold, and its maximum plasma level was increased sevenfold.[9,10] Moreover, **ritonavir** 600 mg twice daily produced a 49-fold increase in the AUC of vardenafil, and prolonged the half-life to 26 hours.[10]

Mechanism

Protease inhibitors inhibit the activity of the cytochrome P450 isoenzyme CYP3A4, the enzyme that metabolises sildenafil, tadalafil and vardenafil. This results in an increase in their serum levels. Ritonavir is the most potent CYP3A4 inhibitor, followed by indinavir, nelfinavir, amprenavir, and then saquinavir, see 'Antivirals', (p.913)).

Importance and management

Information about interactions between phosphodiesterase type-5 inhibitors and protease inhibitors appears to be limited to the studies and case cited, but the interactions are established and of clinical importance.

For **sildenafil**, because of the very marked rises in levels, the concurrent use of ritonavir and sildenafil for pulmonary hypertension is not advised,[11] or in the UK, contraindicated.[12] When single doses of sildenafil are used for erectile dysfunction, the UK manufacturer also says concurrent use with ritonavir is not advised.[13] In this situation, if the decision is taken to use sildenafil in a patient taking ritonavir, the dose of sildenafil should not exceed a single 25-mg dose in a 48-hour period,[3,13,14] but note that the fatality described above[4] occurred despite the use of this dose. For other CYP3A4 inhibitors such as saquinavir, the recommendation for erectile dysfunction is that a low starting dose (25 mg) should be considered.[3,13,14] For pulmonary hypertension, the UK manufacturer says that a downward reduction of the sildenafil dose to 20 mg twice daily should be considered with saquinavir.[12] The authors of the indinavir study suggest that a starting dose of 12.5 mg may be more appropriate for erectile dysfunction in those taking indinavir, and that the maximum dosage frequency should be reduced to once or twice weekly.[1] Direct evidence for other protease inhibitors is lacking but they would be expected to interact similarly (see *Mechanism*, above) and it would seem consistent to follow the broad principle of starting with a low sildenafil dosage.

For **tadalafil**, the US manufacturer advises that the 'as needed' dose should not exceed 10 mg every 72 hours and the daily dose should not exceed 2.5 mg daily in patients taking ritonavir,[5] whereas the UK manufacturer simply advises caution on concurrent use.[6] It is probably prudent to apply this advice to patients taking any protease inhibitor.

For **vardenafil**, due to the very large rises in levels, the UK manufacturer contraindicates its use with protease inhibitors that are potent CYP3A4 inhibitors (they name ritonavir and indinavir).[9] In contrast, the US manufacturer recommends dose restrictions as follows: the dose of vardenafil should not exceed 2.5 mg in 24 hours when used with **atazanavir**, indinavir, or saquinavir, and should not exceed 2.5 mg in 72 hours when used with ritonavir.[10] The manufacturer of tipranavir also advises that the maximum dose of vardenafil should not exceed 2.5 mg in 72 hours.[8]

Phosphodiesterase type-5 inhibitors; Sildenafil + Antidepressants

Retrospective analysis of clinical study data suggested that SSRIs and tricyclic antidepressants did not alter sildenafil pharmacokinetics. However, in one pharmacokinetic study, fluvoxamine was found to modestly increase the levels and vascular effects of sildenafil.

Clinical evidence

The manufacturer notes that population pharmacokinetic analysis of clinical study data indicate that inhibitors of cytochrome P450 isoenzyme CYP2D6 such as **SSRIs** and **tricyclic antidepressants** do not have any effect on the pharmacokinetics of sildenafil.[1,2] However, in a placebo-controlled study in healthy subjects, pre-treatment with **fluvoxamine** 50 mg daily for 3 days then 100 mg daily for 6 days increased the AUC of sildenafil 50 mg by 40%. This resulted in an increase in the vascular effects of sildenafil.[3]

Mechanism

Sildenafil is principally metabolised by the cytochrome P450 isoenzyme CYP3A4, and to a lesser extent by CYP2C9. Fluvoxamine probably raises sildenafil levels by inhibition of both of these isoenzymes. Grouping all SSRIs and tricyclics together in a retrospective analysis would not be a sensitive enough technique to have picked up this modest effect of fluvoxamine.

Importance and management

The increases in sildenafil levels with fluvoxamine are modest, and the authors concluded that they do not suggest a large clinically relevant interaction. Nevertheless, they suggest it may be prudent to consider a 25-mg starting dose of sildenafil in patients taking fluvoxamine.[3] This may be sensible. Although retrospective analyses of clinical study data are useful to identify potentially important drug interactions, they are not sensitive enough to rule out interactions, and should not replace prospective pharmacokinetic studies.

Sildenafil + Cannabis

Myocardial infarction occurred in a man who had smoked cannabis and taken a tablet of sildenafil.

Clinical evidence

A 41-year old man with no history of cardiac disease experienced a myocardial infarction after smoking cannabis and recreationally taking a tablet of sildenafil (strength not specified). Later tests showed that he had no evidence of inducible ischaemia.[1]

Mechanism

Myocardial infarction is a rare adverse effect of sildenafil alone. It was suggested that the metabolism of sildenafil by cytochrome P450 isoenzyme CYP3A4 might be inhibited by constituents of cannabis such as cannabidiol, thereby increasing the risk of adverse events. However, in clinical studies, oral cannabis did not alter levels of other CYP3A4 substrates.

Importance and management

The vasodilatory effects of sildenafil necessitate caution in its use in patients with cardiovascular disease; myocardial infarction has rarely been associated with its use. The contribution of an interaction to this case is unclear, but bear the possibility in mind in the event of adverse effects on concurrent use.

Phosphodiesterase type-5 inhibitors; Sildenafil + Cocaine

An isolated report describes acute aortic dissection possibly associated with the use of cocaine and sildenafil.

Clinical evidence, mechanism, importance and management

A 42-year-old man developed chest pain radiating to his back 2 hours after sniffing cocaine and one hour after taking sildenafil 50 mg. The chest pain subsided spontaneously but he developed severe pain in his right groin and leg and became pale and sweaty. His blood pressure and heart rate were increased (160/100 mmHg and 92 bpm, respectively), his respiration rate was 16 breaths/minute, and an ECG showed occasional isolated ventricular beats. A CT scan and transoesophageal cardiac ultrasonography revealed an aortic dissection in the descending aorta. He was closely monitored and given intravenous glyceryl trinitrate, labetalol, metoprolol, captopril and ranitidine, but died 12 days later.[1]

Cardiovascular complications including aortic dissection have been reported with cocaine.[1] There is also an isolated report of aortic dissection after sildenafil use, in a patient who was taking a number of other medicines including isosorbide mononitrate.[2] It was suggested that acute dssection in the reported case probably coincided with expected peak levels of sildenafil, but after the time period of 30 minutes when the cardiovascular effects of cocaine usually occur. However, the patient's heavy smoking and hypertension may also be factors in this case. It was further suggested that, in cases where acute aortic dissection is associated with cocaine, vasodilatation due to concurrent sildenafil could reduce organ perfusion and aggravate injury due to hypovolaemia and ischaemia.[1]

This is an isolated case, and it is not clear if it is generally applicable.

Phosphodiesterase type-5 inhibitors; Sildenafil + Dihydrocodeine

Two men using sildenafil had prolonged erections following orgasm while also taking dihydrocodeine.

Clinical evidence, mechanism, importance and management

Two men, successfully using 100-mg doses of sildenafil for erectile dysfunction, experienced prolonged erections after orgasm while also taking dihydrocodeine 30 to 60 mg every 6 hours for soft tissue injuries. One of them had two erections lasting 4 hours and 5 hours, and this did not occur on subsequent occasions when the dihydrocodeine was stopped. The other had 2- to 3-hour erections on three occasions during the first week of dihydrocodeine use, but no problems over the next 2 weeks while continuing to take the dihydrocodeine.[1] The reasons are not understood.

Priapism associated with sildenafil use is rare, and there appear to be no other reports about an interaction between sildenafil and dihydrocodeine. Excessively prolonged erections can have serious consequences, and patients are advised to seek immediate medical assistance in the event of an erection lasting longer than 4 hours.

Phosphodiesterase type-5 inhibitors; Sildenafil + Ecstasy

The abuse of sildenafil and ecstasy (MDMA, methylenedioxymethamfetamine) has been reported to result in serious headache and priapism requiring emergency treatment.

Clinical evidence, mechanism, importance and management

A journalist's account, based purely on anecdotal reports, claims that the illicit use of sildenafil with ecstasy (MDMA, methylenedioxymethamfetamine) causes "hammerheading" because of the pounding headache and the prolonged and painful penile erections that require emergency medical treatment.[1] The report does not say how much of each of these drugs is taken to produce these adverse effects. The outcome can clearly be unpleasant, painful and, the priapism, potentially serious.

Phosphodiesterase type-5 inhibitors; Sildenafil + Nitric oxide

The combination of sildenafil and inhaled nitric oxide might have beneficial effects in pulmonary hypertension, but systemic vasodilation and hypotension is possible.

Clinical evidence

In a study in 15 infants at risk of pulmonary hypertension after corrective cardiac surgery, the combined use of intravenous sildenafil and **inhaled nitric oxide** augmented the pulmonary vasodilator effects of inhaled nitric oxide. However, significant systemic hypotension occurred, which, along with a decrease in oxygenation, was considered sufficiently detrimental for the study to be stopped early.[1] Conversely, beneficial combined use has been described in adult patients with severe hypoxaemia caused by pulmonary hypertension: a few references are cited as examples.[2,3]

Mechanism

Patients with pulmonary arterial hypertension are thought to have deficiencies in endogenous nitric oxide. Inhaled nitric oxide is therefore used, and causes some pulmonary-specific vasodilatory effects. Phosphodiesterase type-5 inhibitors also increase the activity of endogenous nitric oxide by inhibiting the breakdown of cyclic guanosine monophosphate. When given in combination, sildenafil augments and prolongs the effects of inhaled nitric oxide, in the same way as other nitric oxide donors, see 'nitrates', (p.1537). Because sildenafil is not pulmonary specific, systemic vasodilation and hypotension is possible.

Importance and management

In contrast to the situation in erectile dysfunction, when the interaction between phosphodiesterase type-5 inhibitors and nitrates is unwanted and potentially serious, in pulmonary hypertension, the same pharmacodynamic interaction might prove to be clinically useful.[3] Nevertheless, a reduction in systemic blood pressure due to sildenafil might be detrimental, and could outweigh any benefits in some patient groups.[1] The manufacturer of a preparation of sildenafil licensed for treating pulmonary artery hypertension contraindicates its use with any nitric oxide donor.[4] Combined use should be considered experimental.

Note that **nitric oxide** is not to be confused with the anaesthetic **nitrous oxide**, which is not a nitric oxide donor.

Phosphodiesterase type-5 inhibitors; Vardenafil + Miscellaneous

No clinically relevant pharmacokinetic interaction has been seen between vardenafil and food, glibenclamide (glyburide), metformin or sulphonylureas.

Clinical evidence, mechanism, importance and management

(a) Antidiabetics

The manufacturers say that the pharmacokinetics of **glibenclamide** (**glyburide**) were not affected by a single 20-mg dose of vardenafil,[1] and that vardenafil had no effect on **glibenclamide** pharmacodynamics (glucose and insulin levels).[2] Also, although no specific pharmacokinetic study has been conducted, the manufacturers say that population pharmacokinetic analysis suggests that **sulphonylureas** (not named) and **metformin** have no effect on vardenafil pharmacokinetics.[1] No additional precautions therefore seem necessary on concurrent use.

(b) Food

In a single-dose study, healthy subjects were given vardenafil 20 mg on four occasions; after an overnight fast, on an empty stomach, following a **high-fat breakfast** (fat 58 g), or following a **moderate-fat evening meal** (fat 23 g). No vardenafil pharmacokinetic changes were noted in the fasting or moderate-fat periods. Although the **high-fat breakfast** caused a slight decrease and a slight delay in the absorption of vardenafil this was not considered to be sufficient to warrant changing the dosing time or making dosage adjustments. Therefore vardenafil may be given without regard to meals.[3]

Urinary antimuscarinics + CYP3A4 inhibitors; Moderate

Erythromycin and fluconazole caused a modest increase in darifenacin exposure. Other moderate CYP3A4 inhibitors are predicted to interact similarly, as is solifenacin. Moderate CYP3A4 inhibitors might also be expected to modestly increase the exposure of fesoterodine, tolterodine or oxybutynin.

Clinical evidence

The manufacturers note that, in a study in healthy subjects, **erythromycin** 500 mg daily increased the steady-state AUC of **darifenacin** 30 mg daily by 95%.[1-3]

Fluconazole 200 mg then 100 mg daily had a similar effect, causing an 84% increase in the steady-state AUC of **darifenacin** 30 mg daily.[1,2]

Mechanism

Erythromycin and fluconazole are moderate inhibitors of the cytochrome P450 isoenzyme CYP3A4, by which darifenacin is principally metabolised, leading to an increase in the levels of darifenacin. Note that fluconazole generally only inhibits CYP3A4 at doses greater than 200 mg. Solifenacin is also primarily metabolised by CYP3A4 and would be expected to interact similarly. Fesoterodine, oxybutynin and tolterodine are also metabolised by CYP3A4 and might also be expected to be inhibited by erythromycin and fluconazole: however, as they are also substrates for CYP2D6, they are likely to be less affected than darifenacin or solifenacin.

Importance and management

An established pharmacokinetic interaction. The clinical relevance of the increase in **darifenacin** levels with erythromycin has not been assessed. At present, the UK manufacturer[3] recommends an initial dose of darifenacin 7.5 mg daily in those taking moderate CYP3A4 inhibitors (such as erythromycin), increasing the dose to 15 mg daily if it is well tolerated, whereas the US manufacturer[1] says that dose adjustments are not required for moderate CYP3A4 inhibitors. Bear in mind the possibility of an interaction if antimuscarinic adverse effects (dry mouth, constipation, drowsiness) are increased.

Solifenacin is expected to interact similarly, and one manufacturer recommends caution with moderate CYP3A4 inhibitors.[4]

Other urinary antimuscarinics would be expected to interact to a lesser extent (see under *Mechanism*, above) and it appears unlikely that a clinically relevant interaction would occur in the majority of patients taking

fesoterodine, **tolterodine** or **oxybutynin** and given moderate CYP3A4 inhibitors. However, until more is known about the clinical outcome of concurrent use, it may be prudent to bear in mind the possibility of an interaction if an increase in antimuscarinic adverse effects (dry mouth, constipation, drowsiness) occurs. Some manufacturers make more specific recommendations. The manufacturers of **fesoterodine** caution the concurrent use of moderate CYP3A4 inhibitors: they recommend assessing the clinical response and tolerability of the recommended starting dose of 4 mg daily before increasing the dose to 8 mg daily.[5,6] Similarly, some manufacturers of **oxybutynin** recommend caution with moderate CYP3A4 inhibitors.[7,8] Note that **moderate CYP3A4 inhibitors** would generally be considered to include erythromycin, fluconazole, grapefruit juice, diltiazem and verapamil, although the UK manufacturer of fesoterodine[5] additionally mentions amprenavir and fosamprenavir (which have also sometimes been considered to be potent inhibitors) and aprepitant. The manufacturers of oxybutynin also mention miconazole.[7]

The situation for **tolterodine** is more complicated because the manufacturers consider erythromycin,[9,10] and miconazole[9] to be potent CYP3A4 inhibitors: the UK manufacturer[10] does not recommend concurrent use, and the US manufacturer[9] recommends that the dose of tolterodine be reduced to 1 mg twice daily. However, erythromycin and miconazole do not appear to be potent inhibitors of CYP3A4 in clinical use (for example, the increase in darifenacin levels with erythromycin above was about ninefold less than that with ketoconazole).

Urinary antimuscarinics + CYP3A4 inhibitors; Potent

Ketoconazole (a potent CYP3A4 inhibitor) markedly increases darifenacin, fesoterodine and solifenacin exposure. Other potent CYP3A4 inhibitors are expected to interact similarly. Itraconazole and ketoconazole increase the exposure to oxybutynin, but do not alter the levels of its active metabolite. Ketoconazole can markedly increase tolterodine exposure, but only in those who have low levels or are lacking CYP2D6.

Clinical evidence

(a) Darifenacin

The manufacturer notes that, in a study in 16 healthy subjects, ketoconazole 400 mg daily for 6 days markedly increased the steady-state AUC of darifenacin 30 mg daily about tenfold.[1,2] The UK manufacturers also note that ketoconazole 400 mg caused a fivefold increase in the steady-state AUC of a 7.5-mg dose of darifenacin.[1,3]

(b) Fesoterodine

In a crossover study in 18 healthy subjects, a single 8-mg dose of fesoterodine was given alone and then on day 5 of a 6-day course of ketoconazole 200 mg twice daily. Ketoconazole increased the AUC of the active metabolite of fesoterodine, 5-hydroxymethyltolterodine, 2.5-fold in CYP2D6 poor metabolisers (that is, those lacking or totally deficient in this isoenzyme) and 2.3-fold in CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme).[4] However, the overall extent of exposure (AUC and maximum concentration) to 5-hydroxymethyltolterodine was about twofold higher in poor metabolisers when compared with extensive metabolisers. Ketoconazole increased fesoterodine exposure in extensive metabolisers to a level similar to that seen in poor metabolisers not taking ketoconazole.

(c) Oxybutynin

In a study, a single 5-mg dose of oxybutynin was given to 10 healthy subjects after they had taken **itraconazole** 200 mg daily or placebo for 4 days. The peak serum levels and the AUC of oxybutynin were increased twofold, while the pharmacokinetics of the active metabolite of oxybutynin were unchanged. The sum of the oxybutynin and its metabolite concentrations were on average about 13% higher than with placebo. No increase in adverse effects was seen.[5] Ketoconazole also increases oxybutynin levels about twofold.[6,7]

(d) Solifenacin

In a crossover study[8] in healthy subjects, ketoconazole 200 mg daily for 20 days caused a twofold increase in the AUC of a single 10-mg dose of solifenacin given on day 7. Moreover, the manufacturer notes that a higher dose of ketoconazole (400 mg daily) increased the AUC of solifenacin about threefold.[9,10]

(e) Tolterodine

A study in 8 healthy subjects who were deficient in the cytochrome P450 isoenzyme CYP2D6 (poor metabolisers) found that after taking ketoconazole 200 mg daily for 4 days the clearance of a single 2-mg dose of tolterodine was reduced by 61% and its AUC was increased 2.5-fold.[11] In a subsequent multiple-dose study, 6 of the original subjects were given tolterodine 1 mg twice daily (half the usual dose). Ketoconazole 200 mg daily caused a 2.1-fold increase in the AUC of tolterodine, and a 2.2-fold increase in the AUC of the active moiety (unbound tolterodine plus metabolite).[11]

Mechanism

Darifenacin and solifenacin are principally metabolised by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a known, potent inhibitor. Concurrent use therefore increases the levels of these urinary antimuscarinics. Oxybutynin is also metabolised by CYP3A4, but most of the pharmacological activity of oxybutynin is attributed to a metabolite, the formation of which does not appear to be dependent on CYP3A4,[5] and therefore the sum of oxybutynin and its active metabolite is largely unchanged.

Fesoterodine is a prodrug and is rapidly converted to its more active metabolite, 5-hydroxymethyltolterodine, which is primarily metabolised by CYP2D6 and CYP3A4. Ketoconazole, an inhibitor of CYP3A4, may therefore increase the levels of 5-hydroxymethyltolterodine.

Although tolterodine is normally metabolised to its active metabolite by CYP2D6, in those with low levels of this isoenzyme (about 5 to 10% of the population), metabolism by CYP3A4 becomes more important. It should be noted that tolterodine levels are already higher in poor CYP2D6 metabolisers than extensive metabolisers,[12] but are likely to rise even further when a potent CYP3A4 inhibitor such as ketoconazole inhibits this other route of metabolism.

Importance and management

Established pharmacokinetic interactions. The very marked increase in **darifenacin** exposure caused by ketoconazole is of concern. The UK manufacturer contraindicates the concurrent use of ketoconazole and other potent CYP3A4 inhibitors,[3] whereas the US manufacturer recommends that the daily dose of darifenacin is limited to 7.5 mg (half the usual dose), both with ketoconazole and other potent inhibitors of CYP3A4.[1] It may be prudent to assess antimuscarinic adverse effects (such as dry mouth, constipation, drowsiness) in these patients, and to withdraw the drug if it is not tolerated.

As a result of the increase in exposure seen with ketoconazole, the manufacturers of **fesoterodine** recommend that its maximum dose should be restricted to 4 mg daily when used with potent CYP3A4 inhibitors.[13,14] In the UK, fesoterodine is contraindicated in patients taking potent CYP3A4 inhibitors and who also have moderate to severe hepatic or renal impairment.[13]

For **oxybutynin**, the available evidence suggests that the pharmacokinetic interaction with itraconazole is only of minor importance,[5] but note that this was only a single-dose study and may not necessarily reflect the full picture in practice. Moreover, some manufacturers recommend caution if oxybutynin is given with itraconazole or ketoconazole,[6,7] and, until more is known this might be prudent, both with these drugs and other potent CYP3A4 inhibitors. Consider the possibility of an interaction if antimuscarinic effects are increased.

For **solifenacin**, the UK and US manufacturers recommend that its daily dose is limited to 5 mg if it is given with ketoconazole or other potent CYP3A4 inhibitors.[9,10] In addition, in the UK, in patients with severe renal impairment or moderate hepatic impairment, the concurrent use of solifenacin and potent CYP3A4 inhibitors is contraindicated.[9] Note that high levels of solifenacin cause a small increase in the QT interval.

For **tolterodine**, the UK manufacturer[15] considers that the twofold increase in levels represents a risk of overdose in CYP2D6 poor metabolisers. Consequently, they do not recommend the use of potent CYP3A4 inhibitors with tolterodine in any patient (note that metaboliser status is rarely known), especially those with risk factors for QT-prolongation (see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.). However, the US manufacturer[12] recommends that the dose of tolterodine be reduced to 1 mg twice daily in patients currently taking drugs that are potent inhibitors of CYP3A4. It may be prudent to assess antimuscarinic adverse effects (such as dry mouth, constipation, drowsiness) in these patients, and to reduce the dose further or withdraw the drug if it is not tolerated.

Potent inhibitors of CYP3A4 include the 'azole antifungals', (p.233), many of the 'protease inhibitors', (p.913), and some macrolides. Note that there is some difference in opinion as to whether or not clarithromycin is a potent CYP3A4 inhibitor. Its interaction with midazolam (a drug used to assess the potency of effect of other drugs on CYP3A4), would suggest it is only a moderate inhibitor (see 'Benzodiazepines and related drugs + Macrolides', p.852). However, many manufacturers consider it to be a potent CYP3A4 inhibitor.

Urinary antimuscarinics + Drugs that prolong the QT interval

Tolterodine and solifenacin caused a small increase in QTc interval (5 to 10 milliseconds) at high doses. On this basis, some caution might be appropriate when using these drugs with other drugs that prolong the QT interval.

Clinical evidence

(a) Solifenacin

In a study in healthy subjects, solifenacin 10 mg increased the Fridericia-corrected QT (QTcF) interval by 2 milliseconds, whereas a higher dose of 30 mg increased it by 8 milliseconds, when compared with placebo. These changes were less than that seen with moxifloxacin, used as a positive control (increase in QTcF interval of 11 to 16 milliseconds, when compared with placebo).[1] The 30 mg dose of solifenacin is three times the maximum dose, and was chosen because it was predicted to result in solifenacin exposure similar to that observed when the maximum dose of solifenacin is used with potent CYP3A4 inhibitors. The US manufacturer notes that, in worldwide postmarketing experience, solifenacin has been associated with QT prolongation and torsade de pointes.[1]

(b) Tolterodine

In a well-designed study in healthy subjects, tolterodine immediate-release tablets 2 mg twice daily and 4 mg twice daily for 4 days caused a rise in the QTcF interval of 5 milliseconds and 11.8 milliseconds, respectively, with a manual reading of the ECG, and 1.2 milliseconds and 5.6 milliseconds, respectively, with a machine reading of the ECG, when compared with placebo. This increase was about half that seen with moxifloxacin 400 mg daily for 4 days, used as a positive control.[2] In this study there was about an equal representation of CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme) and poor metabolisers (that is, those lacking or totally deficient in this isoenzyme), and the QT interval increase appeared to be greater in poor metabolisers. The highest dose of tolterodine used in this study is twice the highest recommended dose, and was chosen because it results in tolterodine exposure similar to that observed when tolterodine 2 mg twice daily is used with potent CYP3A4 inhibitors, in patients who are CYP2D6 poor metabolisers. The US manufacturer notes that there have been no reports of torsade de pointes associated with the use of tolterodine.[3]

Mechanism

The effects of drugs that prolong the QT interval are expected to be additive. Prolongation of the QT interval is associated with an increased risk of the potentially fatal torsade de pointes arrhythmia, see also 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290.

Importance and management

On the basis of what is currently known, see 'Drugs that prolong the QT interval + Other drugs that prolong the QT interval', p.290, the proarrhythmic risk of drugs that prolong the QTc interval by around 5 to less than 20 milliseconds is inconclusive. Solifenacin and tolterodine fit in this category. The manufacturers of tolterodine[3,4] and the US manufacturer of solifenacin[1] recommend that the possible increase in QT interval should be taken into account when prescribing these antimuscarinics to patients with a known history of QT prolongation or using any other drugs known to prolong the QT interval. The tolterodine manufacturer specifically mentions class Ia antiarrhythmics (e.g. **quinidine**, **procainamide**) or class III antiarrhythmics (e.g. **amiodarone**, **sotalol**),[3,4] which are known to significantly prolong the QT interval. The risk of an interaction is likely to be greatest if CYP3A4 inhibitors are also being taken.[4]

Urinary antimuscarinics + Food

Food might reduce the absorption of trospium. Food does not appear to have a clinically relevant effect on the pharmacokinetics of darifenacin, fesoterodine, solifenacin or tolterodine.

Clinical evidence, mechanism, importance and management

(a) Darifenacin

Food had no effect on the steady-state pharmacokinetics of darifenacin, and the tablets may be taken with or without food.[1,2]

(b) Fesoterodine

In a study, 24 healthy subjects given a single 8-mg dose of fesoterodine after an overnight fast or with a standard high-fat, high-calorie breakfast. The AUC and maximum plasma levels of the active metabolite of fesoterodine, 5-hydroxymethyltolterodine, were increased by 12% and 29%, respectively, in the fed state, when compared with the fasted state.[3] In another similar study in 16 healthy subjects, the AUC and maximum plasma levels of 5- hydroxymethyltolterodine were increased by about 19% in the fed state compared with the fasted state.[4] These minor changes are not expected to be clinically relevant, and fesoterodine may be given without regard to food.

(c) Solifenacin

In a crossover study in 23 healthy subjects, food did not affect the pharmacokinetics of solifenacin 10 mg, taken within 5 minutes of a high-fat, high-calorie breakfast, when compared with the fasted state.[5]

(d) Tolterodine

The manufacturer notes that food intake increases the bioavailability of tolterodine by 53%, but does not affect the levels of the 5-hydroxymethyl metabolite in extensive metabolisers [presumably of CYP2D6].[6,7] This change is not expected to be clinically relevant.

(e) Trospium

Giving trospium extended-release capsules immediately after a high fat-content meal reduced the AUC and maximum plasma levels of trospium by 35% and 60%, respectively. These changes are modest, nevertheless, the manufacturer recommends that trospium be taken on an empty stomach at least one hour before a meal.[8,9]

Urinary antimuscarinics + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin, a CYP3A4 inducer, markedly reduces the exposure to the active metabolite of fesoterodine. Other CYP3A4 inducers would be expected to interact similarly. Darifenacin and solifenacin levels are also predicted to be reduced by CYP3A4 inducers.

Clinical evidence

In a study in 12 healthy subjects, a single 8-mg dose of **fesoterodine** was given on day 7 of an 8-day course of rifampicin 600 mg daily. The AUC and maximum plasma levels of the active metabolite of fesoterodine, 5-hydroxymethyltolterodine, were reduced by about 78% and 72%, respectively.[1]

Mechanism

Fesoterodine is a pro-drug and is rapidly converted to 5-hydroxymethyltolterodine, which is primarily metabolised by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4, of which rifampicin is a potent inducer. **Solifenacin** and **darifenacin** are principally metabolised by CYP3A4, and would be expected to be similarly affected.

Importance and management

The clinical relevance of the marked reduction in the levels of the active metabolite of fesoterodine by rifampicin has not been assessed, but reduced efficacy would be expected. In the UK, the manufacturer does not recommend the concurrent use of fesoterodine with other CYP3A4 inducers: they specifically name **carbamazepine**, **phenobarbital**, **phenytoin**, **St John's wort**, and rifampicin.[2] However note that although these drugs are known inducers of CYP3A4, they, unlike rifampicin, do not appear to have any clinically significant effects on CYP2D6, and so would not be expected to interact to the same extent as rifampicin. The US manufacturer notes that reduced fesoterodine plasma levels may occur with concurrent use of CYP3A4 inducers, but state that no fesoterodine dose adjustments are recommended.[3] If concurrent use is necessary, until the clinical relevance of this interaction is known, it would seem prudent to closely monitor the urinary efficacy of fesoterodine.

The efficacy of **darifenacin** and **solifenacin** is also expected to be reduced by CYP3A4 inducers, as they are primarily metabolised by CYP3A4: the manufacturers name **barbiturates**, **carbamazepine**, **phenytoin**, **rifampicin** and **St John's wort**, as potentially interacting CYP3A4 inducers.[4-6] For a list of CYP3A4 inducers, see 'Table 1.4', (p.6).

Urinary antimuscarinics + SSRIs or SNRIs

Fluoxetine can markedly inhibit the metabolism of tolterodine in some patients. Duloxetine increases the maximum levels of tolterodine by 64%. Paroxetine causes a small, clinically irrelevant, increase in darifenacin levels. Cimetidine, quinidine and terbinafine are predicted to increase the levels of darifenacin.

Clinical evidence

(a) Darifenacin

The manufacturers note that, in a study in healthy subjects, **paroxetine** 20 mg daily increased the steady-state AUC of darifenacin 30 mg daily by 33%.[1,2]

(b) Tolterodine

1. Duloxetine. In a placebo-controlled, crossover study, 14 healthy subjects were given duloxetine 40 mg twice daily and tolterodine 2 mg twice daily, for 5 days. Duloxetine increased the steady-state AUC of tolterodine by 71% and increased its maximum level by 64%. However, duloxetine had no effect on the pharmacokinetics of 5-hydroxymethyl-tolterodine, the active metabolite of tolterodine.[3]

2. Fluoxetine. In a study, 13 psychiatric patients with symptoms of urinary incontinence were given tolterodine 2 mg twice daily for 5 doses, followed by fluoxetine 20 mg daily for 3 weeks, and then both drugs together for a further 3 days. Nine of the 13 patients completed the study, the other 4 withdrew because of fluoxetine-related adverse effects. Fluoxetine is an inhibitor of the cytochrome P450 isoenzyme CYP2D6, the main isoenzyme involved in the metabolism of tolterodine. Levels of this enzyme can vary between individuals. In the 7 patients with normal CYP2D6 levels (extensive metabolisers) fluoxetine caused a 4.8-fold increase in the AUC of tolterodine and a minor reduction in its active and equipotent metabolite. In contrast, fluoxetine increased the AUC of tolterodine by about 25% in 2 patients with low levels of CYP2D6 (poor metabolisers). These changes in AUC represent an increase of about 25% in active moiety (unbound tolterodine plus metabolite) for both poor and extensive metabolisers, a figure within normal variation.[4]

Mechanism

Duloxetine, fluoxetine and paroxetine are inhibitors of the cytochrome P450 isoenzyme CYP2D6, by which tolterodine is metabolised. Darifenacin is also metabolised by this isoenzyme, but only in part.

Importance and management

The minor pharmacokinetic interaction between paroxetine and **darifenacin** is very unlikely to be clinically relevant, and no dosage adjustments are recommended by the US manufacturer in the presence of CYP2D6 inhibitors.[1] However, the UK manufacturer recommends that the dose of darifenacin should be started at 7.5 mg daily and, if well tolerated, titrated to 15 mg daily in the presence of CYP2D6 inhibitors (they name paroxetine, '**cimetidine**', (p.1545), **terbinafine** and **quinidine**).[2] This seems a cautious approach. For a list of CYP2D6 inhibitors, see 'Table 1.3', (p.6).

The increases in **tolterodine** levels with duloxetine and fluoxetine were not considered to be clinically relevant, and no routine dosage adjustment of tolterodine was considered necessary when given with these drugs.[3,4] Nevertheless, if CYP3A4 inhibitors are also being used, this interaction could be important, see 'Urinary antimuscarinics + CYP3A4 inhibitors; Potent', p.1542.

Urinary antimuscarinics; Darifenacin + Miscellaneous

Cimetidine causes a small increase in darifenacin levels. Darifenacin increases imipramine levels but does not significantly affect the pharmacokinetics of midazolam. Darifenacin is predicted to increase the levels of other CYP2D6 substrates such as flecainide and thioridazine.

Clinical evidence, mechanism, importance and management

(a) Cimetidine

The manufacturers note that, in a study in healthy subjects, cimetidine 800 mg twice daily increased the steady-state AUC of darifenacin 30 mg daily by 34%.[1,2] Cimetidine is a non-specific moderate inhibitor of cytochrome P450 isoenzymes, in particular CYP3A4 and CYP2D6, by which darifenacin is metabolised. This modest change is unlikely to be clinically relevant. However, the UK manufacturer recommends that, in the presence of cimetidine, the dose of darifenacin should be started at 7.5 mg daily and, if well tolerated, titrated to 15 mg daily.[3] This seems a cautious approach.

(b) CYP2D6 substrates

The US manufacturer notes that, in a study in healthy subjects, steady-state darifenacin 30 mg daily increased the AUC of **imipramine** by 70% and increased the AUC of its active metabolite, desipramine, 2.6-fold.[2] Because of these changes, the manufacturers recommend caution if darifenacin is given with **tricyclic antidepressants** and other CYP2D6 substrates that have a narrow therapeutic window.[1,3] They name **flecainide** and **thioridazine** (see 'Table 1.3', (p.6), for a list).

(c) Midazolam

The manufacturers note that, in a study in healthy subjects, darifenacin 30 mg daily increased the AUC of a single 7.5-mg dose of midazolam by 17%.[1-3] This change is not clinically important.[3]

Urinary antimuscarinics; Tolterodine + Miscellaneous

Tolterodine does not alter the metabolism of debrisoquine, omeprazole or caffeine.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in 12 healthy men, tolterodine 4 mg twice daily for 6 days had no effect on debrisoquine hydroxylation (CYP2D6), omeprazole hydroxylation (CYP2C19) or sulphoxidation (CYP3A4) or caffeine demethylation (CYP1A2), after single doses of **debrisoquine** 10 mg, **omeprazole** 20 mg and **caffeine** 100 mg.[1] This shows that tolterodine has no clinically relevant effect on these isoenzymes, and is therefore unlikely to alter the pharmacokinetics of drugs that are substrates for cytochrome P450 isoenzymes CYP2D6, CYP2C19, CYP3A4 and CYP1A2.

For mention that **omeprazole** slightly increases the maximum level of tolterodine from a controlled-release preparation, see 'Enteric-coated, delayed-release preparations + Drugs that affect gastric pH', p.1558.

1. Brynne N, Böttiger Y, Hallén B, Bertilsson L. Tolterodine does not affect the human *in vivo* metabolism of the probe drugs caffeine, debrisoquine and omeprazole. *Br J Clin Pharmacol* (1999) 47, 145–50.

Urinary antimuscarinics; Trospium + Antacids

Antacids might have some effect on the absorption of trospium.

Clinical evidence, mechanism, importance and management

The manufacturer briefly mentions that, in a pharmacokinetic study in 11 healthy subjects, the mean AUC of **trospium** from extended-release capsules was comparable when given with and without an antacid containing **aluminium hydroxide** and **magnesium carbonate**. However, 5 individuals had either an increase or decrease in trospium exposure in presence of antacid.[1] The clinical relevance of these findings is not known.

1. Sanctura XR (Trospium). Allergan Inc. US Prescribing information, November 2008.

Yohimbine + Glyceryl trinitrate (Nitroglycerin)

No significant hypotensive interaction occurred in healthy subjects given yohimbine and a glyceryl trinitrate infusion.

Clinical evidence, mechanism, importance and management

In a placebo-controlled study, 16 healthy male subjects were given a single 7.7-mg oral dose of yohimbine tartrate (as NMI 861; yohimbine plus l-arginine glutamate) followed by a step-wise infusion of glyceryl trinitrate starting at 2.5 micrograms/minute, which was doubled every 15 minutes until symptomatic hypotension or a sustained decrease in systolic blood pressure of greater than 25 mmHg occurred, or until a maximum dose of 40 micrograms/minute had been reached, at which point the infusion was stopped. There was no significant difference in the hypotensive response to intravenous glyceryl trinitrate given with yohimbine or placebo.[1]

An oral yohimbine/l-arginine combination (NMI 861) for the treatment of male erectile dysfunction: a pharmacokinetic, pharmacodynamic and interaction study with intravenous nitroglycerine in healthy male subjects. *Br J Clin Pharmacol* (2005) 59, 85–93.

38

Miscellaneous drugs

Acamprosate + Miscellaneous

Naltrexone modestly increases the rate and extent of acamprosate absorption. There is no pharmacokinetic interaction between acamprosate and alcohol or diazepam. Disulfiram does not alter the pharmacokinetics of acamprosate, and acamprosate does not alter the pharmacokinetics of imipramine. The combination of acamprosate and barbiturates, meprobamate, or oxazepam does not appear to increase the risk of adverse effects.

Clinical evidence, mechanism, importance and management

(a) Alcohol

In studies in healthy subjects, the pharmacokinetics of both alcohol and acamprosate were unchanged by concurrent use.[1]

(b) Antidepressants, anxiolytics and hypnotics

A 15-day study in 591 patients, to assess the effects of the concurrent use of acamprosate with other drugs commonly used in the management of alcohol withdrawal, found no evidence of additional adverse effects when **meprobamate**, **oxazepam**, or the barbiturate complex **tetrabamate**, which includes **phenobarbital**, were also given.[2] Other studies found that acamprosate caused no clinically relevant changes in **imipramine** pharmacokinetics, and the pharmacokinetics of both **diazepam** and acamprosate were unchanged by concurrent use.[1]

No special precautions would therefore appear to be needed if any of these drugs is given with acamprosate.

(c) Disulfiram

In a study in 12 healthy subjects, disulfiram 500 mg daily for 7 days did not alter the plasma levels of acamprosate 666 mg three times daily.[1]

(d) Naltrexone

In a study in 24 healthy subjects, the concurrent use of naltrexone 50 mg daily and acamprosate 2 g daily for 7 days modestly increased the rate and extent of absorption of acamprosate, as indicated by a 33% increase in maximum level, a 33% reduction in time to maximum level, and a 25% increase in AUC. There was no change in naltrexone pharmacokinetics.[3] Similarly, an increase in acamprosate levels was seen in a study of the use of acamprosate and naltrexone in alcohol-dependent subjects.[4] No particular adverse events were identified on concurrent use,[3,4] suggesting that the drugs may be used together without dose adjustment.

Allopurinol + Aluminium hydroxide

Three haemodialysis patients did not respond to allopurinol while taking aluminium hydroxide. Separating the doses by 3 hours appeared to solve this.

Clinical evidence

Three patients receiving haemodialysis, taking 5.7 g of aluminium hydroxide daily and allopurinol 300 mg daily for high phosphate and uric acid levels, had no reduction in their hyperuricaemia until the aluminium hydroxide was given 3 hours before the allopurinol, whereupon their uric acid levels fell by 40 to 65%. When one patient returned to taking both preparations together, her uric acid levels began to rise.[1]

Mechanism

Not understood. Antacids are well known to reduce the absorption of a number of drugs, but this is the only evidence of this possibly occurring with allopurinol.

Importance and management

Information seems to be limited to this anecdotal report. If allopurinol is not effective in patients with renal impairment taking large doses of aluminium, consider the possibility of an interaction. Try separating the administration of these two drugs by 3 hours or more. The effects of lower doses of aluminium and the effects in patients with normal renal function do not appear to have been studied.

1. Weissman I, Krivoy N. Interaction of aluminum hydroxide and allopurinol in patients on chronic hemodialysis. *Ann Intern Med* (1987) 107, 787.

Allopurinol + Iron compounds

No adverse interaction occurs if iron and allopurinol are given concurrently.

Clinical evidence, mechanism, importance and management

Some early *animal* studies, where allopurinol was given in very large doses, suggested that allopurinol might have an inhibitory effect on the release of iron from hepatic stores. It was feared that this might result in hepatic iron overload. This led the manufacturers of allopurinol in some countries to issue a warning about their concurrent use.[1] However, subsequent research suggests that no special precautions are needed.[1-3]

Allopurinol + Tamoxifen

A single case report describes allopurinol hepatotoxicity in a man given tamoxifen.

Clinical evidence, mechanism, importance and management

An elderly man who had been taking allopurinol 300 mg daily for 12 years developed fever and marked increases in his serum levels of lactic dehydrogenase and alkaline phosphatase within a day of starting to take tamoxifen 10 mg twice daily.[1] He rapidly recovered when the allopurinol was stopped. The reasons for the reaction are not understood, but the authors suggested that the increased hepatotoxic effect may have resulted from tamoxifen inhibiting allopurinol metabolism, thereby increasing the serum levels of allopurinol and its metabolite. The general importance of this isolated report is not known.

1. Shah KA, Levin J, Rosen N, Greenwald E, Zumoff B. Allopurinol hepatotoxicity potentiated by tamoxifen. *N Y State J Med* (1982) 82, 1745–6.

Allopurinol + Thiazide diuretics

Severe allergic reactions to allopurinol have developed a few patients with renal impairment who were also taking thiazide diuretics.

Clinical evidence, mechanism, importance and management

Most patients tolerate allopurinol very well, but life-threatening hypersensitivity reactions (e.g. rash, vasculitis, hepatitis, eosinophilia, progressive renal impairment) develop very occasionally with doses of 200 to 400 mg of allopurinol daily.[1] A report of six such hypersensitivity reactions found that all of the reported cases were associated with pre-existing renal impairment, and in half of these, the patients were also taking thiazide diuretics.[1] Another report describes two patients who developed a hypersensitivity vasculitis while taking allopurinol and **hydrochlorothiazide**.[2] The excretion of oxipurinol (the major metabolite of allopurinol) is reduced in renal impairment, but studies indicate that, in healthy subjects with normal renal function, thiazide diuretics such as **hydrochlorothiazide** do not appear to affect either the plasma levels of oxipurinol or its excretion.[3-5] Furthermore, allopurinol does not appear to affect **hydrochlorothiazide** pharmacokinetics.[5] However, another study found that the effects of allopurinol on pyrimidine metabolism were enhanced by the use of thiazides (i.e. they potentially increase hyperuricaemia, which may lead to renal damage).[6] Some caution is therefore appropriate if both drugs are used, particularly if renal function is impaired, but more study is needed to confirm this possible interaction.

Allopurinol + Uricosuric drugs

Probenecid and benzbromarone increase the renal excretion of oxipurinol, the active metabolite of allopurinol. Theoretically, the use of uricosuric drugs with allopurinol could lead to uric acid precipitation in the kidneys and therefore maintenance of a high urine output is recommended when allopurinol is given by injection. Probenecid markedly increases the serum levels of allopurinol riboside, which may be advantageous in some circumstances.

Clinical evidence, mechanism, importance and management

(a) Allopurinol

Probenecid appears to increase the renal excretion of the active metabolite of allopurinol, oxipurinol,[1] while allopurinol is thought to inhibit the metabolism of **probenecid**.[2] One study suggested that allopurinol can increase the half-life and raise the serum levels of **probenecid** by about 50% and 20%, respectively.[2] However, a subsequent randomised study in 11 healthy subjects found that allopurinol 150 mg twice daily did not affect the pharmacokinetics of **probenecid** 500 mg twice daily when both drugs were given together for 7 days. This study also found that the mean plasma oxipurinol AUC and maximum levels were approximately halved when **probenecid** was added to allopurinol.[3] In another study, **benzbromarone** lowered the AUC of oxipurinol by about 40%, but did not affect allopurinol levels.[4]

It has been suggested that the use of allopurinol and **probenecid** might lead to an increase in the excretion of uric acid, which could result in the precipitation of uric acid in the kidneys. Conversely, increased renal excretion of oxipurinol might decrease the efficacy of allopurinol. However, the clinical importance of these mutual interactions seems to be minimal. No problems were reported in two studies in patients given 100 to 600 mg of allopurinol and 500 mg to 2.5 g of **probenecid** daily for between 8 and 16 weeks,[5] and the concurrent use of allopurinol and **probenecid**[3] or **benzbromarone**[4] was more effective in lowering uric acid levels than allopurinol alone. Nevertheless, the UK manufacturer of allopurinol recommends that the significance of any reduction in efficacy, which may occur when uricosuric drugs are given with allopurinol, should be assessed in each case.[6] For allopurinol injection, the US manufacturer recommends that, to help prevent renal precipitation of urates in patients receiving concurrent uricosuric drugs, a fluid intake sufficient to give a urinary output of at least 2 litres daily, and the maintenance of neutral or slightly alkaline urine, are desirable.[7]

(b) Allopurinol riboside

A study in 3 healthy subjects found that **probenecid** halved the clearance, increased the peak plasma levels and AUC, and extended the half-life of allopurinol riboside.[8] In some circumstances such an interaction may be advantageous as there is some evidence that the cure rate of American trypanosomiasis (Chagas' disease) and cutaneous leishmaniasis is better when the two drugs are used together.[8,9]

Baclofen + Ibuprofen

A man developed baclofen toxicity when given ibuprofen.

Clinical evidence, mechanism, importance and management

An isolated report describes a man taking baclofen 20 mg three times daily, who developed baclofen toxicity (confusion, disorientation, bradycardia, blurred vision, hypotension and hypothermia) after taking 8 doses of ibuprofen 600 mg three times daily. It appeared that the toxicity was caused by ibuprofen-induced acute renal impairment leading to baclofen accumulation.[1] Renal impairment is a relatively rare adverse effect of ibuprofen. The general importance of this interaction is likely to be very small. There appears to be no information about baclofen and other NSAIDs, and little reason for avoiding concurrent use.

1. Dahlin PA, George J. Baclofen toxicity associated with declining renal clearance after ibuprofen. *Drug Intell Clin Pharm* (1984) 18, 805–8.

Baclofen + Miscellaneous

Common adverse effects of baclofen include hypotension, sedation and somnolence. Bear in mind the possibility of additive ef-

fects when baclofen is used with antihypertensives or drugs causing sedation.[1]

1. Lioresal Tablets (Baclofen). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, July 2009.

Baclofen + Tizanidine

No clinically significant pharmacokinetic interaction appears to occur between baclofen and tizanidine.

Clinical evidence, mechanism, importance and management

In a randomised, three-period study, 15 healthy subjects were given baclofen 10 mg three times daily and tizanidine 4 mg three times daily, together and alone, for 7 consecutive doses. None of the pharmacokinetic parameters of either drug were changed by more than 30%, a figure calculated to indicate the presence of an interaction.[1] No changes in the dosages of either drug are therefore likely to be needed if they are taken concurrently.

1. Shellenberger MK, Groves L, Shah J, Novak GD. A controlled pharmacokinetic evaluation of tizanidine and baclofen at steady state. *Drug Metab Dispos* (1999) 27, 201–4.

Benzbromarone + Chlorothiazide

Benzbromarone lowers uric acid levels in patients taking chlorothiazide, without affecting diuretic activity.[1,2]

1. Heel RC, Brogden RN, Speight TM, Avery GS. Benzbromarone: a review of its pharmacological properties and therapeutic use in gout and hyperuricaemia. *Drugs* (1977) 14, 349–66.

Betahistine + Terfenadine

An isolated case report describes the re-emergence of labyrinthine symptoms when a patient taking betahistine was given terfenadine.

Clinical evidence, mechanism, importance and management

An isolated and very brief report describes a patient whose labyrinthine symptoms (vertigo, dizziness, nausea and vomiting), were controlled by betahistine, returned during the concurrent use of terfenadine and other unspecified drugs.[1] An antagonistic interaction had been predicted on theoretical grounds because betahistine is an analogue of histamine, and would therefore be expected to interact like this with any antihistamine.[2] However, this possible case appears to be the only suggestion of an interaction, and the clinical relevance is unclear..

Bisphosphonates + Aminoglycosides

Severe hypocalcaemia occurred in three patients taking sodium clodronate when they were given netilmicin or amikacin. Theoretically, additive calcium lowering effects could occur with any bisphosphonate and aminoglycoside combination.

Clinical evidence

A 62-year-old woman with multiple myeloma was given **sodium clodronate** 2.4 g daily for osteolysis and bone pain. After 7 days she developed grand mal seizures, and her serum calcium was found to be 1.72 mmol/L (reference range 2.25 to 2.6 mmol/L). Despite daily calcium infusions her calcium remained low. The authors state that symptomatic hypocalcaemia with clodronate is rare, and attributed the dramatic response in this patient to an interaction with a course of **netilmicin** given 5 days earlier for septicaemia.[1]

A 69-year-old man with prostate cancer had been taking **sodium clodronate** 2.4 g daily for bone pain for 13 months, and serum calcium levels had always remained within the reference range. After being admitted with febrile neutropenia following a course of chemotherapy, the clodronate was withdrawn and he was given intravenous **amikacin** and ceftazidime. After 7 days he became unconscious, and developed spontaneous twitching movements in his arms and legs. His calcium was found to be 1.39 mmol/L and he was diagnosed with hypocalcaemic tetany. He was given calcium infusions, and his serum calcium returned to normal over the next 12 hours.[2]

A further case report describes a 50-year-old patient taking **clodronate** 1.6 g daily, who developed febrile neutropenia for which he was given **amikacin** and ampicillin. Five days after starting **amikacin** his calcium began to fall and, despite stopping the clodronate and supplementing with calcium 8 g daily, his calcium level stabilised at just 1.65 mmol/L. The patient subsequently died from aspergillus pneumonia.[3]

Mechanism

Not fully understood, but one suggestion is that any fall in blood calcium levels brought about by the use of clodronate is normally balanced to some extent by the excretion of parathyroid hormone, which raises blood calcium levels. However, the aminoglycoside antibacterials can damage the kidneys, not only causing the loss of calcium, but of magnesium as well. Any hypomagnesaemia inhibits the activity of the parathyroid gland, so that the normal homoeostatic response to hypocalcaemia is reduced or even abolished.[1,2] Clodronate itself can sometimes be nephrotoxic.

Importance and management

Direct information seems to be limited to these three reports. Biochemical hypocalcaemia is believed to occur in about 10% of patients taking bisphosphonates,[4] but symptomatic hypocalcaemia is said to be rare.[2] It seems therefore that the addition of the aminoglycoside in these cases precipitated severe clinical hypocalcaemia. The authors of these reports therefore advise care if bisphosphonates are given with aminoglycosides, and recommend close monitoring of calcium and magnesium levels.[1-3] They also point out that the renal loss of calcium and magnesium can continue for weeks after aminoglycosides are stopped, and that bisphosphonates can also persist in bone for weeks.[1,2] This means that the interaction is potentially possible whether the drugs are given concurrently or sequentially.

Bisphosphonates + Aspirin or NSAIDs

The concurrent use of alendronate and naproxen increased the incidence of gastric mucosal damage in a small pharmacological study, and increased the risk of upper gastrointestinal disorders in a case-control study. However, two analyses of placebo-controlled studies found no increased risk of gastrointestinal damage with the combination. There was no increased risk of gastrointestinal adverse effects in patients taking NSAIDs who were given risedronate.

Indometacin raises tiludronate bioavailability, whereas aspirin and diclofenac do not appear to affect the pharmacokinetics of tiludronate. NSAIDs may exacerbate the renal impairment sometimes seen with clodronate.

Clinical evidence, mechanism, importance and management

(a) Alendronate

In a short-term endoscopy study in 26 healthy subjects, gastric mucosal damage developed in 8% of those given alendronate alone, in 12% of those given **naproxen** alone, and 38% of those given both drugs.[1] In a case-control study,[2] the risk of having an acid-related upper gastrointesti-

nal disorder with alendronate was increased by the concurrent use of NSAIDs (relative risk 1.7). However, retrospective analysis of data from a very large long-term placebo-controlled study found no evidence that the risk of upper gastrointestinal adverse effects with concurrent use of NSAIDs and alendronate was any greater than with NSAIDs and placebo.[3] Note that this finding has been questioned,[4] and some of the issues responded to.[5] Similarly, in a retrospective analysis of a 12-week placebo-controlled study, in those taking regular NSAIDs (about half of the patients) there was no difference in the incidence of upper gastrointestinal adverse events between those given alendronate and those given placebo. The most commonly used NSAIDs in this study were **aspirin**, **celecoxib**, **rofecoxib**, **ibuprofen** and **naproxen**.[6]

Alendronate is commonly known to be associated with oesophageal adverse effects, and there are strict dosing instructions to minimise this risk.[7] It may also cause local irritation of the stomach, although its potential to cause gastric ulcers is not considered established.[3,7]

The interpretation of these data has been debated. Some consider that alendronate should not be given to patients taking NSAIDs,[4] while others urge caution in their use together.[1,2] However, some consider that there is no evidence that alendronate adds to the known gastrointestinal toxicity of NSAIDs.[5] The UK manufacturer issues no caution about the concurrent use of NSAIDs with alendronate.[7] The US manufacturer states that alendronate can be used with NSAIDs, but that caution is required.[8] It would seem sensible to monitor the concurrent use of alendronate and NSAIDs carefully.

(b) Clodronate

The manufacturer notes that patients receiving NSAIDs with clodronate have developed renal impairment, although a synergistic action has not been established.[9] Clodronate alone may cause renal impairment, and the manufacturer suggests that renal function should be assessed before giving clodronate.[9] This would seem particularly important in those taking NSAIDs.

(c) Ibandronate

The manufacturer notes that the incidence of upper gastrointestinal adverse events in patients taking NSAIDs or aspirin did not differ between those receiving ibandronate and those receiving placebo in a large clinical osteoporosis study.[10] In this study, 62% of patients were taking aspirin or NSAIDs. Nevertheless, the manufacturers recommend that, since both bisphosphonates and NSAIDs are associated with gastrointestinal irritation, caution should be taken during concurrent use.[10,11]

(d) Risedronate

In a pooled analysis of phase III osteoporosis studies of risedronate, there was no increased risk of upper gastrointestinal adverse events in those also receiving aspirin and/or NSAIDs (63% of patients).[12] Similarly, in a retrospective analysis of a 2-year placebo-controlled study, in those regularly taking NSAIDs (about two-thirds of patients) there was no difference in the incidence of upper gastrointestinal adverse events between those given risedronate and those given placebo.[13] A similar lack of difference in incidence of gastrointestinal adverse effects was also seen in a once-weekly risedronate study.[14] This suggests that no special precautions are likely to be necessary on concurrent use.

(e) Tiludronate

Single-dose studies in 12 healthy subjects found that **diclofenac** 25 mg and aspirin 600 mg had no significant effect on the pharmacokinetics of tiludronate when taken at the same time. When taken 2 hours after tiludronate, aspirin decreased the AUC of tiludronate by about 50% and diclofenac increased it by about 50%, but neither of these changes was statistically significant.[15] On the other hand, **indometacin** 50 mg increased the maximum serum concentration and the AUC of tiludronate about twofold when these drugs were taken together, but not when they were given 2 hours apart.[15] For this reason the manufacturers advise that **indometacin** and tiludronate should be given 2 hours apart.[16,17] The US manufacturer also advises that aspirin should not be taken within 2 hours of tiludronate,[17] but the reason for this is unclear.

Bisphosphonates + Polyvalent cations

The oral absorption of bisphosphonates is reduced by food and polyvalent cations, including aluminium/magnesium hydroxide, bismuth and other antacids, calcium-rich foods, calcium supplements, iron preparations, magnesium-containing laxatives and milk.

Clinical evidence

(a) Alendronate

In pharmacokinetic studies, taking alendronate either 60 or 30 minutes before a standardised breakfast reduced its bioavailability by 40%, when compared with taking it 2 hours before breakfast. Taking alendronate with breakfast markedly reduced its bioavailability by more than 85%, as did taking alendronate 2 hours after breakfast. Both **black coffee** and **orange juice** reduced alendronate bioavailability by about 60%.[1]

(b) Clodronate

In a randomised study in 31 healthy subjects, the AUC of clodronate was reduced to 10% of the optimum level when it was taken with breakfast. Delaying administration until 2 hours after breakfast only slightly improved the AUC (34% of optimum). The best AUC was achieved when clodronate was given 2 hours before breakfast, although the AUC one hour before breakfast was similar (91% of optimum).[2]

(c) Ibandronate

The manufacturer notes that the extent of absorption of ibandronate is impaired when it is taken with food or beverages (other than plain water). Bioavailability is reduced by about 90% when ibandronate is given with a standard breakfast, when compared with the bioavailability seen in fasted subjects. The manufacturers say that there is no meaningful reduction in bioavailability when ibandronic acid is taken 60 minutes before the first food of the day.[3,4]

(d) Risedronate

The absorption of risedronate 30 mg, taken 30 minutes before breakfast, was reduced by 55%, when compared with the fasting state (no food or drink for 10 hours before or for 4 hours after dosing). Administration one hour before breakfast reduces absorption by 30%, when compared with the fasting state. Administration 2 hours after dinner (evening meal) results in similar absorption to administration 30 minutes before breakfast.[5,6] The manufacturer says that risedronate is clinically effective when taken at least 30 minutes before breakfast.[5]

(e) Tiludronate

In a study in 12 healthy subjects the maximum serum levels and AUC of tiludronate were halved when *Maalox* (**aluminium/magnesium hydroxide**) was taken one hour before tiludronate, but the bioavailability was only slightly affected when *Maalox* was taken 2 hours after tiludronate.[7]

Mechanism

The bisphosphonates can form complexes with a number of polyvalent metallic ions (e.g. Al^{3+}, Ca^{2+}, Fe, Mg^{2+}), which can impair their absorption.

Importance and management

Established and important interactions. Bisphosphonates should be prevented from coming into contact with a range of preparations such as **antacids** (containing **aluminium**, **bismuth**, **calcium**, **magnesium**), laxatives (containing magnesium), **iron preparations** and calcium or other **mineral supplements**. **Food**, in particular **milk** and **dairy products**, contain calcium, and may also impair absorption.

Recommendations on the timing of administration of bisphosphonates in relation to food and other drugs vary slightly between products.

- The manufacturers of **alendronate**[8,9] suggest that, in order to avoid absorption interactions, patients should take alendronate after an overnight fast at least 30 minutes before taking any other drug or food, and that alendronate should be taken with plain (not mineral) water only.
- The manufacturers of **clodronate**[10] suggest leaving one hour between the administration of food and clodronate.
- The manufacturers of **etidronate**[11,12] recommend it is given on an empty stomach at least 2 hours from any food, particularly that containing polyvalent cations (as listed above), and from medicines containing these cations.
- The manufacturers of **ibandronate**[3,4,13] recommend it is taken with plain water on an empty stomach (overnight fast of at least 6 hours) at least 30 minutes[13] to one hour[3] before the first food or drink (other than water) of the day, or any other medications.
- The manufacturers of **risedronate**[5,14] recommend it is taken with water at least 30 minutes before the first food or drink of the day. Alternatively, they say it should be given at least 2 hours from any food or drink at any other time of the day, and at least 30 minutes before going to bed.
- The manufacturers of **tiludronate**[15,16] recommend that it is taken with water on an empty stomach (at least 2 hours before or after meals). In addition, they recommend that administration of tiludronate and antacids or calcium compounds should be separated by 2 hours.

Bisphosphonates + Thalidomide

The pharmacokinetics of zoledronate are not affected by thalidomide. It is uncertain if thalidomide increases the risk of osteonecrosis of the jaw caused by bisphosphonates.

Clinical evidence

(a) Renal function and pharmacokinetics

Acute renal failure (a marked rise in creatinine levels with hypocalcaemia) occurred in 2 of 16 patients with myeloma who had their bisphosphonate treatment switched from **pamidronate** to **zoledronate**. Both of these patients were also taking thalidomide, which was speculated to possibly have contributed to the renal impairment.[1] However, in a sub-study of a controlled clinical study, there was no evidence of renal impairment, and no difference in serum creatinine levels between 12 patients receiving thalidomide and 12 patients not receiving thalidomide, for up to 16 infusions of **zoledronate**. In this study, intravenous zoledronic acid 4 mg every 4 weeks with alternate day prednisolone was given, with or without thalidomide 200 mg daily, for up to 16 months. Moreover, the zoledronic acid pharmacokinetics during the first and second infusions did not differ between 12 patients randomised to receive thalidomide and 12 patients not receiving thalidomide. The subjects in this study were patients with multiple myeloma with no disease progression 6 weeks after autologous stem-cell transplantation and conditioning with melphalan.[2]

(b) Osteonecrosis of the jaw

In a retrospective analysis of 28 cases of osteonecrosis of the jaw occurring in 254 patients given **pamidronate** or **zoledronate**, **zoledronate** was associated with a much higher risk than **pamidronate**, and a multivariate model revealed that the concurrent use of thalidomide increased the risk of osteonecrosis of the jaw 2.4-fold.[3] Similarly, in another review of 35 cases of **pamidronate** or **zoledronate**-associated osteonecrosis of the jaw, although no statistical analysis was carried out, concurrent use of thalidomide was frequent (46% of cases), leading the authors to suggest that the possible link should be further investigated.[4] Conversely, in a cohort of 259 patients with multiple myeloma who had all received treatment with **zoledronate**, thalidomide and dexamethasone, just 9 (6.6%) developed osteonecrosis of the jaw, which was stated to be comparable to the incidence previously reported for zoledronic acid alone.[5]

Mechanism

Uncertain. Thalidomide can rarely affect renal function, and was suggested to possibly interact with zoledronate. The antiangiogenic activity of thalidomide might increase the risk of osteonecrosis with bisphosphonates.

Importance and management

No interaction is established, and the data from the controlled study suggest that the combination of thalidomide and zoledronate has no greater risk of renal impairment than zoledronate alone. Thalidomide does not alter the pharmacokinetics of zoledronate. Further study is needed to ascertain if thalidomide increases the risk of osteonecrosis of the jaw seen with bisphosphonates.

Bisphosphonates; Alendronate + Phosphates

An isolated report describes a patient taking alendronate, who developed hypocalcaemic tetany after receiving two doses of oral *Fleet Phospho-Soda* (monobasic sodium phosphate with dibasic sodium phosphate).

Clinical evidence

A patient with Crohn's disease taking a 5-aminosalicylate (unnamed) and prednisone developed mild osteoporosis and was given alendronate 10 mg daily. About 18 months later she underwent elective bowel surgery, receiving 2 doses of oral *Fleet Phospho-Soda* (monobasic sodium phosphate with dibasic sodium phosphate) 2 hours apart before surgery. About

6 hours postoperatively she developed paraesthesia of her extremities and perioral region, hypophosphataemia, and hypocalcaemic tetany. She recovered after treatment with intravenous calcium gluconate 2 g over 30 minutes. Her serum calcium, phosphate and magnesium levels were low, and she was therefore given calcitriol and further calcium supplements.[1]

Mechanism

Hypocalcaemia in this patient was probably due to several factors, including disease of the terminal ileum and a history of diarrhoea, which could have resulted in calcium malabsorption and relative vitamin D deficiency. *Fleet Phospho-Soda* also causes hypocalcaemia, which is usually accompanied by hyperphosphataemia. The authors of the report suggest that alendronate was also a factor in the development of hypocalcaemia, and further, that the hypophosphataemia was possibly linked to high parathyroid hormone levels preoperatively.[1]

Importance and management

The authors of this isolated case advise care if phosphate-based oral laxatives are given to patients taking bisphosphonates, especially in patients with intestinal malabsorption syndromes.[1]

However, this appears to be the only report of hypocalcaemic tetany associated with the use of bisphosphonates and *Fleet Phospho-Soda*. It has also been noted that the patient's low magnesium levels could result in tetany.[2] Long-term prednisone treatment, which decreases calcium absorption, may also be involved. Further, the 2 doses of *Fleet-Phospho-Soda* were given 2 hours apart, rather than at the recommended interval of 10 to 12 hours. Other authors, in considering these factors, suggest that patients taking bisphosphonates are not at increased risk of hypocalcaemic tetany if they are given *Fleet Phospho-Soda*.[2]

Brimonidine or Latanoprost + NSAIDs

The reduction of intraocular pressure by brimonidine eye drops may be reduced by oral indometacin. The reduction in intraocular pressure by latanoprost eye drops was not significantly reduced by oral indometacin, slightly reduced by bromfenac eye drops, but enhanced by oral nimesulide and diclofenac eye drops.

Clinical evidence

In a double-blind study, 20 patients with open-angle glaucoma or ocular hypertension received treatment for their right eye with either latanoprost 0.005% eye drops in the morning and drug-free vehicle in the evening or with brimonidine 0.2% eye drops in the morning and evening. One week later treatment was started for the left eye with the opposite regimen to that used in the right eye. After another week the patients were given oral **indometacin** 25 mg four times daily for 2 weeks. Compared with pretreatment values, the intraocular pressure reduction with brimonidine alone was 14%, which fell to a non-significant 11% reduction when **indometacin** was given. Compared with pretreatment values the intraocular pressure with latanoprost alone was 25%, and this was not significantly altered when **indometacin** was given. Peripheral retinal microcirculation was increased by 23% with latanoprost, but not significantly affected by brimonidine. When **indometacin** was also given the effect of latanoprost became non-significant, and in the case of brimonidine, was reduced to a value lower than that measured before brimonidine was given. **Indometacin** did not affect visual function parameters.[1]

In another study, 11 healthy subjects were given latanoprost 0.005% eye drops daily, in both eyes for 8 weeks, with **bromfenac** eye drops put in one eye twice daily between weeks 4 and 6. After a 4-week washout period, **bromfenac** was again given for 2 weeks to the same eyes as before. Bromfenac alone did not affect intraocular pressure, but was found to significantly inhibit the intraocular pressure-lowering effects of latanoprost. At week 6, latanoprost reduced intraocular pressure by about 23% to 52%, but in those eyes also treated with **bromfenac** the reduction was between about 7% and 35%.[2] In a further similar study in patients with glaucoma, **bromfenac** eye drops twice daily for 12 weeks slightly attenuated the reduction in intraocular pressure seen with latanoprost eye drops (maximum difference 1.08 mmHg).[3]

In contrast to these studies, other researchers have found that 2 hours after a single 100-mg oral dose of **nimesulide**, the intraocular pressure in patients whose glaucoma was controlled by latanoprost was further reduced by about 3 mmHg.[4] Another study in patients with glaucoma found that 5 weeks of **diclofenac** 0.1% eye drops enhanced the intraocular pressure reducing effect of latanoprost eye drops: after one week intraocular pressure was reduced by 4.1 mmHg, compared with a 0.67 mmHg in those given placebo.[5]

Mechanism

Brimonidine may reduce intraocular pressure by decreasing aqueous inflow and increasing uveoscleral outflow. The latter effect is thought to occur by stimulation of endogenous prostaglandin $F_{2\alpha}$ formation.[1] Latanoprost is a synthetic analogue of dinoprost (prostaglandin $F_{2\alpha}$) which also reduces intraocular pressure by increasing uveoscleral outflow. It is also reported to induce endogenous prostaglandins.[2] NSAIDs, such as indometacin and bromfenac, may possibly antagonise this action by inhibiting the induction of endogenous prostaglandins by suppressing cyclooxygenase activity. However, it has also been suggested that the expression of prostaglandin receptors in ocular tissue may be up-regulated in the presence of prostaglandin inhibitors such as NSAIDs, resulting in a greater response to prostaglandin analogues.[4,5]

Importance and management

The reduction in the effect of brimonidine with oral indometacin may be of clinical importance.[1] It may be prudent to consider oral NSAID use in patients receiving treatment for glaucoma with brimonidine where intraocular pressure is not adequately reduced.

The situation with latanoprost is unclear. Both a small reduction, no effect, and an enhanced effect have been seen with various NSAIDs (some oral and some eye drops). Until more is known, additional monitoring may be appropriate when an oral or ocular NSAID is stopped or started in a patient stabilised on latanoprost.

Charcoal, activated + Miscellaneous

Small doses of activated charcoal appear to have little effect on the absorption of ciprofloxacin and oral contraceptives (administration separated), and only modestly reduces nizatidine and amlodipine absorption. Case reports describe the lack of efficacy of mitobronitol and reduced serum phenobarbital levels in the presence of small doses of activated charcoal.

Clinical evidence, mechanism, importance and management

The use of activated charcoal, in a usual dose of 50 g, to reduce the absorption of drugs and poisons after acute overdose is well established, as is repeated doses of activated charcoal to enhance the elimination of some drugs taken in overdose after they have been absorbed. Studies and references supporting these therapeutic uses of activated charcoal are not reviewed here. Activated charcoal is also included in various remedies used for gastrointestinal disorders such as flatulence or diarrhoea. Doses in these instances are very much lower (1 to 2 g daily) than those used in the treatment of poisoning, and there seems to be little reported about the effects of these doses on the absorption of other drugs.

In a study in 8 healthy subjects, a formulation of small spherical activated charcoal particles (*Kremezin* 2-g *granules*), used to adsorb uraemic tox-

ins in renal disease, hardly affected the bioavailability of **amlodipine** 5 mg when both drugs were given together, after a meal. The maximum amlodipine plasma concentration was reduced by 16%, but the AUC_{0-72} was decreased by only 7% (not statistically significant). In one subject the AUC was reduced by 26%, but even this would not be expected to be clinically significant.[1]

In one single-dose study in healthy subjects, **nizatidine** absorption was reduced by about 30% when it was taken one hour before activated charcoal 2 g.[2] In another single-dose study in 6 subjects, taking activated charcoal 1 g soon after ciprofloxacin 500 mg, had little effect on the pharmacokinetics of **ciprofloxacin** 500 mg (AUC reduced by 10%).[3]

In one case report, an antiemetic complementary remedy containing activated charcoal was thought to be the cause of a lack of effect of **mitobronitol** 125 mg used to treat primary thrombocythaemia in one patient.[4] In another case report,[5] activated charcoal 2 g three times daily was given with **phenobarbital** and enteral nutrition via a gastric fistula tube. The charcoal appeared to reduce the absorption of **phenobarbital** (serum level 4.3 mg/L, compared with a previous level of 24.8 mg/L). Giving the activated charcoal at least one hour apart from the **phenobarbital** resulted in an increase in serum levels to about 16 to 18 mg/L.

In a study in 9 healthy subjects, activated charcoal 5 g four times daily was taken for 3 days, mid-cycle, with the first daily dose taken 3 hours after the morning dose of a **combined oral contraceptive** (ethinylestradiol with norethisterone or gestodene), had no effect on the pharmacokinetics of the contraceptive steroids,[6] and ovulation (assessed by hormone measurements and ultrasonography) did not occur.[7] The authors concluded that repeated charcoal treatment, given 3 hours after and at least 12 hours before a **combined oral contraceptive**, can be used to treat diarrhoea in women taking **combined oral contraceptives**.[6,7]

Chlorzoxazone + Disulfiram

Disulfiram markedly increases the plasma levels of chlorzoxazone.

Clinical evidence

In a pharmacokinetic study in 6 healthy subjects, a single 500-mg dose of disulfiram markedly inhibited the metabolism of a single 750-mg dose of chlorzoxazone (clearance reduced by 85%, half-life increased from 0.92 to 5.1 hours, and a twofold increase in peak plasma levels).[1]

Mechanism

Disulfiram inhibits the cytochrome P450 isoenzyme CYP2E1, by which chlorzoxazone is metabolised. Note that chlorzoxazone is used as a probe substrate in evaluating the effects of drugs on CYP2E1, see 'Table 1.3', (p.6).

Importance and management

An established pharmacokinetic interaction. No increased adverse effects were seen while using these single doses, but an increase in chlorzoxazone toxicity (sedation, headache, nausea) would be expected with multiple doses. Be alert for the need to reduce the chlorzoxazone dosage if disulfiram is given concurrently.

1. Kharasch ED, Thummel KE, Mhyre J, Lillibridge JH. Single-dose disulfiram inhibition of chlorzoxazone metabolism: a clinical probe for P450 2E1. *Clin Pharmacol Ther* (1993) 53, 643–50.

Chlorzoxazone + Isoniazid

Isoniazid reduces the clearance of chlorzoxazone. The adverse effects of chlorzoxazone may be increased in some patients (particularly slow acetylators of isoniazid) if they also take isoniazid.

Clinical evidence

Five out of 10 healthy slow acetylators of isoniazid experienced an increase in the adverse effects of a 750-mg dose of chlorzoxazone (sedation, headache, nausea) after taking isoniazid 300 mg daily for 7 days. These symptoms disappeared within 2 days of withdrawing the isoniazid.[1] Pharmacokinetic analysis found that the clearance of chlorzoxazone was reduced by 56% when given on the last day of isoniazid use, then increased by 56% when given 2 days after stopping isoniazid.[1] Similar findings were reported in another study in slow acetylators of isoniazid. In this study, chlorzoxazone clearance was reduced by 78% when subjects had taken isoniazid 300 mg daily for 14 days, at which point the isoniazid was stopped. Two days later chlorzoxazone clearance was increased by 58%, and it had returned to normal 2 weeks later.[2] Rapid acetylators of isoniazid also had a 60% reduction in chlorzoxazone clearance on the last day of isoniazid use, but did not have any increase 2 days later.[2]

Mechanism

Isoniazid appears to cause a dual interaction. During administration, it inhibits the activity of the cytochrome P450 isoenzyme CYP2E1, the enzyme involved in the metabolism of chlorzoxazone. Shortly after stopping isoniazid, the metabolism of chlorzoxazone is increased, possibly because of induction of CYP2E1, although this effect was only evident in the slow acetylators.[1,2]

Importance and management

The increase in chlorzoxazone levels is established, and occurs in both slow and fast acetylators of isoniazid, although the increase in levels is slightly greater in slow acetylators. In practical terms this means that it may be necessary to reduce the chlorzoxazone dosage in some patients if they take isoniazid. Monitor concurrent use carefully. The rebound increase in chlorzoxazone clearance in slow acetylators on stopping isoniazid was short-lived and is probably of little clinical importance.

Cinacalcet + Food

Cinacalcet absorption is increased by food.

Clinical evidence

In a pharmacokinetic study in 29 healthy subjects, the AUC of cinacalcet was raised by 68% when a single 90-mg dose of cinacalcet was taken within 5 minutes of finishing a high-fat, high-calorie breakfast, when compared with the fasted state (10 hours). Similarly, a low-fat, low-calorie breakfast increased the AUC of cinacalcet by 50%. Food had no effect on the elimination half-life of cinacalcet.[1]

Mechanism

Food increases the rate and extent of absorption of cinacalcet, independently of the fat content. Possible mechanisms include increased gastric residence time or decreased presystemic metabolism.[1]

Importance and management

An established pharmacokinetic interaction. Cinacalcet should be taken with food or shortly after a meal[2,3] to maximise absorption.

Cinacalcet + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole causes about a twofold increase in cinacalcet exposure, and is therefore likely to increase cinacalcet adverse effects. Other potent CYP3A4 inhibitors are predicted to affect cinacalcet in the same way as ketoconazole.

Clinical evidence

In a pharmacokinetic study in 20 healthy subjects, the AUC and maximum level of cinacalcet were raised about twofold when a single 90-mg dose of cinacalcet was given on day 5 of a 7-day course of ketoconazole 200 mg twice daily. The median elimination half-life of cinacalcet was slightly increased and its clearance reduced by 65%. This resulted in an increase in the proportion of subjects reporting a treatment-related adverse event (42% versus 21%).[1]

Mechanism

Cinacalcet is extensively metabolised, in part by the cytochrome P450 isoenzyme CYP3A4, of which ketoconazole is a potent inhibitor. Ketoconazole therefore increases cinacalcet levels. The lack of change in elimination half-life suggests that the interaction principally resulted in an increase in the bioavailability of cinacalcet.

Importance and management

The pharmacokinetic interaction is established and likely to be clinically important. Cinacalcet treatment is monitored by measuring parathyroid hormone and serum calcium levels, and these should be closely monitored when ketoconazole is started or stopped, anticipating the need to adjust the cinacalcet dosage accordingly. Other potent CYP3A4 inhibitors would be predicted to interact similarly, and the manufacturers specifically mention **itraconazole**, **voriconazole**, **telithromycin**, **ritonavir** and **erythromycin**[2,3] (although note that erythromycin is sometimes considered to be a moderate CYP3A4 inhibitor).

On the basis that a potent CYP3A4 inhibitor caused just a twofold increase in AUC, weak to moderate CYP3A4 inhibitors would be unlikely to cause clinically relevant increases in cinacalcet levels.

2. Mimpara (Cinacalcet). Amgen Ltd. UK Summary of product characteristics, March 2009.
3. Sensipar (Cinacalcet). Amgen Inc. US Prescribing information, December 2008.

Cinacalcet + Miscellaneous

Potent CYP1A2 inhibitors (e.g. fluvoxamine, ciprofloxacin) are predicted to increase cinacalcet levels. Tobacco smoking induces CYP1A2 and is associated with lower cinacalcet levels. Rifampicin is predicted to reduce cinacalcet levels, because of its CYP3A4-inducing effects. Calcium carbonate, pantoprazole and sevelamer do not alter cinacalcet pharmacokinetics, and cinacalcet does not alter midazolam pharmacokinetics.

Clinical evidence, mechanism, importance and management

(a) Calcium carbonate

In a single-dose study in healthy subjects, the AUC of cinacalcet 100 mg was not changed by calcium carbonate 1.5 g.[1,2]

(b) CYP1A2 inducers and inhibitors

Cinacalcet is extensively metabolised, in part by the cytochrome P450 isoenzyme CYP1A2. The UK manufacturer notes that the clearance of cinacalcet was 36 to 38% higher in **smokers** than non-smokers, and that tobacco smoking induces CYP1A2. They suggest that the cinacalcet dose might need to be adjusted if a patient starts or stops smoking. Moreover, although the effect of CYP1A2 inhibitors such as **fluvoxamine** and **ciprofloxacin** on cinacalcet has not been studied, the manufacturer suggests that cinacalcet dose adjustment might be needed if these potent inhibitors are started or stopped.[3] Until more is known, it would be prudent to increase monitoring of parathyroid hormone and serum calcium levels in these situations.

(c) Midazolam

The manufacturers report that cinacalcet 90 mg daily for 5 days did not affect the pharmacokinetics of a single 2-mg oral dose of midazolam given on day 5, when compared with the pharmacokinetics of midazolam alone.[2,3]

(d) Pantoprazole

In a study in healthy subjects, the AUC of a single 90-mg dose of cinacalcet was not changed by pantoprazole 80 mg daily for 3 days.[1,2]

(e) Rifampicin (Rifampin)

Cinacalcet is extensively metabolised, in part by the cytochrome P450 isoenzyme CYP3A4. On the basis that the CYP3A4 inhibitor 'ketoconazole', (p.1553), causes clinically relevant increases in cinacalcet levels, rifampicin, a CYP3A4 inducer, is predicted to decrease levels of cinacalcet.[3] It would be prudent to monitor cinacalcet efficacy if rifampicin is required, anticipating the need to increase the dose.

(f) Sevelamer

In a study in healthy subjects, the AUC of a single 90-mg dose of cinacalcet was not changed when it was given with the first dose of sevelamer 2.4 g three times daily for 2 days.[1,2]

CNS depressants + CNS depressants

The concurrent use of two or more drugs that are CNS depressants can increase drowsiness and reduce alertness. These drugs include alcohol (even in small amounts), antidepressants, antiemetics, antiepileptics, antihistamines, antipsychotics, anxiolytics, barbiturates, hypnotics, opioid analgesics, and skeletal muscle relaxants. This increases the risk of accidents when driving or handling other potentially dangerous machinery, and may make the performance of everyday tasks more difficult and hazardous.

Clinical evidence, mechanism, importance and management

Many drugs have the propensity to cause depression of the central nervous system, resulting in drowsiness, sedation, respiratory depression and at the extreme, death. If more than one CNS depressant is taken, their effects may be additive. It is not uncommon for patients, particularly the elderly, to be taking numerous drugs (and possibly alcohol as well). Such patients are therefore at risk of cumulative CNS depression ranging from mild drowsiness through to a befuddled stupor, which can make the performance of the simplest everyday task more difficult or even impossible. The importance of this will depend on the context: it may considerably increase the risk of accident in the kitchen, at work, in a busy street, driving a car, or handling other potentially dangerous machinery where alertness is at a premium. It has been estimated that as many as 600 traffic accident fatalities each year in the UK can be attributed to the sedative effects of psychoactive drugs.[1] In a Spanish study of fatal road traffic accidents, blood samples were analysed from 9.7% of drivers killed in road accidents over a 10-year period. Of these drivers, medicines were detected in 4.7% (269 cases), and of these **benzodiazepines** were the most common (73%). Other drugs present in 6% to 12% of cases included **antidepressants**, **analgesics**, **antiepileptics**, **barbiturates** and **antihistamines**. Of the benzodiazepine cases, almost three quarters had another substance detected, mainly illicit drugs (cocaine, **opioids**, or cannabis) or **alcohol**. Only 7.7% had taken **benzodiazepines** or another medicinal drug alone.[2] **Alcohol** almost certainly makes things worse, particularly in the elderly.[3]

An example of the lethal effects of combining an **antihistamine**, a **benzodiazepine** and **alcohol** is briefly mentioned in the monograph 'Alcohol + Antihistamines', p.50. A less spectacular but socially distressing example is that of a woman accused of shop-lifting while in a confused state arising from the combined sedative effects of *Actifed*, a *Beechams Powder*

and *Dolobid* (containing **triprolidine**, **salicylamide** and **diflunisal**, respectively).[4]

Few, if any, well-controlled studies have investigated the cumulative or additive detrimental effects of CNS depressants (except with **alcohol**), but the following is a list of some of the groups of drugs that to a greater or lesser extent possess CNS depressant activity, which therefore might be expected to interact in this way: **alcohol**, **opioids**, **antiepileptics**, **antidepressants**, **antihistamines**, **antiemetics**, **antipsychotics**, **anxiolytics** and **hypnotics**. Some of the interactions of **alcohol** with these drugs are dealt with in individual monographs.

Colchicine + Macrolides

Several case reports describe acute life-threatening colchicine toxicity caused by the concurrent use of erythromycin or clarithromycin. One retrospective study found that 9 of 88 patients who had received the combination of colchicine and clarithromycin died.

Clinical evidence

A 29-year-old woman with familial Mediterranean fever and amyloidosis, who was taking long-term colchicine 1 mg daily, developed acute and life-threatening colchicine toxicity (fever, diarrhoea, myalgia, pancytopenia and later alopecia) 16 days after starting to take **erythromycin** 2 g daily. This patient had both cholestasis and renal impairment, factors that would be expected to reduce colchicine clearance and therefore predispose her to colchicine toxicity. Colchicine levels rose from below 12.6 nanograms/mL to 22 nanograms/mL after the addition of **erythromycin**.[1] In another patient, who had been taking colchicine 1.5 mg daily for 6 years, similar signs of acute colchicine toxicity developed 4 days after a 7-day course of **clarithromycin** 1 g daily, amoxicillin and omeprazole was started for *H. pylori* associated gastritis. The colchicine dose was reduced to 500 micrograms daily and then, after recovery, gradually increased slowly back to 1.5 mg daily.[2]

In another case, a 67-year-old man receiving CAPD, who was taking colchicine 500 micrograms twice daily, was admitted with symptoms of colchicine toxicity (including pancytopenia) 4 days after starting a course of **clarithromycin** 500 mg twice daily for an upper respiratory tract infection. All drugs were stopped and supportive treatment given, but he later died from multi-organ failure.[3]

These case reports led to a retrospective study of patients who had received the combination of colchicine and **clarithromycin** as inpatients. Of 116 patients given the drugs, 88 had received them concurrently and 28 received them sequentially. Nine of the concurrent group died (compared with only 1 of the sequential group), and of the nine, five had pancytopenia, and six had renal impairment. In the 88 patients receiving the drugs concurrently, longer overlapping therapy increased the relative risk of death 2.16-fold, the presence of renal impairment increased the risk 9.1-fold, and the development of pancytopenia increased the risk 23.4-fold.[4]

Three further cases of fatal agranulocytosis, presumed to result from use of colchicine with **clarithromycin**, have been reported,[5,6] and 2 other cases describe colchicine toxicity during **clarithromycin** use in patients with renal impairment.[7]

Mechanism

Clarithromycin and erythromycin might increase the bioavailability of colchicine by affecting P-glycoprotein, and/or may inhibit the hepatic metabolism of colchicine by the cytochrome P450 isoenzyme CYP3A4.[2,4] These effects would be more marked in patients with renal impairment, in whom colchicine clearance is already reduced.

Importance and management

Information on this interaction is limited, but it appears that clarithromycin and erythromycin can provoke acute colchicine toxicity, at the very least in pre-disposed individuals. Other macrolides do not appear to have been studied. However, until more information is available, if any patient is given colchicine and a macrolide be aware of the potential for toxicity, especially in patients with pre-existing renal impairment.

Colchicine + Verapamil

Verapamil may markedly increase colchicine levels, which led to neuromyopathy in one man.

Clinical evidence, mechanism, importance and management

An 83-year-old man who was taking slow-release verapamil 120 mg daily for tachyarrhythmia, as well as furosemide, aspirin, ambroxol and theophylline, took colchicine 2 mg over a 2-day period for acute gout, with diclofenac for pain. He had muscle weakness in his limbs and 4 days later became immobile. On admission to hospital he had flaccid tetraparesis (weakness of all four extremities). A diagnosis of colchicine-induced neuromyopathy was made after excessive levels of colchicine were found in his serum and CSF. The serum half-life was increased eightfold (from a reference value of 34 hours to 272 hours) and the CSF:serum ratio was increased to about 50%, much higher than the usual normal of less than 10%. At follow-up 40 days later he had partially recovered and colchicine was not detectable in his serum.[1]

Usual features of colchicine-induced neuropathy, such as high cumulative dose, long-term treatment, or renal impairment were not found. Colchicine is a substrate for the cytochrome P450 isoenzyme CYP3A4 in the liver. It was suggested that inhibition of CYP3A4 by verapamil may have resulted in increased colchicine serum levels. In addition, inhibition of P-glycoprotein in the blood-brain barrier by verapamil may have resulted in increased colchicine accumulation in the CSF.[1]

Although this is an isolated case, it is in line with the way both drugs interact with other substances. Therefore it would seem prudent to suspect an interaction in the case of otherwise unexplained colchicine toxicity in a patient taking verapamil.

1. Tröger U, Lins H, Scherrmann J-M, Wallesch C-W, Bode-Böger SM. Tetraparesis associated with colchicine is probably due to inhibition by verapamil of the P-glycoprotein efflux pump in the blood-brain barrier. *BMJ* (2005) 331, 613. Correction. ibid., (2006) 332, 882.

Contrast media + Phenothiazines

Two isolated case reports describe epileptiform reactions in two patients when metrizamide was used for lumbar myelography in the presence of chlorpromazine or dixyrazine. No such cases appear to have been reported for intrathecal iohexol: nevertheless, the manufacturer of iohexol advises the avoidance of phenothiazines and other drugs that lower seizure threshold when iohexol is used intrathecally. Phenothiazines should also be avoided if iomeprol is required, and also if iopamidol is used for neuroradiological procedures.

Clinical evidence

A patient receiving long-term treatment with **chlorpromazine** 75 mg daily had a grand mal seizure three-and-a-half hours after being given **metrizamide** (16 mL of 170 mg iodine per mL by the lumbar route). He had another seizure 5 hours later.[1] One out of 34 other patients demonstrated epileptogenic activity on an EEG when given **metrizamide** for lumbar myelography. The patient was taking **dixyrazine** 10 mg three times daily.[2] However, a clinical study in 26 patients given **levomepromazine** for

the relief of lumbago-sciatic pain found no evidence of an increased risk of seizures after they were given **metrizamide** for myelography.[3]

Mechanism

Intrathecal metrizamide or iohexol alone are rarely associated with seizures. Theoretically, this risk might be increased in patients taking other drugs that lower the seizure threshold, such as the phenothiazines.

Importance and management

The case report with intrathecal metrizamide led to the advice to stop phenothiazines before giving this contrast agent.[4] Intrathecal iohexol has also rarely been associated with seizures, and consequently the US manufacturer recommends that drugs that lower the seizure threshold, especially phenothiazines, are not recommended for use with iohexol by this route.[5] They should be stopped 48 hours before the procedure and not restarted until at least 24 hours after the procedure. The manufacturer of **iomeprol** gives the same advice.[6] However, the manufacturer of **iopamidol** advises that stopping phenothiazines is only necessary during neuroradiological use; the phenothiazine should be stopped 48 hours before the procedure and not restarted until at least 12 hours after the procedure has finished.[7] This advice specifically includes phenothiazines used for their antiemetic properties, for example, prochlorperazine. Although this risk is theoretical this would seem to be a prudent precaution. This advice does not apply to other routes of iohexol administration.[5]

Contrast media + Rifampicin (Rifampin)

Rifampicin may impair biliary excretion of contrast media.

Clinical evidence, mechanism, importance and management

The manufacturers of rifampicin advise that tests involving contrast media visualisation of the gall bladder should be undertaken before the morning dose of rifampicin, given orally[1,2] or before the daily dose of rifampicin given parenterally,[3] as biliary excretion of the contrast media may be impaired.

Contrast media; Iopanoic acid + Colestyramine

A single report describes poor radiographic visualisation of the gall bladder due to an interaction between iopanoic acid and colestyramine within the gut.

Clinical evidence, mechanism, importance and management

The cholecystogram of a man with post-gastrectomy syndrome taking colestyramine, who was given oral iopanoic acid as an X-ray contrast medium, suggested that he had an abnormal and apparently collapsed gall bladder. A week after stopping the colestyramine a repeat cholecystogram gave excellent visualisation of a gall bladder of normal appearance.[1] The same effects have been observed experimentally in *dogs*.[1] This effects probably occurs because colestyramine binds with the iopanoic acid in the gut so that little is absorbed and little is available for secretion in the bile, hence the poor visualisation of the gall bladder.

On the basis of reports about other drugs that similarly bind to colestyramine, it seems probable that this interaction could be avoided if the administration of iopanoic acid and colestyramine were to be separated as much as possible (note that it is usually recommended that other drugs are given 1 hour before or 4 to 6 hours after colestyramine). Whether other oral acidic X-ray contrast media bind in a similar way to colestyramine is uncertain, but this possibility should be considered.

Cyclobenzaprine + Fluoxetine and Droperidol

A patient taking cyclobenzaprine and fluoxetine developed torsade de pointes and ventricular fibrillation when droperidol was also taken.

Clinical evidence

A 59-year-old woman receiving long-term treatment with fluoxetine and cyclobenzaprine, and who had a prolonged baseline QTc interval of 497 milliseconds, was given droperidol before surgery on her Achilles tendon. During the surgery she developed torsade de pointes arrhythmia, which progressed to ventricular fibrillation. On the first postoperative day after the cyclobenzaprine had been withdrawn, her QTc interval had decreased towards normal (440 milliseconds).[1]

Mechanism

The authors suggested that fluoxetine might have raised cyclobenzaprine serum levels by inhibition of cytochrome P450 (possibly the isoenzyme CYP3A4, which is involved in the metabolism of cyclobenzaprine), and as a result the patient's QTc interval was prolonged. Cyclobenzaprine can cause arrhythmias, particularly in high doses. Therefore the addition of droperidol, which is known to prolong the QT interval, might have further extended the QTc interval and precipitated the torsade de pointes.

Importance and management

This is an isolated report, nevertheless, it is possible that a pharmacokinetic interaction occurs between cyclobenzaprine and fluoxetine, and that additive QT prolonging effects occur with cyclobenzaprine and droperidol, see also 'drugs that prolong the QT interval', (p.290). Some caution would be appropriate with concurrent use.

1. Michalets EL, Smith LK, Van Tassel ED. Torsade de pointes resulting from the addition of droperidol to an existing cytochrome P450 drug interaction. *Ann Pharmacother* (1998) 32, 761–5.

Cyclobenzaprine + Serotonergic drugs

Two cases of possible serotonin syndrome have been described in patients given cyclobenzaprine while taking serotonergic drugs (phenelzine and oxycodone in one case, and duloxetine, bupropion and oxycodone in the other).

Clinical evidence

A 70-year-old woman who had been taking **phenelzine** 15 mg four times daily for several years underwent surgery for an infected hip replacement. She was receiving cefazolin and, for pain, paracetamol and **oxycodone**. Six days later she started to take cyclobenzaprine 10 mg three times daily for muscle spasm. After the third dose she became confused, agitated, febrile and tachycardic. Cyclobenzaprine and oxycodone were stopped, with no improvement in her condition. Eventually a diagnosis of serotonin syndrome was suspected, and phenelzine was also stopped. She recovered over the subsequent 3 days.[1]

In a similar case, a 53-year-old man taking **duloxetine**, pregabalin, **bupropion** and **oxycodone** or hydromorphone as needed, underwent orthopaedic surgery and was given cyclobenzaprine 10 mg three times daily. Five days after surgery he became tachycardic and markedly agitated, and developed excessive sweating; he eventually required sedation and intubation. Cyclobenzaprine and duloxetine were stopped, and he was treated with cyproheptadine (a serotonin antagonist), and recovered over the following 2 days.[1]

Mechanism

The combined use of serotonergic drugs can, rarely, precipitate the 'serotonin syndrome', (p.9). Cyclobenzaprine is structurally related to the tricyclic antidepressants and might therefore have serotonergic effects, which could be additive with known serotonergic drugs.

Importance and management

These cases illustrate the potential for serotonin syndrome to develop when multiple drugs with serotonergic effects (such as the MAOIs, some opioids, SNRIs) are given together. Although case reports for cyclobenzaprine are generally lacking, based on the way tricyclics (which are related to cyclobenzaprine) are known to interact with MAOIs, it would seem prudent to avoid the concurrent use of cyclobenzaprine and MAOIs: note that the US manufacturer of cyclobenzaprine[2] contraindicates concurrent use.

2. Amrix (Cyclobenzaprine hydrochloride). Cephalon Inc. US Prescribing information, December 2008.

Dantrolene + Metoclopramide

Metoclopramide increases the bioavailability of dantrolene.

Clinical evidence, mechanism, importance and management

A study in 7 paraplegics and 6 quadriplegics with spinal cord injuries found that a single 10-mg intravenous dose of metoclopramide increased the bioavailability of a single 100-mg oral dose of dantrolene by 57%. The reasons for this effect are not known, although it was suggested that absorption may have been affected. The clinical relevance of this interaction is uncertain but the authors of the study suggest that patients should be well monitored if metoclopramide is added or withdrawn from patients who are taking dantrolene.[1]

1. Gilman TM, Segal JL, Brunnemann SR. Metoclopramide increases the bioavailability of dantrolene in spinal cord injury. *J Clin Pharmacol* (1996) 36, 64–71.

Dantrolene + Oestrogens

The concurrent use of dantrolene and oestrogens might increase the risk of hepatotoxicity.

Clinical evidence, mechanism, importance and management

Dantrolene can cause hepatotoxicity, and risk factors include female gender, age over 30 years, and concurrent use of other hepatotoxic drugs.[1,2] The manufacturers also state that dantrolene-related hepatotoxicity in women aged over 35 years appears to be more common in those taking oestrogens.[1] They say that, while a definitive interaction has not been established, caution is recommended on concurrent use.[2] In practice, this means that patients should be advised to seek medical advice if they develop symptoms such as generalised itching, yellowing of the eyes or skin, weight loss, nausea, or vomiting.

2. Dantrium Capsules (Dantrolene sodium). Procter & Gamble Pharmaceuticals. US Prescribing information, September 2002.

Dextromethorphan + Amiodarone

Amiodarone can modestly reduce the clearance of dextromethorphan.

Clinical evidence

A study in 8 patients with cardiac arrhythmias found that amiodarone (1 g daily for 10 days followed by 200 to 400 mg daily for a mean duration of 76 days) changed their excretion of dextromethorphan 40 mg and its metabolite. The amount of unchanged dextromethorphan in the urine rose by nearly 150%, whereas the amount of its metabolite (dextrorphan) fell by about 25%.[1] All patients were of extensive CYP2D6 metaboliser phenotype (that is, they had normal levels of this isoenzyme) before amiodarone, and the effect of the amiodarone was modest (did not change them into pseudo-poor metabolisers, that is, those lacking or deficient in this isoenzyme).[1]

Mechanism

In vitro studies using liver microsomes have shown that amiodarone inhibits the metabolism (*O*-demethylation) of dextromethorphan by inhibiting the cytochrome P450 isoenzyme CYP2D6 within the liver.[1] This will occur in extensive metabolisers, but not poor metabolisers of this isoenzyme, see 'Genetic factors in drug metabolism', (p.4), for further discussion of metaboliser phenotypes.

Importance and management

Information seems to be limited to this study. The implications are that amiodarone might interfere with the results of phenotyping if dextromethorphan is used to determine CYP2D6 activity. The extent of the interaction is unlikely to be clinically relevant in patients taking dextromethorphan, since this drug has a wide therapeutic index and its dose is not individually titrated.

1. Funck-Brentano C, Jacqz-Aigrain E, Leenhardt A, Roux A, Poirier J-M, Jaillon P. Influence of amiodarone on genetically determined drug metabolism in humans. *Clin Pharmacol Ther* (1991) 50, 259–66.

Dextromethorphan + Bupropion

Bupropion may reduce the metabolism of dextromethorphan in some patients.

Clinical evidence, mechanism, importance and management

In a study in 21 subjects who were quitting smoking and were CYP2D6 extensive metabolisers (that is, those with normal levels of this isoenzyme), 6 of 13 subjects who received bupropion 150 mg daily for 3 days and then twice daily for 14 days had metabolic ratios of dextromethorphan 30 mg similar to those seen in poor metabolisers (that is, those lacking or deficient in this isoenzyme): the metabolism of dextromethorphan to dextrorphan was substantially reduced. No such change was seen in the 8 subjects who received placebo.[1]

This suggests that bupropion can inhibit the cytochrome P450 isoenzyme CYP2D6, and is sufficiently potent an inhibitor to change up to half of extensive metabolisers into 'pseudo' poor metabolisers.

It has been suggested that care should be taken when initiating or discontinuing bupropion in patients taking CYP2D6 substrates, due to the possibility of raised levels.[1] Dextromethorphan is used as a probe substrate for CYP2D6, and is generally considered to have a wide therapeutic range and its dose is not individually titrated; therefore, the interaction with bupropion is unlikely to be clinically relevant. Nevertheless, it is possible that some extensive metaboliser patients might become more sensitive to the adverse effects of dextromethorphan while taking bupropion.

1. Kotlyar M, Brauer LH, Tracy TS, Hatsukami DK, Harris J, Bronars CA, Adson DE. Inhibition of CYP2D6 activity by bupropion. *J Clin Psychopharmacol* (2005) 25, 226–9.

Dextromethorphan + Celecoxib

Celecoxib modestly increases the plasma levels of dextromethorphan.

Clinical evidence, mechanism, importance and management

The manufacturers of celecoxib note that the plasma levels of dextromethorphan have been increased by 136% in the presence of celecoxib. Celecoxib inhibits the cytochrome P450 isoenzyme CYP2D6 and thus inhibits the metabolism of dextromethorphan by this isoenzyme.[1]

Dextromethorphan is used as a probe substrate for CYP2D6, and is generally considered to have a wide therapeutic range and its dose is not individually titrated; therefore, its interaction with celecoxib is unlikely to be clinically relevant. However, based on this pharmacokinetic interaction, the manufacturers of celecoxib suggest that caution should be observed with drugs that have a narrow therapeutic margin and are known to be predominantly metabolised by CYP2D6. They mention tricyclics, SSRIs, neuroleptics, and anti-arrhythmics, although not all drugs in these classes

are important CYP2D6 substrates (for a list of CYP2D6 substrates, see 'Table 1.3', (p.6)). They say that the dose of CYP2D6 substrates may need to be decreased on starting celecoxib and increased on stopping it.[1] However, celecoxib is a very moderate CYP2D6 inhibitor when compared with the known potent CYP2D6 inhibitors cinacalcet and quinidine, and therefore any interactions with celecoxib as a result of this mechanism would, at worst, only be expected to be of only modest clinical relevance. So far there appear to be no direct clinical reports of any problems with concurrent use.

1. Celebrex (Celecoxib). Pharmacia Ltd. UK Summary of product characteristics, June 2009.

Dextromethorphan + Cinacalcet

Cinacalcet very markedly increases dextromethorphan levels.

Clinical evidence

In a pharmacokinetic study in 23 healthy subjects who were extensive CYP2D6 metabolisers (that is, those with normal levels of this isoenzyme), the AUC of a single 30-mg dose of dextromethorphan was very markedly increased (by 11.4-fold) when given on day 8 of cinacalcet 50 mg daily for 8 days.[1]

Mechanism

In *vitro*, cinacalcet is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6, comparable to the well-known potent CYP2D6 inhibitor quinidine. This human study with the CYP2D6 probe substrate dextromethorphan confirms that cinacalcet is a clinically important CYP2D6 inhibitor.

Importance and management

A pharmacokinetic interaction between cinacalcet and dextromethorphan is established. However, dextromethorphan has a wide therapeutic range, and its dose is not individually titrated, so the interaction with cinacalcet is unlikely to be generally clinically relevant. Nevertheless, it is possible that some extensive metaboliser patients might become more sensitive to the adverse effects of dextromethorphan while taking cinacalcet.

Dextromethorphan is also used as a probe substrate for CYP2D6. These results therefore also suggest that cinacalcet will increase the levels of drugs that are substrates for CYP2D6. However, this will occur only in individuals who are extensive metabolisers. Poor metabolisers lack or have low levels of CYP2D6, and would not be affected. The effect of cinacalcet on CYP2D6 is likely to be important for CYP2D6 substrates that have a narrow therapeutic window. For a list of drugs that are CYP2D6 substrates, see 'Table 1.3', (p.6).

Dextromethorphan + Grapefruit and other fruit juices

Grapefruit juice and the juice of the bitter orange increase the absorption of dextromethorphan.

Clinical evidence, mechanism, importance and management

In a study, 11 healthy subjects were given single 30-mg doses of dextromethorphan at bedtime, followed by 200 mL of water, 200 mL of grapefruit juice (prepared by diluting 1 part of 100% pure frozen concentrate, *Minute Maid*, with 3 parts water) or 200 mL of freshly-squeezed juice of the bitter orange. Measurement of the amount of dextromethorphan and its metabolites in the urine indicated that the bioavailability of dextromethorphan was increased by more than fivefold by grapefruit juice and by more than fourfold by bitter orange juice. Dextromethorphan levels were still raised 3 days later, indicating a sustained effect of the juices.

It was suggested that these fruit juices increased the absorption of dextromethorphan through the gut wall by inhibiting the cytochrome P450 isoenzyme CYP3A and P-glycoprotein.[1] The authors did not report any adverse effects of the increased exposure to dextromethorphan in these subjects, and dextromethorphan is generally considered to have a wide therapeutic range and the dose is not individually titrated. Therefore, the interaction with these fruit juices is probably unlikely to be clinically relevant. Note that, bitter orange is a different species to oranges that are usually consumed as part of the diet, and these results are not applicable to conventional orange juice.

Dextromethorphan + Quinidine

Quinidine markedly increases the plasma levels of dextromethorphan in those who have normal levels of CYP2D6. This effect is maximal at low doses of quinidine (25 to 30 mg).

Clinical evidence

In a study, 6 subjects with normal levels of CYP2D6 (extensive metabolisers) were given dextromethorphan 60 mg twice daily. Steady-state plasma dextromethorphan levels averaged only 12 nanograms/mL. However, after being given quinidine 75 mg twice daily for a week, then a single 60-mg dose of dextromethorphan, their plasma levels of dextromethorphan were over threefold higher, at 38 nanograms/mL.[1] Some of the patients given the combination had an increase in dextromethorphan adverse effects (nervousness, tremors, restlessness, dizziness, shortness of breath, confusion etc).[1] Similarly, other pharmacokinetic studies have found increases in dextromethorphan levels in extensive CYP2D6 metabolisers, but not in those totally lacking or deficient in this isoenzyme (poor metabolisers).[2-4] In a dose-ranging study, quinidine 25 to 30 mg daily produced maximal increases in dextromethorphan levels, with higher doses producing no further increases, and lower doses producing smaller increases.[5] In one experimental study of citric acid-induced cough, quinidine increased the cough-suppressant effect of dextromethorphan.[6,7]

Mechanism

Quinidine inhibits the oxidative metabolism of dextromethorphan by the cytochrome P450 isoenzyme CYP2D6 to dextrorphan, effectively making extensive metabolisers of CYP2D6 into the poor metaboliser phenotype, see 'Genetic factors in drug metabolism', (p.4), for further discussion of metaboliser phenotypes.

Importance and management

An established interaction. Dextromethorphan is used as a probe substrate for CYP2D6, and is generally considered to have a wide therapeutic range, and its dose is not individually titrated; therefore, the interaction with quinidine is unlikely to be clinically relevant. Nevertheless, it is possible that some extensive metabolisers of CYP2D6 might become more sensitive to the adverse effects of dextromethorphan if they are taking quinidine. This effect is maximal at low doses of quinidine (25 to 30 mg).

Low-dose quinidine has been given with dextromethorphan to sustain therapeutic levels of dextromethorphan and thereby try and improve its efficacy in various neurological disorders (dextromethorphan is a *N*-methyl-D-aspartate antagonist, which means it can affect pain transmission). A fixed dose combination is being investigated.[8]

Disulfiram + Celecoxib

An isolated report describes encephalopathy and polyneuropathy which developed in an elderly patient taking disulfiram when she was also given celecoxib and citalopram.

Clinical evidence, mechanism, importance and management

An elderly, chronic alcoholic patient who had been taking disulfiram 400 mg daily for 4 months was given citalopram 20 mg daily and celecoxib. She became apathetic and confused and also developed ataxia, and was found to have vascular encephalopathy and polyneuropathy. Encephalopathy and polyneuropathy may occur with disulfiram alone, but the authors suggest that it is rare, and only usually occurs in overdose. However, it was suggested that in this case an interaction between either celecoxib or citalopram and disulfiram may have resulted in toxic levels of disulfiram, or that disulfiram had inhibited citalopram and/or celecoxib metabolism and increased their levels. Some of the central effects may have been due to additive effects of the individual drugs.[1]

This appears to be an isolated case, and an interaction is by no means established. No general conclusions can therefore be drawn.

1. Berger A, Pategay N, Vogt N. Encéphalopathie aiguë et polyneuropathie au disulfiram: toxicité propre et interactions. Acute encephalopathy and polyneuropathy secondary to disulfiram administration: self toxicity and interactions. *Therapie* (2002) 57, 505–7.

Enteric-coated, delayed-release preparations + Drugs that affect gastric pH

Theoretically, enteric-coated, delayed-release preparations may possibly dissolve prematurely if they are taken at the same time as antacids. This has been seen with some preparations, but not others. Release characteristics are likely to depend on the specific coating, and the manufacturers advice should be followed.

Clinical evidence

(a) Antacid

A placebo-controlled, crossover study in 21 healthy subjects, found that when extended-release **oxybutynin** 10 mg (*Ditropan XL*) was given at the same time as *Maalox* 20 mL (**aluminium**/**magnesium hydroxide** and **simeticone**) there was no change in the pharmacokinetics of **oxybutynin** or its metabolite.[1]

In an identical study in 23 healthy subjects, *Maalox* increased the maximum plasma level of a single 4-mg dose of extended-release **tolterodine** (*Detrol LA*) by 50%, but did not change the time to maximum level, elimination half-life, or AUC of **tolterodine**.[1]

(b) Omeprazole

In a placebo-controlled, crossover study in 39 healthy subjects, pre-treatment with omeprazole 20 mg daily for 4 days did not alter the pharmacokinetics of extended-release **oxybutynin** 10 mg [*Ditropan XL*]. The metabolites of **oxybutynin** were similarly unaffected. Pre-treatment with omeprazole increased the maximum plasma level of a single 4-mg dose of extended release **tolterodine** [*Detrol LA*] by 38%, but did not change the time to maximum level, elimination half-life, or AUC of **tolterodine**.[2]

The bioavailability of enteric-coated preparations of aspirin, diclofenac, and ketoprofen are unaffected by omeprazole, see 'NSAIDs or Aspirin + Proton pump inhibitors', p.171.

Mechanism

A marked rise in pH caused by antacids might cause premature dissolution of the coating of preparations formulated to prevent release of the contents until they reach the more alkaline conditions within the small intestine. Other types of delayed release preparations that have release characteristics independent of pH, such as those based on the osmotic principle, would not be expected to be affected.

Importance and management

Traditionally, it has been considered that drugs formulated with enteric coatings to resist gastric acid, or formulated as delayed-release preparations, should not be given with antacids. Accelerated drug release from a delayed-release product (dose dumping) might lead to increased adverse effects and lack of efficacy for the duration of the dose interval. The evidence above for extended-release tolterodine suggests that an antacid did cause a faster release of tolterodine from this product, but whether the 50% increase in the maximum level is sufficient to cause an increase in adverse effects is not known. Pre-treatment with omeprazole caused a smaller 38% increase in maximum tolterodine levels. The extended-release oxybutynin product was not affected by antacid or omeprazole, which was not unexpected because release from this product is osmotically driven and pH independent.

Release characteristics are likely to depend on the specific coating, and therefore no general advice can be given. The manufacturers' advice should be followed.

Ethylene dibromide + Disulfiram

The very high incidence of malignant tumours in *rats* exposed to both ethylene dibromide and disulfiram is the basis of the recommendation that concurrent exposure to these compounds should be avoided.

Clinical evidence, mechanism, importance and management

Research conducted to establish the occupational safety of exposure to ethylene dibromide found that the incidence of malignant tumours in *rats* exposed to 20 ppm ethylene dibromide (7 hours daily, 5 days weekly), while receiving a diet containing 0.05% disulfiram by weight, is very high indeed.[1,2] The reasons are not understood. In addition to the precautions needed to protect workers from the toxic effects of ethylene dibromide, it has been strongly recommended that disulfiram should not be given to those who may be exposed to this compound.[2] This information is also summarised in another report.[3]

Glucagon + Beta blockers

The blood glucose-elevating effects of glucagon may be reduced by propranolol and possibly other beta blockers.

Clinical evidence, mechanism, importance and management

In a study in 5 healthy subjects the blood glucose-elevating effect of glucagon was reduced in the presence of **propranolol**.[1] Blood glucose levels increased by about 45% in the presence of glucagon, but when **propranolol** was also given the increase was only about 15%. The reason for this effect is uncertain, but one suggestion is that the **propranolol** inhibits the effects of the catecholamines that are released by glucagon. If this mechanism is correct, it seems possible that other beta blockers may interact in the same way as **propranolol**. However, the clinical importance of the interaction is uncertain.

Note that glucagon may be used for treating beta blocker poisoning.

Iron chelators + Ascorbic acid (Vitamin C)

High-dose vitamin C may cause cardiac disorders in some patients given desferrioxamine (deferoxamine). Other iron chelators are expected to interact similarly.

Clinical evidence, mechanism, importance and management

Vitamin C is given with iron chelators to patients with iron overload because it mobilises iron stores and thus promotes the excretion of iron. One study in 11 patients with thalassaemia noted that a striking deterioration in left ventricular function occurred when the patients were given 500 mg of vitamin C with intramuscular **desferrioxamine** (deferoxamine). In most patients left ventricular function returned to normal when the vitamin C was stopped.[1] For this reason it has been suggested that vitamin C should be used with **desferrioxamine** with caution,[2] only where there is a demonstrated need,[3] and in the lowest possible dose.[1] The manufacturers of **desferrioxamine** recommend that a maximum daily dose of 200 mg of vitamin C should be used in adults, that vitamin C should not be given within the first month of **desferrioxamine** treatment, that cardiac function should be monitored during combined use, and that vitamin C should not be given to those with cardiac failure.[4,5]

The manufacturers of **deferasirox** note that, although concurrent use with vitamin C has not been formally studied, doses of vitamin C up to 200 mg daily were allowed in clinical studies of **deferasirox** without adverse consequences.[6,7]

The manufacturer of **deferiprone** advise caution with the use of vitamin C, based on the way desferrioxamine is expected to interact.[8] It would therefore seem prudent to follow similar precautions to those advised with the other iron chelators.

6. Exjade (Deferasirox). Novartis Pharmaceuticals UK Ltd. UK Summary of product characteristics, March 2009.
7. Exjade (Deferasirox). Novartis. US Prescribing information, April 2009.
8. Ferriprox (Deferiprone). Swedish Orphan International. UK Summary of product characteristics, October 2008.

Iron chelators + Miscellaneous

Food increases the bioavailability of deferasirox but does not affect deferiprone. The use of deferasirox and deferiprone with aluminium antacids is not recommended. Rifampicin (rifampin) reduces the exposure to deferasirox: carbamazepine, phenobarbital, phenytoin, and ritonavir are predicted to interact similarly. Deferasirox increases the levels of midazolam and repaglinide. Other drugs that have similar routes of metabolism are also expected to be affected (e.g. ciclosporin, paclitaxel). Hydroxycarbamide does not alter deferasirox metabolism. Additive blood dyscrasias may occur if hydroxycarbamide is used with deferiprone. Bisphosphonates, corticosteroids, and NSAIDs (including analgesic dose aspirin) may increase the risk of gastrointestinal ulceration with deferasirox. Deferasirox may increase the risk of bleeding with anticoagulants. Deferasirox does not appear to alter the pharmacokinetics of digoxin.

Clinical evidence, mechanism, importance and management

(a) Aluminium-containing antacids

Although concurrent use has not been formally studied, the manufacturer recommends that **deferasirox** is not taken with aluminium-containing antacids.[1,2] **Deferasirox** has a lower affinity for aluminium than for iron, but theoretically aluminium might reduce the efficacy of **deferasirox**. Similar precautions are advised with **deferiprone**.[3]

(b) CYP2C8 substrates

In a study in healthy subjects, **deferasirox** 30 mg/kg daily for 4 days increased the AUC of a single 500-microgram dose of **repaglinide** 2.3-fold and increased its maximum levels by 62%.[1,2] The manufacturers advise monitoring blood glucose levels closely and giving consideration to reducing the **repaglinide** dose. The UK manufacturers advise against doses of **repaglinide** greater than 500 micrograms.[1,2] On the basis of this study, caution is advised with other CYP2C8 substrates, and **paclitaxel** is specifically named.[1,2]

See 'Table 1.3', (p.6), for a list of clinically relevant CYP2C8 substrates.

(c) CYP3A4 substrates

In a study in healthy subjects, **deferasirox** decreased the peak levels of **midazolam** (a probe substrate for the cytochrome P450 isoenzyme CYP3A4) by 23% and decreased the exposure to **midazolam** by 17%. Changes of this magnitude would not be expected to be clinically relevant. However, the manufacturers cautiously suggest that the effect may be greater in a clinical setting, and so advise caution if **deferasirox** is given with **midazolam**, or other substrates of CYP3A4 (they name **ciclosporin** (**cyclosporine**), **ergotamine**, **hormonal contraceptives** and **simvastatin**).[1,2]

(d) Digoxin

In a randomised study in 15 healthy subjects[4], the pharmacokinetics of digoxin (500 micrograms on day 1, and then 250 micrograms daily on days 2 to 8) were not affected by a single 20-mg/kg oral dose of **deferasirox**, given on day 8. No digoxin dose adjustment would be expected to be necessary on concurrent use.

(e) Food

In single-dose studies in healthy subjects, giving **deferasirox** 30 minutes before a high-fat breakfast, 30 minutes before a standard breakfast, or with a standard breakfast modestly increased the AUC by 18%, 29% and 31%, respectively, when compared with the fasted state. In a further study in 12 patients with iron overload, giving **deferasirox** 5 minutes before a high-fat breakfast increased the AUC by 62% when compared with the fasted state. Nevertheless the concentration of iron-**deferasirox** complex in plasma was unaffected by timing in relation to food.[5] However, the manufacturer recommends that, to limit variability, **deferasirox** is taken on an empty stomach at least 30 minutes before food.[1,2]

In a further study, the AUC of **deferasirox** was not significantly different when the tablets for oral suspension were dispersed in water, orange juice, or apple juice.[6] Therefore, any of these drinks is suitable for dispersion.[1,2]

Food does not appear to decrease the absorption of **deferiprone**.[3]

(f) Hydroxycarbamide

In vitro, hydroxycarbamide did not inhibit the metabolism of **deferasirox**.[1,2]

Note that hydroxycarbamide can cause neutropenia, and the manufacturer of **deferiprone** advises against its concurrent use with other drugs that may cause neutropenia or agranulocytosis.[3]

(g) UGT enzyme inducers

In a study in healthy subjects, **rifampicin** (**rifampin**) 600 mg daily for 9 days reduced the AUC of a single 30 mg/kg dose of **deferasirox** by 44%.The mechanism for this interaction was thought to be UGT induction, and therefore caution is warranted with other drugs said to induce this enzyme, such as **carbamazepine**, **phenobarbital**, **phenytoin** and **ritonavir**. The manufacturers recommend that the efficacy of **deferasirox** (serum ferritin levels and clinical response) should be monitored if any of these drugs is started or stopped, and the dose of **deferasirox** adjusted if necessary.[1,2] The US manufacturer does not recommend exceeding a maximum dose of 40 mg/kg of deferasirox.[2]

(h) Other drugs

The manufacturers of **deferasirox** advise that caution is warranted in patients taking analgesic-dose **aspirin**, **bisphosphonates**, **corticosteroids** or **NSAIDs**. This is because **deferasirox** has caused gastrointestinal ulceration, which may be additive with these drugs. Furthermore, they advise caution with **anticoagulants** as the use of **deferasirox** may increase the risk of bleeding.[1,2]

Iron chelators + Phenothiazines

Prochlorperazine caused unconsciousness in two patients receiving desferrioxamine (deferoxamine).

Clinical evidence, mechanism, importance and management

The use of prochlorperazine in 2 patients receiving **desferrioxamine** (deferoxamine) resulted in unconsciousness for 48 to 72 hours. It was suggested that the drug combination resulted in increased removal of iron from the central nervous system, thereby impairing noradrenergic and serotonergic systems.[1] It has also been suggested that **desferrioxamine**-induced damage of the retina may be more likely in the presence of phenothiazines.[2] It would seem wise to avoid the concurrent use of **desferrioxamine** and prochlorperazine. The manufacturer[3] of chlorpromazine predicts that a similar interaction may occur with chlorpromazine, but there seems to be no direct evidence of adverse interactions with chlorpromazine or any other phenothiazine. In addition, there appears to be no evidence of an interaction between the phenothiazines and other iron chelators

Memantine + Antidiabetics

The concurrent use of glibenclamide (glyburide) with metformin and memantine does not appear to affect the pharmacokinetics of these drugs.

Clinical evidence, mechanism, importance and management

In a study in 21 healthy subjects who took glibenclamide (glyburide) 1.25 mg with metformin 250 mg twice daily for 6 days, the administration of a single 20-mg dose of memantine did not result in any changes in the pharmacokinetics of any of the three drugs. Memantine did not reduce the glucose-lowering effects of either antidiabetic drug.[1] Evidence is limited, but dose adjustments would not appear to be necessary on concurrent use.

1. Rao N, Chou T, Ventura D, Abramowitz W. Investigation of the pharmacokinetic and pharmacodynamic interactions between memantine and glyburide/metformin in healthy young subjects: a single-center, multiple-dose, open-label study. *Clin Ther* (2005) 27, 1596–1606.

Memantine + Co-trimoxazole

A single case report describes myoclonus and confusion, which developed when a patient took memantine and co-trimoxazole or trimethoprim.

Clinical evidence, mechanism, importance and management

A 78-year-old woman who was taking memantine 15 mg daily in two divided doses took co-trimoxazole (trimethoprim 160 mg with sulfamethoxazole 800 mg) twice daily for 5 days for a urinary tract infection. During the course of treatment she developed significant upper extremity muscle twitching, confusion and agitation. These symptoms diminished on stopping the co-trimoxazole. The patient experienced a second, similar episode when she started to take trimethoprim 100 mg daily as prophylaxis for urinary tract infections. In light of a similar report of an interaction between the related drug, amantadine, and co-trimoxazole (see 'Amantadine + Co-trimoxazole', p.785) the authors of this report considered it was likely that the patient's symptoms were due to an interaction between memantine and trimethoprim.[1] Note that the patient was also taking a number of drugs, including hydrochlorothiazide, which has been suggested to reduce memantine renal excretion, see 'Memantine + Miscellaneous', below, for details.

1. Moellentin D, Picone C, Leadbetter E. Memantine-induced myoclonus and delirium exacerbated by trimethoprim. Ann Pharmacother (2008) 42, 443–7.

Memantine + Miscellaneous

The use of memantine, an NMDA antagonist, with other NMDA antagonists, such as amantadine, ketamine and dextromethorphan is predicted to increase the risk of adverse effects. Memantine is predicted to interact with other drugs eliminated by the same renal secretion mechanism, but no important interaction was seen with hydrochlorothiazide and triamterene.

Clinical evidence, mechanism, importance and management

(a) Interactions involving cytochrome P450 isoenzymes

The results of *in vitro* studies indicate that memantine is not likely to cause interactions by inducing or inhibiting the major cytochrome P450 isoenzymes involved in drug metabolism (CYP1A2, CYP2C9, CYP3A4).[1,2] However, an *in vitro* study has demonstrated that memantine may inhibit CYP2B6 at clinically relevant concentrations.[3] **Cyclophosphamide** and **ifosfamide** are substrates of this isoenzyme, but there are few other drugs that are metabolised by this route. No metabolic interaction as a result of this mechanism appears to have been described.[3] In addition, memantine is not significantly metabolised by the cytochrome P450 enzyme system, and is therefore not expected to undergo interactions as a result of this mechanism.[1]

(b) Other drugs eliminated by renal tubular secretion

Memantine is predicted to interact with other drugs that use the same renal cationic transport system leading to increased levels of memantine and/or the other drug. The manufacturer lists **cimetidine**, **ranitidine**, **hydrochlorothiazide**, metformin, **nicotine**, **procainamide**, **quinidine**, **quinine** and **triamterene** as possible examples.[1,2] However, in an interaction study, the concurrent use of memantine and **hydrochlorothiazide** with **triamterene** did not result in any change in the steady-state AUC of memantine or **triamterene**, and the AUC of **hydrochlorothiazide** showed a modest *reduction* of about 20%.[1] This degree of change is unlikely to be clinically relevant. Furthermore, a study with metformin found no interaction (see 'Memantine + Antidiabetics', above). Therefore, a clinically important interaction as a result of this mechanism seems unlikely.

(c) Other NMDA antagonists

Memantine is chemically related to **amantadine**, and the manufacturer advises that concurrent use should be avoided[2] or undertaken with caution[1] because of the increased risk of adverse CNS-related drug reactions such as psychosis.[2] Although there are no data, an increased risk is also predicted for **ketamine** and **dextromethorphan**, which are also NMDA antagonists. Avoidance of,[2] or caution with,[1] concurrent use is advised.

(d) Warfarin

The manufacturer of memantine notes that, although no causal relationship has been established, isolated cases of INR increases have been reported in patients taking warfarin. They suggest close monitoring of anticoagulant effects if both drugs are given.[1,2]

(e) Other drugs

Memantine might modify the effects of antispasmodic drugs such as **dantrolene** or **baclofen** and dosage adjustment might be required.[2] Memantine is predicted to enhance the effects of **antimuscarinics**, **levodopa** and

dopaminergic (**dopamine agonist**) drugs.[2] Memantine is predicted to reduce the effects of **barbiturates** and **antipsychotics**.[2]

Memantine + Urinary alkalinisers

Drugs that increase the pH of the urine (e.g. sodium bicarbonate, carbonic anhydrase inhibitors) may reduce the elimination of memantine.

Clinical evidence, mechanism, importance and management

In 12 healthy subjects, the clearance of memantine 10 mg daily was markedly reduced by about 80% when the urine was alkaline (pH 8) compared with acidic urine (pH 5). The maximum plasma memantine levels were not affected by the urinary pH, but the bioavailability of memantine was increased by almost 20%.[1] This might be expected to lead to memantine accumulation and an increase in adverse effects. Drugs that could interact via this mechanism include **sodium bicarbonate** and **carbonic anhydrase inhibitors**[2] [such as **acetazolamide**]. The clinical relevance of these findings does not appear to have been established. Consider the possibility of an interaction if patients taking memantine with a urinary alkaliniser develop memantine adverse effects (e.g. dizziness, headache, constipation).

Metyrapone + Miscellaneous

The results of the metyrapone test for Cushing's syndrome are unreliable in patients taking cyproheptadine or phenytoin. The manufacturer also states that barbiturates, antidepressants, some hormones, and antipsychotics may influence the results of the metyrapone test. Metyrapone may reduce the metabolism of paracetamol (acetaminophen).

Clinical evidence

(a) Cyproheptadine

In 9 a study in healthy subjects, pretreatment with cyproheptadine 4 mg every 6 hours, 2 days before and throughout a standard metyrapone test (750 mg every 4 hours for 6 doses), reduced the metyrapone-induced urinary 17-hydroxycorticosteroid response by 32%, and also reduced the serum 11-deoxycortisol response.[1]

(b) Paracetamol (Acetaminophen)

In a randomised study, 8 healthy subjects were given metyrapone 750 mg one hour before and 3 hours after a single 1-g dose of paracetamol. Metyrapone decreased the glucuronidation of paracetamol from about 52% to 36% of the dose. Although the formation of other metabolites were increased, overall paracetamol excretion in the urine was decreased from about 75% to 69%.[2]

(c) Phenytoin

A study in 5 healthy subjects and 3 patients taking phenytoin 300 mg found that serum metyrapone levels 4 hours after taking a regular 750-mg dose were very low, when compared with those of a control group (6.5 micrograms/100 mL versus 48.2 micrograms/100 mL). The response to metyrapone (i.e. the fall in circulating glucocorticoids) is related to serum levels and was therefore proportionately lower.[3] Other reports confirm that the urinary steroid response to metyrapone is subnormal in patients taking phenytoin.[4,5]

Doubling the dose of metyrapone from 750 mg every 4 hours to every 2 hours has been shown to give results similar to those in subjects not taking phenytoin.[3]

Mechanism

Phenytoin is a potent liver enzyme inducer that increases the metabolism of metyrapone, thereby reducing its effects.[3,6]

Importance and management

The results of metyrapone tests for Cushing's syndrome will be unreliable in patients taking cyproheptadine and phenytoin, and therefore these should be withdrawn before the test; the US manufacturer advises 2 weeks.[7] The UK manufacturer also states that **barbiturates**, antidepressants (they name **amitriptyline**) and antipsychotics (they name **chlorpromazine**), hormones that affect the hypothalamo-pituitary-adrenal axis (the US manufacturers name **oestrogens**[7]), and **antithyroid drugs** may influence the results of the test. They recommend that, if any of these drugs cannot be withdrawn before the test, the necessity of carrying out the metyrapone test should be reviewed.[8]

In addition, the US manufacturer notes that metyrapone inhibits the glucuronidation of paracetamol, and may therefore increase paracetamol toxicity.[7] However, one study suggests that the extent may be modest, and, as metyrapone is usually only given for 24 hours, the clinical relevance of this effect seems small.

Mifepristone + Aspirin or NSAIDs

Theoretically NSAIDs might reduce the efficacy of mifepristone, and combined use is often not recommended. However, evidence from two studies with naproxen and diclofenac suggests no reduction in mifepristone efficacy.

Clinical evidence

(a) Mifepristone

In a study in women undergoing surgical first-trimester termination of pregnancy, patients received mifepristone 100 mg 48 hours and 36 hours before surgery for cervical ripening. There was no difference in the cervical softening effect between 13 women randomised to receive **naproxen** (500 mg given 60, 48, 36, 24 and 12 hours before the procedure) and 15 women randomised to receive placebo.[1]

(b) Mifepristone and misoprostol

Women undergoing second trimester medical terminations of pregnancy were given oral mifepristone 600 mg on day one, then 36 to 48 hours later, intravaginal misoprostol 800 micrograms. Starting 3 hours later, misoprostol 400 micrograms was given orally every 3 hours until expulsion, up to a maximum of nine oral doses of misoprostol. The women were randomised to receive a single dose of either paracetamol 1 g with dihydrocodeine 20 mg (n=38) or **diclofenac** 100 mg (n=36), given at the time of the intravaginal dose of misoprostol. The use of **diclofenac** did not increase either the time required for termination, or the amount of misoprostol needed.[2]

Mechanism

Mifepristone is thought to work by increasing prostaglandin production. Theoretically NSAIDs could reduce this, and therefore reduce the efficacy of mifepristone.

Importance and management

Because of theoretical concerns of antagonistic effects, NSAID analgesics, including **aspirin**, have been avoided in protocols for medical termination of pregnancy. However, the limited available evidence suggests that this might not be necessary.

For more information about the use of vaginal prostaglandins with NSAIDs, see under 'NSAIDs or Aspirin + Prostaglandins', p.171.

Mifepristone + Miscellaneous

***In vitro* study has found that mifepristone is an inhibitor of the cytochrome P450 isoenzyme CYP3A4.[1] The UK manufacturers therefore advise caution when mifepristone is given to patients taking CYP3A4 substrates (the US manufacturers specifically note CYP3A4 substrates with a narrow therapeutic index) as an increase in the levels of the substrate may result.[2,3] The clinical relevance of this prediction is unclear, and published reports describing an interaction between CYP3A4 substrates and mifepristone appear to be lacking. See 'Table 1.4', (p.6), for a list of CYP3A4 substrates.**

3. Mifeprex (Mifepristone). Danco Laboratories, LLC. US Prescribing information, July 2005.

Oxiracetam + Antiepileptics

Limited evidence suggests that the half-life of oxiracetam might be shorter in patients taking carbamazepine with valproate or clobazam, and that oxiracetam probably does not affect the serum levels of sodium valproate, carbamazepine or clobazam.

Clinical evidence, mechanism, importance and management

Oxiracetam 800 mg twice daily for 14 days did not affect the serum levels of **sodium valproate**, **carbamazepine**, or **clobazam** and their metabolites in 3 epileptics taking **carbamazepine** and **valproate** and one taking **carbamazepine** and **clobazam**.[1] However, it was noted that the oxiracetam half-life was 2.8 to 7.56 hours,[1] which tended to be shorter than that seen in a previous study in healthy subjects who had been given oxiracetam 2 g (half-life 5.6 to 11.7 hours).[2] The clinical relevance of this is uncertain, but the authors suggest that it may be necessary to raise the oxiracetam dosage or give it more frequently in the presence of these drugs.[1]

Oxygen; hyperbaric + Miscellaneous

It has been suggested, but not confirmed, that because increased levels of carbon dioxide in the tissues can increase the 'sensitivity' to oxygen-induced convulsions, carbonic anhydrase inhibitors, such as acetazolamide, are contraindicated in those given hyperbaric oxygen, because they cause carbon dioxide to persist in the tissues. Nor should hyperbaric oxygen be given during opioid or barbiturate withdrawal because the convulsive threshold of such patients is already low.[1]

1. Gunby P. HBO can interact with preexisting patient conditions. *JAMA* (1981) 246, 1177–8.

Parathyroid hormones + Alendronate

There is some evidence that alendronate may reduce the anabolic effects of parathyroid hormone, so the combination may not be as effective as parathyroid hormone alone.

Clinical evidence

In a study, postmenopausal women with low mineral density at the hip or spine were given either **human recombinant parathyroid hormone** 100 micrograms daily, alendronate 10 mg daily, or both treatments for 12 months. All patients received calcium and vitamin D supplementation. Bone mineral density at the spine increased in all groups: however, volumetric density of trabecular bone at the spine was increased the most in patients taking parathyroid hormone alone (about twice that found in either of the other groups). Parathyroid hormone alone had greater effects on bone formation than parathyroid hormone with alendronate, and bone resorption decreased in those taking parathyroid hormone with alendronate or alendronate alone.[1]

In another study, men with low bone density were given either alendronate 10 mg daily, subcutaneous **teriparatide** 40 micrograms daily, or both. Alendronate was given for 30 months and parathyroid hormone was started at month 6. Bone mineral density at the lumbar spine and femoral neck increased significantly more in patients receiving parathyroid hormone alone than in patients receiving parathyroid hormone with alendronate, or alendronate alone.[2]

A further study in postmenopausal women found that the previous use of alendronate prevented **teriparatide**-induced increases in bone mineral density, especially in the first 6 months.[3] However, in another study, women who had received alendronate for at least one year were randomised to continue with alendronate alone, or to receive additional cyclical or daily **teriparatide**. Both daily and cyclical treatment with teriparatide in addition to alendronate increased spinal bone mass density more than alendronate alone.[4]

Mechanism

Alendronate may attenuate parathyroid-induced stimulation of bone formation.[2] It has been suggested it is the inhibition of overall bone turnover rather than inhibition of bone resorption by alendronate that impairs the anabolic activity of parathyroid hormone.[5]

Importance and management

The reports suggest that if parathyroid hormone or teriparatide is to be given for osteoporosis, it might be preferable to use them alone and not with alendronate, and possibly not with any other bisphosphonate. However, many patients with osteoporosis may already be receiving a bisphosphonate, and more study is required to establish the optimal regimens for starting parathyroid hormone and discontinuing the bisphosphonate in such patients.[5] Subsequent research suggests that the addition of parathyroid hormone to alendronate is more effective than no treatment, and that patients discontinuing parathyroid hormone do better if they are then given alendronate.[6]

Parathyroid hormones; Teriparatide + Miscellaneous

The clinical effects of teriparatide are not significantly affected by furosemide, hormone replacement therapy, hydrochlorothiazide, or raloxifene.

Clinical evidence, mechanism, importance and management

(a) Furosemide

A study in 28 subjects (9 healthy subjects and 17 subjects with mild to moderate renal impairment) found that furosemide 20 to 100 mg had no clinically significant effect on the response to teriparatide.[1]

(b) Hormone replacement therapy

The effects of teriparatide on serum and urine calcium levels, and teriparatide adverse effects, are not affected by the concurrent use of hormone replacement therapy.[2]

(c) Hydrochlorothiazide

A study in 20 healthy subjects found that although hydrochlorothiazide 25 mg caused a minor reduction in the urinary excretion of calcium, the serum calcium response to a 40-microgram dose of teriparatide was unaffected.[1]

(d) Raloxifene

In a study, postmenopausal women were given subcutaneous teriparatide 20 micrograms daily for 18 months. The expected teriparatide-induced increases in bone mineral density were not affected by previous treatment with raloxifene.[3] Similarly, the manufacturer states that the effects of teriparatide on serum and urine calcium levels, and teriparatide adverse effects, are not affected by raloxifene.[2]

Penicillamine + Antacids

The absorption of penicillamine can be reduced by 30 to 40% if antacids containing aluminium/magnesium hydroxide are taken at the same time. This does not occur with sodium bicarbonate.

Clinical evidence

In a study in 6 healthy fasting subjects, *Maalox-plus* (**aluminium**/**magnesium hydroxide**, **simeticone**) 30 mL reduced the absorption of a single 500-mg dose of penicillamine by one-third.[1] Another similar study found that 30 mL of *Aludrox* (**aluminium**/**magnesium hydroxide**) reduced the absorption of penicillamine by about 40%.[2] In contrast, a single 7.06-g dose of **sodium bicarbonate** had little effect on the absorption of penicillamine (non-significant 15% reduction in AUC).[2]

Mechanism

The most likely explanation is that the penicillamine forms less soluble chelates with magnesium and aluminium ions in the gut, which reduces its absorption.[2]

Importance and management

The interaction between penicillamine and aluminium and magnesium-containing antacids is established, and might be of clinical importance. If maximal absorption is needed the administration of the two drugs should be separated to avoid mixing in the gut. Two to three hours has been found enough for most other drugs that have reduced absorption in the presence of aluminium/magnesium hydroxide antacids. Sodium bicarbonate does not interact and therefore the timing of the doses does not need to be adjusted in patients taking penicillamine.

Penicillamine + Disease-modifying antirheumatic drugs

Penicillamine plasma levels are increased by chloroquine and an increase in penicillamine toxicity is possible. Penicillamine should not be used with gold.

Clinical evidence, mechanism, importance and management

(a) Chloroquine or Hydroxychloroquine

Studies in which chloroquine was given to patients taking penicillamine found that giving both drugs was more effective, less effective, or indistinguishable from giving penicillamine alone. However, in some instances penicillamine toxicity was reported to be increased by chloroquine.[1] A pharmacokinetic study in patients with rheumatoid arthritis taking penicillamine 250 mg daily found that a single 250-mg dose of chloroquine phosphate increased the AUC of penicillamine by 34%, and raised its peak plasma levels by about 55%.[1] It therefore seems possible that any increased toxicity is a reflection of increased plasma penicillamine levels. Be alert for evidence of toxicity if both drugs are used. Note that the US manufacturer states that penicillamine should not be used in patients who are receiving antimalarials (which would include chloroquine and hydroxychloroquine) because these drugs are also associated with serious haematological effects.[2]

(b) Gold

There is some evidence that using gold with penicillamine may increase the risk of adverse effects, and the manufacturer says that they should not be used together.[2,3] In addition, patients who have had an adverse reaction to gold may be at a greater risk of serious adverse reactions to penicillamine,[2,3] and caution is recommended.[3]

3. Distamine (Penicillamine). Alliance Pharmaceuticals. UK Summary of product characteristics, January 2009.

Penicillamine + Food

Food can reduce the absorption of penicillamine by as much as a half.

Clinical evidence

In a study in healthy subjects, the presence of food reduced the plasma levels of penicillamine 500 mg by about 50%. The total amount absorbed was similarly reduced.[1,2] These figures are in good agreement with previous findings.[3]

Mechanism

Uncertain. One suggestion is that food delays gastric emptying so that the penicillamine is exposed to more prolonged degradation in the stomach.[2] Another idea is that the protein in food reduces penicillamine absorption.

Importance and management

An established interaction. If maximal effects are required the penicillamine should be taken at least 30 minutes before food.

Penicillamine + Iron compounds

The absorption of penicillamine can be reduced as much as two-thirds by oral iron compounds.

Clinical evidence

In a study in 5 healthy subjects, **ferrous iron** 90 mg (as *Fersamal*) reduced the absorption of penicillamine 250 mg by about two-thirds (using the cupruretic effects of penicillamine as a measure).[1]

A two-thirds reduction in the absorption of penicillamine 500 mg has been described in 6 other subjects who were also given **ferrous sulfate** 300 mg.[2] Other studies confirm this interaction.[3,4] There is also evidence that the withdrawal of iron from patients stabilised on penicillamine can lead to the development of toxicity (nephropathy) unless the penicillamine dosage is reduced.[5]

Mechanism

It is believed that the iron and penicillamine form a chemical complex or chelate within the gut, which is less easily absorbed.

Importance and management

An established and clinically important interaction. For maximal absorption give iron at least 2 hours after penicillamine. This should reduce their admixture in the gut.[1] Only ferrous sulfate and fumarate have been studied but other iron compounds would be expected to interact similarly. Do not withdraw iron suddenly from patients stabilised on penicillamine because the marked increase in absorption that follows may precipitate penicillamine toxicity. The toxic effects of penicillamine seem to be dependent on the size of the dose and are possibly also related to the rate at which the dosage is increased.[5]

Penicillamine + Miscellaneous

An isolated report describes penicillamine-induced breast enlargement in a woman taking an oral combined hormonal contraceptive. This might also have occurred when penicillamine was given with a corticosteroid or cimetidine.

Clinical evidence, mechanism, importance and management

A woman with Wilson's disease began to develop dark facial hair about 10 months after starting to take penicillamine 1.25 to 1.5 g daily. After 20 months her testosterone levels were found to be slightly raised, and so she was given an oral **combined hormonal contraceptive**, but within a month her breasts began to enlarge and become more tender. After a further 6 months the penicillamine was replaced by trientine hydrochloride.[1] The reasons are not understood, but the authors of the report suggest that the penicillamine was the prime cause of the macromastia, but it possibly needed the presence of a 'second trigger' (i.e. the contraceptive) to set things in motion.[1]

There are 12 other cases of macromastia and gynaecomastia on record associated with the use of penicillamine. In some of these cases the second trigger may possibly have been a **corticosteroid** or **cimetidine**.[1] Macromastia appears to be an unusual adverse effect of penicillamine and there would seem to be no general reason for patients taking penicillamine to avoid hormonal contraceptives.

1. Rose BI, LeMaire WJ, Jeffers LJ. Macromastia in a woman treated with penicillamine and oral contraceptives. *J Reprod Med* (1990) 35, 43–5.

Penicillamine + NSAIDs

Indometacin slightly increases penicillamine levels. The use of penicillamine and an NSAID might increase the risk of renal damage.

Clinical evidence, mechanism, importance and management

Indometacin has been found to increase the AUC of penicillamine by 26% and the peak plasma levels by about 22%.[1] The UK manufacturer notes that use of NSAIDs may increase the risk of renal damage with penicillamine.[2] The US manufacturer specifically recommends avoiding **oxyphenbutazone** or **phenylbutazone** because these drugs are also associated with serious haematological and renal effects.[3] Urinalysis for detection of haematuria or proteinuria should be regularly carried out in patients taking penicillamine.[2,3] Be alert for evidence of toxicity if NSAIDs and penicillamine are used together.

3. Cuprimine (Penicillamine). Merck & Co., Inc. US Prescribing information, October 2004.

Phenylpropanolamine + Indinavir

A report describes a hypertensive crisis when a patient taking indinavir was also given phenylpropanolamine.

Clinical evidence, mechanism, importance and management

A 28-year-old woman was prescribed HIV-prophylaxis following a needle stick injury. She was initially given zidovudine, indinavir and lamivudine, but after one week stavudine was substituted for zidovudine as she was experiencing nausea and vomiting. Six hours after taking *Tavist-D* (clemastine with phenylpropanolamine) for a sinus complaint she had a feeling of chest tightness associated with difficulty in breathing, and shortly afterwards she experienced left-sided upper extremity weakness, followed by a severe right-sided temporal headache. Her blood pressure was 220/120 mmHg, but returned to normal within 4 hours, and the neurological deficit resolved over the next 8 hours. However, 12 hours later, the same neurological deficit recurred, although no increase in blood pressure was noted. The neurological deficit was thought to be due to reversible cerebral vasoconstriction, secondary to phenylpropanolamine toxicity. She was treated with nimodipine 60 mg every 4 hours and aspirin 325 mg daily, and her symptoms did not recur.[1]

The patient had been taking phenylpropanolamine intermittently for several years without any adverse reaction and it was thought that the recent addition of the HIV prophylaxis potentiated the effect of the phenylpropanolamine.[1] It seems likely that the indinavir was responsible for the interaction as it is a potent enzyme inhibitor.

This is an isolated report and its general significance is not known, but it would be prudent to be alert for this interaction in patients taking both drugs. Note that phenylpropanolamine is no longer available in the US and UK and its use has been restricted in many other countries.

Phenylpropanolamine + Indometacin

An isolated report describes a patient taking phenylpropanolamine who developed serious hypertension after taking a sin-

gle dose of indometacin, but a controlled study in other subjects did not find any evidence of an adverse interaction.

Clinical evidence

A woman who had been taking phenylpropanolamine 85 mg daily for several months as an appetite suppressant, developed a severe bifrontal headache within 15 minutes of taking indometacin 25 mg. Thirty minutes later her systolic blood pressure was 210 mmHg and her diastolic blood pressure was unrecordable. A later study in this patient confirmed that neither drug on its own caused this response, but when they were taken together the blood pressure rose to a maximum of 200/150 mmHg within about 30 minutes of taking the indometacin, and was associated with bradycardia. Her blood pressure was rapidly reduced by phentolamine.[1]

In contrast, a controlled study in 14 healthy young women found no evidence that sustained-release indometacin 75 mg twice daily, given with sustained-release phenylpropanolamine 75 mg daily, caused a rise in blood pressure.[2]

Mechanism

Not understood.

Importance and management

Direct information seems to be limited to these reports. They suggest that an adverse hypertensive response is unlikely in most individuals given these drugs. However, note that phenylpropanolamine alone has been associated with severe hypertension and has been implicated in causing stroke.[3] It is therefore no longer available in the US and UK and its use has been restricted in many other countries.

Polystyrene sulfonate + Antacids

The concurrent use of some antacids with sodium polystyrene sulfonate can result in metabolic alkalosis. Use with aluminium hydroxide has resulted in intestinal obstruction. Calcium polystyrene sulfonate is said to interact similarly.

Clinical evidence, mechanism, importance and management

A man with hyperkalaemia developed metabolic alkalosis when given 30 g of sodium polystyrene sulfonate with **magnesium hydroxide** 30 mL three times daily.[1] Alkalosis has also been described in a study in a number of patients given this cation exchange resin with *Maalox* (**magnesium/aluminium hydroxide**) and **calcium carbonate**.[2]

The suggested reason is that the breakdown of the **magnesium hydroxide** usually requires equal amounts of bicarbonate and hydrogen ions, and so does not cause any acid-base disturbance. However, when sodium polystyrene sulfonate is given, it binds the **magnesium**, while the hydroxide is neutralised by the hydrogen ions. This results in a relative excess of bicarbonate ions, which are absorbed, leading to metabolic alkalosis.

This interaction appears to be established. Concurrent use should be undertaken with caution and serum electrolytes should be closely monitored. Giving the resin rectally as an enema can avoid the problem. Calcium polystyrene sulfonate is said to interact similarly.[3]

In addition to alkalosis, the manufacturer also notes that concurrent use of **aluminium hydroxide** and the resins has resulted in intestinal obstruction due to 'concretions' of **aluminium hydroxide**.[3,4] Caution is advised.

Polystyrene sulfonate + Sorbitol

Potentially fatal colonic necrosis may occur if sodium polystyrene sulfonate is given as an enema with sorbitol. Calcium polystyrene sulfonate may interact similarly.

Clinical evidence

Five patients with uraemia developed severe colonic necrosis after being given enemas containing sodium polystyrene sulfonate and sorbitol for the treatment of hyperkalaemia. Four of the 5 patients died as a result. Associated studies in uraemic *rats* found that all of them died over a 2-day period after being given enemas of sodium polystyrene sulfonate with sorbitol. Extensive haemorrhage and transmural necrosis developed. No deaths occurred when enemas without sorbitol were given.[1] A number of other similar cases have been reported, a few of which are cited.[2-4] In one retrospective analysis, intestinal necrosis occurred in 2 of 117 patients (1.7%) who had received sodium polystyrene sulfonate within one week of surgery, and in both of these cases it had been given in sorbitol. Conversely, of 862 patients who did not receive sodium polystyrene sulfonate, none developed intestinal necrosis.[5]

Mechanism

Not understood.

Importance and management

Information is limited and the interaction between sorbitol and polystyrene sulfonate is not firmly established; nevertheless, its seriousness indicates that sodium polystyrene sulfonate should not be given as an enema in aqueous vehicles containing sorbitol. Note that the manufacturers advise against the concurrent use of both *oral* and rectal sorbitol with sodium or calcium polystyrene sulfonate, because of the risk of colonic necrosis.[6,7]

Pseudoephedrine + Antacids or Antidiarrhoeals

Kaolin does not appear to interact significantly with pseudoephedrine. Aluminium hydroxide may possibly cause a more rapid onset of pseudoephedrine.

Clinical evidence

In a single-dose, crossover study in 6 healthy subjects, 30 mL of **aluminium hydroxide gel** did not affect the total amount of a single 60-mg dose of pseudoephedrine absorbed over 24 hours, but the rate of absorption was significantly increased during the first 3 hours.[1] Conversely, 30 mL of a 30% suspension of **kaolin** reduced the amount of a single 60-mg dose of pseudoephedrine absorbed by just 10%. The rate of absorption was also decreased.[1]

Mechanism

The increased rate of absorption of pseudoephedrine seen with aluminium hydroxide is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine. The reduced absorption with kaolin is probably due to adsorption of the pseudoephedrine onto the surface of the kaolin.

Importance and management

Aluminium hydroxide may possibly cause a more rapid onset of pseudoephedrine activity (but this needs confirmation). Any interaction seems unlikely to be clinically significant. Similarly, the effects of kaolin on pseudoephedrine absorption are small and unlikely to be clinically important.

For the effect of sodium bicarbonate on pseudoephedrine and ephedrine, see 'urinary alkalinisers', (p.1567).

Pseudoephedrine and related drugs + Caffeine

Phenylpropanolamine can raise blood pressure and in some cases this may be further increased by caffeine. Combined use has resulted in hypertensive crises in a few individuals. Ephedrine may interact similarly. Phenylpropanolamine can markedly raise plasma caffeine levels, and isolated reports describe the development of acute psychosis when caffeine was given with phenylpropanolamine or ephedrine.

Clinical evidence

(a) Ephedrine

1. Clinical studies. In a single-dose, randomised study, 15 healthy subjects were given ephedrine 25 mg, caffeine 200 mg, both drugs together, or placebo. An assessment of systolic blood pressure found that ephedrine had no significant effect, caffeine caused a 9.1 mmHg increase, and the use of both drugs resulted in an 11.7 mmHg increase. Caffeine alone did not increase heart rate, but both ephedrine and ephedrine plus caffeine caused heart rate increases of roughly 11%. Subjective tests suggested that there was no significant difference in feelings of headache, chest pain, heart pounding or shortness of breath between the treatments. There was no significant pharmacokinetic interaction between the drugs.[1] Another randomised study, investigating the combination of ephedrine 20 mg and caffeine 200 mg, both three times daily, compared with either drug alone, or placebo, for weight loss, did not find any significant hypertensive effects with the combination, although the authors suggested that this may have been due to the favourable effects of weight loss on blood pressure. However, one patient was withdrawn due to a rise in blood pressure, to 185/125 mmHg.[2]

Numerous other clinical studies have investigated the haemodynamic effects of combinations of ephedrine or ephedra with caffeine or caffeine-containing herbs, some showing increases in heart rate and blood pressure and others not. However, none of these compared the combination with either constituent alone, so it is not possible to assess the possibility of an interaction from these reports.

2. Case reports. A review of reports from the FDA in the US revealed that several patients have experienced severe adverse effects (subarachnoid haemorrhage, cardiac arrest, hypertension, tachycardia and neurosis) after taking dietary supplements containing ephedrine or **ephedra** alkaloids with caffeine.[3] However, it is not possible to definitively say that these effects were the result of an interaction because none of the patients took either drug separately. Similarly, a meta-analysis assessing the safety of ephedra or ephedrine and caffeine found a two- to threefold increase in the risk of adverse events (including psychiatric symptoms and palpitations) with ephedra or ephedrine, but it was concluded that it was not possible to assess the contribution of caffeine to these events.[4]

Two episodes of acute psychosis occurred in a 32-year-old man after he took *Vigueur fit* tablets (containing **ephedra** alkaloids and caffeine), *Red Bull* (containing caffeine) and alcohol. He had no previous record of aberrant behaviour despite regularly taking 6 to 9 tablets of *Vigueur fit* daily (about twice the recommended dose). However, on this occasion, over a 10-hour period, he consumed 3 or 4 bottles of *Red Bull* (containing about 95 mg of caffeine per 250-mL bottle) and enough alcohol to reach a blood-alcohol level of about 335 mg%. No more episodes occurred after he stopped taking the *Vigueur fit* tablets. **Ephedra** alkaloids (ephedrine and **pseudoephedrine**) may cause psychosis and it appears that their effects may be exaggerated by an interaction with caffeine and alcohol.[5]

(b) Phenylpropanolamine

In a placebo-controlled study, the mean blood pressure of 16 healthy subjects rose by 11/12 mmHg after they took caffeine 400 mg, by 12/13 mmHg after they took phenylpropanolamine 75 mg, and by 12/11 mmHg when both drugs were taken. Phenylpropanolamine 150 mg caused a greater rise of 36/18 mmHg. One of the subjects had a hypertensive crisis after taking phenylpropanolamine 150 mg and again 2 hours after taking caffeine 400 mg. This needed antihypertensive treatment.[6] The same group of workers describe a similar study in which the AUC of caffeine 400 mg increased by more than threefold, and the mean peak caffeine concentration increased almost fourfold (from 2.1 to 8 micrograms/mL) after phenylpropanolamine 75 mg was given.[7] Additive increases in blood pressure are described in another report.[8]

Mania with psychotic delusions occurred in a healthy woman (who normally drank 7 to 8 cups of **coffee** daily) within 3 days of her starting to take a phenylpropanolamine-containing decongestant. She recovered within a week of stopping both the **coffee** and the phenylpropanolamine.[9]

Mechanism

Ephedrine and caffeine may cause catecholamine release and an increase in intracellular calcium release which leads to vasoconstriction. Myocardial ischaemia may occur as a result of this vasoconstriction (in the coronary artery), and this may result in myocardial necrosis and cell death.

Importance and management

Fairly well established interactions. These studies illustrate the potential hazards of these drugs, even in normal healthy individuals. However, it has to be said that there seem to be few reports of adverse interactions, which is perhaps surprising bearing in mind that coffee/caffeine is very widely used and ephedrine and phenylpropanolamine have also been widely available without prescription. One possible explanation for this could be that these interactions may go unrecognised or be attributed to one drug only e.g. phenylpropanolamine, whereas caffeine has also been taken either as part of the preparation[3,10] or in beverages (often not reported). Nevertheless, serious adverse events have been reported with caffeine and phenylpropanolamine or dietary supplements containing ephedra alkaloids (sometimes called ma huang) and therefore these preparations may pose a serious health risk to some users.[3] The risk may be affected by individual susceptibility, the additive stimulant effects of caffeine, the variability in the contents of alkaloids in non-prescription dietary supplements, or pre-existing medical conditions,[3] including compromised cardiac function,[1] and hypertension, or obesity and old age.[6]

Note that, phenylpropanolamine is no longer available in the US and UK and its use has been restricted in many other countries. In addition, because of the associated health risks, the FDA bans combinations of caffeine with ephedrine or pseudoephedrine, and also bans herbal products containing ephedra. As a result of this, many manufacturers replaced ephedra with bitter orange (*Citrus aurantium*), which contains a similar sympathomimetic alkaloid (synephrine). Evidence shows that these products are no safer than ephedra products when used in a similar way. It would be prudent to avoid using herbal products containing combinations of bitter orange and caffeine or caffeine-containing herbs, especially in patients with risk factors such as heart conditions, diabetes, thyroid disease, or hypertension.

Pseudoephedrine and related drugs + Urinary acidifiers or alkalinisers

Alkalinisation of the urine (e.g. by sodium bicarbonate) causes retention of ephedrine and pseudoephedrine by the kidneys, leading to the possible development of toxicity (tremors, anxiety, insomnia, tachycardia). Acidification of the urine (e.g. with ammonium chloride) has the opposite effect.

Clinical evidence

(a) Ephedrine

When the urine was made acidic (pH of about 5) with **ammonium chloride**, the excretion of ephedrine in the urine of 3 healthy subjects was two- to fourfold higher than when the urine was made alkaline (pH of about 8) with **sodium bicarbonate**.[1]

(b) Pseudoephedrine

A patient with renal tubular acidosis and persistently alkaline urine developed unexpected toxicity (cachexia and personality changes) when given therapeutic doses (not stated) of pseudoephedrine for 2.5 months. She was found to have a very prolonged pseudoephedrine half-life of 50 hours (10 times expected). Therefore 8 subjects (adults and children) were studied, to establish the possible effects of changing the urinary pH on pseudoephedrine elimination. When the urinary pH was adjusted using **ammonium chloride** or **sodium bicarbonate**, within the approximate range of 5.7 to 7.8, the half-life of a single dose of pseudoephedrine (about 5 mg/kg) was found to increase from 1.9 hours at the lowest pH to 21 hours at the highest pH.[2]

This confirms an earlier study, in which it was found that at a urinary pH of 8, the half-life of pseudoephedrine was 16, 9.2, and 15 hours in 3 subjects, respectively. At a urinary pH of about 5, the half-life was 4.8, 3, and 6.4 hours, respectively.[3] **Sodium bicarbonate** was given to raise urinary pH and **ammonium chloride** to lower urinary pH.

Another study in 6 healthy subjects found that **sodium bicarbonate** 5 g initially increased the excretion rate of a single 60-mg dose of pseudoephedrine, but as the urinary pH increased the excretion of pseudoephedrine was reduced.[4]

Mechanism

Ephedrine and pseudoephedrine are basic drugs, which are mainly excreted unchanged in the urine. In acidic urine, most of the drug is ionised in the tubular filtrate and unable to diffuse passively back into the circulation, and is therefore lost in the urine. In alkaline urine, these drugs mostly exist in lipid-soluble forms, which are reabsorbed.

The increased rate of absorption of pseudoephedrine seen with sodium bicarbonate is probably also due to pH rises, which favour the formation of the lipid-soluble absorbable form of pseudoephedrine.

Importance and management

The interaction between ephedrine or pseudoephedrine and urinary alkalinisers are established but reports of adverse reactions in patients appear to be rare. Be aware that any increase in the adverse effects of these drugs (tremor, anxiety, insomnia, tachycardia, etc.) could be due to drug retention brought about by this interaction. **Acetazolamide** also makes the urine alkaline and would be expected to interact with ephedrine and pseudoephedrine in the same way as sodium bicarbonate.

Acidification of the urine with ammonium chloride increases the loss of ephedrine and pseudoephedrine in the urine and could be exploited in cases of drug overdosage.

PUVA + Herbal medicines or Foods

Two case reports describe photosensitivity in patients taking methoxsalen and undergoing PUVA, one in a patient taking rue (*Ruta graveolens*) and another in a patient who ate large amounts of celery soup.

Clinical evidence, mechanism, importance and management

A 35-year-old woman taking **methoxsalen** and undergoing PUVA for psoriasis unexpectedly developed increased photosensitivity. Over the previous weekend and on the morning of therapy she had been drinking a concoction of **rue** (***Ruta graveolens***).[1] This plant naturally contains 5-methoxypsoralen so it would appear that a pharmacodynamic interaction occurred, which resulted in the photosensitivity.

The authors note that other herbal products contain photosensitising substances (e.g. those containing members of the **Umbelliferae** family; such as **celery**, or ***Chlorella*** species), and so suggest that patients undergoing PUVA should be warned about the potential interactions.[1] This warning appears justified by the case of a woman taking **methoxsalen** and undergoing PUVA, who developed photosensitivity after eating a large quantity of soup containing **celery**, parsnip and parsley.[2]

2. Boffa MJ, Gilmour E, Ead RD. Celery soup causing severe phototoxicity during PUVA therapy. *Br J Dermatol* (1996) 135, 330–45.

PUVA + Metoclopramide

Metoclopramide does not appear to affect the pharmacokinetics of methoxsalen.

Clinical evidence, mechanism, importance and management

In a study, 6 healthy subjects were given a single 25-mg/m^2 dose of **methoxsalen** and a single 10-mg dose of metoclopramide, with a standard breakfast, followed by a 4 hour period during which no further food or drink was taken. Metoclopramide increased the intersubject variation in the pharmacokinetics of methoxsalen, but overall, its pharmacokinetics were not significantly altered.[1] It would therefore appear that metoclopramide can be given with methoxsalen without the need for dosage adjustment.

PUVA + Phenytoin

The serum levels of methoxsalen can be markedly reduced by the concurrent use of phenytoin. This resulted in the failure of PUVA for psoriasis in one patient.

Clinical evidence, mechanism, importance and management

A patient with epilepsy failed to respond to treatment for psoriasis with PUVA (12 treatments of **methoxsalen** 30 mg given orally and ultraviolet A irradiation) while taking phenytoin 250 mg daily. Methoxsalen serum levels were normal in the absence of phenytoin, but abnormally low while taking phenytoin,[1] due, it is suggested, to the enzyme-inducing effects of phenytoin. This interaction could lead to serious erythema and blistering if the phenytoin dose is reduced during therapy, as methoxsalen levels rise and therefore photosensitivity caused by the methoxsalen may be increased. Concurrent use should be avoided if possible, or very closely monitored.

Raloxifene + Miscellaneous

The absorption of raloxifene is reduced by colestyramine and predicted to be reduced by colestipol. No clinically relevant changes

in raloxifene pharmacokinetics occur with aluminium/magnesium hydroxide, amoxicillin, ampicillin or calcium carbonate. Raloxifene does not alter digoxin or methylprednisolone levels. Oral antibacterials, antihistamines, aspirin, benzodiazepines, H_2-receptor antagonists, ibuprofen or paracetamol (acetaminophen) were used in clinical studies without any obvious effect on raloxifene levels. Smoking does not appear to alter the efficacy of raloxifene.

Clinical evidence, mechanism, importance and management

(a) Ampicillin and Amoxicillin

Ampicillin is reported to reduce the maximum serum levels of raloxifene by 28% and the extent of the absorption by 14% without affecting the elimination rate.[1] This is thought to be because ampicillin reduces the number of enteric bacteria and so reduces enterohepatic recycling of raloxifene. These small changes are unlikely to be clinically relevant. In another clinical efficacy study, there was no discernible difference in the plasma levels of raloxifene when it was taken with amoxicillin.[1]

(b) Antacids

The manufacturer of raloxifene reports that an antacid containing **aluminium/magnesium hydroxide**, given 1 hour before and 2 hours after raloxifene, had no effect on its absorption. Also, no interaction was seen with **calcium carbonate**.[2] There would therefore appear to be no reason for avoiding the concurrent use of these antacids and raloxifene.

(c) Colestyramine

The manufacturer reports that colestyramine reduced the absorption of raloxifene by about 60% due to an interruption in enterohepatic cycling.[1] It is recommended that these two drugs should not be used concurrently.[1,3] The manufacturers also predict that **colestipol** will interact similarly.[1,3]

(d) Digoxin

Raloxifene is reported not to affect the steady-state AUC of digoxin, while the maximum serum levels of digoxin were increased by less than 5%.[3]

(e) Methylprednisolone

Steady state raloxifene had no effect on the pharmacokinetics of a single oral dose of methylprednisolone.[1,3]

(f) Tobacco

Retrospective analysis of data from a placebo-controlled study of raloxifene found that raloxifene was equally effective in current tobacco smokers as non-smokers, although smokers had a lower baseline bone mineral density.[4]

(g) Miscellaneous

Data from clinical efficacy studies revealed no clinically relevant differences in the plasma levels of raloxifene when stratified according to concurrent drug use. These drugs included **oral antibacterials** (not named), **antihistamines** (not named), **aspirin**, **benzodiazepines** (not named), **H_2-receptor antagonists** (not named), NSAIDs (**ibuprofen**, **naproxen**), and **paracetamol** (**acetaminophen**).[3] There would therefore appear to be no reason for avoiding the concurrent use of any of these drugs with raloxifene.

Retinoids + Food

Fatty foods increase the absorption of acitretin, etretinate and isotretinoin.

Clinical evidence

(a) Acitretin

In a study in 18 healthy subjects the absorption of acitretin was increased by 90% and its peak plasma concentrations were increased by 70% when acitretin 50 mg was taken with a standard breakfast. The breakfast consisted of two poached eggs, two slices of toast, two pats of margarine and 8 oz (about 240 mL) of skimmed milk.[1]

(b) Etretinate

Studies have found that high-fat meals and **milk** cause about a two- to fivefold increase in the absorption of **etretinate**, when compared with high-carbohydrate meals or when fasting.[2,3]

(c) Isotretinoin

In a study in 20 healthy subjects the AUC of a single 80-mg dose of isotretinoin was increased by 40%, 70%, and 90% when taken one hour before a **standard breakfast**, during **breakfast**, and one hour after **breakfast**, respectively, when compared with the same dose of isotretinoin taken 4 hours before breakfast.[4]

Mechanism

It is thought that, because these retinoids are lipid soluble, they become absorbed into the lymphatic system by becoming incorporated into the bile-acid micelles of the fats in the food. In this way losses due to first-pass liver metabolism and gut wall metabolism are minimised, and bioavailability is increased.

Importance and management

Established interactions of clinical importance. The manufacturers of acitretin recommend taking it with meals[5,6] or with milk,[5] and the manufacturers of isotretinoin recommend taking it with food.[7,8] Similar recommendations were made with etretinate.[9] On the basis of these interactions, the UK manufacturers of oral **alitretinoin**[10] and oral **tretinoin** also recommend administration with food.[11]

Retinoids + Protease inhibitors

Symptoms of retinoid toxicity and reduced plasma levels of retinoic acid occurred in a patient who took isotretinoin with indinavir and ritonavir. Protease inhibitors are predicted to inhibit the metabolism of alitretinoin.

Clinical evidence, mechanism, importance and management

An HIV-positive patient taking oral isotretinoin 50 mg daily for severe acne developed signs of retinoid toxicity after starting to take **indinavir** 800 mg daily, **ritonavir** 600 mg daily, zidovudine 600 mg daily, and lamivudine 300 mg daily. However, plasma levels of 4-oxo retinoic acids and non-oxidised retinoic acids were *decreased*. Since protease inhibitors such as **indinavir** and **ritonavir** are inhibitors of the cytochrome P450 isoenzyme CYP3A4, this finding was not expected. Oxidative metabolism of retinoic acid is reduced by other CYP3A4 inhibitors with resultant increases in plasma retinoic acid.[1] It was suggested that the symptoms of retinoid toxicity and reduced plasma retinoid levels may have resulted from increased cellular uptake of retinoids and this may be associated with modulation of retinoic acid signalling by protease inhibitors[1,2]

The clinical relevance of this case is unclear, but bear it in mind in the event of unexpected toxicity on concurrent use.

The UK manufacturers of alitretinoin note that, although the concurrent use of drugs such as the protease inhibitors have not been studied, other

drugs that inhibit CYP3A4 raise **alitretinoin** levels.[3] It may therefore be prudent to be alert for an increase in the adverse effects of **alitretinoin** if protease inhibitors are also being taken.

Retinoids + Tetracyclines

The development of pseudotumour cerebri (benign intracranial hypertension) has been associated with the concurrent use of acitretin or isotretinoin and tetracyclines. Other retinoids are expected to interact similarly.

Clinical evidence, mechanism, importance and management

The concurrent use of **isotretinoin** and a tetracycline has resulted in the development of pseudotumour cerebri (i.e. a clinical picture of cranial hypertension with headache, dizziness and visual disturbances). By 1983, the FDA in the US had received reports of 10 patients with pseudotumour cerebri and/or papilloedema associated with the use of **isotretinoin**. Four had retinal haemorrhages, and 5 of the 10 were also taking a tetracycline.[1] The manufacturers also have similar reports on file of 3 patients given **isotretinoin** and either **minocycline** or **tetracycline**.[2] The same reaction has been seen in a patient given **etretinate** with **minocycline**.[3]

Both retinoids and tetracyclines alone can cause increased intracranial pressure, and they might have an additive effect when used together.

The manufacturers of **acitretin**,[4,5] oral **alitretinoin**,[6] **isotretinoin**[7] and oral **tretinoin**[8] contraindicate their use with tetracyclines, or advise avoiding the concurrent use of tetracyclines.[9]

Retinoids + Vitamin A (Retinol)

A condition similar to vitamin A (retinol) overdosage may occur if oral retinoids such as acitretin, alitretinoin, isotretinoin or tretinoin are given with vitamin A.

Clinical evidence, mechanism, importance and management

Combined treatment with **isotretinoin** and vitamin A may result in a condition similar to overdosage with vitamin A. Signs and symptoms of hypervitaminosis A include skin changes (yellowing, dryness, alopecia), anorexia, vomiting, neuropsychiatric effects, raised intracranial pressure, and musculoskeletal effects, including premature fusion of the epiphyseal discs in children (which is irreversible). Concurrent use should therefore be avoided or very closely monitored.

The manufacturers of **acitretin** say that the concurrent use of high-dose vitamin A should be avoided: in the UK[1] they advise no more than 4000 to 5000 units of vitamin A daily, which is the recommended daily allowance, and in the US[2] they advise doses of no more than the minimum recommended daily allowance. Similarly, the manufacturers of oral **alitretinoin**,[3] **isotretinoin**[4,5] and oral **tretinoin**[6,7] say that vitamin A should be avoided.

Ritodrine + Miscellaneous

Supraventricular tachycardia developed in a woman given ritodrine when she was also given glycopyrronium (glycopyrrolate), and tachycardia has been reported in two patients when atropine was used with ritodrine. Hypertension has been reported when cyclopropane was given to patients who had recently received ritodrine. The abuse of cocaine does not appear to increase the incidence of adverse effects in patients given ritodrine. Hypokalaemia is a known adverse effect of ritodrine and this effect may be additive with other drugs that lower potassium levels.

Clinical evidence, mechanism, importance and management

(a) Antimuscarinics

A case report describes premature labour in a 39-year-old woman who was 28 weeks pregnant, which was arrested with an intravenous infusion of ritodrine hydrochloride. Two weeks later, while she was receiving the maximum dose of ritodrine (300 micrograms/minute), her uterine contractions began again and she was scheduled for an emergency caesarean section. The ritodrine was discontinued 40 minutes before the operation. It was noted in the operating room that she had copious oral secretions so she was given 100% oxygen by mask and 200 micrograms of intravenous **glycopyrronium** (**glycopyrrolate**). Shortly afterwards she developed a supraventricular tachycardia (a rise in heart rate from 80 up to 180 bpm), which was converted to sinus tachycardia of 130 bpm when she was given intravenous propranolol 500 micrograms, in divided doses over several minutes.[1] Two other patients given intravenous ritodrine 6 mg over 3 minutes developed tachyarrhythmias when they were premedicated with **atropine**.[2]

The reason for these reactions is not understood. Ritodrine alone has been responsible for tachyarrhythmias and one possible explanation for this interaction is that the effects of ritodrine and the antimuscarinic drug were additive.

Information is very limited and the interaction is not well established but some caution is clearly appropriate if both drugs are used. The authors of the first report advise avoidance. Arrhythmias have occurred when other sympathomimetics have been given with antimuscarinics, see 'Inotropes and Vasopressors + Antimuscarinics', p.1061.

(b) Cocaine

A study in 51 pregnant patients given ritodrine for premature labour found no evidence of an increase in adverse effects in 17 of the patients who had been abusing cocaine.[3]

(c) Cyclopropane

In an analysis of 43 women who had a caesarean section under cyclopropane anaesthesia, all of the 6 who had previously been given ritodrine developed unacceptably high blood pressure (185/103 mmHg) after cyclopropane was started. Arrhythmias were reported in two of these patients.[4]

(d) Drugs that lower potassium

Ritodrine is a $beta_2$ agonist, and in common with other drugs of this class, may lower potassium levels. These effects may be additive with other drugs that are known to lower potassium levels, such as **amphotericin B**, the **corticosteroids**, **loop** or **thiazide diuretics**, consider 'Beta-agonist bronchodilators + Potassium-depleting drugs', p.1417, and **theophylline**, consider 'Theophylline + Beta-agonist bronchodilators', p.1432.

Sodium oxybate + Miscellaneous

Additive CNS depressant effects are predicted when sodium oxybate is given with other CNS depressant drugs, and concurrent use of sedative hypnotics should be avoided. In theory, sodium oxybate may interact with valproate, phenytoin and ethosuximide. No pharmacokinetic interaction occurs with omeprazole, protriptyline, zolpidem or modafinil, but a pharmacodynamic interaction cannot be ruled out. Food markedly delays and modestly reduces the absorption of sodium oxybate.

Clinical evidence, mechanism, importance and management

(a) Antiepileptics

The UK manufacturer suggests that, as sodium oxybate is metabolised by gamma hydroxybutyrate dehydrogenase there is a potential risk of an interaction with drugs that induce or inhibit this enzyme. They name **valproate**, **phenytoin** and **ethosuximide**.[1] However, there do not appear to be any *in vivo* studies to confirm this prediction and its clinical relevance is unclear.

See also *Barbiturates*, below.

(b) CNS depressants

Sodium oxybate is the sodium salt of **gamma hydroxybutyrate** (GHB), a CNS depressant substance with well known abuse potential. When used clinically it is predicted to have additive effects with other CNS depressants and the manufacturers specifically say it should not be used with these.[1,2]

1. Antidepressants. The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **protriptyline**, but that the possibility of a pharmacodynamic interaction was not assessed.[1,2] The UK manufacturer states that the rate of adverse effects was increased when sodium oxybate was given with **tricyclic antidepressants**.[1]

2. Barbiturates. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking barbiturates.[1]

3. Benzodiazepines and related hypnotics. The manufacturer states that sodium oxybate should not be given in combination with sedative hypnotics,[1,2] and the UK manufacturer specifically cautions against the concurrent use of benzodiazepines because of the possibility of increased risk of respiratory depression.[1]

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **zolpidem**, but that the possibility of a pharmacodynamic interaction was not assessed,[1] and cannot be ruled out.[2]

4. Opioids. The UK manufacturer specifically contraindicates the use of sodium oxybate in patients taking opioids.[1]

(c) Food

In a study in 34 healthy subjects, giving 4.5 g of sodium oxybate solution after a high-fat meal delayed the time to maximum level from 0.75 hours to 2 hours, and reduced the maximum level by 58% and the AUC by 35%, when compared with the fasted state.[3] The first dose of sodium oxybate should be taken at least 2 to 3 hours after the evening meal, and patients should always try to keep the same timing of dosing in relation to meals.[1,2]

(d) Modafinil and other CNS stimulants

The manufacturer notes that there was no pharmacokinetic interaction between sodium oxybate and **modafinil**, but that the possibility of a pharmacodynamic interaction was not assessed.[1,2] About 80% of patients in clinical studies of sodium oxybate were also taking CNS stimulants.[1]

(e) Proton pump inhibitors

In a crossover study in 44 healthy subjects, pretreatment with **omeprazole** 40 mg daily for 5 days did not alter the pharmacokinetics of a single 3-g dose of sodium oxybate. There was no difference in the frequency and severity of adverse events.[4] No sodium oxybate dose adjustment is therefore expected to be needed in patients taking proton pump inhibitors.[1]

Strontium ranelate + Miscellaneous

Foods and calcium compounds markedly reduce the absorption of strontium ranelate, whereas aluminium and magnesium antacids only slightly reduce strontium ranelate absorption. Strontium ranelate is predicted to reduce the absorption of the quinolones and the tetracyclines. Vitamin D does not affect strontium ranelate bioavailability.

Clinical evidence, mechanism, importance and management

(a) Antacids

The manufacturer notes that **aluminium**/**magnesium hydroxide** slightly reduced the absorption of strontium ranelate (AUC decreased by 20 to 25%) when given either at the same time or 2 hours before the strontium. However, when the antacid was given 2 hours *after* strontium, absorption was barely affected.[1] Therefore, the manufacturers recommend that antacids should be taken 2 hours after strontium ranelate. However, because it is also recommended that strontium ranelate is taken at bedtime, they say that, if this is impractical, concurrent intake is acceptable.[1] Note that **calcium**-containing antacids would have a greater effect, see *Foods and Calcium compounds* below, and concurrent intake would not be recommended.

(b) Foods and Calcium compounds

The manufacturer notes that food, milk, dairy products, and calcium supplements reduce the bioavailability of strontium ranelate by about 60 to 70%, when compared with administration 3 hours after a meal.[1] This is because divalent cations such as calcium form complexes with strontium ranelate, preventing its absorption. Therefore, strontium ranelate should not be taken within 2 hours of eating, or presumably within 2 hours of any calcium compound. The manufacturer recommends that strontium ranelate should be taken at bedtime, at least 2 hours after eating.[1]

(c) Quinolones and Tetracyclines

The manufacturer predicts that strontium will complex with quinolones and tetracyclines, preventing their absorption. Because of this, they recommend that when treatment with quinolones or tetracyclines is required, treatment with strontium ranelate should be temporarily suspended.[1]

(d) Vitamin D

The manufacturer notes that vitamin D supplements had no effect on strontium ranelate bioavailability.[1]

1. Protelos (Strontium ranelate). Servier Laboratories Ltd. UK Summary of product characteristics, January 2008.

Sugammadex + Miscellaneous

Sugammadex is predicted to modestly reduce progestogen levels from oral hormonal contraceptives. Toremifene, high-dose intravenous flucloxacillin and intravenous fusidic acid are predicted to displace vecuronium or rocuronium from sugammadex, and so result in recurrence of the neuromuscular blockade, or delay in recovery. Drugs with neuromuscular blocking activity may reduce the effectiveness of sugammadex. Cases of QT prolongation have been seen in patients who have received sugammadex with sevoflurane or propofol.

Clinical evidence, mechanism, importance and management

No pharmacokinetic drug interaction studies have been conducted with sugammadex, and interactions have been predicted on the basis of the binding affinity of sugammadex and other drugs.

(a) Anaesthetics

The manufacturer of sugammadex notes that a few cases of QTc interval prolongation have been reported in patients who have received sugammadex and **sevoflurane** or **propofol**. Details of the other drugs given during

the period of anaesthesia were not given.[1] Note that sugammadex alone does not appear to prolong the QTc interval to a clinically relevant extent.[1]

(b) Antibacterials

The manufacturer of sugammadex predicts that intravenous **flucloxacillin** given pre-operatively in doses of 500 mg or more, or intravenous **fusidic acid** may cause some displacement of vecuronium or rocuronium from the sugammadex complex, and may delay recovery. In addition, they advise avoidance of high-dose intravenous **flucloxacillin** and intravenous **fusidic acid** in the 6-hour postoperative period because of the possibility of recurrence of neuromuscular blockade. If this is not possible, the patient's ventilation should be closely monitored, particularly in the first 15 minutes after the flucloxacillin dose. Consideration may be given to using a further dose of sugammadex.[1] The importance of this potential interaction requires confirmation. Until further data are available these recommendations should be followed.

(c) Hormonal contraceptives

The manufacturer predicts that the AUC of progestogens may be reduced (by 34%, an amount they say is similar to the decrease seen when a hormonal contraceptive is taken 12 hours late) when patients also receive a single bolus dose of sugammadex, and that the effect on the estrogen will be lower. This is based on the fact that sugammadex might bind progestogens in the blood, so lowering the free plasma levels. They advise that the same precautions should be followed as for when one daily dose of the oral hormonal contraceptive is missed.[1] For non-oral hormonal contraceptives, they advise that patients should use an additional non-hormonal contraceptive method for the next 7 days, and also follow the specific product guidelines.[1]

Even if this predicted pharmacokinetic interaction is proved, it is difficult to envisage that a 34% reduction in AUC of a progestogen on a single day when the woman has undergone surgery will be clinically relevant, even for oral progestogen-only contraceptives, and especially for parenteral progestogen-only contraceptives and the levonorgestrel IUD. Note that combined hormonal contraceptives are usually discontinued before major surgery or surgery involving prolonged immobilisation of a lower limb, because of the increased risk of thrombosis.

(d) Neuromuscular blocking drugs

Sugammadex is used therapeutically to reverse the activity of **rocuronium** or **vecuronium**. If further neuromuscular blockade is required within 24 hours of giving sugammadex, a non-steroidal neuromuscular blocking agent should be used.[1] Examples of non-steroidal neuromuscular blocking agents (that is, benzylisoquinolinium type neuromuscular blocking agents) are given in 'Table 5.2', (p.101).

The manufacturer states that, if other drugs that potentiate the neuromuscular blocking effect of **rocuronium** or **vecuronium** are given in the postoperative period (after reversal of the effects of **rocuronium** or **vecuronium** with sugammadex) there is the possibility of recurrence of blockade, and a further dose of sugammadex may be required.[1]

(e) Toremifene

The manufacturer of sugammadex predicts that toremifene may displace vecuronium or rocuronium from the sugammadex complex. This may result in a delayed recovery following neuromuscular blockade if toremifene has been given on the same day.[1] The importance of this potential interaction requires confirmation.

1. Bridion (Sugammadex sodium). Organon Laboratories Ltd. UK Summary of product characteristics, July 2008.

Sulfinpyrazone + NSAIDs

A brief report suggests that the uricosuric effects of sulfinpyrazone are not opposed by the concurrent use of flufenamic acid, meclofenamic acid or mefenamic acid.[1,2] However, note that sulfinpyrazone can cause gastric bleeding and inhibit platelet aggregation, effects that might be additive with NSAIDs.
Consider also 'Uricosuric drugs + Aspirin or other Salicylates', p.1575.

2. Robinson RG, Radcliff FJ. The effect of meclofenamic acid on plasma uric acid levels. *Med J Aust* (1972) 1, 1079–80.

Sulfinpyrazone + Probenecid

Probenecid reduces the urinary excretion of sulfinpyrazone, but the overall uric acid clearance remains unaltered.

Clinical evidence, mechanism, importance and management

A study in 8 patients with gout found that although probenecid inhibited the renal tubular excretion of sulfinpyrazone, reducing it by about 75%, the maximal uric acid clearance was about the same as when either drug was given alone.[1] There would therefore seem to be no advantage in using these drugs together. The possibility of an increase in the adverse effects of sulfinpyrazone, caused by this reduction in excretion, does not seem to have been studied.

Testosterone + Miscellaneous

Dutasteride and finasteride increase the levels of oral testosterone. Food has little effect on the absorption of oral testosterone.

Clinical evidence, mechanism, importance and management

In a pharmacokinetic study in healthy men, **dutasteride** 500 micrograms daily for 6 days increased the AUC of testosterone and testosterone enanthate given as single oral doses of 200 mg, 400 mg and 800 mg on days 4, 5 and 6 of dutasteride administration. The increases in testosterone AUC ranged from 42% with the 200 mg dose to 2.6-fold with the 800 mg dose. Moreover, **dutasteride** attenuated the increase in serum dihydrotestosterone seen with oral testosterone. In this study, subjects had their endogenous testosterone temporarily suppressed by the injection of the GnRH antagonist acyline.[1]

In a similar subsequent study, **finasteride** 5 mg daily increased AUC of testosterone 400 mg 2.3-fold. **Food** caused a slight non-significant decrease in testosterone levels, when compared with the fasting state.[2]

Testosterone is poorly bioavailable by the oral route, and is rapidly metabolised to dihydrotestosterone by 5-alpha reductase. By inhibiting this enzyme, dutasteride and finasteride reduce the formation of dihydrotestosterone and increase testosterone levels.[1,2]

These studies suggest that the 5-alpha reductase inhibitors might be useful in increasing testosterone oral bioavailability for oral replacement therapy.[1,2]

Tizanidine + Antihypertensives

Tizanidine is predicted to increase the effects of antihypertensive drugs; two case reports describe severe hypotension with lisinopril. The manufacturer of tizanidine advises against the use of antihypertensives that are related to tizanidine (e.g. clonidine).

Clinical evidence

A 10-year-old child taking **lisinopril** developed severe hypotension within a week of starting to take tizanidine.[1] Similarly, a 48-year-old stroke patient taking **amlodipine**, **nimodipine**, **lisinopril**, and **labetalol**, which had been added sequentially to control hypertension, had a dramatic reduction in blood pressure (from 130/85 to 66/42 mmHg) within 2 hours of her first dose of tizanidine 2 mg. She was given dopamine to maintain her blood pressure, and tizanidine and all the antihypertensives were withdrawn. Later **labetalol**, **amlodipine**, **nimodipine** and tizanidine were successfully resumed without producing similar problems.[2]

Mechanism

Tizanidine is a centrally acting α_2-adrenergic agonist structurally related to clonidine and can cause dose-related hypotension (66% of patients giv-

en a single 8-mg dose of tizanidine had a 20% reduction in blood pressure). This can result in bradycardia, dizziness or light-headedness, and rarely syncope. The antihypertensive effects of tizanidine are said to be less than one-tenth of those of clonidine.[3] Nevertheless, these effects are expected to be additive with other antihypertensive drugs. However, in the cases with lisinopril, it was suggested that ACE inhibition, combined with the alpha-agonist effects of tizanidine prevented the usual sympathetic response to hypotension (that is, it was not thought to be due to simple additive hypotensive effects).[1,2]

Importance and management

Tizanidine alone can cause hypotension, an effect which is usually minimised by titration of the dose. Patients should be warned about this effect. Because of this, the manufacturers caution that tizanidine might increase the effects of antihypertensive drugs, including **diuretics**, and recommend caution on concurrent use.[3,4] This is a prudent precaution. The US manufacturer additionally states that tizanidine (an α_2-adrenergic agonist that is structurally related to clonidine) should not be used with other α_2-adrenergic agonists [e.g. **clonidine**, **methyldopa**].[3] The UK manufacturer additionally says that the concurrent use of **beta blockers** may potentiate bradycardia and hypotension.[4] This seems a reasonable prediction, as this effect has been seen with clonidine, see 'Clonidine and related drugs + Beta blockers', p.1053.

Tizanidine + Cranberry juice

Limited evidence suggests that cranberry juice does not affect the pharmacokinetics of tizanidine.

Clinical evidence

In a randomised, crossover study in 10 healthy subjects, 200 mL of cranberry juice three times daily for 10 days had no significant effect on the pharmacokinetics of a single 1-mg oral dose of tizanidine, taken on day 5. In this study, the cranberry juice used was a concentrate (*Kontiomehu sokeroitu karpalomehu*) diluted 1 to 4 with tap water before use.[1]

Mechanism

This study suggests that cranberry juice has no clinically relevant effect on the activity of the cytochrome P450 isoenzyme CYP1A2.

Importance and management

Although the evidence is limited to this particular study, there appears to be no need for any special precautions when taking cranberry juice with tizanidine.

Tizanidine is used as a probe drug for CYP1A2 activity, and therefore these results also suggest that a pharmacokinetic interaction between cranberry juice and other CYP1A2 substrates is unlikely.

1. Lilja JJ, Backman JT, Neuvonen PJ. Effects of daily ingestion of cranberry juice on the pharmacokinetics of warfarin, tizanidine, and midazolam – probes of CYP2C9, CYP1A2, and CYP3A4. *Clin Pharmacol Ther* (2007) 81, 833–9.

Tizanidine + CYP1A2 inhibitors

Fluvoxamine causes a very marked 33-fold increase in tizanidine levels with a consequent increase in hypotensive and sedative effects. Similarly, ciprofloxacin markedly increases tizanidine levels and adverse effects. Combined oral contraceptives increase tizanidine levels fourfold and might increase its adverse effects. Other inhibitors of CYP1A2 are predicted to interact similarly.

Clinical evidence

(a) Ciprofloxacin

In a placebo-controlled, crossover study in 10 healthy subjects, ciprofloxacin 500 mg twice daily for 3 days markedly increased the AUC of a single 4-mg dose of tizanidine tenfold and increased its maximum level sevenfold, without significantly affecting its half-life. The hypotensive and sedative effects of tizanidine were also markedly increased by ciprofloxacin.[1]

A case report describes a 45-year-old Japanese woman with multiple sclerosis, taking tizanidine 3 mg daily, had a reduction in blood pressure (from 124/88 to 102/74 mmHg) and heart rate (from 86 to 58 bpm) shortly after starting to take ciprofloxacin 400 mg daily. After 2 days she complained of drowsiness and her blood pressure was 92/54 mmHg.[2] Retrospective analysis revealed 8 patients who had taken tizanidine with ciprofloxacin. In these patients, the mean reduction in blood pressure on starting ciprofloxacin was 21.3/15.4 mmHg, and the heart rate reduction was 14.9 bpm. Adverse effects attributable to tizanidine occurred in three of the patients.[2]

(b) Fluvoxamine

In a placebo-controlled, crossover study in 10 healthy subjects, fluvoxamine 100 mg daily for 4 days very markedly increased the AUC of a single 4-mg dose of tizanidine 33-fold and increased its maximum level 12-fold. The elimination half-life of tizanidine was prolonged from 1.5 to 4.3 hours. The hypotensive and sedative effects of tizanidine were also markedly increased by fluvoxamine, with all of the 10 subjects somnolent and dizzy for 3 to 6 hours.[3]

A case report describes a 70-year-old Japanese woman who started taking tizanidine 3 mg daily 15 days after starting fluvoxamine (100 mg increased to 150 mg daily). Her heart rate dropped from about 85 bpm to a range of 56 to 60 bpm. After tizanidine was stopped, the symptoms improved immediately.[4] Retrospective analysis revealed 23 patients who had received tizanidine with fluvoxamine. Of these patients, 6 had adverse effects including low heart rate, dizziness, drowsiness and hypotension. The patients with adverse effects were, on average, taking higher doses of fluvoxamine and tizanidine than those without adverse effects.[4]

(c) Oral contraceptives

In a study in 15 healthy women taking a combined oral contraceptive (**ethinylestradiol** with **gestodene**), the AUC of a single 4-mg dose of tizanidine was 3.9-fold higher than in 15 healthy women not taking an oral contraceptive. The elimination half-life of tizanidine was unchanged. In addition, the blood pressure-lowering effect of tizanidine was increased by 12/8 mmHg in the oral contraceptive users.[5] The manufacturer also notes that retrospective analysis of population pharmacokinetic data found that the clearance of tizanidine is about 50% lower in women taking oral contraceptives.[6,7]

Mechanism

Tizanidine is a substrate of the cytochrome P450 isoenzyme CYP1A2, and undergoes substantial presystemic metabolism by this route. Ciprofloxacin appears to inhibit mainly the presystemic metabolism of tizanidine by this isoenzyme, leading to increased absorption, as reflected by the increase in maximum level without a change in elimination half-life. Fluvoxamine inhibited both the presystemic metabolism of tizanidine and the elimination phase. Fluvoxamine, which is a known potent inhibitor of CYP1A2, had the most marked effect. The contraceptive steroids were modest inhibitors of CYP1A2 by comparison.

Importance and management

These pharmacokinetic interactions are well established, and clinically important. The common adverse effects of tizanidine, such as hypotension and sedation, are dose related, and consequently the manufacturers recommend starting with a low dose of tizanidine (2 or 4 mg) and carefully titrating to the usual maximum of 24 mg daily, and not exceeding 36 mg daily.[6,7] This represents a maximum 18-fold variation in dosage. **Fluvoxamine** increases the exposure to tizanidine by a mean of 33-fold, which, broadly speaking, changes a 2 mg dose into a 66 mg dose, which is far higher than the maximum recommended dose. For this reason, the authors of one of the studies conclude that the combination is potentially hazardous and should be avoided,[3] and the manufacturers contraindicate the combination.[6,7] Given the available data this is sensible advice. Note that other **SSRIs** are generally not considered to inhibit CYP1A2, see 'Theo-

phylline + SSRIs', p.1457, and may therefore be suitable alternatives to fluvoxamine.

For **ciprofloxacin**, there is a marked tenfold increase in exposure to tizanidine, with a consequent increase in adverse effects. Some authors recommend caution if both drugs are necessary,[1] whereas other suggest that this combination should be avoided.[2] The manufacturers contraindicate the combination.[6,7] If ciprofloxacin is considered the most appropriate antibacterial to use in a patient already taking tizanidine, anticipate the need to reduce the tizanidine dose before starting ciprofloxacin, and closely monitor adverse effects: starting ciprofloxacin may cause marked hypotension, bradycardia, and sedation. Note that the manufacturers also recommend that the use of tizanidine with **enoxacin** and **norfloxacin** should generally be avoided, or undertaken with caution. However, note that enoxacin is usually considered a more potent inhibitor of CYP1A2 than ciprofloxacin, whereas norfloxacin only has modest effects on CYP1A2. Other quinolones may also inhibit CYP1A2, to varying degrees, see 'Table 34.4', (p.1453).

For **combined oral contraceptives**, the increase in exposure to tizanidine is a more moderate fourfold. The manufacturer states that clinical response or adverse effects might occur at lower doses of tizanidine in patients taking oral contraceptives,[6] and that during dose titration, individual doses should be reduced.[7] Care is needed.[7]

In addition, the manufacturers also recommend that the use of tizanidine with other inhibitors of CYP1A2 should generally be avoided, or used with caution, and they specifically mention **aciclovir**, **amiodarone**, **cimetidine**, **famotidine**, **mexiletine**, **propafenone**, **ticlopidine**, **verapamil** and **zileuton**.[6,7] However, note that a number of these drugs have not been shown to have clinically relevant effects on this isoenzyme. For a list of some clinically relevant CYP1A2 inhibitors, see 'Table 1.2', (p.4).

Tizanidine + Food

Food modestly increases the maximum levels and AUC of tizanidine tablets, but modestly decreases the maximum levels and slightly increases the AUC of tizanidine modified-release capsules.

Clinical evidence, mechanism, importance and management

In a single-dose pharmacokinetic study in 81 healthy subjects, the absorption of tizanidine modified-release capsules was equivalent to that of tablets in fasted subjects. When the *tablets* were taken with food, the mean maximum level of tizanidine was increased by about 25%, and the median time to peak plasma concentration increased from about one hour to 1 hour and 25 minutes, and the extent of absorption was increased by about 30%. Conversely, when the *capsules* were taken with food, the maximum level of tizanidine decreased by about 15%, the median time to peak plasma concentration increased from one hour to 3 hours, and the extent of absorption increased by just 10%. This means that, when taken with food, the amount absorbed from the capsule is more than 80% of the amount absorbed from the tablet.[1] Similar findings were reported in another study.[2]

The manufacturer notes that taking the capsule contents sprinkled on apple sauce is not bioequivalent to taking an intact capsule under fasting conditions. Giving the capsule contents on apple sauce results in a 15 to 20% increase in the maximum levels and AUC of tizanidine, when compared with giving an intact capsule while fasting.[3]

Although modest, the changes described could be clinically relevant in terms of onset of effect and adverse effects. The effects differ between the capsule and tablet formulations, and are probably of greatest importance if patients are changed from capsules to tablets, or vice versa.

3. Zanaflex (Tizanidine hydrochloride). Acorda Therapeutics, Inc. US Prescribing information, April 2008.

Tizanidine + Miscellaneous

The sedative effects of tizanidine and other sedative drugs and alcohol are additive. Increased bradycardia might occur if digoxin is given with tizanidine. It is unclear whether tizanidine prolongs the QT interval in humans. No interaction occurs with paracetamol (acetaminophen).

Clinical evidence, mechanism, importance and management

(a) CNS depressants

One of the most common adverse effects of tizanidine is somnolence or drowsiness (occurring in up to 50% of patients[1]) for which reason the manufacturers warn about the possibility of increased sedation with other **sedative drugs**, and **alcohol**.[2,3] In addition to additive sedative effects, **alcohol** increased the AUC of tizanidine by about 20% and increases its maximum level by 15%, which was associated with an increase in the adverse effects of tizanidine.[3] Patients should be warned that concurrent use may increase drowsiness, and be advised to avoid driving and related skilled tasks if affected.

(b) Digoxin

Tizanidine alone can cause bradycardia.[2,3] The UK manufacturer says that the concurrent use of digoxin may potentiate bradycardia.[2]

(c) Drugs that prolong the QT interval

The US manufacturer states that prolongation of the QT interval and bradycardia were noted in chronic toxicity studies in *dogs* at doses equal to the maximum dose of tizanidine.[3] The UK information advises caution if tizanidine is prescribed with drugs known to increase the QT interval.[2] However, in one pharmacological interaction study in healthy subjects, there was no evidence of QT prolongation either with tizanidine 4 mg, or almost 14-fold increased tizanidine levels caused by 'rofecoxib', (below), despite adverse effects such as increased bradycardia and hypotension occurring.[4] This suggests that a clinically significant interaction resulting in QT prolongation is unlikely.

(d) Paracetamol (Acetaminophen)

In 20 healthy subjects, no clinically significant interaction occurred between 325 mg of paracetamol and 4 mg of tizanidine.[1]

Tizanidine + NSAIDs

Celecoxib and tolfenamic acid do not appear to affect the pharmacokinetics or pharmacodynamics of tizanidine. Rofecoxib (now withdrawn) caused a very marked rise in the AUC of tizanidine.

Clinical evidence

(a) Celecoxib

In a pharmacokinetic study in 12 healthy subjects, celecoxib 200 mg twice daily for 4 days had no effect on the pharmacokinetics of a single 2-mg

dose of tizanidine given on the morning of day 4. The pharmacodynamic effects of tizanidine were not altered by celecoxib.[1]

(b) Rofecoxib

In a placebo-controlled, crossover study in 9 healthy subjects, rofecoxib 25 mg daily for 4 days markedly increased the AUC of a single 4-mg dose of tizanidine 13.6-fold and increased the maximum level 6.1-fold. The hypotensive and sedative effects of tizanidine were also markedly increased by rofecoxib. There was no evidence of QT prolongation in this study.[2]

A case report describes an otherwise healthy 59-year-old woman, who developed sinus bradycardia (30 bpm) with chest pain and acute right heart failure while taking tizanidine, diclofenac and rofecoxib. This resolved promptly after stopping the medication.[3]

(c) Tolfenamic acid

In a pharmacokinetic study in 10 healthy subjects, tolfenamic acid 200 mg three times daily for 3 days had no effect on the pharmacokinetics of a single 4-mg dose of tizanidine given on day 3. The only change was a slight 13% decrease in the plasma levels of the secondary metabolite of tizanidine, M4. The pharmacodynamic effects of tizanidine were not altered by tolfenamic acid.[4]

Mechanism

Tizanidine is a substrate of the cytochrome P450 isoenzyme CYP1A2, and undergoes substantial presystemic metabolism by this isoenzyme. Rofecoxib, an inhibitor of CYP1A2, decreases both the presystemic metabolism of tizanidine, and its elimination phase.[5] Despite *in vitro* evidence of CYP1A2 inhibition,[1,4] neither celecoxib nor tolfenamic acid appear to alter the pharmacokinetics of tizanidine.

Importance and management

The pharmacokinetic interaction of rofecoxib with tizanidine is well established, and the combination should be avoided. However, note that rofecoxib was generally withdrawn worldwide in 2004 because of its cardiovascular adverse effects, but the interaction is included here for completeness.

Neither celecoxib nor tolfenamic acid interact, so no special precautions are required if these NSAIDs are given to patients taking tizanidine.

Tizanidine + Rifampicin (Rifampin)

Rifampicin moderately decreases the plasma concentrations of tizanidine.

Clinical evidence, mechanism, importance and management

In a placebo-controlled, crossover study in 10 healthy subjects, pre-treatment with rifampicin 600 mg daily for 5 days moderately reduced the AUC and peak level of a single 4-mg dose of tizanidine given on day 6 by about 50%, without altering its half-life.[1]

Rifampicin appears to be only a weak inducer of the cytochrome P450 isoenzyme CYP1A2, by which tizanidine is metabolised.[1]

Although rifampicin moderately reduces the levels and effects of tizanidine, because the tizanidine dose is titrated to effect, this seems unlikely to be clinically important. A small increase in dose might be required if rifampicin is given to those on established tizanidine treatment.

1. Backman JT, Granfors MT, Neuvonen PJ. Rifampicin is only a weak inducer of CYP1A2-mediated presystemic and systemic metabolism: studies with tizanidine and caffeine. *Eur J Clin Pharmacol* (2006) 62, 451–61.

Tolvaptan + Diuretics; Loop, Thiazide and related

The concurrent use of tolvaptan and furosemide or hydrochlorothiazide does not appear to affect the pharmacokinetics or pharmacodynamics of either drug to a clinically relevant extent. However, the concurrent use of tolvaptan and diuretics can increase the risk of dehydration and hypovolaemia.

Clinical evidence, mechanism, importance and management

In a single-dose, randomised, crossover study in 6 healthy subjects given tolvaptan 30 mg, **furosemide** 80 mg or both drugs together, there were no differences in the pharmacokinetics of **furosemide**, but the AUC of tolvaptan was slightly increased, by 24%.[1] However, there were no changes in the pharmacodynamics of either drug.

In the same study, a further 6 healthy subjects were given tolvaptan 30 mg, **hydrochlorothiazide** 100 mg or both drugs together. There were no differences found in the pharmacokinetics or pharmacodynamics of either drug.[1] The concurrent use of tolvaptan and either **furosemide** or **hydrochlorothiazide** did not result in a greater 24-hour urinary volume than tolvaptan alone, suggesting that the diuretic effect of these drugs was not additive.[1]

This study provides evidence that no clinically important pharmacokinetic interaction would be expected if tolvaptan is given with **furosemide** or **hydrochlorothiazide**. However, note that the US manufacturer of tolvaptan[2] states that it induces copious aquaresis, which can result in dehydration and hypovolaemia, particularly in patients also taking diuretics. Therefore some caution is warranted on concurrent use.

2. Samsca (Tolvaptan). Otsuka America Pharmaceutical Inc. US Prescribing information, May 2009.

Tolvaptan + Ketoconazole and other CYP3A4 inhibitors

Ketoconazole (a potent CYP3A4 inhibitor) markedly increased the exposure to tolvaptan in one study, and other potent CYP3A4 inhibitors are likely to interact similarly. Grapefruit juice also increases the exposure to tolvaptan.

Clinical evidence, mechanism, importance and management

The manufacturer briefly notes that the AUC of tolvaptan is increased fivefold when ketoconazole 200 mg daily is also given.[1] **Grapefruit juice** also increases the exposure to tolvaptan, by 80%.[1,2] Ketoconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4 in the liver, by which tolvaptan is primarily metabolised, and **grapefruit juice** is also an inhibitor of this isoenzyme in the intestine. Concurrent use therefore decreases tolvaptan metabolism and increases its exposure.

The clinical relevance of the marked increase in tolvaptan exposure with ketoconazole has not been assessed, but an increase in its effects would be expected. The US manufacturer contraindicates the concurrent use of ketoconazole and other potent CYP3A4 inhibitors, because there is no adequate experience to define the dose adjustment necessary to allow safe concurrent use. They specifically name **itraconazole**; the macrolides **clarithromycin** and **telithromycin**; the protease inhibitors **nelfinavir**, **ritonavir** and **saquinavir**, and **nefazodone**.[1] In addition, they also say that moderate CYP3A4 inhibitors, such as **aprepitant**, **diltiazem**, **erythromycin**, **fluconazole**, and **verapamil** should generally be avoided.[1] However, in the UK, the manufacturer simply advises caution with any CYP3A4 inhibitor, irrespective of potency.[2] For a list of CYP3A4 inhibitors see 'Table 1.4', (p.6). Both manufacturers suggest that the use of **grapefruit juice** should be avoided in patients taking tolvaptan.[1,2]

If any CYP3A4 inhibitor is considered essential in a patient taking tolvaptan, monitor the patient for increased adverse effects such as dry mouth, thirst and increased frequency of urination, and, ideally monitor fluid and electrolyte status. Reduce the dose of tolvaptan as necessary.

1. Samsca (Tolvaptan). Otsuka America Pharmaceutical Inc. US Prescribing information, May 2009.
2. Samsca (Tolvaptan). Otsuka Pharmaceuticals (UK) Ltd. UK Summary of product characteristics, August 2009.

Tolvaptan + Miscellaneous

The risk of hyperkalaemia with tolvaptan is slightly increased in patients taking drugs known to increase serum potassium levels such as ACE inhibitors, angiotensin II receptor antagonists and potassium-sparing diuretics. Tolvaptan modestly increases lovastatin levels, but lovastatin does not alter tolvaptan levels. Tolvaptan does not alter the pharmacokinetics of warfarin. P-glycoprotein inhibitors such as ciclosporin are predicted to increase levels of tolvaptan.

Clinical evidence, mechanism, importance and management

(a) Lovastatin

Exposure to tolvaptan is not affected by lovastatin; however, tolvaptan increased the plasma levels of lovastatin and its active metabolite by 40% and 30%, respectively.[1] This is because tolvaptan is a weak inhibitor of the cytochrome P450 isoenzyme CYP3A4,[1] by which lovastatin is metabolised. The increase in lovastatin exposure seen is probably not clinically relevant.

(b) P-glycoprotein inhibitors

The US manufacturer states that tolvaptan is a substrate of P-glycoprotein, and predicts that P-glycoprotein inhibitors (they name **ciclosporin**) may increase the levels of tolvaptan. The dose of tolvaptan may need to be reduced if **ciclosporin** or other P-glycoprotein inhibitors are also given.[1] Until more is known, some caution would be prudent.

(c) Potassium-sparing drugs

Tolvaptan may increase serum potassium levels.[1,2] The US manufacturer notes that, in clinical studies, the incidence of hyperkalaemia was about 1 to 2% higher in patients who had taken tolvaptan with **ACE inhibitors**, **angiotensin II receptor antagonists** and **potassium-sparing diuretics** than when any of these drugs were given with placebo. They therefore recommend monitoring of serum potassium levels on the concurrent use of tolvaptan and any of these drugs.[1] On this basis, the same precautions would also seem prudent in patients taking **potassium supplements**.

(d) Warfarin

The manufacturer briefly notes that the pharmacokinetics of warfarin are not altered to a clinically relevant extent by tolvaptan.[1,2] No warfarin dose adjustment would be expected to be needed on concurrent use.

Tolvaptan + Rifampicin (Rifampin) and other CYP3A4 inducers

Rifampicin, a CYP3A4 inducer, markedly reduces the exposure to tolvaptan, and other CYP3A4 inducers are likely to interact similarly.

Clinical evidence, mechanism, importance and management

The manufacturer of tolvaptan briefly notes that the concurrent use of rifampicin reduces the AUC of tolvaptan by 85%.[1] Rifampicin is a potent inducer of the cytochrome P450 isoenzyme CYP3A4, by which tolvaptan is primarily metabolised. The reduction in tolvaptan exposure seen with rifampicin is likely to markedly reduce its effectiveness. The manufacturers predict that other CYP3A4 inducers are likely to interact similarly, and they name the **barbiturates**, **carbamazepine**, **phenytoin**, **rifabutin**, **rifapentine** and **St John's wort**.[1,2] Because of the potency of the effect of rifampicin, the US manufacturer states that concurrent use should be avoided, but note that most of these are weaker inducers than rifampicin. However, they do state that if concurrent use is necessary, the dose of tolvaptan may need to be increased.[1] The UK manufacturer simply advises caution on concurrent use.[2] If tolvaptan is given with a CYP3A4 inducer, it may be prudent to monitor the outcome of concurrent use, being alert for a reduction in tolvaptan efficacy, and increase the dose of tolvaptan, as necessary. For a list of CYP3A4 inducers see 'Table 1.4', (p.6).

Trientine + Miscellaneous

Trientine can possibly chelate with iron thereby reducing its absorption. On theoretical grounds a similar chelation interaction may occur with calcium and magnesium antacids, and mineral supplements.

Clinical evidence, mechanism, importance and management

(a) Iron compounds

Trientine is a copper-chelating agent used for Wilson's disease. One of the adverse effects of trientine is that it can cause iron deficiency, probably because it chelates with iron in the gut and thereby reduces its absorption. It is usual to resolve this iron deficiency, where necessary, by giving an iron supplement. The manufacturers suggest that the iron supplement should be given at a different time of the day from trientine to minimise their admixture in the gut.[1,2] A separation of at least 2 hours is recommended.[2]

(b) Other mineral supplements and antacids

Trientine may be inactivated by metal binding in the gastrointestinal tract. The UK manufacturers say that there is no evidence that **calcium** or **magnesium antacids** alter the efficacy of trientine, but it is good practice to separate their administration.[1] The US manufactures say that, in general, mineral supplements should not be given with trientine. They say that it is important that trientine is taken at least one hour apart from any other drug or **milk**.[2]

Uricosuric drugs + Aspirin or other Salicylates

The uricosuric effects of high doses of aspirin or other salicylates and uricosuric drugs such as benzbromarone, probenecid and sulfinpyrazone are not additive as might be expected but are mutually antagonistic. Low-dose, enteric-coated aspirin appears not to interact with probenecid.

Clinical evidence

(a) Benzbromarone

In a study in 6 subjects with gout,[1] a single 160-mg dose of benzbromarone increased the percent ratio of urate to creatinine clearance by 371% at its peak (i.e. benzbromarone increases urate clearance). However, when the same dose of benzbromarone was given with a single 600-mg dose of aspirin, the peak ratio of urate to creatinine clearance with benzbromarone 160 mg was reduced by about 75% (i.e. aspirin reduces the effect of benzbromarone on urate clearance). In another study aspirin, in divided doses of 650 mg, up to a total of 5.2 g daily, was given to 29 healthy subjects taking benzbromarone 40 to 80 mg daily. The urate lowering effects of benzbromarone were most affected by aspirin 2.7 g; benzbromarone reduced the urate levels by 60%, but in the presence of aspirin 2.7 g the levels were only reduced by 48%.[2]

(b) Probenecid

A study found that the average urinary uric acid excretion in 24 hours was 673 mg with a single 3-g daily dose of probenecid, 909 mg with a 6-g daily dose of **sodium salicylate**, but only 114 mg when both drugs were given.[3] Similar antagonism has been seen in other studies in patients given aspirin 2.6 to 5.2 g daily.[4-6] No antagonism is seen until serum salicylate

levels of 50 to 100 mg/L are reached.[6] Therefore no interaction would be expected with low, antiplatelet-dose aspirin. This was confirmed by a crossover study in 11 patients with gouty arthritis, regularly taking probenecid, which found that enteric-coated aspirin 325 mg daily, taken either with probenecid or 6 hours after probenecid, had no effect on serum urate levels or on the 24-hour urate excretion.[7]

(c) Sulfinpyrazone

When **sodium salicylate** 6 g was given with sulfinpyrazone 600 mg daily to one patient the average urinary uric acid excretion in 24 hours was 30 mg, whereas when each drug was used alone in the same doses the average 24-hour urinary excretion was 281 mg for **sodium salicylate** and 527 mg for sulfinpyrazone.[3] A later study in 5 men with gout, given sulfinpyrazone for about an hour (300 mg bolus followed by a 10 mg/minute infusion), found that the addition of **sodium salicylate** (3 g bolus followed by a 10 to 20 mg/minute infusion) virtually abolished uricosuria. When the drugs were given in the reverse order to 3 other patients the same result was seen.[8]

In another study, the uricosuria caused by sulfinpyrazone 400 mg daily was found to be completely abolished by aspirin 3.5 g.[9] In 5 healthy subjects the clearance of a single 400-mg dose of sulfinpyrazone was modestly increased by 12 to 27% by four doses of aspirin 325 mg, given over 24 hours.[10]

Mechanism

Not fully understood. Uricosuric drugs compete successfully with salicylate for secretion by the kidney tubules so that salicylate excretion is reduced, but the salicylate blocks the inhibitory effect of uricosuric drugs on the tubular reabsorption of uric acid causing the uric acid to accumulate within the body.[8]

Importance and management

Well established and clinically important interactions. Regular administration of anti-inflammatory doses of aspirin and other salicylates antagonises the effects of uricosuric drugs such as benzbromarone, probenecid, and sulfinpyrazone, and should generally be avoided in those with hyperuricaemia or gout. Serum salicylate levels of 50 to 100 mg/L are necessary before this interaction occurs. Doses of aspirin as low as 700 mg can cause an appreciable fall in uric acid excretion,[9] but the effects of an occasional small dose are probably of little practical importance. Low-dose aspirin (325 mg or less daily) does not seem to interact.

Note that sulfinpyrazone can cause gastric bleeding and inhibit platelet aggregation; effects that might be additive with those of aspirin.

Vaccines + Chloroquine or Hydroxychloroquine

Chloroquine reduces the antibody response to oral cholera vaccine and intradermal human diploid rabies vaccine. Hydroxychloroquine may also reduce the antibody response to intradermal human diploid rabies vaccine. Chloroquine does not appear to alter the antibody response to tetanus, diphtheria, measles, poliomyelitis, oral typhoid (live), or BCG vaccines.

Clinical evidence, mechanism, importance and management

(a) Cholera vaccine

A study in healthy subjects found that chloroquine reduced the vibriocidal antibody titre of *Vibrio cholerae* CVD103-HgR live oral vaccine in the 30 subjects who received both treatments. The seroconversion rate fell from 91% in subjects who received the oral cholera vaccine alone to 67% in those who were also given two doses of chloroquine diphosphate 250 mg, 7 days apart. It was suggested that concurrent use should be avoided, and chloroquine prophylaxis started no sooner than 8 days after vaccination.[1]

(b) Rabies vaccine

In a study, 51 healthy subjects were given intradermal rabies vaccine 0.1 mL on days 0, 7, and 28. Of these subjects, 26 were also given chloroquine base 300 mg weekly, starting 9 days before the first dose of vaccine until day 48. The other 25 subjects not given chloroquine served as controls. The mean neutralising antibody titre for the chloroquine group was significantly lower than that for the control group on days 28, 49, and 105. The results indicate that chloroquine, in the doses used for malaria prophylaxis, can reduce the antibody response to primary immunisation with intradermal human diploid rabies vaccine.[2] Another study similarly found that chloroquine prophylaxis was associated with poor antibody response to this vaccine.[3] One manufacturer of chloroquine advises against the use of pre-exposure intradermal human diploid rabies vaccine in patients taking chloroquine prophylaxis. When vaccinating against rabies with this vaccine, they recommend giving the vaccine before starting chloroquine, to avoid reducing the effectiveness of the vaccine.[4]

The manufacturers of **hydroxychloroquine** note that it may also reduce the antibody response to primary immunisation with intradermal human diploid rabies vaccine.[5]

(c) Typhoid vaccine

A study in healthy subjects investigated the use of chloroquine with a combination of cholera and *oral* typhoid vaccine (Ty21a vaccine strain). Cholera and typhoid vaccines had previously been shown not to affect each other, and the addition of chloroquine did not significantly reduce the serum antibody response to these vaccines. The authors therefore concluded that chloroquine could be given at the same time as *oral* typhoid vaccine without reducing its efficacy.[1] Similarly, a study (unpublished) suggests that the use of chloroquine with pyrimethamine and sulfadoxine did not alter the immune response to oral typhoid vaccine.[6]

(d) Yellow fever vaccine

A study in 50 healthy subjects found chloroquine phosphate 500 mg, given weekly for 4 weeks, did not affect the antibody titre of a single dose of yellow fever 17D vaccine.[7] Another study also reported that chloroquine does not adversely affect the antibody response to yellow fever vaccine.[8]

(e) Other vaccines

Chloroquine has does not appear to alter the immune response to tetanus, diphtheria, measles, oral poliomyelitis, or BCG vaccines.[6,9,10]

Vaccines + Proguanil

Proguanil, but not proguanil with atovaquone, appears to reduce the effectiveness of live oral typhoid vaccine. Note that the capsular polysaccharide typhoid vaccine for injection would not be affected. Atovaquone with proguanil did not alter the efficacy of cholera vaccine.

Clinical evidence, mechanism, importance and management

(a) Cholera vaccine

In a placebo-controlled study, 330 children were given a cholera vaccine (*Vibrio cholerae* CVD103-HgR) 3 weeks after starting a 12-week course of atovaquone with proguanil (for malaria prophylaxis) or placebo. Atovaquone with proguanil was found to be effective and did not alter the immunogenicity of the cholera vaccine.[1]

(b) Typhoid vaccine

In a study in 30 healthy subjects, the anti-*Salmonella typhi* lipopolysaccharide antibody response was reduced when proguanil was given both with, and 7 days after, oral typhoid vaccine (live attenuated *S. typhi* Ty21a strain).[2]

In a placebo-controlled study, 330 children were given an oral typhoid vaccine (live attenuated *S typhi* Ty21a strain) 3 weeks after starting a 12-week course of atovaquone with proguanil (for malaria prophylaxis) or placebo. Atovaquone with proguanil was found to be effective and did not alter the immunogenicity of the oral typhoid vaccine.[1]

The WHO has stated that proguanil should be stopped from 3 days before until 3 days after receiving live oral typhoid vaccine (Ty21a strain).[3] The UK manufacturers similarly recommend an interval of at least 3 days between the last dose of live oral typhoid vaccine (Ty21a strain) and the first dose of antimalarial prophylaxis. However, they also state that malaria prophylaxis with the fixed dose combination of atovaquone and proguanil may be given concurrently with the vaccine.[4] The US manufacturer says that proguanil should only be given if 10 days or more have elapsed since the final dose of live oral typhoid vaccine.[5] Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection, because this does not contain live organisms.

Vaccines; Cholera + Vaccines; Yellow fever

The efficacy of cholera and yellow fever vaccines do not appear to be affected by concurrent administration.

Clinical evidence, mechanism, importance and management

A study in healthy subjects found that yellow fever vaccine did not affect the vibriocidal antibody titre of *Vibrio cholerae* CVD103-HgR live oral vaccine, when both vaccines were given at the same time.[1] Another retrospective study of subjects who had been given cholera vaccine alone or with yellow fever vaccine found that the rates of seroconversion and antibody titres after yellow fever vaccine was not affected by concurrent administration.[2]

Résultats d'une étude rétrospective. *Bull Soc Pathol Exot Filiales* (1990) 83, 529–35.

Vaccines; Typhoid + Antibacterials

Live oral typhoid vaccine should not be given to patients taking antibacterials, or within three days of their use. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Clinical evidence, mechanism, importance and management

The manufacturer notes that sulfonamides and antibacterials may be active against the vaccine organism (live attenuated *Salmonella typhi,* Ty21a strain), and could therefore prevent multiplication and reduce the immune response achieved.[1,2] Note that this has been shown with some antimalarials such as proguanil, see 'Vaccines + Proguanil', above.

It would be prudent to avoid the concurrent use of antibacterials and the live oral typhoid vaccine. The WHO recommends that antibacterial drugs should be stopped from 3 days before to 3 days after receiving live oral typhoid vaccine (Ty21a strain).[3] Similarly, the UK manufacturers and Department of Health recommend that vaccination with live oral typhoid vaccine should not start within 3 days of completing treatment with antibacterials, nor should antibacterials be given within 3 days of receiving the last dose of vaccine.[1,4]

These precautions do not apply to the capsular polysaccharide typhoid vaccine for parenteral use, because this does not contain live organisms.

Vaccines; Typhoid + Mefloquine

Some sources suggest that mefloquine should not be given at the same time as oral attenuated live typhoid vaccine, whereas others suggest that concurrent administration is acceptable. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Clinical evidence

An *in vitro* study found that mefloquine killed a significant amount of *S.typhi* (Ty21a vaccine strain), which suggested that concurrent administration could possibly reduce the efficacy of the vaccine.[1] A study in healthy subjects investigated the use of mefloquine with a combination of cholera and oral typhoid vaccine (Ty21a vaccine strain). Cholera and typhoid vaccines had previously been shown not to affect each other, and the addition of mefloquine did not significantly reduce the serum antibody response to these vaccines. The authors therefore concluded that mefloquine could be given at the same time as oral typhoid vaccine without reducing its efficacy.[2]

Mechanism

Oral typhoid vaccine requires active replication of the attenuated *Salmonella typhi* strain in the ileum for the development of immunity. Mefloquine is thought to have some antibacterial effect, which may diminish the amount of *S. typhi* present, and therefore reduce the immune response produced by the vaccine.[2,3]

Importance and Management

As mefloquine is rapidly absorbed it has been suggested that by 8 hours after a dose, the levels of mefloquine will be insufficient to inhibit live oral typhoid vaccine.[4] Based on the results of the above study the US manufacturers note that mefloquine can be given at the same time as oral typhoid vaccine.[2,5] The UK manufacturers of the oral typhoid vaccine recommend separating the dose of oral typhoid vaccine and mefloquine by at least 12 hours.[6] However, the manufacturers of mefloquine say that immunisation with vaccines such as oral typhoid should be completed at least 3 days before the first dose of mefloquine.[7,8] The UK Department of Health say

that mefloquine can be given 12 hours before or after vaccination with oral typhoid vaccine.[9] It would therefore seem acceptable to separate administration by 12 hours. Note that this advice does not apply to the capsular polysaccharide typhoid vaccine for injection.

Vinpocetine + Antacids

In a study in 18 healthy subjects, aluminium/magnesium hydroxide gel (one sachet four times daily) had no significant effects on the serum levels of vinpocetine (20 mg three times daily).[1] No special precautions seem necessary if these drugs are taken together.

Index

All of the pairs of drugs included in the text of this book which are known to interact or not are listed in this index. They may also be listed under the group names if two or more members of the group interact, **but you should always look up the names of both individual drugs and their groups to ensure that you have access to all the information in this book.** You can possibly get a lead on the way unlisted drugs behave if you look up those which are related, but bear in mind that none of them are indentical and any conclusions reached should only be tentative.

Brand names have been avoided but tables of international proprietary names/generic names are included in the introductory sections of most chapters. You can find these tables by looking up the group names of the drugs in question (e.g. Anticoagulants, Antiepileptics, etc.).
