β -Blockers (general)	Myodepressant Heart block	Bronchoconstriction (β_2) Vasoconstriction Hallucinations/vivid dreams (greater with more lipophilic agents) Decreased renal blood flow Changes in serum lipid profile Drowsiness, fatigue	Asthma, COPD, Raynaud's disease, diabetes mellitus, depression
Dofetilide	Torsade de pointes		Combination with disopyramide or amiodarone or drugs in Table 22.5
Amiodarone	Torsade de pointes	Hyperthyroidism/hypothyroidism, pneu- monitis, myopathy, neuropathy, hepatitis, corneal deposits, photosensitivity	Thyroid disease, liver dysfunction, lung disease (e.g. pneumonectomy)
Bretium	Hypotension	Initial sympathomimetic response, nausea	
Verapamil	Heart block	Constipation, headaches, flushing, ankle oedema, light-headedness	Myasthenia gravis
Adenosine	Heart block	Bronchoconstriction, flushing, chest pain	Asthma, COPD, combination with dipyridamole Decompensated heart failure, patients with a history of convulsions/seizures or recent heart transplant (<1 year)

COPD, Chronic obstructive pulmonary disease.

Table 22.8 Pharmacokinetics of selected antiarrhythmics

	Oral absorption	Protein binding (%)	Elimination, metabolism, half-life (therapeutic range if recommended to be measured)
Amiodarone	Slow, variable	>95	Extensive metabolism, very variable rate, $t_{1/2}$ 2 days initially increasing to 40–60 days
Bretylum	Intravenous/intramuscular only	Unbound	Renal, $t_{1/2}$ 5–10 h
Digoxin	Variable, 70%	25	70% renal, variable, $t_{1/2}$ 36 h (0.8–2 ng/mL)
Diltiazem	40% absorbed	80	Hepatic, $t_{1/2}$ 3 h
Disopyramide	Rapid, >80%	30–90	50% renal, 15% bile, active metabolite, $t_{1/2}$ 4–10 h
Flecainide	Complete, slow	40	30% renal, $t_{1/2}$ 20 h
Lidocaine	Intravenous/intramuscular only	60–80	10% renal, rapid hepatic metabolism to central nervous system-toxic products, $t_{1/2}$ 8–100 min increases with duration of dosing
Mexiletine	>90%	60–70	10% renal, $t_{1/2}$ 10–12 h, hepatic metabolites mostly inactive
Procainamide	Rapid, >75%	15–20	50% renal, 25–40% converted to <i>N</i> -acetylprocainamide (active, $t_{1/2}$ 6 h), procainamide $t_{1/2}$ 2.5–4.5 h
Propafenone	Complete, rapid	>95	Extensive first-pass metabolism, capacity-limited, $t_{1/2}$ 2–12 h
Quinidine	Rapid, >80%	80–90	Mixed renal and hepatic, $t_{1/2}$ 6 h
Verapamil	Rapid, >90%	90	Hepatic, $t_{1/2}$ 4–12 h, marked first-pass effect

All values quoted are subject to marked interindividual variability. Most therapeutic ranges are poorly defined. Oral absorption does not account for drug lost by first-pass hepatic metabolism. Rapid absorption indicates a peak plasma concentration in less than 2 hours.
 $t_{1/2}$, Elimination half-life at normal renal function.

drugs is attributed to critical depression of conduction in already slowly conducting areas such as the diastolic pathway of re-entry circuits associated with structural heart disease, resulting in conduction block and abolishing or preventing re-entry. The properties of class I antiarrhythmic drugs fall into three subgroups: class Ia, class Ib and class Ic antiarrhythmic drugs.

Class Ia antiarrhythmic drugs. Drugs in this class (quinidine, disopyramide and procainamide) have an intermediate inhibitory effect on the inward sodium current I_{Na} , generally causing significant slowing of conduction only at faster heart rates. Class Ia drugs also inhibit the rapid component of the delayed rectifier current I_{Kr} , resulting in prolongation of the cardiac action potential and hence effective refractory period. This property is responsible for a propensity to cause Torsade de pointes. Both quinidine and disopyramide additionally block muscarinic cholinergic receptors, which may contribute to their efficacy for the treatment of arrhythmias in which the parasympathetic nervous system plays a role, such as AF.

Class Ia antiarrhythmic drugs have been used for the treatment of a variety of atrial and ventricular arrhythmias but are now rarely used because of their proarrhythmic and non-cardiac side effects and potential for drug interactions.

Class Ib antiarrhythmic drugs. Class Ib drugs (lidocaine, mexiletine) are the weakest sodium channel blockers, producing little change in the QRS duration in normal cardiac tissue, and also have no significant effect on repolarisation.

Lidocaine is occasionally used in the treatment of VT, particularly when VT occurs in patients already taking amiodarone and β -blockers. Lidocaine acts preferentially on ischaemic myocardium and is more effective in the presence of a high external potassium concentration. Therefore, hypokalaemia must be corrected for maximum efficacy. Lidocaine has no value in treating supraventricular tachyarrhythmias.

Mexiletine may be administered intravenously or orally to control VT. Frequent gastro-intestinal and central nervous system (CNS) side effects (dizziness, light-headedness, tremor, nervousness, difficulty with coordination) limit the dose and possible therapeutic benefit.

Class Ic antiarrhythmic drugs. Class Ic antiarrhythmic drugs (flecainide, propafenone) inhibit the inward sodium current I_{Na} with a slow time-constant for recovery, leading to marked slowing of conduction, which is most prominent in depolarised tissue. They also inhibit the ultra-rapid (I_{Kur}) and rapid (I_{Kr}) components of the delayed rectifier outward potassium current, prolonging the cardiac action potential and hence increasing

the effective refractory period. This action is more prominent at higher heart rates ('use dependency'), which may help to explain the efficacy of these drugs for the treatment of AF. Propafenone is also a β -adrenoceptor antagonist.

Class Ic agents are potent antiarrhythmics used largely in the control of paroxysmal supraventricular and ventricular tachyarrhythmias resistant to other drugs, although they have acquired a particularly bad reputation as a result of the proarrhythmic effects seen in the CAST (Echt et al., 1991) and the Cardiac Arrest Study Hamburg (CASH) (Kuck et al., 2000) studies. Faster heart rates, increased sympathetic activity, and diseased or ischaemic myocardium all contribute to the proarrhythmic effects of these drugs. This has led to these drugs being contraindicated in patients with structural heart disease because poor systolic function exaggerates the proarrhythmic effects. However, flecainide is effective for the treatment of both supraventricular and ventricular arrhythmias in patients without structural heart disease and is moderately successful for maintenance of sinus rhythm after cardioversion of AF. Propafenone has mild β -blocking properties, especially in higher doses, so it should be avoided in patients with reversible obstructive airways disease.

Class II antiarrhythmic drugs: β -adrenoceptor antagonists (β -blockers)

β -Adrenoceptors are widely distributed throughout the atrial and ventricular myocardium, with particularly high concentrations in the sinoatrial and AV nodes. β_1 -Adrenoceptors account for 70–80% of the total, and β_2 -adrenoceptors a majority of the remainder. Stimulation of β_1 -adrenoceptors by binding of adrenaline or noradrenaline activates a G_s protein, which in turn activates adenylyl cyclase, which catalyses the formation of cAMP from adenosine triphosphate (ATP) (Fig. 22.13).

cAMP increases the inward current I_f , which increases the pacemaker rate, I_{Na} , which increases conduction velocity in tissue with an action potential upstroke carried by that current, and $I_{Ca,L}$, which is responsible for a positive inotropic effect, and increases the conduction velocity and reduces the refractory period in the AV node. cAMP also increases the repolarising current I_{Ks} , which shortens APD and hence effective refractory period. β -Blockers compete with adrenaline and

Fig. 22.13 Principal mechanisms of antiarrhythmic action of β -adrenoceptor antagonists.

AC, adenylyl cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

noradrenaline for occupation of β -adrenoceptors and therefore reduce the sinus rate, slow conduction, and increase refractory period in the AV node; have a negative inotropic effect; and slightly prolong cardiac action potential and effective refractory period. The latter effect is probably clinically unimportant. Although some of the antiarrhythmic effects of β -blockers may be explained in terms of their acute effects on transmembrane currents, the effects of adrenergic stimulation, and hence those of β -blockers, are complex, differ between acute and chronic stimulation, and are modified by a variety of disease states. Furthermore, although many of the effects of β -blockers are as a direct result of changes in transmembrane currents, others result from changes in heart rate: for example, APD and effective refractory period are inversely proportional to heart rate.

β -Blockers licensed for the treatment of arrhythmias include propranolol, acebutolol, atenolol, esmolol, metoprolol and sotalol. The antiarrhythmic activity of the various β -blockers is reasonably uniform, the critical property being β_1 -adrenoceptor blockade. Atenolol, metoprolol, propranolol and esmolol are available for intravenous use. Esmolol, a selective β_1 -adrenoceptor antagonist, has a half-life of 9 minutes with full recovery from its β -blockade properties within 30 minutes. Esmolol is quickly metabolised in red blood cells, independent of renal and hepatic function, and due to its short half-life can be useful in situations where there are relative contraindications or concerns about the use of a β -blocker. Sotalol has some class III activity, as well as class II effects.

The use of β -blockers is somewhat constrained by their adverse effects. β_2 -Adrenoceptors on bronchial smooth muscle are tonically activated by circulating catecholamines to cause bronchodilation. β -Blockers can, therefore, cause bronchoconstriction and are contraindicated in patients with asthma, and should be used with caution in chronic obstructive pulmonary disease. β_2 -Adrenoceptors are also found on vascular smooth muscle and are tonically activated by circulating catecholamines to cause vasodilatation. β -Blockers may, therefore, cause vasoconstriction and exacerbate the symptoms of peripheral vascular disease.

Cardiac adverse effects of β -blockers include sinus bradycardia, exacerbation of AV conduction block, reduced exercise capacity, and exacerbation of acute heart failure. In patients with chronic, stable heart failure due to mild-to-moderate LV systolic dysfunction and already treated by ACE inhibitors and diuretics, however, β -blockers improve both symptoms and prognosis. Other adverse effects of β -blockers include nightmares and impotence.

β -Blockers vary in their lipid solubility. Agents such as propranolol and carvedilol are highly lipid-soluble, whereas others such as atenolol and nadolol are more hydrophilic. Lipid solubility determines the degree of drug penetration into the CNS and the utility of haemodialysis or haemofiltration. High lipid solubility is associated with a larger volume of distribution and better CNS penetration. Lipophilic β -blockers are primarily metabolised by the liver. Conversely, hydrophilic β -blockers have a small volume of distribution and are eliminated essentially unchanged by the kidneys; this property allows hydrophilic β -blockers to be removed by haemodialysis.

Class III antiarrhythmic drugs

Class III antiarrhythmic drugs inhibit the delayed rectifier current I_K , which prolongs cardiac APD and hence effective refractory period. Most clinically important arrhythmias are as a result of re-entry. For re-entry to sustain, the activation wavefront must continuously meet electrically excitable tissue as it progresses around the re-entry circuit, the so-called excitable gap. Prolongation of the effective refractory period by a class III antiarrhythmic drug reduces or even abolishes the excitable gap, thus reducing the likelihood of sustained re-entry.

Class III drugs include sotalol, dofetilide, amiodarone and dronedarone. Sotalol and dofetilide selectively inhibit the rapid component of the delayed rectifier current I_{Kr} , whereas amiodarone and dronedarone are less specific, also inhibiting the slow component I_{Ks} . Selective I_{Kr} inhibitors are more effective at slower heart rates, a phenomenon termed reverse use dependence. It is this property that predisposes to the development of Torsade de pointes, a polymorphic VT that may be life-threatening. The development of Torsade de pointes is attributed to a combination of triggered activity as a result of EADs and increased transmural dispersion of repolarisation within the ventricles because action potential prolongation is not uniform across the ventricular wall. Hypokalaemia, hypomagnesaemia or bradycardia increase the likelihood of Torsade de pointes; therefore, sotalol, with marked class II activity, may be uniquely arrhythmogenic.

Amiodarone is a potent antiarrhythmic drug with additional class I, II and IV activity that is effective in treating a wide variety of atrial and ventricular arrhythmias, but its use is constrained by complex pharmacokinetics and concern about toxicity. Many heart rhythm specialists would consider that the side effect profile of amiodarone precludes its use for the long-term treatment of atrial arrhythmias. Amiodarone may be extremely effective in the emergency treatment of VT and VF, especially where recurrent. Amiodarone may also reduce the likelihood of recurrent ventricular arrhythmias when taken on a long-term basis but confers no prognostic benefit and should be considered as an adjunct to treatment with an ICD.

When rapid control of an arrhythmia is needed, the intravenous route is preferred, with 300 mg given over 30–60 minutes followed by 900 mg over 23–24 hours, administered through a central vein. Higher loading doses may cause hypotension. A concurrent oral loading regimen of up to 2400 mg daily in two to four divided doses is usually given for 7–14 days and then reduced to a maintenance dosage of 200 mg daily or less.

During the early stages of therapy with amiodarone (whether intravenous or oral), the kinetics of the drug are different from those after chronic administration. Amiodarone is highly lipid-soluble and thus has a very large volume of distribution. As the slowly equilibrating tissue stores are penetrated to a minimal extent during the early days of therapy, the effective elimination half-life ($t_{1/2}$) is initially dependent upon a more rapidly exchanging compartment, with a half-life of 10–17 hours, substantially shorter than the half-life seen during chronic administration. The short half-life becomes important during the acute phase and any intravenous to oral changeover period because

the absorption of oral amiodarone is very slow, taking up to 15 hours. The combination of a relatively fast elimination and a poor rate of absorption could lead to a significant fall in serum amiodarone levels if intravenous therapy is stopped abruptly when oral therapy is initiated, with the period of maximum risk being the first 24 hours of oral therapy. It is therefore advisable to phase out intravenous therapy gradually and allow an intravenous/oral overlap period of at least 24 hours. Once amiodarone has reached saturation, amiodarone is eliminated very slowly, with a half-life of about 25–110 days. Because of the long terminal half-life of amiodarone, there is a potential for drug interactions to occur several weeks (or even months) after treatment with it has been stopped. Common interactions include antibacterials, other antiarrhythmics, lipid-regulating drugs and digoxin.

Amiodarone has been associated with toxicity involving the lungs, thyroid gland, liver, eyes, skin and peripheral nerves. The incidence of most adverse effects is related to total amiodarone exposure (i.e. dosage and duration of treatment). Therefore, practitioners must consider carefully the risk–benefit ratio of the use of amiodarone in each patient, use the lowest possible dose of amiodarone, monitor for adverse effects and, if possible, discontinue treatment if adverse effects occur.

Corneal microdeposits (reversible on withdrawal of treatment) develop in nearly all adult patients given prolonged amiodarone; these rarely interfere with vision, but drivers may be dazzled by headlights at night. However, if vision is impaired or if optic neuritis or optic neuropathy occur, amiodarone must be stopped to prevent blindness. Long-term administration of amiodarone is associated with a blue-grey discoloration of the skin. This is more commonly seen in individuals with lighter skin tones. The discoloration may revert upon cessation of the drug. However, the skin colour may not return completely to normal.

Individuals who are taking amiodarone may become more sensitive to the harmful effects of ultraviolet A (UV-A) light. Using sunblock that also blocks UV-A rays appears to prevent this side effect. Amiodarone contains iodine and can cause disorders of thyroid function. Both hypothyroidism and hyperthyroidism may occur. Clinical assessment alone is unreliable, and laboratory tests should be performed before treatment and every 6 months including tri-iodothyronine (T_3), T_4 and thyroid stimulating hormone (TSH). A raised T_3 and T_4 with a very low or undetectable TSH concentration suggests the development of thyrotoxicosis. Amiodarone-associated thyrotoxicosis may be refractory to treatment, and amiodarone should usually be withdrawn, at least temporarily, to help achieve control, although treatment with carbimazole is often required. Hypothyroidism can be treated safely with replacement therapy without the need to withdraw amiodarone if amiodarone is considered essential. Amiodarone is also associated with hepatotoxicity, and treatment should be discontinued if severe liver function abnormalities or clinical signs of liver disease develop.

The most serious adverse effect of amiodarone therapy is pulmonary toxicity, typically acute pneumonitis or more insidious pulmonary fibrosis. Although acute pneumonitis may respond to corticosteroids, pulmonary fibrosis is largely irreversible.

Class IV antiarrhythmic drugs (calcium channel blockers)

CCBs bind to and inhibit voltage-gated transmembrane calcium channels carrying an inward current $I_{Ca,L}$. This current is responsible for phase 0 depolarisation of the action potential in the sinoatrial and AV nodes. CCBs reduce the sinus rate and reduce conduction velocity and increase the effective refractory period of the AV node. By reducing calcium entry, CCBs have a negative inotropic effect. L-type calcium channels are also present in vascular smooth muscle, and CCBs therefore cause vasodilatation. In vivo, dihydropyridine CCBs such as nifedipine and amlodipine are relatively selective for vascular smooth muscle, with only minor cardiac effects, whereas phenylalkylamine (verapamil) and benzothiazepine (diltiazem) CCBs are considerably more cardioselective.

Verapamil possesses a chiral carbon and is marketed as a racemic mixture of R- and S-stereoisomers. In humans, both isomers share qualitatively similar negative chronotropic and dromotropic effects on the sinoatrial and AV nodes, respectively, but the S-stereoisomer is 10–20 times more potent than the R with respect to these effects. Hence the S-stereoisomer determines the negative chronotropic and dromotropic effects of verapamil, whereas the R-stereoisomer is of minor importance.

Verapamil also undergoes extensive stereoselective first-pass hepatic metabolism. S-verapamil is more rapidly metabolised than R-verapamil after oral administration, resulting in a lower bioavailability of the S-stereoisomer and a proportionally higher concentration of the R-stereoisomer in the systemic circulation (20% and 50%, respectively). However, because C_{max} is higher with the immediate-release formulation and S-verapamil is 10–20 times more potent than R-verapamil, it is unsurprising that this difference is also clinically significant. With the immediate-release formulation, a plot of PR-interval change versus time has the same shape as the concentration–time curve. The extended-release formulation does not have the same concentration–time effect relationship. This has been attributed to the difference in oral input rates, to the concentration-related saturable first-pass hepatic metabolism, or both.

Because the formulation of verapamil may play a role in the drug's complex pharmacokinetics and efficacy, one formulation of verapamil cannot be safely substituted for another. Immediate-release preparations are preferred to maximise bioavailability of the S-stereoisomer.

Class IV antiarrhythmic drugs should be avoided in sick sinus syndrome or second- or third-degree heart block unless the patient has a permanent pacemaker. Combined therapy with a CCB and β -blocker should be instituted with caution because of the risk of excessive AV block, and should be used where only where monotherapy is insufficient to control ventricular rate during atrial flutter or fibrillation. Verapamil causes greater arterial vasodilation than diltiazem and may be especially useful in patients with hypertension or angina. Both agents have a negative inotropic effect and are thus contraindicated in heart failure. Adverse effects are mostly predictable and include ankle oedema, flushing, dizziness, light-headedness and headache. Constipation is common in patients receiving verapamil, whereas a rash is common with diltiazem.

Fig. 22.14 Principal mechanisms of antiarrhythmic action of adenosine.

AC, adenylyl cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

Adenosine

The electrophysiological effects of adenosine are mediated by A_1 adenosine receptors in the cell membrane of atrial, sinoatrial and AV nodal, but not ventricular, myocytes. Binding of adenosine to the A_1 receptor activates a G protein that in turn activates an outward potassium current I_{KAdo} , resulting in hyperpolarisation, and inhibits the pacemaker current I_f and an inward calcium current I_{Ca} . Activation of A_1 receptors also has indirect electrophysiological effects mediated by an inhibitory G protein, which inhibits production of cAMP by adenylyl cyclase, thus opposing the action of catecholamines (Fig. 22.14). The effects of these actions are a reduction in the firing rate of cells with pacemaker activity (negative chronotropic effect), a reduction in conduction velocity in the AV node (negative dromotropic effect) manifest as varying degrees of AV block, and a shortening of atrial effective refractory period, occasionally manifest as the development of AF following the administration of adenosine.

The ultra-short duration of action (<10 seconds) of intravenous adenosine makes it very suitable as a diagnostic aid and for interrupting supraventricular arrhythmias in which the AV node is part of the re-entry pathway. Adenosine is, however, a bronchoconstrictor and causes dyspnoea, flushing, chest pain and further transient arrhythmias in a high proportion of patients, and its metabolism is inhibited by dipyridamole, a vasodilator drug that blocks adenosine uptake by cells, thereby reducing the metabolism of adenosine.

Ivabradine

Ivabradine is a selective inhibitor of the I_f current that plays an important role in pacemaker activity in cells of the cardiac conduction system. I_f is an inward depolarising current of sodium and potassium via specific membrane channels that are activated by hyperpolarisation. Predominantly as a result of I_f , the transmembrane potential in cells of the sinoatrial node becomes progressively less negative until the threshold potential for action potential generation is reached. The magnitude of I_f is increased by cAMP. The sinoatrial node is innervated by both sympathetic and parasympathetic (the vagus) nerves. Binding of catecholamines to β -adrenoceptors stimulates the production of cAMP and hence increases the rate of discharge of the sinoatrial node. Binding of acetylcholine to muscarinic cholinergic receptors has the

Fig. 22.15 Principal mechanisms of antiarrhythmic action of ivabradine. AC, Adenyl cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

opposite effect (Fig. 22.15). Ivabradine selectively blocks I_f channels, resulting in a dose-dependent reduction in the slope of diastolic depolarisation in cells of the sinoatrial node, and hence a reduction in the sinus rate. Ivabradine exhibits use dependence, which means its effect is more pronounced at higher heart rates. Ivabradine was developed as an antianginal drug and is also used in patients with chronic heart failure associated with sinus tachycardia. It has been used for the treatment of inappropriate sinus tachycardia, although it is not currently licensed in the UK for that indication.

Digoxin

The therapeutic effect of digoxin results from central and peripheral augmentation of vagal tone, manifest as reduced conduction velocity and prolonged effective refractory period of the AV node. The latter property has the effect of reducing the ventricular rate during atrial tachyarrhythmias. The effect of digoxin is most pronounced under conditions of vagal predominance (i.e. rest and sleep), whereas the drug is relatively ineffective during conditions of sympathetic predominance, such as exercise or AF of acute onset.

Digoxin also directly inhibits the transmembrane $\text{Na}^+\text{-K}^+\text{-ATPase}$ exchange pump. As a result there is a tendency for intracellular sodium concentration to increase, which in turn activates a $\text{Na}^+\text{-Ca}^{2+}$ exchange pump, which extrudes sodium in exchange for calcium, increasing intracellular calcium concentration. The latter is responsible for the positive inotropic effect of digoxin but also, in overdose, for intracellular calcium overload, resulting in DADs, which may lead to triggered activity.

Digoxin is not indicated for the treatment of paroxysmal AF because it has no direct antiarrhythmic effect and neither terminates an episode of AF nor reduces the likelihood of further episodes of AF occurring. Furthermore, digoxin has limited efficacy for ventricular rate control at the start of an episode of AF, where sympathetic nervous system activity is often high.

The long half-life of digoxin (about 36 hours) warrants special consideration when treating arrhythmias as several days of constant dosing would be required to reach steady-state. Therefore, loading doses of up to 1.5 mg may be used rapidly to increase digoxin serum levels. Digoxin is given once daily thereafter, usually in 125- or 250-microgram doses, and has a narrow therapeutic window with the ideal blood concentration regarded as 1–2 micrograms/L. Because digoxin is excreted

Table 22.9 Interactions involving digoxin

Effect	Offending agent or condition
Serum level increased by	Amiodarone, verapamil, diltiazem, quinidine, propafenone, clarithromycin, broad-spectrum antibiotics (erythromycin, tetracyclines), decreased renal blood flow (β -blockers, non-steroidal anti-inflammatory drugs), renal failure, heart failure
Serum level decreased by	Colestyramine, sulfasalazine, neomycin, rifampicin, antacids, improved renal blood flow (vasodilators), levothyroxine (thyroxine)
Therapeutic effect increased by	Hypokalaemia, hypercalcaemia, hypomagnesaemia, antiarrhythmic classes IA, II and IV, diuretics that cause hypokalaemia, corticosteroids, myxoedema, hypoxia (acute or chronic), acute myocardial ischaemia or myocarditis
Therapeutic effect decreased by	Hyperkalaemia, hypocalcaemia, thyrotoxicosis

predominantly by the kidney (70% renal elimination in normal renal function), renal function is the most important determinant of the daily digoxin dosage. Importantly, in severe renal insufficiency, there is also a decrease in the volume of distribution of digoxin; therefore, lower loading doses should be used.

Both the therapeutic and toxic effects of digoxin are potentiated by hypokalaemia and hypercalcaemia. There are also numerous drug interactions (Table 22.9), some of which are pharmacokinetic and some of which are pharmacological.

The occurrence of adverse drug reactions is common, because of the narrow therapeutic index of digoxin. Adverse effects are concentration dependent and are rare when serum digoxin concentration is less than 0.8 micrograms/L. Common adverse effects include loss of appetite, nausea, vomiting and diarrhoea as gastro-intestinal motility increases. Other common effects are blurred vision, visual disturbances (yellow-green halos and problems with colour perception), confusion and drowsiness. The often described adverse effect of digoxin, xanthopsia, the disturbance of colour vision (mostly yellow and green colour), is rarely seen.

Patient care

Patients with cardiac arrhythmia may experience considerable anxiety related to their condition. The symptoms typically occur unpredictably, may be extremely unpleasant and may result in the need for urgent medical attention. Many patients are worried that their condition may be life-threatening, whereas others presenting with arrhythmia are found to have prognostically important

Table 22.10 Common therapeutic problems in the management of arrhythmias

Problem	Comment
All antiarrhythmics are proarrhythmic	Prevention is better than cure. Minimise the requirement for drugs by careful attention to precipitating factors. Consider use of pacemakers or non-pharmacological therapies if appropriate.
Nausea and vomiting with blurred vision and visual discolouration on digoxin	These are symptoms and signs of digoxin toxicity noting digoxin has a narrow therapeutic range. Poor renal function may have also contributed.
β -Blockers are generally contraindicated in bronchial and peripheral vascular disease	Consider verapamil or diltiazem.
Calcium channel blockers–induced constipation	If it occurs, give regular osmotic laxatives.
Torsade de pointes may be precipitated by taking other medication with amiodarone or disopyramide	Patients should remind members of healthcare team that they are taking antiarrhythmic drugs; also consider electrolyte disturbance such as hypokalaemia.
Patients experiencing myopathy	Healthcare professionals involved in screening prescriptions for antiarrhythmics should be aware of the clinically relevant interactions and how to manage these. Patients who are taking statins will need regular monitoring for signs of myopathy, particularly those receiving high-intensity statin therapy.
Patient with severe asthma admitted with supraventricular tachycardia	Adenosine is contraindicated because of the risk of bronchospasm. Verapamil is a suitable alternative.
Amiodarone is commonly associated with an increased tendency to sunburn	Warn all patients to stay covered up when outdoors, use sun block or stay indoors.
Acutely treated patient with atrial fibrillation cardioverted initially with i.v. amiodarone, but on converting to oral therapy, reverted back to atrial fibrillation	Although amiodarone has a long terminal half-life once saturated, amiodarone has a very large volume of distribution, and because tissue stores are penetrated to a minimal extent during the early days of therapy, the effective elimination half-life ($t_{1/2}$) is initially dependent upon a more rapidly exchanging compartment, with a $t_{1/2}$ of 10–17 h, substantially shorter than the $t_{1/2}$ seen during chronic administration. The shorter $t_{1/2}$ becomes important during the acute phase and any intravenous to oral changeover period because the absorption of oral amiodarone is very slow, taking up to 15 h. The combination of a relatively fast elimination and a poor rate of absorption could lead to a significant fall in serum amiodarone levels if intravenous therapy is stopped abruptly when oral therapy is initiated, with the period of maximum risk being the first 24 h of oral therapy. It is, therefore, advisable to phase out intravenous therapy gradually and allow an intravenous/oral overlap period of at least 24 h.

underlying heart disease. The diagnosis of an inherited cardiac condition also raises concern for potentially affected relatives. An individual's anxiety may be exacerbated by the fact that most antiarrhythmic drugs work in only a proportion of patients, and several treatment options may be tried before the most appropriate one is identified.

Many patients therefore require considerable reassurance. The patient's family and friends may need to be advised on what to do in the event of an acute arrhythmia. Patients should give informed consent for all interventions, and prescribers must be prepared that a patient's views on the use of a medicine may differ from their own. Prescribers should seek and respect patients' views on treatment choices, rather than assume all patients are the same or that they will always agree with their own views.

Examples of some common therapeutic problems that may occur during the management of arrhythmias are set out in [Table 22.10](#).

Case studies

Case 22.1

Ms AJ, a 25-year-old woman, presents to the hospital emergency department with a 2-hour history of palpitation and chest tightness. She has experienced several similar episodes in the past, all of which have started abruptly at rest and consisted of rapid, regular palpitations. Previous episodes have all stopped after a few minutes and between events she has been entirely well. Ms AJ has no history of heart disease or other ongoing

medical problems and is on no regular drug treatment. She drinks alcohol within recommended weekly limits and takes no other recreational drugs. On examination Ms AJ is anxious, has a slightly cool periphery, her pulse is 190 beats/min and regular, and blood pressure is 130/90 mmHg. The remainder of the examination is unremarkable. A 12-lead ECG demonstrates a regular narrow-complex tachycardia with no discernible P waves.

Question

What is the most likely diagnosis, and how should Ms AJ be managed?

Answer

Ms AJ has the signs and symptoms of SVT. Non-pharmacological means of restoring sinus rhythm include carotid sinus massage, subjecting the patient to the Valsalva manoeuvre or eliciting the diving reflex by immersion of the face in ice-cold water. Either approach should result in a brief vagal discharge sufficient to block conduction in the AV node and terminate the tachycardia. If these manoeuvres are unsuccessful, intravenous adenosine can be given in doses of up to 12 mg as a rapid bolus injection followed quickly by a saline flush. Intravenous verapamil 5 mg may also be administered as a rapid bolus injection and is a good alternative where adenosine is contraindicated.

Case 22.2

Mr DS was admitted to hospital for an emergency laparotomy for a perforated gut. He has a history of paroxysmal AF for which he has recently been started on amiodarone 200 mg once daily.

Following the laparotomy Mr DS has new-onset AF that the medical team would like to treat pharmacologically. His only other current medication is thromboprophylaxis with enoxaparin 20 mg once daily.

Questions

1. What treatment plan would you initially suggest for Mr DS?
2. What longer-term monitoring would be appropriate for Mr DS if he was to remain taking amiodarone?

Answers

1. If Mr DS has any electrolyte abnormalities, these should be corrected. If he remains in AF he should be prescribed amiodarone by i.v. infusion, because acutely amiodarone can be effective in cardioversion. The reduced dose of enoxaparin is because Mr DS is a post-surgical patient and at high risk of bleeding.

Mr DS cardioverts back to sinus rhythm following a bolus dose of 300 mg amiodarone. The plan is to maintain him on amiodarone for a short period, for example, a week (600 mg daily) to try to keep him in sinus rhythm, with a view to stopping if he is maintained back in sinus rhythm during this period.

2. If Mr DS was to continue amiodarone therapy longer-term, then the following monitoring would be appropriate:

Chest X-ray: pulmonary	Baseline and if symptoms present
Thyroid function test	Baseline and every 3–6 months
Liver function tests	Baseline and every 3–6 months
Eye examination	Baseline and every 12 months
ECG	Baseline and as required
Clinical evaluation	Baseline and every 3 months

Case 22.3

Mr SB is 77 years of age. He attends the hospital emergency department with worsening shortness of breath. His medical history includes a myocardial infarction 10 years ago which left him with left ventricular dysfunction (ejection fraction <40%). He also has hypertension. Mr SB's current medication is:

- bisoprolol 2.5 mg daily,
- ramipril 5 mg daily,
- aspirin 75 mg daily,
- furosemide 80 mg each morning,
- atorvastatin 40mg daily.

His heart rate is 65 beats/min and irregular, and he has a blood pressure of 160/85 mmHg. Mr SB's ECG shows AF. It was decided to control his AF with an increased dose of bisoprolol.

Questions

1. What drug is most appropriate for stroke prevention in Mr SB?
2. Should anticoagulation be initiated along with aspirin or in place of it?

Answers

1. All patients presenting with AF (or atrial flutter) should undergo assessment of their risk of stroke. Although various risk-stratification schemes exist, the CHA₂DS₂-VASc score is widely used. For Mr SB the following is determined: Congestive cardiac failure 1; Hypertension 1; Age older than 75 years 2; Diabetes mellitus 0; Stroke 0; Vascular disease 1; Sex category 0. Given that Mr SB has a CHA₂DS₂-VASc score of 5, this suggests an annual stroke risk of 6.7% if no therapy is prescribed (Lip et al., 2010b). This risk will reduce to 5.4% if he is prescribed aspirin, or 2.2% if he is prescribed an anticoagulant. Assuming no contraindications or concerns, anticoagulation should be prescribed.
2. In patients with stable vascular disease, such as those with no acute ischaemic events or percutaneous coronary intervention/stent procedure in the preceding year, anticoagulation monotherapy should be used (Kirchhof et al., 2016). There is no need for concomitant aspirin, which could increase the risk of a major bleed. Therefore, concomitant antiplatelet therapy should not be prescribed for Mr SB. In patients with AF treated for acute coronary syndrome, and in those receiving a coronary stent, the doctor may consider a combination of an anticoagulant and aspirin (Kirchhof et al., 2016); however, it should be noted that such a combination will significantly increase the risk of a major bleed. Optimising the modifiable risk factors in HAS-BLED (e.g. blood pressure) will help minimise the risk of bleeding if a decision is taken to prescribe aspirin and an anticoagulant together.

23 Thrombosis

Philip A. Routledge, Hamsaraj Shetty and Simon J. Wilkins

Key points

Venous thromboembolism

- Venous thromboembolism (VTE) is the development of a 'thrombus', principally containing fibrin and red blood cells, in the venous circulation. This most often occurs as a deep vein thrombosis (DVT) in the deep, as distinct from the superficial, veins of the legs.
- If part of a thrombus in the venous circulation breaks off and enters the right heart, it may become lodged in the pulmonary arterial circulation, causing pulmonary embolism (PE).
- Combinations of sluggish blood flow and hypercoagulability are the most common causes of VTE. Vascular injury is also a recognised causative factor.
- Treatment of VTE involves the use of anticoagulants and, in severe cases, thrombolytic drugs.
- Anticoagulant therapy often involves an immediate-acting agent, such as heparin, followed by maintenance treatment with an oral anticoagulant, such as warfarin.
- Another option is the use of a direct oral anticoagulant (DOAC), also sometimes known as a non-vitamin K antagonist oral anticoagulant/novel oral anticoagulant (NOAC), with a marketing authorisation for such use. The use of heparin in the early stages is not necessary with all of the DOACs, but requirements change, and thus product literature should be consulted.
- Unfractionated heparins increase the rate of interaction of thrombin with antithrombin III 1000-fold and prevent the production of fibrin from fibrinogen.
- Low-molecular-weight heparins inactivate factor Xa, have a longer half-life and produce a more predictable response than unfractionated heparins.
- Warfarin is the most widely used coumarin because of potency, reliable bioavailability and an intermediate half-life of elimination (36 hours).
- Warfarin consists of an equal mixture of two enantiomers, (*R*)- and (*S*)-warfarins, that have different anticoagulant potencies and routes of metabolism. The latter enantiomer is a much more potent anticoagulant.
- DOACs currently available include dabigatran etexilate, a direct thrombin (factor IIa) inhibitor, and apixaban, edoxaban and rivaroxaban, which are direct inhibitors of activated factor Xa.

Arterial thromboembolism

- Arterial thromboembolism is normally associated with vascular injury and hypercoagulability.

- Acute myocardial infarction is the commonest form of arterial thrombosis.
- Arterial thromboembolism affecting the cerebral circulation results in either transient ischaemic attacks (TIAs) or, in more severe cases, cerebral infarction (stroke).
- Arterial thrombosis is the development of a 'thrombus' consisting of platelets, fibrin, red blood cells and white blood cells in the systemic circulation.
- An embolus may result in peripheral arterial occlusion, either in the lower limbs or in the cerebral circulation (where it may cause thromboembolic stroke).

Venous thromboembolism

Epidemiology

Venous thromboembolism (VTE) is common, with an incidence of 2–5%. Deep vein thrombosis (DVT) may result in not only pulmonary embolism (PE) but also subsequent morbidity as a result of the post-phlebotic limb. Thrombosis and thromboembolism are the most common direct cause of maternal death in the UK (Knight et al., 2016). Thromboembolism appears to increase in prevalence past the age of 50 years, and the diagnosis is more often missed in this age group.

Aetiology

VTE occurs primarily due to a combination of stagnation of blood flow and hypercoagulability. Vascular injury is also a recognised causative factor but is not necessary for the development of venous thrombosis. In VTE, the structure of the thrombus is different from that in arterial thromboembolism. In the former, platelets seem to be uniformly distributed through a mesh of fibrin and other blood cell components, whereas in arterial thromboembolism the white platelet 'head' is more prominent, and it appears to play a much more important initiatory role in thrombus.

Sluggishness of blood flow may be related to bed rest, surgery or reduced cardiac output, for example, in heart failure. Factors increasing the risk of hypercoagulability include surgery, pregnancy, oestrogen administration, malignancy, myocardial infarction and several acquired or inherited disorders of coagulation (for further detail on genetic factors, see Rosendaal and Reitsma [2009]).

Protein C deficiency

Protein C deficiency is inherited through autosomal-dominant transmission and has a prevalence of 0.2–0.5% in the general population (Bauer et al., 2017). Such patients are at increased risk not only for VTE but also for warfarin-induced skin necrosis, which occurs because protein C (and its closely related co-factor, protein S) is a vitamin K–dependent antithrombotic factor that can be further suppressed by the administration of warfarin. Thrombosis in the small vessels of the skin may occur if large loading (induction) doses of warfarin are given to such patients when the suppression of the antithrombotic effects of these factors occurs before the antithrombotic effects of blockade of vitamin K–dependent clotting factor (II, VII, IX and X) production has occurred. The prevalence of protein C deficiency in individuals who have had a VTE is 2–5% (Bauer et al., 2017).

Protein S deficiency

Protein S deficiency is probably even rarer than protein C deficiency; the prevalence in the general population is unknown (Bauer et al., 2017). The familial form, inherited in an autosomal-dominant fashion, is a high-risk state, accounting for VTE in some individuals. The prevalence of protein S deficiency in individuals who have had a VTE is reported to be 1% (Bauer et al., 2017).

Factor V Leiden

The presence of factor V Leiden, a point mutation in the factor V gene, causes the activated factor V molecule to be resistant to deactivation by activated protein C (APC). This defect may have a prevalence of 4–5% in Caucasian populations (Bauer et al., 2017) and higher in patients with thromboembolic disease, and it may in itself be of little consequence until there is another risk factor, such as immobility or use of the contraceptive pill. In these circumstances, the combination of risks may be responsible for the increased predisposition to thromboembolism in a high proportion of affected individuals.

Antithrombin III deficiency

Antithrombin III deficiency is a rare autosomal-dominant inherited abnormality associated with a reduced plasma concentration of this protein. The defect may not result in clinical problems until pregnancy or until patients enter their fourth decade, when venous and, to a lesser extent, arterial thrombosis becomes more common. Nevertheless, its prevalence in individuals with VTE has been estimated to be between 1% and 7% (Bauer et al., 2017).

Lupus anticoagulant

Lupus anticoagulant, an antibody against phospholipid, is so named because it increases the clotting time in blood when measured by some standard coagulation tests. Patients affected are more prone to thromboembolism. It is also found in the primary antiphospholipid syndrome (PAPS), where it may signify an increased risk of venous and arterial thrombosis and for recurrent miscarriage (Derksen et al., 2001).

Prothrombin G20210A mutation

A mutation in part of the prothrombin gene (prothrombin G20210A) results in increased prothrombin concentrations and an increased risk of venous thrombosis by three- to fourfold over controls (Bauer et al., 2017).

Fibrinogen gamma 10034T

Approximately 6% of individuals carry this variant gene, which increases thrombotic risk approximately twofold (Rosendaal, 2009).

Oestrogens

Oestrogens increase the circulating concentrations of clotting factors I, II, VII, VIII, IX and X and reduce fibrinolytic activity. They also depress the concentrations of antithrombin III, which is protective against thrombosis. This effect is dose related, and venous thrombosis was more often seen with contraceptive pills containing high (50 micrograms) oestrogen than with the present lower-dose preparations (Rosendaal, 2009). Hormone replacement therapy, pregnancy and the puerperium (up to 6 weeks after delivery) are also recognised risk factors for VTE (National Institute for Health and Care Excellence [NICE], 2015a).

Malignancy

VTE is more common in malignancy, and the risk may be up to fivefold greater than in those without malignancy. Although first described in association with carcinoma of the pancreas, all solid tumours seem to be associated with this problem. The absolute risk seems to be related to the type of tumour and its stage and treatment with chemotherapy. The exact mechanisms responsible for the increased risk of VTE in malignancy are not known but may be related to the expression of tissue factor or factor X activators (Elyamany et al., 2014).

Surgery

The increased risk of VTE in surgery is related, in part, to stagnation of venous blood in the calves during the operation and recovery. Tissue trauma may also play a role because VTE appears to be more common in operations that involve marked tissue damage, such as orthopaedic surgery. This may in turn be related to release of tissue thromboplastin and to reduced fibrinolytic activity. The most important risk factors associated with VTE after surgery are duration of anaesthesia and procedure of more than 90 minutes (or 60 minutes if surgery involves lower limbs or pelvis), acute surgical admission with an inflammatory or intra-abdominal condition and expected significant reduction in mobility (NICE, 2015a). Other patient-related risk factors for VTE include age older than 60 years, dehydration, known thrombophilias, obesity (body mass index >30 kg/m²), one or more significant comorbidities, personal history or first-degree relative with previous VTE, use of hormone replacement therapy or oestrogen-containing contraceptives and varicose veins with associated phlebitis. These will add to the risk, if present, but are also independent risk factors.

Clinical manifestations

DVT occurs commonly in the veins of the lower limbs and pelvis. In some patients, there may not be any local symptoms or signs, and the onset of PE may be the first evidence of the presence of VTE. In other cases, patients classically present with pain involving the calf or thigh, associated with swelling, redness of the overlying skin and increased warmth. In a large DVT that prevents venous return, the leg may become discoloured and oedematous. Massive venous thrombus can occasionally result in gangrene, although this occurs very rarely now that effective drug therapies are available.

PE may occur in the absence of clinical signs of venous thrombosis. It may be very difficult to diagnose because of the non-specificity of symptoms and signs. Clinical diagnosis is often made because of the presence of associated risk factors. Obstruction with a large embolus of a major pulmonary artery may result in acute massive PE, presenting with sudden shortness of breath and dull central chest pain, together with marked haemodynamic disturbance, for example, severe hypotension and right ventricular failure, sometimes resulting in death due to acute circulatory failure unless rapidly treated.

Acute submassive PE occurs when less than 50% of the pulmonary circulation is occluded by embolus, and the embolus normally lodges in a more distal branch of the pulmonary artery. It may result in some shortness of breath, but if the lung normally supplied by that branch of the pulmonary artery becomes necrotic, pulmonary infarction results, with pleuritic pain and haemoptysis (coughing up blood), and there may be a pleural 'rub' (a sound like Velcro being torn apart when the patient breathes in) as a result of inflammation of the lung. Patients may, rarely, develop recurrent thromboembolism. This may not result in immediate symptoms or signs, but the patient may present with increasing breathlessness and signs of pulmonary hypertension (right ventricular hypertrophy) and, if untreated, progressive respiratory failure.

Investigations

Deep vein thrombosis

A DVT is the most common cause of pain, swelling and tenderness within the leg, although other conditions, such as a Baker's cyst (which involves rupture of the posterior aspect of the synovial capsule of the knee), may mimic it. The two-level DVT Wells score is advocated as a helpful initial clinical screening test to ascertain whether DVT is likely or unlikely (NICE, 2015b). The clinical scoring tool for this approach is shown in Table 23.1.

A DVT Wells Score of 2 points or more means that a DVT is classified as *likely*. If this is the case, a proximal leg vein ultrasound scan should be carried out within 4 hours of being requested, and if the result is negative, a D-dimer test should be performed (D-dimer is a product formed in the body when blood is broken down). If a proximal leg vein ultrasound scan cannot be carried out within 4 hours, a D-dimer test should be performed and an interim 24-hour dose of a parenteral anticoagulant given while waiting for the proximal leg vein ultrasound scan to be carried out within 24 hours. The NICE (2015b) guidance also recommends that the proximal leg vein ultrasound scan should be repeated 6–8 days later for all patients with a positive D-dimer test and a negative proximal leg vein ultrasound scan.

Table 23.1 Two-level deep vein thrombosis Wells score

Clinical feature	Points
Active cancer (treatment ongoing, within 6 months, or palliative)	1
Paralysis, paresis or recent plaster immobilisation of the lower extremities	1
Recently bedridden for 3 days or more or major surgery within 12 weeks requiring general or regional anaesthesia	1
Localised tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than asymptomatic side	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented DVT	1
An alternative diagnosis is at least as likely as DVT	-2
Clinical probability simplified score	
DVT – likely	2 points or more
DVT – unlikely	1 point or less
DVT, Deep vein thrombosis. Adapted from Wells et al. (2003) and NICE (2015b).	

Ultrasound. Ultrasound is a non-invasive alternative to venography that does not involve exposure to ionising radiation or potentially allergenic contrast media. It is now the initial investigation of choice in clinically suspected DVT, although it is less sensitive for below-knee and isolated pelvic deep vein thrombosis.

Venography. Venography involves injection of radio-opaque contrast medium, normally into a vein on the top of the foot, and subsequent radiography of the venous system. Although specific, it is also invasive.

Magnetic resonance imaging. Magnetic resonance imaging (MRI) is also non-invasive and avoids radiation exposure. When used with direct thrombus imaging (DTI), which detects methaemoglobin in the clot, MRI DTI is sensitive and specific, even with below-knee and isolated pelvic deep vein thrombosis. However, it is not widely clinically available, and ultrasound remains the primary initial investigation.

Pulmonary embolism

If PE is suspected, and the two-level PE Wells Score indicates that PE is *likely* (more than 4 points using the two-level

Table 23.2 Two-level pulmonary embolism Wells Score

Clinical feature	Points
Clinical signs and symptoms of DVT (minimum of leg swelling and pain with palpation of the deep veins)	3
An alternative diagnosis is less likely than PE	3
Heart rate >100beats/min	1.5
Immobilisation for more than 3 days or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Haemoptysis	1
Malignancy (on treatment, treated in the last 6 months, or palliative)	1
Clinical probability simplified scores	
PE – likely	More than 4 points
PE – unlikely	4 points or less
DVT, Deep vein thrombosis; PE, pulmonary embolism. Adapted from Wells et al. (2000).	

PE Wells Score; Table 23.2), either an immediate computed tomography pulmonary angiogram (CTPA) should be performed or immediate interim parenteral anticoagulant therapy initiated, followed by a CTPA, if a CTPA cannot be carried out immediately. A proximal leg vein ultrasound scan should be considered if the CTPA is negative and DVT is suspected (NICE, 2015b).

Computed tomography pulmonary angiogram. CTPA is a minimally invasive test that has now largely superseded pulmonary angiography as the most specific test in the diagnosis of PE. It involves the intravenous administration of iodine-containing contrast media to allow sophisticated radiographic imaging to detect whether blood is flowing to all parts of the lungs or whether a PE is causing blockage in the pulmonary arterial vasculature.

Ventilation–perfusion scanning. Ventilation–perfusion scanning involves the injection of a radiolabelled substance into the vein and measurement of perfusion via the pulmonary circulation, using a scintillation counter. This is often combined with a ventilation scan in which radiolabelled gas, normally xenon, is inhaled by the patient. PE classically results in an area of under- or non-perfusion of a part of the lung that, nevertheless, because the airways are patent, ventilates normally. This pattern is called ventilation–perfusion mismatch and is a specific sign of PE. The preferred technique is a ventilation/perfusion single-photon emission computed tomography (V/Q SPECT) scan. If a V/Q SPECT scan is not available, a V/Q planar scan is an alternative, although it has lower sensitivity and specificity. NICE recommends that ventilation-perfusion scanning can be considered

as an alternative to CTPA in patients who are allergic to contrast media, or who have renal impairment or whose risk from irradiation is considered to be high, because total radiation exposure is lower than with CTPA (NICE, 2015b).

Other findings. Other findings occur in PE, such as changes in the chest radiograph, for example, a raised right hemidiaphragm as a result of the loss of lung volume (PE more commonly affects the right than the left lung). Hypoxia is also seen, and the larger the PE, the worse this is. The electrocardiogram may show signs of right ventricular strain. The echocardiogram may show right ventricular overload and dysfunction in massive PE. However, all these changes are relatively nonspecific and do not obviate the need for the specific tests mentioned previously.

Treatment

The aim of treatment of venous thrombosis is to allow normal circulation in the limbs and, wherever possible, to prevent damage to the valves of the veins, thus reducing the risk of the swollen post-phlebotic limb. Secondly, it is important to try to prevent associated PE and also the recurrence of either venous thrombosis or PE in the risk period after the initial episode.

In acute massive PE, the initial priority is to correct the circulatory defect that has caused the haemodynamic upset, and in these circumstances, rapid removal of the obstruction using thrombolytic drugs or surgical removal of the embolus may be necessary. In acute submassive PE, the goal of treatment is to prevent further episodes, particularly of the more serious acute massive PE. In both DVT and PE, a search must be made for underlying risk factors, such as carcinoma, and particularly in those with repeated episodes of VTE.

The treatment of VTE consists of the use of anticoagulants and, in severe cases, thrombolytic drugs. Anticoagulant therapy involves the use of immediate-acting agents (particularly heparin) and oral anticoagulants, the commonest of which is warfarin, but direct oral anticoagulant (DOACs) are also an option as alternatives. Anticoagulation may be necessary for some time after the initial event, depending on the persistence of risk factors for recurrent thromboembolism.

Prophylaxis

Prevention of initial episodes of VTE in those at risk is clearly of great importance. It has been estimated that around 25,000 people in the UK die from preventable hospital-acquired VTE annually, including patients admitted to hospital for medical care and surgery (House of Commons Health Committee, 2005). There is also widespread evidence of inconsistent use of prophylactic measures for VTE in hospital patients, including mechanical and pharmacological means of VTE prophylaxis. Some of the medicines described in the following sections contribute to those pharmacological measures. Guidelines on reducing the risk of VTE in patients admitted to hospital are available (NICE, 2015a).

Heparins

Conventional or unfractionated heparin (UFH) is a heterogeneous mixture of large mucopolysaccharide molecules ranging widely

in molecular weight between 3000 and 30,000, with immediate anticoagulant properties. It acts by increasing the rate of the interaction of thrombin with antithrombin III by a factor of 1000. It, thus, prevents the production of fibrin (factor I) from fibrinogen. Heparin also inhibits the production of activated clotting factors IX, X, XI and XII, and these effects occur at concentrations lower than its effects on thrombin.

Unlike UFH, low-molecular-weight heparins (LMWHs) contain polysaccharide chains ranging in molecular weight between 4000 and 6000. Whereas UFH produces its anticoagulant effect by inhibiting both thrombin and factor Xa, LMWHs predominantly inactivate only factor Xa. In addition, unlike UFH, they inactivate platelet-bound factor Xa and resist inhibition by platelet factor 4 (PF4), which is released during coagulation. Dalteparin, enoxaparin and tinzaparin are LMWHs with similar efficacy and adverse effects.

Because UFH and LMWHs all consist of high-molecular-weight molecules that are highly ionised (heparin is the strongest organic acid found naturally in the body), they are not absorbed via the gastro-intestinal tract and must be given by intravenous infusion or deep subcutaneous (never intramuscular) injection. UFH is highly protein bound, and it appears to be restricted to the intravascular space, with a consequently low volume of distribution. It does not cross the placenta and does not appear in breast milk. Its pharmacokinetics are complex, but it appears to have a dose-dependent increase in half-life. The half-life is normally about 60 minutes but is shorter in patients with PE. It is removed from the body by metabolism, possibly in the reticuloendothelial cells of the liver, and by renal excretion. The latter seems to be more important after high doses of the compound.

LMWHs have a number of potentially desirable pharmacokinetic features compared with UFH. They are predominantly excreted renally and have longer and more predictable half-lives than UFH and so have a more predictable dose response than UFH. They can, therefore, be given once or, at the most, twice daily in a fixed dose, sometimes based on the patient's body weight, without the need for laboratory monitoring, except for patients given treatment doses and those at a high risk of bleeding.

The major adverse effect of all heparins is haemorrhage, which is more common in patients with severe heart or liver disease, renal disease, general debility and in women older than 60 years. The risk of haemorrhage is increased in those with prolonged clotting times and in those given UFH by intermittent intravenous bolus rather than by continuous intravenous administration. UFH is monitored by derivatives of the activated partial thromboplastin time (APTT), for example, the kaolin–cephalin clotting time (KCCT); in those patients with a KCCT three times greater than control, there is an eightfold increase in the risk of haemorrhage. The therapeutic range for the KCCT during UFH therapy, therefore, appears to be between 1.5 and 2.5 times the control values. Rapid reversal of the effect of UFH can be achieved using protamine sulphate, but this is rarely necessary because of its short duration of action. LMWHs may produce fewer haemorrhagic complications, and at the doses normally used for treatment, they do not significantly affect coagulation tests, so routine monitoring is not necessary (Baglin et al., 2006). Protamine sulfate can inhibit the prolongation in clotting time induced by LMWHs, but does not fully inhibit their anti-factor Xa activity.

Box 23.1 Guidelines to control unfractionated heparin treatment

Loading dose
5000 IU over 5 min

Infusion
Start at 1400 IU/h (e.g. 8400 IU in 100 mL of normal saline over 6 h). Check after 6 h.
Adjust dose according to ratio of the KCCT to the control value using the following values

KCCT ratio	Infusion rate change
>7.0	Discontinue for 30 min to 1 h and reduce by >500 IU/h
>5.0	Reduce by 500 IU/h
4.1–5.0	Reduce by 300 IU/h
3.1–4.0	Reduce by 100 IU/h
2.6–3.0	Reduce by 50 IU/h
1.5–2.5	No change
1.2–1.4	Increase by 200 IU/h
<1.2	Increase by 400 IU/h

After each dose change, wait 10 h before next KCCT estimation unless KCCT >5, when more frequent (e.g. 4-hourly) estimation is advisable. Developed using Diogen (Bell and Alton); local validation may be necessary.

KCCT, Kaolin–cephalin clotting time.
Modified from Fennerty et al. (1986).

Heparins, particularly UFH, may also cause thrombocytopenia (low platelet count). This may occur in two forms. The first occurs 3–5 days after treatment and does not normally result in complications. The second type of thrombocytopenia occurs after about 6 days of treatment and often results in much more profound decreases in platelet count and an increased risk of thromboembolism. LMWHs are thought to be less likely to cause thrombocytopenia, but this complication has been reported, including in individuals who had previously developed thrombocytopenia after UFH. For these reasons, patients should have a platelet count on the day of starting UFH, and alternate-day platelet counts should be performed from days 4–14 thereafter. For patients on LMWH, platelet counts should be performed at 2- to 4-day intervals from days 4–14 (Keeling et al., 2006). If the platelet count falls by 50% and/or the patient develops new thrombosis or skin allergy during this period, heparin-induced thrombocytopenia (HIT) should be considered; if HIT is strongly suspected or confirmed, heparin should be stopped and an alternative agent such as a heparinoid or hirudin commenced.

Heparin-induced osteoporosis is rare but may occur when the drug is used during pregnancy and may be dose related. The exact mechanism is unknown. Other adverse effects of heparin are alopecia, urticaria and anaphylaxis, but these are also rare.

It has been shown that there is a nonlinear relationship between the dose of UFH infused and the KCCT. This means that disproportionate adjustments in dose are required depending on the KCCT if under- or overdosing is to be avoided (Box 23.1). Because the half-life of UFH is 1 hour, it would take 5 hours (five half-lives of the drug) to reach a steady state. A loading dose is therefore administered to reduce the time to achieve adequate anticoagulation. UFH in full dose can also be given by repeated

subcutaneous injection, and in these circumstances the calcium salt appears to be less painful than the sodium salt. Opinions differ as to whether the subcutaneous or intravenous route is preferable. The subcutaneous route may take longer to reach effective plasma heparin concentrations but avoids the need for infusion devices.

Use of a LMWH or fondaparinux is recommended in the immediate stages of proximal DVT and PE. UFH may be considered for use, with appropriate monitoring and care, in patients with severe renal impairment, at increased risk of bleeding or with haemodynamic instability. LMWH, UFH or fondaparinux should be administered with warfarin for at least 5 days or until the international normalised ratio (INR) has been in the therapeutic range for 2 successive days, whichever is the longer. Monitoring, as detailed previously, is essential to avoid the complications of HIT. Patients with previous exposure to heparin within the past 100 days should also have a platelet count performed before the second dose of heparin is administered (Winter et al., 2005). Requirements with DOACs differ, and not all require cover with a parenteral anticoagulant when used to treat a VTE.

Heparinoids

Danaparoid is a heparinoid that is licensed for prophylaxis of DVT in patients undergoing general or orthopaedic surgery. It is a mixture of the low-molecular-weight sulphated glycosaminoglycans: heparin sulphate, dermatan sulphate and a small amount of chondroitin sulphate. It acts by inhibiting factor Xa and, like LMWHs, is given by subcutaneous injection. It normally has a low cross-reactivity rate with heparin-associated antiplatelet antibodies, and if this is not present, it can be used in the treatment of individuals who develop HIT but still need ongoing anticoagulation. It is administered intravenously, with monitoring of anti-Xa activity only required in those at high risk of bleeding, for example, in renal insufficiency. It should be avoided in severe renal insufficiency and severe hepatic insufficiency.

Hirudins

Lepirudin, a recombinant hirudin, is licensed for anticoagulation in patients with type II (immune) HIT who require parenteral antithrombotic treatment. The dose of lepirudin is adjusted according to the APTT, and it is given intravenously by infusion. The risk of haemorrhage is greater in those with poor renal function. Severe anaphylaxis occurs rarely in association with lepirudin treatment and is more common in previously exposed patients (Keeling et al., 2006). Bivalirudin is an analogue of hirudin but acts as a direct thrombin inhibitor. It is licensed for anticoagulation in patients undergoing percutaneous coronary intervention (PCI). It has to be administered parenterally, and the activated clotting time (ACT) is used to assess its activity. Haemorrhage is also an important adverse effect of this agent.

Fondaparinux

Fondaparinux sodium is a synthetic pentasaccharide that binds to antithrombin III, thus inhibiting factor Xa but without effect on factor IIa. Therefore, at doses normally used for treatment, it does not significantly affect coagulation tests, and routine monitoring

of these is not necessary. It has to be given parenterally. It is used for prophylaxis of VTE in high-risk situations and for treatment of acute DVT and treatment of acute PE, except in haemodynamically unstable patients or patients who require thrombolysis or pulmonary embolectomy. It also has an indication for the treatment of unstable angina or non-ST-segment-elevation myocardial infarction (NSTEMI) and for the treatment of ST-segment-elevation myocardial infarction (STEMI). Haemorrhage is the most important adverse effect.

Oral anticoagulants

Warfarin. Although it is not the only coumarin anticoagulant available, warfarin is by far the most widely used drug in this group because of its potency, duration of action and more reliable bioavailability. When given by mouth, warfarin is completely and rapidly absorbed, although food decreases the rate (but not the extent) of absorption. It is extremely highly plasma-protein bound (99%) and, therefore, has a small volume of distribution (7–14 L). It consists of an equal mixture of two enantiomers, (*R*)- and (*S*)-warfarins. They have different anticoagulant potencies and routes of metabolism.

Both enantiomers of warfarin act by inducing a functional deficiency of vitamin K and thereby prevent the normal carboxylation of the glutamic acid residues of the amino-terminal ends of clotting factors II, VII, IX and X. This renders the clotting factors unable to cross-link with calcium and thereby bind to phospholipid-containing membranes. Warfarin prevents the reduction of vitamin K epoxide to vitamin K by epoxide reductase. (*S*)-warfarin appears to be at least five times more potent in this regard than (*R*)-warfarin. Because warfarin does not have any effect on already carboxylated clotting factors, the delay in onset of the anticoagulant effect of warfarin is dependent on the rate of clearance of the fully carboxylated factors already synthesised. The half-life of removal of factor VII is approximately 6 hours, that of factor IX is 24 hours, that of factor X is 36 hours and that of factor II is 50 hours. Some of the variability in response to warfarin may be related to genetic variations in the gene encoding the vitamin K epoxide reductase multiprotein complex (VKORC1 gene).

The effect of warfarin is monitored using the one-stage prothrombin time, for example, the INR. This test is sensitive chiefly to factors VII, II and X (and to a lesser extent factor V, which is not a vitamin K-dependent clotting factor). However, factor VII is the most important factor in the extrinsic pathway of clotting. The optimum therapeutic range for the INR differs depending on the clinical indication because the lowest INR consistent with therapeutic efficacy is the best in reducing the risk of haemorrhage. Examples of therapeutic ranges recommended for various indications are given in Table 23.3 (Keeling et al., 2011).

Warfarin is metabolised by the liver via the cytochrome P450 system. Only very small amounts of the drug appear unchanged in the urine. The average clearance is 4.5 L/day, and the half-life ranges from 20 to 60 hours (mean 40 hours). It thus takes approximately 1 week (around five half-lives) for the steady state to be achieved after warfarin has been initiated. The enantiomers of warfarin are metabolised stereo-specifically, (*R*)-warfarin being mainly reduced at the acetyl side chain into

Table 23.3 Recommended target INRs for different conditions

Indication	Target INR
Pulmonary embolus (first episode)	2.5
Proximal deep vein thrombosis (first episode)	2.5
Recurrence of venous thromboembolism while on warfarin therapy (and INR >2.0)	3.5
Antiphospholipid syndrome	2.5
Non-rheumatic atrial fibrillation	2.5
Atrial fibrillation associated with mitral stenosis or regurgitation	2.5
Cardioversion	2.5
Mechanical prosthetic heart valve (depends on prosthesis thrombogenicity; consult full guideline) Bioprosthetic valve (depends on valve affected and associated risk factors; consult full guideline)	
INR, International normalised ratio. Adapted from Keeling et al. (2011); consult the full guideline for further information.	

secondary warfarin alcohols, whereas (*S*)-warfarin is predominantly metabolised at the coumarin ring to hydroxywarfarin. The clearance of warfarin may be reduced in liver disease and during the administration of a variety of drugs known to inhibit either the (*S*) or (*R*), or both, enantiomers. The number of possible interactions and the potential severity of their outcome mean that it is essential not to prescribe any medicine concomitantly with warfarin until a thorough check on all possible interactions has been undertaken. The British National Formulary (BNF) contains comprehensive information on possible interactions between warfarin and other medicines. It is advised that the BNF is always consulted before the use of any other medication with warfarin. Some examples of significant interactions with warfarin are provided in Table 23.4.

Renal function is thought to have little effect on the pharmacokinetics of, or anticoagulant response to, warfarin. Some of the variability in warfarin dose requirement is related to genetic polymorphisms of the cytochrome (CYP2C9) mediating the rate of hepatic metabolism of (*S*)-warfarin. Individuals with the variant isoform (either heterozygotes or in particular homozygotes) metabolise this more active enantiomer more slowly and so require lower doses.

The major adverse effect of warfarin is haemorrhage, which often occurs at the site of a predisposing abnormality, such as an ulcer or a tumour. The risk of bleeding is increased by excessive anticoagulation, although this may not need to be present for severe haemorrhage to occur. Close monitoring of the degree of anticoagulation of warfarin is, therefore, important, and guidelines for reversal of excessive anticoagulation are shown in Box 23.2.

It is also important to reduce the duration of therapy of the drug to the minimum effective period to reduce the period of risk.

Table 23.4 Some clinically important drug interactions with warfarin

Interacting drug	Effect	Probable mechanism(s)
Carbamazepine Rifampicin St John's wort	Reduced anticoagulant effect	Induction of warfarin metabolism
Oral contraceptives, oestrogens and progestogens Vitamin K (e.g. in some enteral feeds)	Reduced anticoagulant effect	Pharmacodynamic antagonism of anticoagulant effect
Amiodarone Cimetidine Ciprofloxacin Clarithromycin Erythromycin Fibrates Fluconazole Fluvastatin Itraconazole Ketoconazole Leflunomide Metronidazole Miconazole Norfloxacin Ofloxacin Paracetamol Rosuvastatin Sulfinpyrazone Sulfamethoxazole Trimethoprim	Increased anticoagulant effect	Inhibition of warfarin metabolism
Danazol Tamoxifen	Increased anticoagulant effect	Pharmacodynamic potentiation of anticoagulant effect
Cranberry juice	Increased anticoagulant effect	Mechanism unknown
NSAIDs (including aspirin at all doses) Clopidogrel	Increased risk of bleeding	Additive effects on coagulation Haemostasis
NSAIDs, Non-steroidal anti-inflammatory drugs.		

Skin reactions to warfarin may also occur but are rare. The most serious skin reaction is warfarin-induced skin necrosis, which may occur over areas of adipose tissue such as the breasts, buttocks or thighs, especially in women, and is related to relative deficiency of protein C or S. This is important because these deficiencies result in an increased risk of thrombosis, and therefore warfarin may more often be used in such subjects. Preventing excessive anticoagulation in the initial stages of induction of therapy may reduce the severity of the reaction. A dosing schedule which helps achieve this is shown in Table 23.5.

Warfarin may also be teratogenic, producing in some instances a condition called chondrodysplasia punctata. This is associated with 'punched-out' lesions at sites of ossification, particularly of

Box 23.2 Recommendations for management of bleeding and excessive anticoagulation in patients receiving warfarin

- Major bleeding – stop warfarin sodium; give phytonadione (vitamin K₁) 5 mg by slow intravenous injection; give dried prothrombin complex (factors II, VII, IX and X) 25–50 units/kg; if dried prothrombin complex unavailable, fresh frozen plasma 15 mL/kg can be given but is less effective; recombinant factor VIIa is not recommended for emergency anticoagulation reversal.
- INR >8.0, minor bleeding – stop warfarin sodium; give phytonadione (vitamin K₁) 1–3 mg by slow intravenous injection; repeat dose of phytonadione if INR is still too high after 24 h; restart warfarin sodium when INR <5.0.
- INR >8.0, no bleeding – stop warfarin sodium; give phytonadione (vitamin K₁) 1–5 mg by mouth using the intravenous preparation orally (unlicensed use); repeat dose of phytonadione if INR is still too high after 24 h; restart warfarin when INR <5.0.
- INR 5.0–8.0, minor bleeding – stop warfarin sodium; give phytonadione (vitamin K₁) 1–3 mg by slow intravenous injection; restart warfarin sodium when INR <5.0.
- INR 5.0–8.0, no bleeding – withhold 1 or 2 doses of warfarin sodium and reduce subsequent maintenance dose.
- Unexpected bleeding at therapeutic levels – always investigate the possibility of an underlying cause (e.g. unsuspected renal or gastro-intestinal tract pathology).

INR, International normalised ratio.

Based on Keeling et al. (2011), and adapted from information within the British National Formulary 2018.

the long bones but also of the facial bones, and may be associated with the absence of the spleen. Although it has been associated predominantly with warfarin anticoagulation during the first trimester of pregnancy, other abnormalities, including cranial nerve palsies, hydrocephalus and microcephaly, have been reported at later stages of pregnancy if the child is exposed.

Other coumarin anticoagulants are available. Acenocoumarol (nicoumalone) has a much shorter duration of action than warfarin, and phenindione may be associated with a higher incidence of non-haemorrhagic adverse effects. In the vast majority of cases, these drugs have not been shown to have any clear benefits over warfarin, but they may be used occasionally where a patient does not tolerate warfarin. It is now the case that a patient who does not tolerate warfarin would be more likely to receive a DOAC rather than another vitamin-K antagonist instead.

The necessary duration of anticoagulation in venous thrombosis and pulmonary embolus is still uncertain. On the basis of the available evidence, therapy may be required for approximately 6 months after the first DVT or PE. It may be possible to reduce the duration of therapy in patients who have had a postoperative episode because it is likely that the risk factor has been reversed (unless immobility continues). In patients with a second episode, therapy may be required for even longer, and in patients with more than two episodes, lifelong treatment may be necessary to reduce the risk of recurrence (Keeling et al., 2011).

Direct acting oral anticoagulants. DOACs (e.g. apixaban, dabigatran, edoxaban and rivaroxaban) are highly effective agents, but like all anticoagulants, they can cause potentially life-threatening bleeding in some patients. The various DOACs have

Table 23.5 Suggested warfarin induction schedule

Day	INR	Warfarin dose (mg)	
First	<1.4	10 (5 may be more appropriate for the elderly and those with low body weight, liver disease, cardiac failure or at high risk of bleeding)	
	1.4–1.8	10	
	>1.8	1	
Second	<1.8	10	
	1.8	1	
	>1.8	0.5	
	Third	<2.0	10
		2.0–2.1	5
		2.2–2.3	4.5
		2.4–2.5	4
		2.6–2.7	3.5
		2.8–2.9	3
		3.0–3.1	2.5
3.2–3.3		2	
3.4		1.5	
3.5		1	
Fourth	3.6–4.0	0.5	
	>4.0	0 (predicted maintenance dose)	
	<1.4	>8	
	1.4	8	
	1.5	7.5	
	1.6–1.7	7	
	1.8	6.5	
	1.9	6

2.4–2.6	4.5		
2.7–3.0	4		
3.1–3.5	3.5		
3.6–4.0	3		
4.1–4.5	Miss out next day's dose, then give 2 mg		
>4.5	Miss out 2 days' doses, then give 1 mg		

INR, International normalised ratio.
Modified from Fennerty et al. (1984).

different marketing authorisations for use in different indications, and because these are relatively new agents, their authorisations are subject to regular change. Product literature and/or the BNF should be consulted before use to ensure that an appropriate agent is selected for the indication.

Although DOACs interact with fewer drugs than vitamin-K antagonists such as warfarin, some potentially significant interactions do occur. All of the available agents appear to be substrates for p-glycoprotein (p-GP), and so various inhibitors or inducers of this system will respectively increase or decrease the effect of the DOACs to different extents. A DOAC dose reduction is advised when certain other medicines are co-prescribed and some are contraindicated in combination. As with warfarin, the BNF should be consulted before the co-administration of any other medicine with a DOAC.

The relatively short half-lives of the DOACs means adherence to treatment is essential for them to be optimally effective. They are not, therefore, a panacea for a patient who is nonadherent to warfarin or other medicines.

There is sometimes a perception that there is no requirement for biochemical or physiological monitoring with DOACs. It is true that no routine anticoagulant monitoring is required; indeed, this is not currently possible. However, there is a requirement to assess renal function before initiation and periodically thereafter, particularly where a decline in renal function is suspected, and also to monitor for signs of suspected bleeding or anaemia.

The DOACs have been shown in clinical trials to be generally safe for use without routine anticoagulant monitoring; however, arguments for and against laboratory monitoring have been published (Kitchen et al., 2014). The absence of such monitoring may be a disadvantage in some cases, as it is not possible to identify signs of sub-therapeutic or supra-therapeutic plasma levels until a thromboembolism or haemorrhage occurs. Further information on the effects of DOACs on laboratory measures of anticoagulation can be found in the relevant British Society for Haematology guideline (Kitchen et al., 2014).

When considering the use of a DOAC, it is advised that the Cockcroft–Gault formula is used to calculate an accurate creatinine clearance before initiation. Dose reductions are advised with DOACs at different levels of renal impairment, and they are also contraindicated at different levels of impairment. This is sometimes dependent on the indication for which they are prescribed. In patients with moderate to severe renal impairment, a drug which is not predominantly renally excreted, with a marketing authorisation for this use, should be used. Some further information is given in the following sections, but again, the product literature and/or the BNF should also be consulted.

Haemorrhage is the major adverse effect of the DOACs, and patients should be advised to seek urgent medical attention if they notice signs of bleeding. Idarucizumab, a monoclonal antibody fragment, is licenced in the UK for reversal of the anticoagulant effect of dabigatran (NICE, 2016). It binds to both free and thrombin-bound dabigatran, reversing the anticoagulant effect within minutes. Andexanet alfa, which is a recombinant modified human factor Xa decoy protein, has been shown to reverse the anticoagulant effects of apixaban and rivaroxaban (Connolly et al., 2016). It does not yet have a marketing authorisation in the UK.

Dabigatran. Dabigatran is an orally active inhibitor of both free and clot-bound thrombin (Wittkowsky, 2010). It has a rapid onset of action. Dabigatran etexilate is a prodrug which is hydrolysed to active dabigatran in the liver. Because 80% of activated dabigatran is excreted unchanged through the kidneys, it should be avoided in patients with severe renal impairment (creatinine clearance <30 mL/min), and the dose should be reduced in moderate renal impairment (creatinine clearance 30–50 mL/min). Dabigatran is a substrate for the transport protein p-GP, which facilitates renal elimination of certain drugs. Amiodarone, an inhibitor of p-GP, reduces the clearance of dabigatran, and so doses should be reduced in patients who are on concurrent treatment with amiodarone. In patients who are on strong p-GP inhibitors, such as verapamil and clarithromycin, dabigatran should be used with caution, and it should not be used together with quinidine. Drugs such as rifampicin and St John's wort, which are potent p-GP inducers, may potentially reduce its efficacy.

Rivaroxaban. Rivaroxaban is an orally active inhibitor of both the 'free' and prothrombinase complex-bound forms of activated factor X (Xa) (Wittkowsky, 2010). Two-thirds of the dose is metabolised, principally by CYP450 enzymes, and the remaining third is excreted unchanged in the urine. It should also be used with caution in patients with creatinine clearance less than 30 mL/min (severe renal impairment) and is contraindicated in those with creatinine clearance less than 15 mL/min.

Like dabigatran, rivaroxaban also appears to be a p-GP substrate, and it should be used with caution when prescribed concomitantly with p-GP inhibitors and potent p-GP inducers. Several CYP3A4 inhibitors and inducers have also been shown to affect its metabolism. Some CYP3A4 inhibitors significantly increase the area-under-the-curve (AUC) of rivaroxaban, particularly ketoconazole and otherazole-antimycotics, such as itraconazole, voriconazole and posaconazole and also HIV protease inhibitors such as ritonavir. Therefore, the use of rivaroxaban is not recommended in patients receiving concomitant systemic treatment with these agents. The CYP3A4 inducer rifampicin (and possibly other inducers of this cytochrome) reduces the AUC for rivaroxaban.

Apixaban. Apixaban is an orally active direct inhibitor of activated factor X (factor Xa). Around 30% of the dose is excreted unchanged in urine. The normal elimination half-life is around 12 hours, but this is prolonged in renal dysfunction. It is not recommended if the creatinine clearance is less than 15 mL/min. The dose should be reduced if the eGFR is between 15 and 29 mL/min/1.73 m², or if serum-creatinine ≥133 mmol/L and the patient's age is ≥80 years or the patient's body weight is ≤60 kg.

Like dabigatran and rivaroxaban, apixaban also appears to be a p-GP substrate, and so it should be used with caution when prescribed concomitantly with p-GP inhibitors and potent p-GP inducers.

Edoxaban. Edoxaban is also an orally active direct inhibitor of activated factor X (factor Xa). Around 50% of the clearance of the drug is via the kidney as unchanged drug in the urine, the remainder being cleared by metabolism and biliary or intestinal excretion. The terminal elimination half-life of edoxaban following oral administration in health is around 10–14 hours. The

manufacturer advises a reduction in edoxaban dose in moderate to severe renal impairment and to avoid using the medicine in end-stage renal disease or in dialysis.

Edoxaban is a substrate of p-GP, and co-administration of potent inhibitors like ciclosporin, dronedarone, erythromycin, ketoconazole, quinidine or verapamil increases edoxaban exposure, necessitating a recommended reduction in dose.

Fibrinolytic drugs

Thrombolytic therapy is used in life-threatening acute massive PE. It has been used in DVT, particularly in those patients where a large amount of clot exists and venous valvular damage is likely. However, fibrinolytic drugs are potentially more dangerous than anticoagulant drugs, and evidence is not available in situations other than acute massive embolism to show a sustained benefit from their use.

Streptokinase. Streptokinase was the first agent available in this class. It was produced from streptococci and is a large protein that binds to and activates plasminogen, thus encouraging the breakdown of formed fibrin to fibrinogen degradation products. It also acts on the circulating fibrinogen to produce a degree of systemic anticoagulation. Because it is a large protein molecule, it cannot be administered orally and has to be given by intravenous infusion. The half-life of removal from the body is 30 minutes. It is cleared chiefly by the reticuloendothelial system in the liver.

Its major adverse effect is to increase the risk of haemorrhage, but it may also be antigenic and produce an anaphylactic reaction. It may also cause hypotension during infusion, and in some patients, particularly those who have been administered the drug within the previous 12 months, a relative resistance to the drug may occur. Thrombolytic therapy is contraindicated in patients who have had major surgery or with active bleeding sites in the gastro-intestinal or genitourinary tract; those who have a history of stroke, renal or liver disease; and those with hypertension. It should also be avoided during pregnancy and the postpartum period.

Alteplase. Tissue plasminogen activator (rt-PA) or alteplase was developed using recombinant DNA technology. Although this agent is much more expensive than streptokinase, it can be used in those situations where streptokinase may be less effective because of development of antibodies, for example, within 1 year of previous streptokinase use or where allergy to streptokinase has previously occurred. Alteplase produces a lesser degree of systemic anticoagulation because it is more active against plasminogen associated with the clot; immediate use of heparin subsequently is necessary to prevent recurrence of thrombosis. Alteplase is also used for acute ischaemic stroke, where its prompt use may improve outcome in carefully selected individuals in whom cerebral haemorrhage has been excluded using appropriate imaging techniques (NICE, 2012). Currently, it is the only thrombolytic licensed for this indication (see discussion of arterial thromboembolism).

Retepase and tenecteplase. Retepase and tenecteplase are also fibrin-specific agents, and so heparin is required to prevent rebound thrombosis. They are indicated for the treatment of

acute myocardial infarction. In this clinical situation, reteplase is administered as an intravenous bolus, followed by a second bolus 30 minutes later (double bolus), and tenecteplase is given as a single intravenous bolus. They, therefore, have the advantage of convenience of administration compared with alteplase, and they are the preferred option in pre-hospital settings, particularly when administered by paramedics (NICE, 2002).

Urokinase. Urokinase, like alteplase and streptokinase, can be used for the treatment of DVT and PE. It is also licensed to restore patency in intravenous catheters and cannulas blocked by fibrin thrombi.

Patient care

Patients taking oral anticoagulants should be given full information on what to do in case of problems and what circumstances and drugs to avoid. An anticoagulant card with previous INR values and doses should also be provided to those taking warfarin, and patients should be told of the colour codes for the different strengths of warfarin tablets and advised to carry their treatment card at all times. Similarly, patients taking a DOAC should be provided with an appropriate anticoagulant card for their treatment. The likely duration of any anticoagulant therapy should be made clear to the patient to avoid unnecessary and potentially dangerous prolongations of treatment. Patients who have received a fibrinolytic agent should also carry a card identifying the drug given and the date of administration.

Arterial thromboembolism

Acute myocardial infarction is the commonest clinical presentation of acute arterial thrombosis. Stroke is commonly caused by atherothromboembolism from the great vessels or embolism arising from the heart (approximately 80% of strokes). These two conditions are discussed elsewhere. Peripheral arterial thrombosis or thromboembolism may also occur, most often in the lower limb. Antiplatelet drugs are often used for prophylaxis, but surgical embolectomy and/or fibrinolytic therapy may be needed for treatment of acute thrombotic or thromboembolic events to avoid consequent ischaemic damage.

Aetiology

Arterial thromboembolism is normally associated with vascular injury and hypercoagulability. Vascular injury is most often due to atheroma, itself aggravated by smoking, hypertension, hyperlipidaemia or diabetes mellitus. Although the exact mechanism is not clear, it is thought that platelet aggregation may be induced by the shear stresses caused by the stenosis of an atherosclerotic vessel. This thrombotic material may embolise to cause occlusion further downstream. Hypercoagulability is also a risk factor. It may be associated with increased plasma fibrinogen levels and an increase in circulating cellular components, for example, polycythaemia or thrombocythaemia. As mentioned earlier, the thrombus formed in the artery contains a much larger proportion of

platelets, possibly reflecting the fact that other blood components that are not as readily adherent may be dissipated by the higher flow rates in the arterial circulation. Oestrogens, by the mechanisms described earlier, are likely to increase the risk of arterial and venous thrombosis. Hyperlipidaemia may also increase the risk of hypercoagulability, as well as enhance thrombotic risk through its role in the progression of atheroma and vascular injury.

Treatment and prevention

Aspirin

Aspirin (acetylsalicylic acid) is a potent inhibitor of the enzyme cyclo-oxygenase, which catalyses the production of prostaglandins. It reduces the production of a pro-aggregatory prostaglandin, thromboxane A₂, in the platelet, an effect that lasts for the life of the platelet.

Aspirin is well absorbed after oral administration. It is rapidly metabolised by esterases in the blood and liver (so that its half-life is only 15–20 minutes) to salicylic acid and other metabolites that are excreted in the urine. In the doses used in prophylaxis against thromboembolism, aspirin is largely metabolised by the liver, but in overdose, urinary excretion of salicylate becomes a limiting factor in drug elimination.

The major adverse effect of aspirin is gastro-intestinal irritation and bleeding. This problem is much more common with higher doses of aspirin (300 mg or more) that were once used in the prevention of arterial thromboembolism but are less common with the doses (e.g. 75 mg) now used. Concomitant use of ulcer-healing drugs, particularly proton pump inhibitors, can reduce the risk of peptic ulceration induced by non-steroidal anti-inflammatory drug (NSAID) use in patients susceptible to the problem (NICE, 2015c). There is also little evidence that buffered or enteric-coated preparations of aspirin are safer in this respect. However, the vast majority of patients tolerate low-dose aspirin well, and it is normally given as a single oral dose of soluble aspirin. Aspirin may also, rarely, induce asthma, particularly in patients with co-existing reversible airway obstruction. Other patients have a form of aspirin hypersensitivity that may result in urticaria and/or angioedema. In this situation, there may be cross-reactivity with other NSAIDs.

Haemorrhagic stroke is a rare but very serious complication of therapy with aspirin (and with other antiplatelet agents). Aspirin must not be given to children or people younger than 16 years because of the risk of the rare but life-threatening possibility of Reye's syndrome, which may cause liver and renal failure.

Aspirin is an established treatment for the secondary prevention of cardiovascular events. However, a review of its use for primary prevention found that the risks and benefits are more finely balanced than previously thought, and low-dose aspirin is no longer routinely recommended for this indication, even in high-risk patients such as those with diabetes or hypertension (Anon., 2009). It should also be noted that it does not have a marketing authorisation for such use.

Clopidogrel

Clopidogrel is a prodrug that is metabolised in part to an active thiol derivative. The latter inhibits platelet aggregation by rapidly

and irreversibly inhibiting the binding of adenosine diphosphate (ADP) to its platelet receptor, thus preventing the ADP-mediated activation of the glycoprotein IIb/IIIa receptor for the life of the platelet. It is an orally active prodrug and is given once daily for the reduction of atherosclerotic events in those with pre-existing atherosclerotic disease. In this respect, it may be a useful alternative to aspirin in aspirin-allergic subjects, but haemorrhage occurs with the same frequency as aspirin, and thrombocytopenia (sometimes severe) may be commoner than with aspirin therapy. Activation to its active metabolite may be subject to a genetic polymorphism of CYP450 2C19 and may also be reduced by the proton pump inhibitor omeprazole or esomeprazole, so the use of alternative gastroprotective agents may need to be considered if required.

Clopidogrel is licensed in the UK for the prevention of atherothrombotic events (myocardial infarction, ischaemic stroke, established peripheral arterial disease, and acute coronary syndrome in combination with aspirin) and the prevention of atherothrombotic and thromboembolic events in atrial fibrillation (Consilient Health, 2017).

Prasugrel

Prasugrel inhibits platelet activation and aggregation. It is a prodrug whose active metabolite irreversibly binds to P2Y₁₂ class of ADP receptors on platelets. This prevents activation of the GPIIb/IIIa receptor complex and thus causes inhibition of ADP-mediated platelet activation and aggregation. In combination with aspirin, it is recommended by NICE as an option, within its marketing authorisation, for preventing atherothrombotic events in adults with acute coronary syndrome (unstable angina [UA], NSTEMI or STEMI) having primary or delayed percutaneous coronary intervention (NICE, 2014).

Ticagrelor

Like prasugrel and clopidogrel, ticagrelor blocks ADP receptors of subtype P2Y₁₂. However, unlike the other antiplatelet drugs, it has a binding site different from ADP (it is an allosteric antagonist), and the blockade is therefore reversible. It is an active drug in its own right and does not require activation by metabolism. Ticagrelor in combination with low-dose aspirin is recommended for up to 12 months as a treatment option in adults with acute coronary syndromes (NICE, 2011).

Dipyridamole

Dipyridamole is prescribed as an adjunct to oral anticoagulation for prophylaxis of thromboembolism associated with prosthetic heart valves. Dipyridamole modified-release preparations 200 mg twice a day may be used in combination with aspirin 75 mg daily for long-term vascular prevention in people with ischaemic stroke or TIA without paroxysmal or permanent atrial fibrillation, but only if clopidogrel 75 mg daily cannot be used (Bowen et al., 2016). If clopidogrel and aspirin cannot be tolerated or are contraindicated, then modified-release dipyridamole 200 mg twice a day would be used by itself.

Dipyridamole is a phosphodiesterase inhibitor and, thus, elevates concentrations of cyclic AMP. It may also block the uptake

of adenosine by erythrocytes and other cells. Adverse effects include headache (to which tolerance may gradually develop) gastro-intestinal problems, flushing and hypotension.

Glycoprotein IIb/IIIa inhibitors

Glycoprotein IIb/IIIa inhibitors prevent platelet aggregation by blocking the binding of fibrinogen to receptors on platelets.

Abciximab. Abciximab is a monoclonal antibody which binds to coronary glycoprotein IIb/IIIa receptors and to other related sites. It is recommended as an adjunct to heparin and aspirin for the prevention of ischaemic complications in high-risk patients undergoing percutaneous transluminal coronary intervention (NICE, 2010). Abciximab should be used once only to avoid further risk of thrombocytopenia.

Eptifibatid and tirofiban. Eptifibatid and tirofiban also inhibit glycoprotein IIb/IIIa receptors; they are licensed for use with heparin and aspirin to prevent early myocardial infarction in patients with unstable angina or NSTEMI.

Abciximab, eptifibatid and tirofiban all have to be administered parenterally and should be used by specialist clinicians only (NICE, 2010).

Patient care

Aspirin is normally well tolerated at the doses used for stroke prevention. However, it should not be given to patients with a history of gastro-intestinal ulceration. Because it may induce bronchospasm in susceptible individuals, it should be used cautiously in such circumstances. It is best tolerated if taken once daily as soluble aspirin after food.

Case studies

Case 23.1

Mr AJ, a 75-year-old patient receiving warfarin to prevent DVT, comes to the clinic with an INR of 12, despite taking the same dose of the drug. There is no evidence of bleeding. He was previously well controlled on warfarin.

Question

What should be done?

Answer

Because Mr AJ's INR is more than 8 (even if there is no bleeding), the national guidelines recommend that warfarin be stopped (Keeling et al., 2011). The patient should then be given phytomenadione (vitamin K₁) 1–5 mg by mouth using the intravenous preparation orally (unlicensed use). The dose of phytomenadione should be repeated if the INR is still too high after 24 hours. However, a single dose often helps the INR return to close to the target level at 24 hours without causing warfarin resistance subsequently. The warfarin can be restarted when the INR is less than 5.0. A search for clinical conditions or drugs which might cause warfarin sensitivity should also be made. Measurement of plasma warfarin concentration may help in difficult cases.

Case 23.2

A patient, Mr FG, receiving heparin for 7 days for extensive VTE develops arterial thrombosis.

Question

What would you suspect in this situation, and what should be done?

Answer

The rare but serious heparin-induced thrombocytopenia (HIT) may be responsible. The platelet count should be measured immediately, and if HIT is strongly suspected or confirmed, the heparin should be discontinued. An alternative anticoagulant should be started at full dose whilst specific confirmatory tests are being performed, unless there are significant contraindications. Danaparoid and lepirudin may be considered as alternative anticoagulants in these circumstances.

Case 23.3

Mr MT, admitted to an acute hospital with suspected myocardial infarction, says that he had a myocardial infarction 4 years ago and was treated with a drug to 'dissolve the clot in the coronary artery'. The chest pain started 4 hours earlier, and his electrocardiogram shows ST-segment elevation in the anterior leads.

Question

What relevance may Mr MT's previous treatment, present history and findings have to his management on this occasion?

Answer

Thrombolytic drugs are indicated for any patient with acute myocardial infarction, provided the likely benefits outweigh the possible risks. Trials have shown that the benefit is greatest in those with electrocardiogram (ECG) changes that include ST-segment elevation, especially in those with anterior infarction, and in patients with bundle branch block. The patient has received a thrombolytic, possibly streptokinase, in the past. Mr MT should be asked if he was given a card to carry with him with the identity of the therapy he was given. If the prior treatment was with streptokinase or anistreplase (no longer available), prolonged persistence of antibodies to streptokinase may reduce the effectiveness of subsequent treatment. Therefore, streptokinase should not be used again beyond 4 days of first administration of streptokinase (or anistreplase), and urgent consideration should be given to the use of an alternative thrombolytic agent such as alteplase, reteplase or tenecteplase.

Case 23.4

A 64-year-old male patient, Mr TS, is to be prescribed aspirin therapy following an acute myocardial infarction.

Question

What questions should you ask Mr TS before starting treatment with aspirin?

Answer

Mr TS should be asked if he has had aspirin before and, if so, whether he tolerated it. Caution is necessary in elderly patients, in those with uncontrolled hypertension and in patients taking other drugs that increase the risk of bleeding. Caution is also required in those with a previous history of peptic ulceration, and some manufacturers advise avoidance in such circumstances; active peptic ulceration is a definite contraindication. Other contraindications include severe hepatic impairment, severe renal failure, haemophilia and other bleeding disorders. Aspirin may induce bronchospasm or angioedema in susceptible individuals, for example, in asthmatics, and caution should be exercised in these circumstances.

Case 23.5

Mrs BC, a 56-year-old woman on warfarin therapy for atrial fibrillation with mitral stenosis, appears to become resistant to warfarin after previously good control on 5 mg daily. Her INR does not

rise above 1.4 even when her warfarin dose is increased to 20 mg daily.

Question

What can be done to find the cause of the resistance?

Answer

Mrs BC should be asked about any new medications which might have been introduced recently, including over-the-counter and herbal preparations. Some proprietary medicines may contain vitamin K, which could cause resistance by pharmacodynamic mechanisms. Other medicines, including the herbal medicine St John's wort, might induce warfarin metabolism and result in resistance as a result of a pharmacokinetic interaction (see Table 23.4). One other cause of apparent resistance to warfarin is poor adherence, and this should, therefore, be considered. Supervised administration of the dose and/or measurement of plasma warfarin concentrations may be of value if this is suspected.

24 Dyslipidaemia

Helen Williams

Key points

- Elevated concentrations of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) increase the risk of cardiovascular disease (CVD), whereas high-density lipoprotein cholesterol (HDL-C) confers protection.
- Two-thirds of the UK adult population has a serum TC greater than 5 mmol/L. The average TC concentration is 5.6 mmol/L.
- Dyslipidaemia may develop secondary to disorders such as diabetes mellitus, hypothyroidism, chronic renal failure, nephrotic syndrome, obesity, high alcohol intake and some drugs.
- Understanding and managing dyslipidaemia is of particular importance to reduce cardiovascular (CV) events in patients with or at risk of CV disease, but dyslipidaemia can also predispose patients to other disorders; for example, severe hypertriglyceridaemia (>10 mmol/L) is responsible for up to 4% of cases of acute pancreatitis.
- Androgens, β -blockers, ciclosporin, oral contraceptives, diuretics, glucocorticoids and vitamin A derivatives are examples of drugs that can have an adverse effect on the lipid profile.
- There are five main classes of lipid-lowering agents: statins, fibrates, resins, nicotinic acid derivatives and absorption blockers. More recently, proprotein convertase subtilisin/kexin type 9 inhibitors have been introduced.
- Statins are the drugs of choice in the treatment of primary prevention and secondary prevention of CVD.
- The aim of treatment in primary prevention ($\geq 10\%$ risk of CVD over 10 years) is to reduce overall CV risk by treatment with a high-intensity statin, such as atorvastatin 20 mg. No specific target treatment levels are recommended in primary prevention, although a 40% or more drop in non-HDL-C should be used as a marker of adherence.
- In secondary prevention, treatment should be started with a high dose of a high-intensity statin, such as atorvastatin 80 mg daily. No specific target treatment levels are recommended in secondary prevention, although a 40% or more decline in non-HDL-C should be used as a marker of adherence.

Disorders of lipoprotein metabolism together with high-fat diets, obesity and physical inactivity have all contributed to the current epidemic of atherosclerotic disease seen in developed countries. Disorders of lipoprotein metabolism that result in elevated serum concentrations of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) increase the risk of development of cardiovascular disease (CVD). In contrast, high-density lipoprotein

cholesterol (HDL-C) confers protection against CVD, with the risk reducing as HDL-C increases. It is, therefore, clear that the term hyperlipidaemia, which was formerly used to describe disorders of lipoprotein metabolism, is inappropriate. It is more appropriate to use the term dyslipidaemia, which encompasses both abnormally high levels of specific lipoproteins, for example, LDL-C, and abnormally low levels of other lipoproteins, for example, HDL-C, as well as disorders in the composition of the various lipoprotein particles. It is particularly appropriate when considering the individual at risk of CVD with a normal or high TC and low HDL-C (TC:HDL-C ratio).

Epidemiology

Lipid and lipoprotein concentrations vary among different populations, with countries consuming a Western type of diet generally having higher TC and LDL-C levels than those where regular consumption of saturated fat is low. The UK's cholesterol level is ninth highest in the world, slightly less than 5.5 mmol/L. However, UK men and women have both shown one of the largest drops in cholesterol in all high-income countries, from 6.2 to 5.4 mmol/L (Farzadfar et al., 2011). In contrast, in China and Japan, the average cholesterol reading is less than 5 mmol/L (Research Committee on Serum Lipid Level Survey 1990 in Japan, 1996; Yang et al., 2012).

The ideal serum lipid profile is unknown and varies between different populations, even across Europe, and also within a given population. Until recently, calculated LDL-C level was a key target for lipid lowering and monitoring, but in 2014 the National Institute for Health and Care Excellence (NICE) recommended the use of non-high-density lipoprotein cholesterol (non-HDL-C) rather than LDL-C. Non-HDL-C is TC minus HDL-C. LDL-C is not directly measured; it requires a calculation using a fasting sample and for the triglyceride levels to be less than 4.5 mmol/L (NICE, 2014). Measurement of non-HDL-C does not require either of these. Non-HDL-C represents the total of cholesterol circulating on apoprotein B (apoB) particles, that is, both LDL and triglyceride-rich lipoproteins, and represents the main atherogenic particles. A desirable value is less than 3 mmol/L.

The values presented in Table 24.1 represent what might be considered as an optimal lipid profile in the UK. Specific target levels for patients receiving treatment for primary or secondary

Table 24.1 Optimal serum lipid profile

Total cholesterol	<4.0 mmol/L
Low-density lipoprotein cholesterol	<2.0 mmol/L
Triglyceride	<1.7 mmol/L (fasting)
High-density lipoprotein cholesterol	>1.0 mmol/L in men >1.2 mmol/L in women

prevention of CVD are no longer recommended by [NICE \(2014\)](#); they state that a 40% reduction in non-HDL-C from pretreatment baseline is an indication of adherence to treatment.

Despite a 50% reduction in the death rate from CVD over the past 25 years, CVD remains the leading cause of death in the UK ([NICE, 2014](#)). The death rate from CVD is threefold higher in males than females, but because women live longer and are at increased risk of stroke after the age of 75 years, their lifetime risk of disease is greater ([NICE, 2014](#)). Death from CVD is responsible for one quarter of premature deaths in men and 17% of premature deaths in women ([British Heart Foundation, 2015](#)). The higher the levels of TC in an individual, the greater is the chance of development of CVD. For an individual, there appears to be no level below which a further reduction of TC or LDL-C is not associated with a lower risk of CVD.

Population-based approaches to vascular screening have the potential to provide significant health gain for society because most deaths from CVD occur in individuals who are not yet identified as at increased risk. Moreover, a small reduction in average population levels of TC and LDL-C/non-HDL-C can potentially prevent many deaths. In England, the NHS Health Checks scheme was introduced in 2009 for everyone between 40 and 74 years of age to receive a free health check every 5 years; this health check includes measurement of TC and the TC:HDL-C ratio and a calculation of cardiovascular (CV) risk. The intention is that individuals are given the necessary information about their health to make changes to lifestyle and avoid preventable disease.

Lipid transport and lipoprotein metabolism

The clinically important lipids in the blood (unesterified and esterified cholesterol and triglycerides) are not readily soluble in serum and are rendered miscible by incorporation into lipoproteins. There are six main classes of lipoproteins: chylomicrons, chylomicron remnants, very low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), LDL and HDL.

The protein components of lipoproteins are known as apoproteins (apo), of which apoA-I, apoE, apoC and apoB are perhaps the most important. ApoB exists in two forms: B-48, which is present in chylomicrons and associated with the transport of

ingested lipids; and B-100, which is found in endogenously secreted VLDL-C and associated with the transport of lipids from the liver ([Fig. 24.1](#)).

When dietary cholesterol and triglycerides are absorbed from the intestine they are transported in the intestinal lymphatics as chylomicrons. These are the largest of the lipoprotein particles of which triglycerides normally constitute approximately 80% of the lipid core. The chylomicrons pass through blood capillaries in adipose tissue and skeletal muscle, where the enzyme lipoprotein lipase is located, bound to the endothelium. Lipoprotein lipase is activated by apoC-II on the surface of the chylomicron. The lipase catalyses the breakdown of the triglyceride in the chylomicron to free fatty acid and glycerol, which then enter adipose tissue and muscle. The cholesterol-rich chylomicron remnant is taken up by receptors on hepatocyte membranes, and in this way dietary cholesterol is delivered to the liver and cleared from the circulation.

VLDL-C is formed in the liver and transports triglycerides, which again make up approximately 80% of its lipid core, to the periphery. The triglyceride content of VLDL-C is removed by lipoprotein lipase in a similar manner to that described earlier for chylomicrons, and forms IDL-C particles. The core of IDL-C particles is roughly 50% triglyceride and 50% cholesterol esters, acquired from HDL-C under the influence of the enzyme lecithin-cholesterol acyltransferase (LCAT). Approximately 50% of the body's IDL particles are cleared from serum by the liver. The other 50% of IDL-C are further hydrolysed and modified to lose triglyceride and apoE1, and become LDL-C particles. LDL-C is the major cholesterol-carrying particle in serum.

LDL-C provides cholesterol, an essential component of cell membranes, bile acid and a precursor of steroid hormones to those cells that require it. LDL-C is also the main lipoprotein involved in atherogenesis, although it appears to take on this role only after it has been modified by oxidation. For reasons that are not totally clear, the arterial endothelium becomes permeable to the lipoprotein. Monocytes migrate through the permeable endothelium and engulf the lipoprotein, resulting in the formation of lipid-laden macrophages that have a key role in the subsequent development of atherosclerosis. The aim of treatment in dyslipidaemia is normally to reduce concentrations of LDL-C (and consequently atherogenesis), and thus reduce TC at the same time.

Non-HDL cholesterol (TC minus HDL-C) is a measure of all the 'bad elements' of the lipid profile and is now used in preference to LDL-C, because it can be calculated without the need to take a fasting blood sample and is not affected by the presence of high triglyceride levels.

Whereas VLDL-C and LDL-C are considered the 'bad' lipoproteins, HDL-C is often considered to be the 'good' antiatherogenic lipoprotein. In general, about 65% of TC is carried in LDL-C and about 25% in HDL.

High-density lipoprotein

HDL-C is formed from the unesterified cholesterol and phospholipid removed from peripheral tissues and the surface of triglyceride-rich proteins. The major structural protein is apoA-I. HDL-C mediates the return of lipoprotein and cholesterol from peripheral tissues to the liver for excretion in a process known as reverse cholesterol transport.

Fig. 24.1 Schematic representation of lipoprotein metabolism in plasma. Dietary cholesterol and fat are transported in the exogenous pathway. Cholesterol produced in the liver is transported in the endogenous pathway.

HDL-C, High-density lipoprotein cholesterol; IDL-C, intermediate-density lipoprotein cholesterol; LCAT, lecithin-cholesterol acyltransferase; LDL-C, low-density lipoprotein cholesterol; VLDL-C, very low-density lipoprotein cholesterol.

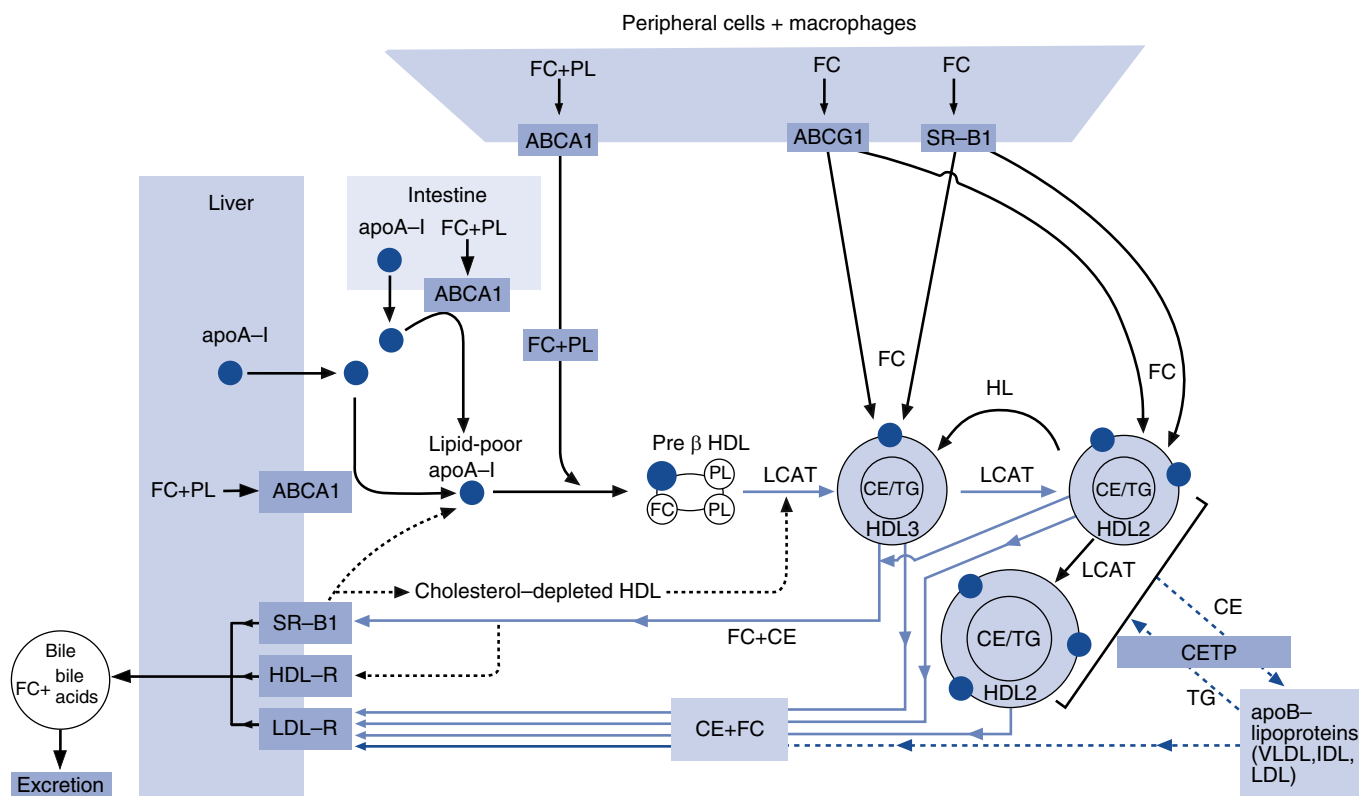

Reverse cholesterol transport pathway

The reverse cholesterol transport pathway (Fig. 24.2) controls the formation, conversion, transformation and degradation of HDL-C and is the target site for a number of drugs (Chapman et al., 2010).

The reverse cholesterol transport system involves lipoprotein-mediated transport of cholesterol from peripheral, extrahepatic tissues and arterial tissue (potentially including cholesterol-loaded foam cell macrophages of the atherosclerotic plaque) to the liver for excretion, either in the form of biliary cholesterol or bile acids. The ATP-binding cassette transporters, ABCA1 and ABCG1, and the scavenger receptor B1 are all implicated in cellular cholesterol efflux mechanisms to specific apoA-1/HDL acceptors. The progressive action of lecithin cholesterol acyltransferase (LCAT) on free cholesterol in lipid-poor, apolipoprotein A-I-containing nascent HDLs, including pre- β -HDL, gives rise to the formation of a spectrum of mature, spherical HDLs with a neutral lipid core of cholesteryl ester and triglyceride. Mature HDLs consist of two major subclasses, large cholesteryl ester-rich HDL₂ and small cholesteryl ester-poor, protein-rich HDL₃ particles; the latter represent the intravascular precursors of HDL₂. The reverse cholesterol transport system involves two key pathways: (1) the direct pathway (blue lines in Fig. 24.2), in which the cholesteryl

ester content (and potentially some free cholesterol) of mature HDL particles is taken up primarily by a selective uptake process involving the hepatic scavenger receptor B1; and (2) an indirect pathway (dotted blue lines in Fig. 24.2) in which cholesteryl ester originating in HDL is deviated to potentially atherogenic VLDL, IDL and LDL particles by cholesteryl ester transfer protein. Both the cholesteryl ester and free cholesterol content of these particles are taken up by the liver, predominantly via the LDL receptor, which binds their apoB100 component. This latter pathway may represent up to 70% of cholesteryl ester delivered to the liver per day. The hepatic LDL receptor is also responsible for the direct uptake of HDL particles containing apoE; apoE may be present as a component of both HDL₂ and HDL₃ particles, and may be derived either by transfer from triglyceride-rich lipoproteins or from tissue sources (principally liver and monocyte-macrophages). Whereas HDL uptake by the LDL receptor results primarily in lysosomal-mediated degradation of both lipids and apolipoproteins, interaction of HDL with scavenger receptor B1 regenerates lipid-poor apoA-I and cholesterol-depleted HDL, both of which may re-enter the HDL/apoA-I cycle.

From this description it is evident that HDL-C plays a major role in maintaining cholesterol homeostasis in the body. As a

consequence it is considered desirable to maintain both levels of the protective HDL-C and the integrity of the reverse cholesterol transport pathway. Low levels of HDL-C are found in 17% of men and 5% of women, and may be a risk factor for atherogenesis that is comparable in importance to elevated levels of LDL-C. Drugs that reduce HDL-C levels are considered to have an undesirable effect on lipid metabolism and increase the risk of development of CVD. Examples of drugs that can lower HDL-C include some progestins, anabolic steroids, danazol, β -blockers and first-generation antipsychotics (Herink and Ito, 2015).

Triglycerides

The role of hypertriglyceridaemia as an independent risk factor for atherosclerotic CVD is unclear because triglyceride levels are confounded by an association with low HDL-C, hypertension, diabetes and obesity, and a synergistic effect with LDL-C and/or low HDL-C. An isolated elevation of triglyceride may be the consequence of a primary disorder of lipid metabolism; it may be secondary to the use of medicines such as oestrogens, protease inhibitors, retinoids, corticosteroids, some immunosuppressants and some antipsychotics (Herink and Ito, 2015); or it may be a component of the metabolic syndrome or type 2 diabetes

mellitus. Many individuals have a mixed dyslipidaemia that includes elevated levels of triglycerides and LDL-C, but a reduction of LDL-C normally remains the primary focus of treatment. A recent analysis, in more than 73,000 individuals, of a genetic variant that regulates triglyceride concentrations has demonstrated a causal association between triglycerides and coronary heart disease (CHD) (Triglyceride Coronary Disease Genetics Consortium and Emerging Risk Factors Collaboration, 2010).

Aetiology

Primary dyslipidaemia

Up to 60% of the variability in cholesterol fasting lipids may be genetically determined, although expression is often influenced by interaction with environmental factors. The common familial (genetic) disorders can be classified as:

- the primary hypercholesterolaemias such as familial hypercholesterolaemias (FHs) in which LDL-C is raised;
- the primary mixed (combined) hyperlipidaemias in which both LDL-C and triglycerides are raised; or
- the primary hypertriglyceridaemias such as type III hyperlipoproteinaemia, familial lipoprotein lipase deficiency and familial apoC-II deficiency.

Box 24.1 Simon Broome criteria indicating familial hypercholesterolaemia (NICE, 2008a)

Definite FH is defined as:

1. TC >6.7 mmol/L or LDL cholesterol >4.0 mmol/L in a child <16 years old, or TC >7.5 mmol/L or LDL cholesterol >4.9 mmol/L in an adult (levels are either pretreatment or highest on treatment.)
PLUS
2. Tendon xanthomas in patient, or in first-degree relative (parent, sibling, child), or in second-degree relative (grandparent, uncle, aunt)
OR
3. DNA-based evidence of an LDL receptor mutation or familial defective apoB-100

Possible FH is defined as:

Above criteria PLUS one of the following:

- Family history of myocardial infarction: <50 years of age in second-degree relative or <60 years in first-degree relative
- Family history of raised cholesterol: >7.5 mmol/L in adult first- or second-degree relative or >6.7 mmol/L in child or sibling <16 years of age

DNA, Deoxyribonucleic acid; LDL-C, low-density lipoprotein cholesterol; TC, total cholesterol.

Familial hypercholesterolaemia

Heterozygous FH is an inherited metabolic disease, which NICE estimates to affect approximately 1 in 500 of the population (110,000 individuals in England and Wales) (NICE, 2008a). However, more recent data suggest a higher prevalence, with a Danish study of more than 69,000 people detecting a prevalence of 1 in 137 (Benn et al., 2012). FH is caused by a range of mutations, which vary from family to family, in genes for the pathway that clear LDL-C from the blood. The most common mutation affects the LDL receptor gene. Given the key role of LDL receptors in the catabolism of LDL-C, patients with FH may have serum levels of LDL-C two to three times higher than the general population. It is important to identify these individuals from birth and initiate treatment early in life; otherwise, they will be exposed to high concentrations of LDL-C and will suffer the consequences. FH is transmitted as a dominant gene, with siblings and children of a parent with FH having a 50% risk of inheriting it. It is important to suspect FH in people who present with TC greater than 7.5 mmol/L, particularly where there is evidence of premature CV disease within the family (NICE, 2014). The clinical criteria that indicate FH are listed in Box 24.1. Guidance on diagnosis, identifying affected relatives, and management are available, but it is important to seek specialist advice for this group of high-risk patients (NICE, 2008a).

In patients with heterozygous FH, CVD presents about 20 years earlier than in the general population, with some individuals, particularly men, dying of atherosclerotic heart disease often before the age of 40 years. The adult heterozygote typically exhibits the signs of cholesterol deposition such as corneal arcus (crescentic deposition of lipids in the cornea), tendon xanthoma (yellow papules or nodules of lipids deposited in tendons) and xanthelasma (yellow plaques or nodules of lipids deposited on eyelids) in their third decade.

In contrast with the heterozygous form, homozygous FH is rare (1–2 per 1 million individuals) and is associated with an absence of LDL receptors and almost absolute inability to clear LDL-C. In these individuals, involvement of the aorta is evident by puberty and usually accompanied by cutaneous and tendon xanthomas. Myocardial infarction (MI) has been reported in homozygous children younger than 5 years (Dumić et al., 2007; Gautschi et al., 2012; Widhalm et al., 2011). Up to the 1980s, sudden death from acute coronary insufficiency before the age of 20 years was normal.

Familial combined hyperlipidaemia

Familial combined hyperlipidaemia has a prevalence of 1 in 50–200 and is associated with excessive synthesis of VLDL-C (Gaddi et al., 2007). In addition to increases in triglyceride and LDL-C levels, patients also typically have raised levels of apoB and elevated levels of small, dense LDL particles. It is associated with an increased risk of atherosclerosis and occurs in approximately 10% of patients who present with CHD before the age of 60 years (Gaddi et al., 2007).

Familial type III hyperlipoproteinaemia

Familial type III hyperlipoproteinaemia has an incidence of 1 in 5000–10,000 (National Organization of Rare Disorder, 2005). It is characterised by the accumulation of chylomicron and VLDL remnants that fail to get cleared at a normal rate by hepatic receptors because of the presence of less active polymorphic forms of apoE. Triglycerides and TC are both elevated and accompanied by corneal arcus, xanthelasma, tuberoeruptive xanthomas (groups of flat or yellowish raised nodules on the skin over joints, especially the elbows and knees), and palmar striae (yellow raised streaks across the palms of the hand). The disorder predisposes to premature atherosclerosis.

Familial lipoprotein lipase deficiency

Familial lipoprotein lipase deficiency is characterised by marked hypertriglyceridaemia and chylomicronaemia, and usually presents in childhood. It has an incidence of 1 per 1 million individuals (Gotoda et al., 1991) and is due to a deficiency of the extrahepatic enzyme lipoprotein lipase, which results in a failure of lipolysis and the accumulation of chylomicrons in plasma. The affected patient presents with recurrent episodes of abdominal pain, eruptive xanthomas, lipaemia retinalis (retinal deposition of lipid) and enlarged spleen. This disorder is not associated with an increased susceptibility to atherosclerosis; the major complication is acute pancreatitis.

Familial apolipoprotein C-II deficiency

In the heterozygous state, familial apoC-II deficiency is associated with reduced levels of apoC-II, the activator of lipoprotein lipase. Typically, levels of apoC-II are 50–80% of normal. This level of activity can maintain normal lipid levels. In the rare homozygous state, there is an absence of apolipoprotein C-II and despite normal levels of lipoprotein lipase, it cannot be activated. Consequently, homozygotes have triglyceride levels from 15 to greater than 100 mmol/L (normal range <1.7 mmol/L) and may

Box 24.2 Examples of disorders known to adversely affect the lipid profile

- Anorexia nervosa
- Bulimia
- Type 1 diabetes
- Type 2 diabetes
- Hypothyroidism
- Pregnancy
- Inappropriate diet
- Alcohol abuse
- Chronic renal failure
- Nephrotic syndrome
- Renal transplantation
- Cardiac transplantation
- Hepatocellular disease
- Cholestasis
- Myeloma

experience development of acute pancreatitis. Premature atherosclerosis is unusual but has been described.

Lipoprotein(a)

There are many other familial disorders of lipid metabolism in addition to those mentioned earlier, but most are rare. However, a raised level of lipoprotein(a), otherwise known as Lp(a), appears to be a genetically inherited determinant of CVD. Lp(a) is an LDL-like particle synthesised by the liver and first described more than 40 years ago. It is found in the serum of virtually everyone in a wide concentration range (0.01–2 g/L), with up to 70% of the variation in concentration being genetically determined. The concentration of Lp(a) is not normally distributed, and the contribution of inheritance to circulating Lp(a) levels is more pronounced than for any other lipoprotein or apoprotein. A parental history of early-onset CVD is associated with raised concentrations of Lp(a), and these appear to play a role in both atherogenesis and thrombosis. An important component of Lp(a) is apo(a), which is structurally and functionally similar to plasminogen and may competitively bind to fibrin and impair fibrinolysis.

Concentrations of Lp(a) greater than 0.3 g/L occur in about 20% of Caucasians (von Depka et al., 2000) and increase the risk of coronary atherosclerosis and stroke. Under a wide range of circumstances, there are continuous, independent, and modest associations of Lp(a) concentration with the risk of CHD and stroke (Erqou et al., 2009).

Secondary dyslipidaemia

Dyslipidaemias that occur secondary to a number of disorders (Box 24.2), dietary indiscretion, or as a side effect of drug therapy (Table 24.2) account for up to 40% of all dyslipidaemias. Fortunately, the lipid abnormalities in secondary dyslipidaemia can often be corrected if the underlying disorder is treated, effective dietary advice implemented, or the offending drug withdrawn.

On occasion, a disorder may be associated with dyslipidaemia, but not the cause of it. For example, hyperuricaemia (gout) and hypertriglyceridaemia co-exist (Emmerson, 1998). In this particular example, neither is the cause of the other, and treatment of

Table 24.2 Typical effects of selected drugs on lipoprotein levels

Drug	VLDL-C	LDL-C	HDL-C
Alcohol	↑	0	↑

one does not resolve the other. There are, however, two notable exceptions to the rule with this example: nicotinic acid and fenofibrate. Both drugs reduce triglyceride levels, but nicotinic acid increases urate levels, whereas fenofibrate reduces them by an independent uricosuric effect.

Some of the more common disorders that cause secondary dyslipidaemias include the following.

Diabetes mellitus

Premature atherosclerotic disease is the main cause of reduced life expectancy in patients with diabetes. The atherosclerotic disease is often widespread, and complications such as plaque rupture and thrombotic occlusion occur more often and at a younger age. The prevalence of CHD is up to four times higher among patients with diabetes, with more than 80% likely to die of a CV event (Haffner et al., 1998; Malmberg et al., 2000). LDL levels are a stronger predictor of CV risk in patients with diabetes than blood glucose control or blood pressure.

Type 1 diabetes. In patients with type 1 diabetes, HDL-C may appear high, but for reasons which are unclear it does not impart

the same degree of protection against CVD as in those without diabetes. It is, therefore, not appropriate to use CV risk prediction charts that utilise the TC:HDL-C ratio in patients with type 1 diabetes. Patients with type 1 diabetes have a twofold to threefold increased risk of development of CVD. [NICE \(2014\)](#) recommends that people with type 1 diabetes should be considered for treatment with a statin if they are more than 40 years old or have had type 1 diabetes for more than 10 years, or have evidence of kidney disease or other CVD risk factors.

Type 2 diabetes. Patients with type 2 diabetes typically have increased triglycerides and decreased HDL-C. Levels of TC may be similar to those found in individuals without diabetes, but the patient with type 2 diabetes often has increased levels of highly atherogenic small, dense LDL particles.

Individuals with type 2 diabetes and older than 40 years, but without CVD, are often considered to have the same CV risk as patients without diabetes who have survived an MI. This assumption is generally appropriate but influenced by patient age, duration of diabetes and gender, and it holds better for women than men. This probably occurs because the impact of type 2 diabetes is more marked in women than men. In previous [NICE \(2008b\)](#) guidance, the criteria for at risk was age older than 40 years but with one other risk factor present, for example, hypertension, obesity, smoker, etc. [NICE \(2014\)](#) now recommends CV risk assessment using QRisk2 for individuals with type 2 diabetes to assess whether a statin should be considered.

Hypothyroidism

Abnormalities of serum lipid and lipoprotein levels are common in patients with untreated hypothyroidism. Hypothyroidism may elevate LDL-C because of reduced LDL receptor activity, and it frequently causes hypertriglyceridaemia and an associated reduction in HDL-C as a result of reduced lipoprotein lipase activity. Remnants of chylomicrons and VLDL-C may also accumulate. However, once adequate thyroid replacement has been initiated the dyslipidaemia should resolve.

Chronic renal failure

Dyslipidaemia is frequently seen in patients with renal failure in the predialysis phase, during haemodialysis, or when undergoing chronic ambulatory peritoneal dialysis. The hypertriglyceridaemia that most commonly occurs is associated with reduced lipoprotein lipase activity and often persists despite starting chronic maintenance renal dialysis. [NICE \(2014\)](#) recommends that people with chronic kidney disease and an estimate of glomerular filtration rate less than 60 mL/min/1.73 m² and/or albuminuria should be considered for a statin.

Nephrotic syndrome

In patients with the nephrotic syndrome, dyslipidaemia appears to be caused by an increased production of apoB-100 and associated VLDL-C along with increased hepatic synthesis of LDL-C and a reduction in HDL-C. The necessary use of glucocorticoids in patients with the nephrotic syndrome may exacerbate underlying lipoprotein abnormality.

Obesity

Chronic, excessive intake of calories leads to increased concentrations of triglycerides and reduced HDL-C. Obesity per se can exacerbate any underlying primary dyslipidaemia. Individuals with central obesity appear to be at particular risk of what has become known as the metabolic or DROP (dyslipidaemia, insulin resistance, obesity and high blood pressure) syndrome which represents a cluster of risk factors. Obesity and sedentary lifestyle coupled with inappropriate diet and genetic factors interact to produce the syndrome ([Kolovou et al., 2005](#)).

Alcohol

In the heavy drinker, the high-calorie content of beer and wine may be a cause of obesity with its associated adverse effect on the lipid profile. In addition, alcohol increases hepatic triglyceride synthesis, which in turn produces hypertriglyceridaemia.

Light-to-moderate drinkers (1–3 units/day) have a lower incidence of CVD and associated mortality than those who do not drink. This protective effect is probably due to an increase in HDL-C and appears independent of the type of alcohol. Men and women should be advised to limit their alcohol intake to 2–3 units/day with a maximum intake of 14 units/week. Everyone should be advised not to binge drink and aim to have two or more alcohol-free days a week ([Department of Health, 2016](#)).

Drugs

A number of drugs can adversely affect serum lipid and lipoprotein concentrations (see [Table 24.2](#)).

Antihypertensive agents. Hypertension is a major risk factor for atherosclerosis, and the beneficial effects of lowering blood pressure are well recognised. It is, however, a concern that, although treatment of patients with some antihypertensives has reduced the incidence of cerebrovascular accidents and renal failure, there has been no major impact in reducing the incidence of CHD. It has been suggested that some of these antihypertensive agents have an adverse effect on lipids and lipoproteins that override any beneficial reduction of blood pressure.

Diuretics. Thiazide and loop diuretics increase VLDL-C and LDL-C by mechanisms that are not completely understood. Whether these adverse effects are dose dependent is also unclear. Use of a thiazide for less than 1 year has been reported to increase TC by up to 7% with no change in HDL-C ([Ames, 1988](#)). However, short-term changes in lipids do not occur with the low doses in current use and in the longer-term there is little effect on TC levels.

β -Blockers. The effects of β -blockers on lipoprotein metabolism are reflected in an increase in serum triglyceride concentrations, a decrease in HDL-C, but with no discernible effect on LDL-C ([Herink and Ito, 2015](#)). β -Blockers with intrinsic sympathomimetic activity appear to have little or no effect on VLDL-C or HDL-C. Pindolol has intrinsic sympathomimetic activity but is rarely used as an antihypertensive agent because it may exacerbate angina. Alternatively, the combined α - and β -blocking effect of labetalol may be of use because it would appear to have a negligible effect on the lipid profile.

Overall, the need to use a diuretic or a β -blocker must be balanced against patient considerations. A patient in heart failure should receive a diuretic if indicated regardless of the lipid profile. Likewise, the patient with heart failure may also benefit from a β -blocker such as bisoprolol or carvedilol. Patients who have had an MI should be considered for the protective effect of a β -blocker, and again the benefits of use will normally override any adverse effects on the lipid profile.

If an antihypertensive agent without adverse effects on lipoproteins is required, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, calcium channel blockers, or α -adrenoceptor blockers can be used.

Oral contraceptives. Oral contraceptives that contain an oestrogen and a progestogen provide the most effective contraceptive preparations for general use and have been well studied with respect to their harmful effects.

Oestrogens and progestogens both possess mineralocorticoid and glucocorticoid properties that predispose to hypertension and diabetes mellitus, respectively. However, the effects of the two hormones on lipoproteins are different. Oestrogens cause a slight increase in hepatic production of VLDL-C and HDL-C, and reduce serum LDL-C levels. In contrast, progestogens increase LDL-C and reduce serum HDL-C and VLDL-C (Herink and Ito, 2015).

The specific effect of the oestrogen or progestogen varies with the actual dose and chemical entity used. Ethinylloestradiol at a dose of 30–35 micrograms or fewer would appear to create few problems with lipid metabolism (Herink and Ito, 2015), while norethisterone is one of the more favourable progestogens even though it may cause a pronounced decrease in HDL-C.

Corticosteroids. The effect of glucocorticoid administration on lipid levels has been studied in patients treated with steroids for asthma, rheumatoid arthritis and connective tissue disorders. Administration of a glucocorticoid such as prednisolone has been shown to increase TC and triglycerides by elevating LDL-C and, less consistently, VLDL-C (Herink and Ito, 2015). The changes are generally more pronounced in women. Alternate-day therapy with glucocorticoids has been suggested to reduce the adverse effect on lipoprotein levels in some patients.

Ciclosporin. Ciclosporin is primarily used to prevent tissue rejection in recipients of renal, hepatic and cardiac transplants. Its use has been associated with increased LDL-C levels, hypertension and glucose intolerance (Herink and Ito, 2015). These adverse effects are often exacerbated by the concurrent administration of glucocorticoids. The combined use of ciclosporin and glucocorticoid contributes to the adverse lipid profile seen in transplant patients. Unfortunately, the administration of a statin to patients treated with ciclosporin increases the incidence of myositis, rhabdomyolysis (dissolution of muscle associated with excretion of myoglobin in the urine) and renal failure. Use of a statin is, therefore, contraindicated in patients who are receiving ciclosporin. Similar interactions between statins and other drugs used to prevent tissue rejection, including tacrolimus and sirolimus, have been reported, and hence concomitant use is not recommended (Wiggins et al., 2016).

Hepatic microsomal enzyme inducers. Drugs such as carbamazepine, phenytoin, phenobarbital, rifampicin and griseofulvin increase hepatic microsomal enzyme activity and can also increase serum HDL-C. The administration of these drugs may also give rise to a slight increase in LDL-C and VLDL-C. The overall effect is one of a favourable increase in the TC:HDL-C ratio.

Cardiovascular risk assessment

Primary prevention

It is recommended that CV risk assessment is carried out every 5 years for all adults from the age of 40 years, with no history of CVD or diabetes, and not receiving treatment for raised blood pressure or dyslipidaemia. A number of CVD risk calculators are available, including QRisk (UK and recommended by NICE; <https://www.qrisk.org/>), SCORE (Europe; <https://www.escardio.org/Education/Practice-Tools/CVD-prevention-toolbox/SCORE-Risk-Charts#>), Joint British Societies-3 (JBS-3; <http://www.jbs3risk.com>) and ASSIGN (Scotland; <http://assign-score.com>).

QRisk2

QRisk2 is based on a database, established in 2003, of anonymised UK primary care patients. It contains more than 20 million sets of encrypted patient records. A cohort of 1.28 million patients without evidence of diabetes mellitus or CVD was identified and followed up for more than 5 years looking for the first development of CVD as an endpoint (Hippisley-Cox et al., 2007).

The following parameters, with any missing values calculated by a complex averaging procedure, are used to calculate a patient's CV risk:

- patient age (35–84 years)
- patient sex
- smoking status
- family history of heart disease aged less than 60 years
- existing treatment with blood pressure agent
- postcode (postcode is linked to Townsend score measure of deprivation)
- body mass index (BMI) (height and weight)
- systolic blood pressure (use current, not pretreatment, value)
- TC and HDL-C
- self-assigned ethnicity (not nationality)
- rheumatoid arthritis
- chronic kidney disease
- atrial fibrillation

The QRisk2 risk assessment tool should be used to assess CVD risk of the primary prevention of CVD in people up to and including age 84 years. It calculates the risk of an individual having a heart attack or stroke in the next 10 years. Patients with a CV risk $\geq 10\%$ over 10 years are considered to be at sufficient risk to warrant lipid-lowering therapy according to current NICE (2014) guidelines, although recommendations as to when to intervene with medication vary internationally. It should be noted that although NICE (2014) recommends using the tool for people with type 2 diabetes, it does not recommend using it for patients with type 1 diabetes.

Other risk assessment tools

Framingham. Up to 2008, risk charts and calculators based on Framingham data were the most widely used and researched approach for calculating CV risk and are the data on which the risk charts discussed earlier are based.

ASSIGN. ASSIGN is a risk calculator based on data from a Scottish population and includes many of the variables utilised in the Framingham-based model. It also takes into account social status, determined by postcode of residence in Scotland, and family history of CVD (Woodward et al., 2007).

SCORE. The European SCORE risk charts were developed from a large dataset tested thoroughly on European data. It operates with hard, reproducible endpoints (CVD death), and risk of CHD and stroke death can be derived separately. The SCORE risk function can be calibrated to each country's national mortality statistics. The SCORE database was developed through combining results from 12 European cohort studies with 250,000 patients' data equating to 3 million person-years of observation and 7000 fatal CV events recorded (European Society of Cardiology, 2017).

Secondary prevention

Patients with CVD and levels of TC greater than 4 mmol/L and LDL-C greater than 2 mmol/L are those most likely to benefit from treatment with lipid-lowering agents. Typical of individuals who fall into this category are patients with a history of angina, MI, acute coronary syndrome (ACS), coronary artery bypass grafting, coronary angioplasty, or cardiac transplantation, as well as patients with evidence of atherosclerotic disease in other vascular beds, such as patients post-stroke or transient ischaemic attack, and those with peripheral arterial disease.

As in the situation with primary prevention outlined earlier, if an individual is to receive a lipid-lowering agent as part of a secondary prevention strategy, the possibility of a familial dyslipidaemia and the need to assess other family members must not be overlooked (NICE, 2008b, 2014).

Treatment

Lipid profile

When a decision has been made to determine an individual's lipid profile, a random serum TC and HDL-C, from which non-HDL-C levels can be calculated, will often suffice. If a subsequent decision is made to commence treatment and monitor outcome, a more detailed profile may be obtained, although it may not be essential if non-HDL-C is used for monitoring. Treatment should not be initiated on the basis of a single random sample.

Serum concentrations of triglycerides increase after the ingestion of a meal and, therefore, if a full lipid profile is to be obtained, patients must fast for 12–15 hours before they can be measured. Patients must also be seated for at least 5 minutes before drawing a blood sample. TC level and HDL are little affected by food intake, and this is, therefore, not a consideration if only these are to be measured. However, it is important that whatever is being measured reflects a steady-state value. For example, during periods of weight loss, lipid concentrations decline as they do following

Box 24.3 Lifestyle targets

- Do not smoke.
- Maintain ideal body weight (BMI 20–25 kg/m²).
- Avoid central obesity.
- Reduce total dietary intake of fat to ≤30% of total energy intake.
- Reduce intake of saturated fats to ≤7% of total fat intake.
- Reduce intake of dietary cholesterol to <300 mg/day.
- Replace saturated fats by an increased intake of monounsaturated fats.
- Increase intake of fresh fruit and vegetables to at least five portions per day.
- Regularly eat fish and other sources of omega-3 fatty acids (at least two portions of fish each week).
- Choose whole-grain varieties of starchy food.
- Reduce intake of sugar and food products that contain refined sugars including fructose.
- Eat at least four to five portions of unsalted nuts, seeds and legumes per week.
- Limit alcohol intake to <14 units/week (men and women).
- Restrict intake of salt to <100 mmol/day (<6 g of sodium chloride or <2.4 g sodium/day).
- Undertake regular aerobic exercise, aiming for 150 min of moderate-intensity aerobic activity or 75 min of vigorous-intensity aerobic activity per week.
- Avoid excess intake of coffee or other caffeine-rich products.

an MI. In the case of the latter, samples drawn within 24 hours of infarct onset will reflect the preinfarction state. In general, measurement should be deferred for 2 weeks after a minor illness and for 3 months after an MI, serious illness or pregnancy.

Once the TC and HDL-C are known, non-HDL-C can be calculated as follows:

$$\text{Non-HDL-C} = \text{TC} - \text{HDL-C}$$

If the TC, HDL-C and triglyceride values are known, then the value for LDL-C can be calculated using the Friedewald equation:

$$\text{LDL-C} = (\text{total cholesterol} - \text{HDL-C}) - (0.45 \times \text{triglyceride}) \text{ mmol/L}$$

The Friedewald equation should not be used in non-fasting individuals, it is less reliable in individuals with diabetes, and it is not valid if the serum triglyceride concentration is greater than 4.5 mmol/L.

Lifestyle

When a decision is made to start treatment with a lipid-lowering agent, other risk factors must also be tackled as appropriate, such as smoking, obesity, high alcohol intake and lack of exercise (Box 24.3). Underlying disorders such as diabetes mellitus and hypertension should be treated as appropriate. Issues around body weight, diet and exercise will be briefly covered in the following sections.

Body weight and waist measurement

The overweight patient is at increased risk of atherosclerotic disease and typically has elevated levels of serum triglycerides,

raised LDL-C and a low HDL-C. This adverse lipid profile is often compounded by the presence of hypertension and raised blood glucose, that is, the metabolic syndrome. A reduction in body weight will generally improve the lipid profile and reduce overall CV risk.

It is useful to classify the extent to which an individual is overweight by calculating their BMI. The BMI (kg/m^2) in all but the most muscular individual gives a clinical measure of adiposity.

- BMI 18.5: underweight
- BMI 18.6–24.9: ideal
- BMI 25–29.9: overweight
- BMI 30–40: obese
- BMI >40: morbidly obese

The distribution of body fat is also recognised as a factor that influences CVD risk. Measurement of waist circumference is perhaps the most accurate indicator of central obesity and correlates well with CVD risk. Target waist circumference should be less than 102 cm in white Caucasian men, less than 88 cm in white Caucasian women, less than 90 cm in Asian men and less than 80 cm in Asian women ([World Health Organization, 2011](#)).

Diet

Diet modification should always be encouraged in a patient with dyslipidaemia, but it is rarely successful alone in bringing about a significant improvement in the lipid profile. Reduction or modification of dietary fat intake has shown variable results on CV morbidity and mortality. Systematic review of dietary interventions to lower cholesterol in community settings indicates that mean reductions in TC of up to 6% can be achieved, although there is a wide variation in response to diet between individuals ([Tang et al., 1998](#)). The overall picture is that patients with dyslipidaemia should receive dietary advice, and a small number of those who adhere to the advice will experience a decline in TC.

There is a common misconception that a healthy diet is one that is low in cholesterol. However, generally it is the saturated fat content that is important, although many components of a healthy diet are not related to fat content. For example, the low incidence of CVD in those who consume a Mediterranean-type diet suggests an increased intake of fruit and vegetables is also important. The typical Mediterranean diet has an abundance of plant food (fruit, vegetables, breads, cereals, potatoes, beans, nuts and seeds), minimally processed, seasonally fresh and locally grown; fresh fruit as the typical daily dessert, with sweets containing concentrated sugars or honey consumed a few times per week; olive oil as the principal source of fat; dairy products (principally cheese and yoghurt) consumed daily in low-to-moderate amounts; 0–4 eggs consumed weekly; and red meat consumed in low-to-moderate amounts. This diet is low in saturated fat (<8% of energy) and varies in total fat content from less than 25% to greater than 35% of energy.

Fish. Regular consumption of the long-chain omega-3 fatty acids, principally eicosapentaenoic acid and docosahexaenoic acid, typically found in fatty fish and fish oils, has been linked to the low levels of CHD seen in Inuits (Eskimos). [Hu et al. \(2002\)](#) studied a group of 84,688 women enrolled in the Nurses' Health Study, all of whom were registered nurses aged 30–55 years and were free from CVD and cancer

at baseline in 1980. During the 16-year follow-up, a significant inverse association between fish intake and incidence of CHD was observed. The Lyon Heart Study ([de Lorgeril et al., 1999](#)) was an intervention trial involving 605 survivors of first MI, of whom 303 were randomised to be control patients and 302 were advised to adopt a Mediterranean-style diet, including use of margarine with higher levels of linoleic acid and α -linoleic acid (ALA) than olive oil. In the experimental group the relative risk of MI-caused death was 0.44 and that of cardiac death and nonfatal MI was 0.28, whereas other clinical events such as unstable angina, heart failure and stroke were also less frequently observed.

Consumption of omega-3 fatty acids decreases triglyceride levels but has little effect on LDL-C or HDL-C. The proposed mechanisms are thought to involve the omega-3 fatty acids and their antiarrhythmic properties, ability to reduce blood pressure and heart rate, lower triglyceride levels, stimulate endothelial-derived nitric oxide, increase insulin sensitivity, decrease platelet aggregation and decrease proinflammatory eicosanoids. There would appear to be benefits in consuming at least two portions (portion = 140 g) of fish per week, including a portion of oily fish, particularly in those who have had an MI. Pregnant women are advised to limit their intake of oily fish to two portions per week because of the potential accumulation of low-level pollutants in the fish.

Trans fats. Trans fats are unsaturated fatty acids with at least one double bond in the trans configuration. They are formed when vegetable oils are hydrogenated to convert them into semi-solid fats that can be incorporated into margarines or used in commercial manufacturing processes. Trans fats are typically found in deep-fried fast foods, bakery products, packaged snack foods, margarines and crackers. When the calorific equivalent of saturated fats, cis unsaturated fats and trans fats are consumed, trans fats raise LDL-C, reduce HDL-C and increase the ratio of TC:HDL-C. In addition to these harmful effects, trans fats also increase the blood levels of triglycerides, increase levels of Lp(a) and reduce the particle size of LDL-C, all of which further increase the risk of CHD. It is, therefore, necessary to reduce the dietary intake of trans fatty acids to less than 0.5% of total energy intake, and this has led to calls for a complete ban on trans fats in foods.

Stanol esters and plant sterols. The availability of margarines and other foods enriched with plant sterols or stanol esters appears to increase the likelihood that LDL-C can be reduced by dietary change. Both stanol esters and plant sterols at a maximum effective dose of 2 g/day inhibit cholesterol absorption from the gastro-intestinal tract and reduce LDL-C by an average of 10%. They compete with cholesterol for incorporation into mixed micelles, thereby impairing its absorption from the intestine. However, as with other dietary changes, the reduction seen varies between individuals and is probably dependent on the initial cholesterol level and the total amount of stanol esters and/or plant sterols ingested. There is currently no evidence that ingestion lowers the risk of CV events, and as a result they are not recommended by [NICE \(2014\)](#).

Antioxidants. Antioxidants occur naturally in fruit and vegetables and are important components of a healthy diet. Their consumption is thought to be beneficial in reducing the formation of

atherogenic, oxidised LDL-C. Primary and secondary prevention trials with antioxidant vitamin supplements, however, have not been encouraging. Neither vitamin E nor β -carotene supplements would appear to reduce the risk of CHD but likewise have not been shown to be harmful.

Salt. Dietary salt (sodium) has an adverse effect on blood pressure and, therefore, a potential impact on CHD and stroke. It is recommended that the average adult intake of sodium should be reduced from approximately 150 mmol (9 g) to 100 mmol (6 g) of salt or even lower. This intake can be reduced by consuming fewer processed foods, avoiding many ready meals and not adding salt to food during cooking and at the table.

Exercise

Moderate amounts of aerobic exercise (brisk walking, jogging, swimming, cycling) on a regular basis have a desirable effect on the lipid profile of an individual. These beneficial effects have been demonstrated within 2 months in middle-aged men exercising for 30 minutes, three times a week. Current advice from [NICE \(2014\)](#) is to advise people at high risk of or with CVD to do the following every week:

- at least 150 minutes of moderate-intensity aerobic activity, or
- 75 minutes of vigorous-intensity aerobic activity or a mix of moderate and vigorous aerobic activity.

People are also advised to do muscle strengthening activities on 2 or more days a week that work all major muscle groups (legs, hips, back, abdomen, chest, shoulders and arms). If people cannot perform moderate-intensity physical activity because of comorbidity, medical conditions or personal circumstances, then they need to exercise at their maximum safe capacity.

Exercise per se probably has little effect on TC levels in the absence of a reduction in body weight, body fat or dietary fat. Perhaps the most important effect of regular exercise is to raise levels of HDL-C in a dose-dependent manner according to energy expenditure.

Overall, comprehensive dietary and lifestyle changes (stopping smoking, stress management training and moderate exercise) can bring about regression of coronary atherosclerosis. Unfortunately, many find it difficult to attain or sustain the necessary changes. In others, dietary and lifestyle changes alone will never be adequate or will not bring about the necessary improvement in lipid profile quickly enough. As a consequence, the use of lipid-lowering drugs is widespread.

Drugs

If an individual is found to be at risk of CVD (primary prevention), including people with type 2 diabetes, then all other modifiable risk factors should be addressed, including dietary and lifestyle changes, before statin therapy is offered. CV risk assessment should then be repeated using QRisk2, and if the CV risk remains high, drug therapy in the form of a statin should be offered. In an individual who requires treatment for secondary prevention, a delay of several months in starting treatment is not appropriate and treatment will normally be commenced immediately with a lipid-lowering agent.

Primary prevention

In primary prevention, dyslipidaemia should not be treated in isolation, and management must be embarked upon with clear goals. In addition to lifestyle advice, this will not only address management of dyslipidaemia, but will also seek to optimise use of antihypertensive agents and other CV protective therapies, and achieve tight blood glucose control as appropriate. In patients without evidence of arterial disease, statin treatment must be considered if the risk of CVD is $\geq 10\%$ over 10 years ([NICE, 2014](#)). Although some dispute the benefit of statins in primary prevention ([Kausik et al., 2010](#)), treatment will normally include:

- a lipid-lowering agent such as atorvastatin 20 mg/day (or alternative) with an aim of a 40% decline in non-HDL-C from baseline to indicate adherence to treatment ([NICE, 2014](#));
- personalised information on modifiable risk factors including physical activity, diet, alcohol intake, weight and tight control of diabetes;
- advice to stop smoking; and
- advice (and treatment if appropriate) to achieve blood pressure below 140 mmHg systolic and 90 mmHg diastolic.

Some consider an isolated raised TC:HDL ratio greater than 6.5 warrants treatment regardless of the risk assessment outcome, but this approach has received little support in national treatment guidelines.

For primary prevention in patients with type 1 diabetes who are more than 40 years old or have had type 1 diabetes for more than 10 years or have established nephropathy or other CVD risk factors, atorvastatin 20 mg daily should be offered and lifestyle modifications made ([NICE, 2014](#)). Patients with type 2 diabetes who have a risk of CVD of $\geq 10\%$ over 10 years should be offered atorvastatin 20 mg daily for primary prevention ([NICE, 2014](#)).

Secondary prevention

In individuals diagnosed with CVD or other occlusive arterial disease, treatment should include:

- a lipid-lowering agent such as atorvastatin 80 mg/day (or alternative) with an aim of a 40% decline in non-HDL-C from baseline to indicate adherence to treatment ([NICE, 2014](#));
- advice to stop smoking;
- personalised information on modifiable risk factors including physical activity, diet, alcohol intake, weight and diabetes;
- advice and treatment to achieve blood pressure at least below 140 mmHg systolic and 90 mmHg diastolic;
- tight control of blood pressure and glucose in those with diabetes;
- low-dose aspirin (75 mg daily) or clopidogrel (75 mg daily);
- ACE inhibitors in selected groups, specifically those with left ventricular dysfunction, diabetes, chronic kidney disease or nephropathy;
- β -blocker for those who have had an MI and in those with heart failure; and
- anticoagulant therapy for those with atrial fibrillation and additional stroke risk factors.

In patients with chronic kidney disease, atorvastatin 20 mg daily should be offered for primary or secondary prevention of CVD ([NICE, 2014](#)).

Lipid-lowering therapy

Five well-established classes of lipid-lowering agents are available:

- statins
- cholesterol absorption inhibitors
- fibrates
- bile acid binding agents
- nicotinic acid and derivatives

Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors have recently been introduced for use in selected indications.

Agents such as soluble fibre and fish oils have also been used to reduce lipid levels. The choice of lipid-lowering agent depends on the underlying dyslipidaemia, the response required and patient acceptability. The various groups of drugs available have different mechanisms of action and variable efficacy depending on the lipid profile of an individual. Statins are currently the drugs of choice in the majority of patients with dyslipidaemia due to the overwhelming evidence that treatment with these agents reduces CV events.

Statins

The discovery of a class of drugs, the statins, which selectively inhibit 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA reductase) was a significant advance in the treatment of dyslipidaemia. Their primary site of action is the inhibition of HMG-CoA reductase in the liver and the subsequent inhibition of the formation of mevalonic acid, the rate-limiting step in the biosynthesis of cholesterol. This results in a reduction in intracellular levels of cholesterol, an increase in expression of hepatic LDL receptor, and enhanced receptor-mediated catabolism and clearance of LDL-C from serum. Production of VLDL-C, the precursor of LDL-C, is also reduced. The overall effect is a reduction in TC, LDL-C, VLDL-C and triglycerides with an increase in HDL-C. The reduction in LDL-C occurs in a dose-dependent manner, with a lesser and dose-independent effect on VLDL-C and triglycerides.

Simvastatin was the first member of the group to be marketed in the UK, and it was followed by pravastatin, fluvastatin, atorvastatin, cerivastatin and rosuvastatin. Cerivastatin was withdrawn from the market in 2001 because of an observed increased risk of fatal rhabdomyolysis. Lovastatin is available in the USA and pitavastatin is available in Japan since 2003. The relative potencies of the statins available in the UK are shown in [Table 24.3](#).

The efficacy of statins has been demonstrated in a number of landmark randomised placebo-controlled trials and evaluated by meta-analysis ([Cholesterol Treatment Trialists, 2012](#)). A greater absolute benefit was seen in those trials that involved established CVD, that is, secondary prevention studies, compared with those that involved individuals without established CVD, that is, primary prevention studies. Statins are currently the lipid-lowering agents of choice in both primary and secondary prevention of CVD. Over time there has been a shift towards more intensive lipid lowering, with the [Cholesterol Treatment Trialist Collaboration \(2010\)](#) undertaking a meta-analysis of 26 trials including more than 170,000 participants, concluding further

Table 24.3 Relative potency of statins

Dosage (mg/day)	% Reduction in low-density lipoprotein cholesterol				
	5	10	20	40	80
Fluvastatin	–	–	21	27	33
Pravastatin	–	20	24	29	–
Simvastatin	–	27	32	37	42 ^a
Atorvastatin	–	37	43	49	55
Rosuvastatin	38	43	48	53	–

^aThe Medicines and Healthcare products Regulatory Agency advises that because there is an increased risk of myopathy associated with high-dosage 80 mg/day simvastatin, this dosage should be considered only in patients with severe hypercholesterolaemia and high risk of cardiovascular complications who have not achieved their treatment goals on lower doses, when the benefits are expected to outweigh the potential risks. Adapted from [NICE \(2014\)](#).

reductions in LDL-C safely produce definite further reductions in the incidence of heart attack, of revascularisation and of ischaemic stroke, with each 1.0 mmol/L reduction reducing the annual rate of these major vascular events by just more than a fifth. There was no evidence of any threshold within the cholesterol range studied suggesting that reduction of LDL-C by 2–3 mmol/L would reduce risk by about 40–50%.

There is much debate around the statin of choice. Atorvastatin is currently the preferred agent because of its low cost, safety profile and evidence of efficacy. Of paramount importance is the need to identify patients who need treatment and ensure they receive an appropriate, effective dose of a statin and adhere to treatment. Despite overwhelming evidence of benefit, effectiveness is frequently compromised by poor adherence and persistence. For example, [Helin-Salmivaara et al. \(2008\)](#) studied persistence with therapy in more than 18,000 new statin users and reported 1-year persistence rate of 73% and 10-year persistence rate of 44%. Thirteen percent of patients stopped taking the statin after the first prescription. Patient factors that influence this include perception of risk, side effects of medication, expected treatment duration and socio-demographic factors.

Rosuvastatin is the most potent of the statins, with evidence of impact on morbidity and mortality (see [Table 24.3](#)) ([Ridker et al., 2008](#)). It is normally reserved for those individuals who have had an inadequate response to their first-line statin or failure to tolerate other statins. There remains concern about its safety profile, rhabdomyolysis in particular, when used at the higher dosage of 40 mg/day. It is recommended that this dosage should be used only under specialist supervision in individuals with severe FH and at high CV risk. In patients of Asian origin (Japanese, Chinese, Filipino, Vietnamese, Korean and Indian), the maximum dose should not exceed 20 mg/day because of their increased predisposition to myopathy and rhabdomyolysis.

All the statins require the presence of LDL receptors for their optimum clinical effect, and consequently they are less effective in patients with heterozygous FH because of the reduced

number of LDL receptors. However, even in the homozygous patient where there are no LDL receptors, they can bring about some reduction of serum cholesterol, although the mechanism is unclear.

Adverse effects

Many side effects appear mild and transient. The commonest include gastro-intestinal symptoms, altered liver function tests and muscle aches. Less common are elevation of liver transaminase levels in excess of three times the upper limit of normal, hepatitis, rash, headache, insomnia, nightmares, vivid dreams and difficulty concentrating.

Myopathy (unexplained muscle soreness or weakness) leading to myoglobinuria secondary to rhabdomyolysis is also a rare but serious potential adverse effect of all the statins that can occur at any dose. The risk of myopathy is increased:

- when there are underlying muscle disorders, a family history of muscle disorders, renal impairment, untreated hypothyroidism, alcohol abuse, or the recipient is aged over 65 years or female;
- where statins are co-prescribed with other lipid-lowering drugs, for example, fibrates or nicotinic acid;
- when there is a history of myopathy with another lipid-lowering drug or statin; or
- where there is co-prescription of simvastatin or atorvastatin with drugs that inhibit cytochrome P450 3A4 (CYP3A4).

The statins are a heterogeneous group metabolised by different cytochrome P450 (CYP450) isoenzymes. Simvastatin, atorvastatin and lovastatin are metabolised by CYP3A4, fluvastatin is metabolised by CYP2C9, and pravastatin and rosuvastatin are eliminated by other metabolic routes and less subject to interactions with CYP450 isoenzymes than other members of the family. Nevertheless, caution is still required because a 5- to 23-fold increase in pravastatin bioavailability has been reported with ciclosporin. Simvastatin and atorvastatin do not alter the activity of CYP3A4 themselves, but their serum levels are increased by known inhibitors of CYP3A4 (Table 24.4). Advice has been published on drug interactions with simvastatin (Medicines and Healthcare products Regulatory Agency, 2012) (Table 24.5).

Pleiotropic properties

Although the effect of statins on the lipid profile contributes to their beneficial outcome in reducing morbidity and mortality from CVD, other mechanisms, known as pleiotropic effects, may also play a part. These effects include plaque stabilisation, inhibition of thrombus formation, reduced serum viscosity, and anti-inflammatory and antioxidant activity. These pleiotropic properties, that is, cholesterol-independent effects, are far reaching and reveal a clinical impact beyond a process of reducing TC. For example, lowering TC produces only modest reductions of a fixed, atherosclerotic, luminal stenosis but results in a qualitative change of the plaque and helps stabilise it. This protects the plaque from rupturing and triggering further coronary events.

Inflammation is thought to play a prominent part in the development of atherosclerosis, and increased levels of C-reactive

Table 24.4 Examples of drug interactions involving statins and the cytochrome P450 enzyme pathway

CYP 450 isoenzyme	Inducers	Inhibitors
CYP3A4		
Atorvastatin	Phenytoin	Ketoconazole
Lovastatin	Barbiturate	Itraconazole
Simvastatin	Rifampicin	Fluconazole
	Dexamethasone	Erythromycin
	Cyclophosphamide	Clarithromycin
	Carbamazepine	Tricyclic antidepressants
	Omeprazole	Nefazodone
		Venlafaxine
		Fluoxetine
		Sertraline
		Ciclosporin
		Tacrolimus
		Diltiazem
		Verapamil
		Protease inhibitors
		Midazolam
		Corticosteroids
		Grapefruit juice
		Tamoxifen
		Amiodarone
CYP2C9		
Fluvastatin	Rifampicin	Ketoconazole
	Phenobarbitone	Fluconazole
	Phenytoin	Sulfaphenazole

protein have been used to identify individuals at risk of plaque rupture and consequent MI and stroke. Statins can reduce levels of C-reactive protein.

An important aspect of vascular endothelium dysfunction is the impaired synthesis, release and activity of endothelial-derived nitric oxide, an important and early marker of atherosclerosis. After the administration of a statin, one of the earliest effects observed (within 3 days) is an increased endothelial nitric oxide release, thereby mediating an improvement in vasodilation of the endothelium.

For some, although it has been thought that part of the beneficial effect of statins on CVD could be attributed to an effect on blood coagulation, it is now evident that statins, amongst their many actions, decrease platelet activation and activity, reduce prothrombin activation, factor Va generation, fibrinogen cleavage and factor XIII activation, and increase factor Va inactivation.

Over-the-counter sale

Low-dose (10 mg) simvastatin can be purchased from community pharmacies in the UK to treat individuals at moderate CV risk. Men aged 55–70 years with or without risk factors and men aged 45–54 years or women aged 55–70 years with at least one risk factor (smoker, obese, family history of premature CHD or of South Asian origin) are eligible for treatment. Simvastatin cannot be sold to individuals who have CVD, diabetes or familial dyslipidaemia, or are taking lipid-lowering agents or medication that may interact with simvastatin. The rationale for over-the-counter

Table 24.5 Advice on drug interactions with simvastatin

Avoid with simvastatin as contraindicated	HIV protease inhibitors Azole antifungals Erythromycin, clarithromycin, telithromycin Nefazodone Ciclosporin Danazol Gemfibrozil
Do not exceed a dose of simvastatin 10 mg daily	Other fibrates (except fenofibrate)
Do not exceed a dose of simvastatin 20 mg daily	Amiodarone Amlodipine Verapamil Diltiazem
Avoid when taking simvastatin	Grapefruit juice
Adapted from Medicines and Healthcare products Regulatory Agency (2012) .	

sale is to reduce the risk of a first major coronary event in adults at moderate risk, but sales have been low. Moreover, the evidence base to support the use of 10 mg simvastatin and achieve long-term CV benefit is limited.

Patient counselling

In patients who are receiving a statin, a once-daily regimen involving an evening dose is often preferred. Several of the statins (fluvastatin, pravastatin, simvastatin) are claimed to be more effective when given as a single dose in the evening compared with a similar dose administered in the morning. This has been attributed to the fact that cholesterol biosynthesis reaches peak activity at night. However, atorvastatin and rosuvastatin may be taken in the morning or evening with similar efficacy. A reduction in TC and LDL-C is usually seen with all statins within 2 weeks, with a maximum response occurring by week 4 and maintained thereafter during continued therapy.

Cholesterol absorption inhibitors

Ezetimibe is a 2-azetidione derivative that interacts with a putative cholesterol transporter in the intestinal brush-border membrane and thereby blocks cholesterol re-absorption from the gastro-intestinal tract. It can reduce LDL-C by 15–20% when added to diet. Ezetimibe also brings about a small increase in HDL-C and a reduction in triglycerides. When added to a statin, ezetimibe lowers LDL-C by approximately 20% over and above that achieved by statin therapy alone ([Kastelein et al., 2008](#)).

Ezetimibe monotherapy is recommended by [NICE \(2016a\)](#) for the treatment of primary hypercholesterolaemia in patients where initial statin therapy is contraindicated or not tolerated. Ezetimibe plus statin therapy is recommended for the treatment of primary hypercholesterolaemia where the TC or LDL-C is not controlled, either after dose optimisation of statin therapy or where the dose

is limited by intolerance and a change to an alternative statin is being considered ([NICE, 2016a](#)).

Ezetimibe use has been limited because of a lack of CV outcomes data. The IMPROVE-IT study ([Cannon et al., 2015](#)) demonstrated that the addition of ezetimibe to simvastatin 40 mg in 18,144 patients following an ACS reduced the primary endpoint, a composite of CV death, MI, unstable angina requiring rehospitalisation, coronary revascularisation or stroke, by 6.4% (absolute risk reduction 2% over 7 years) when compared with patients who received simvastatin alone. As a result, ezetimibe is now licensed to reduce the risk of CV events in patients with CHD and a history of ACS when added to ongoing statin therapy or initiated concomitantly with a statin.

Ezetimibe should be prescribed at a dosage of 10 mg daily and can be taken at any time of the day, with or without food. Ezetimibe is contraindicated in patients who have a hypersensitivity to the active substance or excipients, are pregnant or lactating and, if co-administered with a statin, in patients with active liver disease or unexplained persistent elevations in serum transaminases.

Fibrates

The use of fibrates has waned over the last 10–15 years because of lack of efficacy data compared with the statins. However, some agents from this class, such as bezafibrate and fenofibrate, are still used in selected patients. Members of this group include bezafibrate, ciprofibrate, fenofibrate and gemfibrozil. They are thought to act by binding to peroxisome proliferator-activated receptor α on hepatocytes. This then leads to changes in the expression of genes involved in lipoprotein metabolism. Consequently, fibrates reduce triglyceride and, to a lesser extent, LDL-C levels, while increasing HDL-C. Fibrates take 2–5 days to have a measurable effect on VLDL-C, with their optimum effect present after 4 weeks. In addition to their effects on serum lipids and lipoproteins, the fibrates may also have a beneficial effect on the fibrinolytic and clotting mechanisms. The fibrates also produce an improvement in glucose tolerance, although bezafibrate probably has the most marked effect.

In the patient with elevated triglycerides and gout, only fenofibrate has been reported to have a sustained uricosuric effect on chronic administration. Overall, there appears little to differentiate members of the group with regard to their effect on the lipid profile, with fenofibrate and ciprofibrate being the most potent members of the group.

In patients with diabetes, the typical picture of dyslipidaemia is one of raised triglycerides, reduced HDL-C and near-normal LDL-C. Despite the effect of fibrates to reduce triglycerides and increase HDL-C, statins are first-line lipid-lowering agent in most guidelines because of a lack of clear evidence that fibrates prevent CVD in diabetes. Early data for fibrate monotherapy in primary and secondary prevention studies did show promise with a significant reduction in coronary events and stroke, and even a modest impact on CV mortality ([Frick et al., 1987](#); [Rubins et al., 1999](#)). It was hoped that a 5-year study of fenofibrate in individuals with type 2 diabetes ([Keech et al., 2005](#)) would clarify the issue. However, in the final analysis the results provided little convincing evidence to change from recommending a statin, although they did confirm the safety of using a combination of a

Table 24.6 Typical drug interactions involving bile acid binding agents and fibrates^a

Drug group	Interacting drug	Comment
Bile acid binding agents		
Colestyramine/colestipol		All medication should be taken 1 h before or at least 4 h after colestyramine/colestipol to reduce absorption caused by binding in the gut
	Acarbose	Hypoglycaemia enhanced by colestyramine
	Digoxin	Absorption reduced
	Diuretics	Absorption reduced
	Levothyroxine	Absorption reduced
	Mycophenolate mofetil	Absorption reduced
	Paracetamol	Absorption reduced
	Raloxifene	Absorption reduced
	Valproate	Absorption reduced
	Statins	Absorption reduced
	Vancomycin	Effect of oral vancomycin antagonised by colestyramine
Warfarin	Increased anticoagulant effect due to depletion of vitamin K or reduced anticoagulant effect due to binding of warfarin in gut	
Colesevelam		All medication should be taken at least 4 h before or 4 h after colesevelam to reduce absorption caused by binding in the gut
	Ciclosporin	Absorption reduced
	Digoxin	Absorption unchanged
	Glyburide	Absorption reduced
	Levothyroxine	Absorption reduced
	Oral contraceptive	Absorption reduced
	Statins	Absorption unchanged
	Valproate	Absorption unchanged
	Warfarin	Absorption unchanged Increased anticoagulant possible because of depletion of vitamin K
Fibrates	Antidiabetic agents	Improvement in glucose tolerance
	Ciclosporin	Increased risk of renal impairment
	Colestyramine/colestipol	Reduced bioavailability of fibrate if taken concomitantly
	Statin	Increased risk of myopathy
	Warfarin	Increased anticoagulant effect

^aAbsorption studies involve concomitant administration.

statin and fenofibrate. In contrast, gemfibrozil should not be used with a statin. Similarly, the ACCORD study (ACCORD Study Group, 2010) compared combination statin plus fibrate therapy with statin alone in patients with type 2 diabetes and concluded that the combination of fenofibrate and simvastatin did not reduce the rate of fatal CV events, nonfatal MI or nonfatal stroke, as compared with simvastatin alone.

Overall, fibrates should not be used first line to reduce lipid levels in either primary or secondary prevention of CVD (NICE, 2014). Fibrates may be considered first line in patients with isolated severe hypertriglyceridaemia, especially in individuals with triglyceride levels greater than 10 mmol/L where there is a risk of acute pancreatitis (Fortson et al., 1995). In those with mixed hyperlipidaemia, fibrates may be considered when a statin or other agent is contraindicated or not tolerated, or as an add-on therapy where monotherapy is ineffective.

Adverse effects

Overall, the side effects of fibrates are mild and vary between members of the group. Their apparent propensity to increase the cholesterol saturation index of bile renders them unsuitable for patients with gallbladder disease. Gastro-intestinal symptoms such as nausea and abdominal pain are common but transient, and often resolve after a few days of treatment. Myositis has been described and is associated with muscle pain, unusual tiredness or weakness. The mechanism is unclear, but it is thought that fibrates may have a direct toxic action on muscle cells in susceptible individuals.

Fibrates have been implicated in a number of drug interactions (Table 24.6), of which two in particular are potentially serious. Fibrates are known to significantly increase the effect of anticoagulants, while concurrent use with a statin is associated with an increased risk of myositis and, rarely, rhabdomyolysis.

Concurrent use of cerivastatin and gemfibrozil was noted to cause rhabdomyolysis, and this contributed to the withdrawal of cerivastatin from clinical use in 2001.

Bile acid binding agents

The three bile acid binding agents in current use are colestyramine, colestipol and colesevelam. Both colestyramine and colestipol were formerly considered first-line agents in the management of patients with FH but now have limited use. Colesevelam is the most recent of the bile acid binding agents to receive marketing authorisation (in 2004) and consequently has never had a first-line indication. Each of the bile acid binding agents reduce TC and increase triglyceride levels.

Following oral administration, neither colestyramine, colestipol nor colesevelam is absorbed from the gut. They bind bile acids in the intestine, prevent reabsorption and produce an insoluble complex that is excreted in the faeces. The depletion of bile acids results in an increase in hepatic synthesis of bile acids from cholesterol. The depletion of hepatic cholesterol upregulates the hepatic enzyme 7- α -hydroxylase which increases the conversion of cholesterol to bile acids. This increases LDL receptor activity in the liver and removes LDL-C from the blood. Hepatic VLDL-C synthesis also increases, and it is this which accounts for the raised serum triglycerides. There is little evidence that bile acid binders reduce the risk of CV events, and therefore they are not recommended for use for primary or secondary prevention of CVD (NICE, 2014). This class should only be considered for use by specialists as adjunctive therapy where first-line therapies for the management of dyslipidaemia are contraindicated or ineffective.

Colestyramine has a starting dosage of one 4-g sachet twice a day. Over a 3- to 4-week period the dosage should normally be built up to 12–24 g daily taken in water or a suitable liquid as a single dose, or up to four divided doses each day. Occasionally, 36 g/day may be required, although the benefits of increasing the dose above 16 g/day are offset by gastro-intestinal disturbances and poor patient adherence.

Colestipol is also available in a granular formulation and can be mixed with an appropriate liquid at a dose of 5 g once or twice daily. This dose can be increased every 1–2 months to a maximum of 30 g in a single- or twice-daily regimen.

Colesevelam is up to six times as potent as the other bile acid binding agents, probably because of a greater binding to glycolic acid. Whether this translates into better clinical outcomes or more, or less, problems with drugs administered concurrently is unclear. Colesevelam is administered as a 625 mg tablet to a maximum dosage of 4.375 g/day (7 tablets). There is limited evidence to suggest it may achieve a higher adherence than colestyramine or colestipol. It can be taken as a single- or twice-daily regimen.

Adverse effects

With all three agents, side effects are more likely to occur with high doses and in patients older than 60 years. Bloating, flatulence, heartburn and constipation are common complaints. Constipation is the major subjective side effect, and although usually mild and transient, it may be severe.

Colestyramine, colestipol and colesevelam are known to interact with many drugs primarily by interfering with absorption

(see Table 24.6). Whether these absorption-type interactions are qualitatively and quantitatively similar between the different agents is unclear, and the picture is confused when the absorption of a given drug is known to interact with one bile acid binding agent but has not been tested with other members of the group.

Long-term use of bile acid binding agents may also interfere with the absorption of fat-soluble vitamins, and supplementation with vitamins A, D and K is recommended.

Patient counselling

Palatability is often a major problem with the bile acid binding agents, and patients need to be well motivated and prepared for the problems they may encounter.

Both colestyramine and colestipol are available in an orange flavour and/or as a low-sugar (aspartame-containing) powder. Colestipol is without taste and is odourless. Each sachet of colestyramine or colestipol should be added to at least 150 or 100 mL of liquid, respectively, and stirred vigorously to avoid the powder clumping. The powder does not dissolve but disperses in the chosen liquid, which may be water, fruit juice, skimmed milk or non-carbonated beverage. Both may also be taken in soups, with cereals and with pulpy fruits with high moisture content, such as apple sauce.

All patients who are receiving a bile acid binding agent should be advised that reduced absorption with co-administered drugs should be anticipated. Medication that has to be taken should be administered 1 hour before (at least 4 hours for colesevelam) or at least 4 hours after the bile acid binding agent. As a consequence, for individuals receiving multiple-drug therapy, bile acid binding agents may not be appropriate for this reason alone.

Nicotinic acid and derivatives

Nicotinic acid in pharmacological doses (1.5–6 g) lowers serum LDL-C, TC, VLDL-C, apolipoprotein B, triglycerides and Lp(a), and increases levels of HDL-C (particularly the beneficial HDL₃ subfraction). While nicotinic acid and its derivatives may have beneficial effects on the lipid profile and did hold promise in terms of reducing CV events, these products have been withdrawn from the market in the UK due to safety concerns (European Medicines Agency, 2014), following a meta-analysis indicating increased risk of diabetes, myositis and infection. Only patients under the management of a lipid specialist should be prescribed nicotinic acid or nicotinic acid derivatives in line with NICE guidance for FH, with supplies imported on a named patient basis (NICE, 2008a).

The commonest side effect of nicotinic acid is flushing which is most prominent in the head, neck and upper torso and occurs in more than 90% of patients. It is cited as the major reason for discontinuation of treatment in 25–40% of patients. A number of strategies have been devised to overcome this, including co-administration of a cyclo-oxygenase inhibitor such as aspirin. Other strategies include regular consistent dosing, the use of extended-release formulations, patient education, dosing with meals or at bedtime, and the avoidance of alcohol, hot beverages, spicy foods, and hot baths or showers close to or after dosing. Less common side effects of nicotinic acid include postural hypotension, diarrhoea, exacerbation of peptic ulcers, hepatic dysfunction, gout and increased blood glucose levels.

Fish oils

Fish oil preparations rich in omega-3 fatty acids have been shown to markedly reduce serum triglyceride levels by decreasing VLDL-C synthesis, although little change has been observed in LDL-C or HDL-C levels. The effect is, however, inconsistent, and significant increases in LDL-C have also been reported to accompany the use of fish oils. Available commercial products contain omega-3-acid ethyl esters (Omacor) and omega-3-marine triglycerides (Maxepa). Either can be used as an alternative to a fibrate or in combination with a statin to manage hypertriglyceridaemia. However, they are not recommended by [NICE \(2014\)](#) for use in the primary or secondary prevention of CVD.

Soluble fibre

Preparations that contain soluble fibre, such as ispaghula husk, have been shown to reduce lipid levels. The fibre is thought to bind bile acids in the gut and increase the conversion of cholesterol to bile acids in the liver. However, their role in the management of dyslipidaemia is unclear, and they are much less effective than statins in reducing TC and LDL-C.

Proprotein convertase subtilisin/kexin type 9 inhibitors

Key to the removal of LDL cholesterol from the circulation is the LDL receptor PCSK9, a secreted protease that has a role in controlling the number of LDL receptors available by binding LDL-C receptors and preventing them from being expressed on the cell surface. High levels of PCSK9 suppress LDL-C receptor activity, reducing the number of available receptors, and result in raised circulating cholesterol. Inhibition of PCSK9 will facilitate increased LDL-C receptor activity through increased number of receptors, and hence lower circulating cholesterol levels.

Alirocumab and evolocumab, both monoclonal antibody PCSK9 inhibitors, have recently been licensed as options in the management of primary FH and non-FH. In the studies to date, evolocumab with or without background statin therapy has been shown to reduce LDL-C levels between 55% and 75% compared with placebo, and by up to 50% more than ezetimibe ([Raal et al., 2015](#); [Robinson et al., 2014](#); [Stroes et al., 2014](#)). Across five clinical trials involving 2476 patients with FH receiving optimal statin therapy, the average reduction in LDL-C with alirocumab ranged from 36% to 59%, compared with placebo ([U.S. Food and Drug Administration, 2015](#)). The first CV outcomes study investigated the impact of evolocumab in addition to statins in patients with atherosclerotic coronary disease ([Sabatine et al., 2017](#)). Over 2.2 years of follow-up, the addition of evolocumab to statin therapy demonstrated a significant reduction in CV events: 9.8% versus 11.3% for statins alone with an absolute risk reduction of 1.5%.

Currently, these drugs are recommended by NICE as an option for the treatment of primary hypercholesterolaemia or mixed dyslipidaemia provided a set of usage criteria are met, including minimum baseline LDL levels before initiation of treatment ([NICE, 2016b, 2016c](#)).

Both drugs are administered by subcutaneous injection and require storage in a refrigerator. Both are contraindicated in patients with known hypersensitivity to the active ingredient or

excipients. In the trials to date, both drugs have been well tolerated with the most common side effects being symptoms of influenza, nasopharyngitis, upper respiratory tract infection, rash, nausea, backache, arthralgia and injection-site reactions.

Drugs in development

Cholesterol ester transfer protein inhibitors

Low levels of cholesterol ester transfer protein (CETP) are associated with increased levels of HDL-C and reduced CV risk. CETP transfers cholesterol from HDL-C to LDL-C and VLDL-C, thereby altering the HDL-C:LDL-C ratio in a potentially unfavourable manner. In epidemiological studies, higher circulating levels of HDL have been associated with reduced CV events, hence the CETP inhibitors were thought to be a promising therapeutic option. However, of the original four CETP inhibitors in development, three have been abandoned because of increased mortality (torcetrapib) or lack of impact on CV events despite adequate HDL increases (dalcetrapib and evacetrapib). Recently announced results of the REVEAL study of anacetrapib indicate a modest reduction in CV events when added to intensive statin therapy, with no major safety signals ([Bowman et al., 2017](#)). Whether this will result in a change to clinical practice in the future remains to be seen.

Other options

Low-density lipoprotein apheresis

Lipoprotein apheresis is a treatment option used in patients with severe treatment-resistant hypercholesterolaemia. Currently approximately 70 patients are receiving apheresis treatment in England and Wales. Lipoprotein apheresis removes LDL-C, Lp(a) and triglycerides from the plasma. Treatment can lower LDL-C by upwards of 75%, but the effect is transient, and hence treatment needs to be repeated at regular intervals ([Thompson et al., 1995](#)). The efficacy and superiority of lipoprotein apheresis in comparison with standard lipid-lowering therapies is well established; however, there is still uncertainty regarding the ability of lipoprotein apheresis to promote atherosclerotic plaque regression, because its effects are only transient. Furthermore, although LDL apheresis is a highly effective treatment, its uptake and application are somewhat restricted because of its limited availability at specialist centres only and the need for repeated treatments on a weekly or twice-weekly basis.

[NICE \(2008a\)](#) recommends that apheresis is considered for the management of people with clinical homozygous FH and also for those with heterozygous FH in exceptional circumstances, for example, progressive, symptomatic CHD despite maximal oral lipid-lowering therapy and optimal medical-surgical intervention.

Lomitapide

Lomitapide inhibits microsomal triglyceride transfer protein which plays a major role in the assembly and secretion of the lipoproteins in the intestine and liver. As a result, lomitapide inhibits the synthesis of triglyceride-rich chylomicrons in the intestine and VLDL (the precursor of LDL) in the liver. This results in an overall reduction in circulating cholesterol. Lomitapide has been studied

extensively in patients with homozygous FH and at a dosage of 1 mg/kg/day lowered LDL-C by 50.9% from baseline (Cuchel et al., 2007). It is licensed for use only in patients with homozygous FH and may have a role in preventing progression to LDL apheresis or, in those already receiving apheresis, to reduce the frequency of sessions to minimise the impact on quality of life. It is an option for a very small cohort of patients across the country and at a cost of more than £200,000 per annum, usage will remain very low.

Lomitapide is initiated at a low 5 mg dose and increased gradually every 4 weeks to a maximum of 60 mg daily. It is contraindicated where there is hypersensitivity to the active substance or any excipients, in patients with moderate or severe hepatic impairment and those with unexplained persistent abnormal liver function tests, in patients with a known significant or chronic bowel disease such as inflammatory bowel disease or malabsorption, where there is concomitant administration of greater than 40 mg simvastatin or strong or moderate CYP3A4 inhibitors and in pregnancy. Adverse events include gastro-intestinal (mainly diarrhoea), deranged liver function tests (increased levels of aspartate transaminase and/or alanine transaminase and alkaline phosphatase) and increased hepatic fat content and possible steatohepatitis.

Case studies

Case 24.1

Mr DF is a 43-year-old man who has been relatively fit and well for the past 20 years during which he has rarely visited his primary care doctor. Two weeks ago he was admitted to hospital having suffered an MI. On questioning it was revealed that his brother had died in a road traffic accident at the age of 19 and his father had died of CHD at age 54 years.

Examination of Mr DF revealed a corneal arcus and tendon xanthomas. Blood drawn within 2 hours of the onset of his MI revealed TC 7.8 mmol/L, HDL-C 0.9 mmol/L and triglycerides 2.3 mmol/L.

Questions

1. What is the likely diagnosis of Mr DF?
2. What are the treatment options?
3. Mr DF wants to know why he was not identified as being at high risk of CHD before he suffered his MI.

Answers

1. Mr DF has the signs and family history of classic heterozygous FH, most likely because of a genetic defect in the LDL receptor on hepatocytes. His presentation with an acute cardiac event at such an early age is indicative of the raised CV risk present for individuals with FH.
2. Mr DF has a high level of LDL-C, and action is required to reduce it. Appropriate lifestyle advice is necessary, but a high-dose high-intensity statin, such as atorvastatin 80 mg daily, will be required to achieve the desired outcome of at least a 50% reduction in LDL-C. In addition, this patient has recently suffered an MI, which in itself is an indication for a high-intensity statin first line. Mr DF should be managed by a lipid specialist in the first instance and relatives, including any children, should be screened for the presence of FH to allow early initiation of lipid-lowering therapy.

3. Unfortunately, Mr DF's father probably died of heart disease at a time when the practice of detecting affected families and screening first-degree relatives was not widespread. The early, unrelated death of his brother and Mr DF's previous good health would not have given an opportunity to identify any underlying familial disorder. From population data it is known that the prevalence of heterozygous FH is about 1 in 500. Consequently, 120,000 cases would be expected in the UK. However, far fewer cases are known, and cascade screening programmes to track cases in affected families are now recommended once an index case has been identified. A family history of elevated TC or death from CHD before the age of 55 years in a first-degree male relative, as in the case of Mr DF, is an important sign that should highlight the potential risk to other family members. The NHS Health Checks programme in England will assist in the identification of undetected FH.

Case 24.2

Mr PT is a 52-year-old active school teacher. Four years ago he was found to have a raised TC and elevated blood pressure for which he was started on 10 mg simvastatin and 2.5 mg ramipril. Over the years his dose of simvastatin has been gradually increased to 40 mg/day, but apart from this his medication has remained unchanged. He presents at the clinic complaining of aches and pains in his legs over the past 10 days. On questioning he reveals that over recent months he has been eating fresh grapefruit and consuming the occasional glass of grapefruit juice. A tentative diagnosis of myopathy is initially made.

Questions

1. What is the likelihood that grapefruit juice has contributed to Mr PT's problem?
2. Are any additional biochemical tests warranted?
3. Would atorvastatin, rosuvastatin or pravastatin be a more appropriate statin to prescribe if Mr PT wanted to continue with the occasional glass of grapefruit juice?

Answers

1. Grapefruit juice is known to interact with statins through its inhibition of the CYP3A4 enzyme. It has been suggested that it is the furanocoumarin in the grapefruit juice which binds to CYP3A4 and inactivates it in both the liver and the gastro-intestinal tract. As little as 200 mL of grapefruit juice may inhibit CYP3A4, thereby prolonging the half-life of the statin and increasing serum levels. When taken on a regular basis this can increase the risk of dose-related side effects such as rhabdomyolysis and increase the risk of myopathy. Current advice is that grapefruit juice should be avoided altogether when taking simvastatin, regardless of whether it is fresh grapefruit or grapefruit juice, grapefruit juice diluted from concentrate or frozen grapefruit juice.
2. A creatine kinase (CK) level should be checked in patients reporting significant muscle pain to exclude overt myopathy.
 - If CK is raised significantly (>5 times upper normal level), temporary withdrawal of the statin is warranted. Once the CK declines to normal levels, and in view of the suspicion that grapefruit intake was a precipitating factor, the statin could be reinitiated and the patient warned to avoid grapefruit and seek advice promptly should the muscle aches recur.
 - If the CK is normal, then this is a simple myalgia. Grapefruit should be avoided and hopefully the symptoms will resolve. If the pain does not resolve this may have an impact on adherence and an alternate statin should be considered. Of all the

agents currently on the UK market, simvastatin is most likely to cause myalgia and myopathy.

- Atorvastatin is also metabolised by CYP3A4. Although the effect is less dramatic than with simvastatin, the concurrent intake of large quantities of grapefruit juice with atorvastatin is not recommended. Neither pravastatin nor rosuvastatin is substantially metabolised by CYP450 and may be better alternatives. However, when there is a history of myopathy, the need for caution remains because the risk of recurrence is enhanced whatever lipid-lowering agent is prescribed. There are separate concerns regarding the muscle toxicity of rosuvastatin, especially when used at the higher dose of 40 mg.

Because this patient is being treated with a statin for primary prevention, the [NICE \(2014\)](#) guidelines suggest that if a person is not able to tolerate a high-intensity statin, then one should aim to treat with the maximum tolerated dose. Patients should be reassured that any statin at any dose reduces CVD risk. Strategies for dealing with adverse effects include:

- stopping the statin and trying again when the symptoms have resolved to check whether the symptoms are related to the statin,
- reducing the dose within the same intensity group, or
- changing the statin to a lower intensity group.

Case 24.3

Mrs MC is a very active, 51-year-old Caucasian woman who for the past 6 months has been suffering from the classic symptoms of the menopause. Six months ago on a routine visit to her doctor she had her lipid profile measured and this revealed an HDL-C of 0.8 mmol/L and TC of 5 mmol/L. Her blood pressure was 140/80 mmHg. She is currently prescribed no medication but is receiving intensive lifestyle support to lower her cholesterol. She has no other medical history of note other than a record that her mother died at the age of 66 years from a heart attack.

Mrs MC would like to be prescribed hormone replacement therapy (HRT) to control her menopausal symptoms and reduce her risk of CVD.

Questions

- Is it appropriate to prescribe HRT to reduce Mrs MC's CV risk?
- What is the value of measuring HDL-C?
- Does Mrs MC have a risk of CVD that requires treatment with a lipid-lowering agent?

Answers

- The impact of HRT on CV risk has been a subject of much debate over many years. There are no compelling data to justify the use of HRT for the prevention or treatment of CVD in postmenopausal women. In fact, current evidence indicates that HRT may increase the risk of breast cancer, ovarian cancer, CVD and thromboembolic disease. NICE guideline NG23, "Menopause: Diagnosis and Management" ([NICE, 2015](#)), concluded that HRT does not increase CVD risk when started in women younger than 60 years and does not affect the risk of dying of CVD. In addition, [NICE \(2015\)](#) states that HRT with oestrogen alone is associated with no, or reduced, risk of CHD, whereas HRT with oestrogen and progestogen is associated with little or no increase in the risk of CHD. The presence of CV risk factors is not a contraindication to HRT as long as they are optimally managed. If Mrs MC is to be prescribed HRT, then this should be based on the need to control her menopausal symptoms and improve her quality of life.

- HDL-C is a major fraction of cholesterol in serum and an important determinant of CV risk in men and women, even when the level of TC appears to be within the normal range. The incidence of MI is positively correlated with the cholesterol concentration and inversely related to the concentration of HDL-C. The TC:HDL-C ratio is another way to represent this risk and has been shown to have good predictive capabilities in women. Until the menopause, women generally have high levels of HDL-C as a result of the circulating oestrogen. However, following the menopause, HDL-C levels fall rapidly. Lifestyle advice may improve the TC:HDL ratio, especially via increased physical activity.

- With reference to the Qrisk2 CV risk calculator, it can be determined that with a TC:HDL-C ratio of 6.25 (5/0.8) and a systolic blood pressure of 140 mmHg Mrs MC has a 8.2% risk of development of CVD over the next 10 years. This would not automatically make her a candidate for treatment with a lipid-lowering agent because her 10-year CV risk is not more than 10%. Knowledge of Mrs MC's BMI and blood glucose level would be useful additional information, as would a more detailed insight into her family history of CVD. It is only when all the relevant information has been gathered that a final decision on the use of a lipid-lowering agent can be made. It would also be of interest to determine whether the lifestyle support has brought about any improvement in Mrs MC's lipid profile or blood pressure. It is important to recognise that Mrs MC's CV risk will increase as she gets older; if nothing changes in 5 years' time her CV risk will be 11.9%, which is over the threshold for offering statin therapy. She should be offered advice and support to address all modifiable risk factors for CVD including optimising her diet, undertaking regular physical activity and taking steps to control her blood pressure.

Case 24.4

Mr EC is a 48-year-old Pakistani executive for a large, multinational company who works long hours and frequently has to travel abroad. He has a family history of CHD, and 9 months ago he attended a coronary screening clinic for a health check. At the clinic he was found to have a normal blood pressure (132/84 mmHg) but a blood screen revealed a TC of 5.7 mmol/L and triglycerides of 11.8 mmol/L. When he revisited the clinic 4 weeks later after trying to follow dietary advice, a fasting blood sample revealed a TC of 5 mmol/L and triglycerides of 2.7 mmol/L. Liver function tests were normal. He is a non-smoker and claims never to drink more than 10 units of alcohol per week. His BMI is 27 kg/m².

After repeated requests to revisit the clinic he eventually turned up stating he had been away from home for 6 months on a series of business trips. He was trying to keep to a low-fat diet and his blood profile revealed TC 5.7 mmol/L, triglycerides 4.3 mmol/L, HDL-C 0.7 mmol/L and LDL-C 3 mmol/L, non-HDL-C 5 mmol/L.

Questions

- Is Mr EC at high risk of CHD?
- Is Mr EC a candidate for lipid-lowering therapy?
- Should Mr EC's children be screened for dyslipidaemia?

Answers

- Mr EC has a TC:HDL-C ratio of 8.1 (5.7/0.7). Qrisk2 indicates a CVD risk score of 12.3%, which indicates he should be considered for statin therapy after other modifiable risk factors have been

addressed and if QRisk score remains ≥ 10 . However, it should also be remembered that QRisk will underestimate the risk of CVD in those with familial hyperlipidaemia. Mr EC would appear to have a mixed lipidaemia, although it is difficult to interpret non-fasting triglycerides because of the influence of food intake. The low HDL-C and raised BMI indicate he is overweight and/or has a non-ideal lifestyle. Exclusion of diabetes, high alcohol intake, liver and renal impairment is necessary. The possibility of impaired glucose tolerance should not be overlooked and a haemoglobin A_{1c} level should be checked.

- Given the elevated triglycerides and TC, Mr EC is certainly a candidate for lifestyle advice. The use of a statin should be considered if the lifestyle changes do not bring about the necessary improvements in the lipid profile. However, the dyslipidaemia may be secondary to obesity, alcoholism, diabetes or hypothyroidism. If any of these disorders are present, appropriate treatment may correct the underlying dyslipidaemia.
- The family history of CHD is important but is only significant if the age of onset in a parent or sibling was younger than 60 years. In this case, the children should have CV risk assessment undertaken every 5 years from the age of 40 years. However, were a rare familial disorder, for example, familial dysbetalipoproteinaemia, be identified as the causative factor, his children should be screened after puberty because the offending gene may not express itself in the younger child.

Mr EC was subsequently found to have diabetes for which he initially received metformin together with a statin. In this scenario where a patient is diagnosed with type 2 diabetes, it is also important to consider advising children about lifestyle issues and the need to control weight throughout life.

Case 24.5

Mr JT is a 68-year-old man with stable angina. He is currently receiving simvastatin 40 mg daily with well-controlled lipid levels (TC 3.8 mmol/L, LDL-C 1.8 mmol/L, HDL-C 0.9 mmol/L, triglycerides 1.3 mmol/L, non-HDL-C 2.9 mmol/L). He has been receiving simvastatin for the past 7 years and has complained previously about muscle aches, but on this visit he states that his muscle pain has become more troublesome, to the extent that he wishes to stop taking the statin. He asks if there is anything else he can take to control his cholesterol.

Questions

- What action would you take immediately?
- What options are available for Mr JT?
- What would you recommend to Mr JT?

Answers

- A CK level should be checked to exclude myopathy in this patient, because this can occur at any time during statin treatment. Assuming the CK is normal and this is myalgia, then it is still essential to address Mr JT's concerns, because this muscle pain is likely to impact on his adherence over time. An important issue is to ensure that the patient understands why he is taking a statin. The emphasis should be on the expected reduction in the risk of death, heart attack or stroke, rather than on achieving specific cholesterol treatment targets. It may be worth temporarily stopping the statin to demonstrate the causal relationship. If the aches and pains remain despite cessation of simvastatin, then this is unlikely to be a statin-related issue. Many people report aches and pains, particularly as they get older, and it is easy to blame the statin for all of these complaints.

- Options for Mr JT include:

- Reducing the dose of simvastatin: Mr JT has been receiving simvastatin for many years and a simple reduction in dosage to 20 mg/day may improve tolerability without compromising the lipid control substantially. Although an increase in TC and LDL-C is expected with dose reduction, this is usually small (in the order of 6%) and should have little overall impact on risk.
- Substituting an alternative statin: Simvastatin causes more myalgia and myopathy than other statins; therefore, an alternative agent may be better tolerated. Pravastatin is particularly well tolerated and may be a suitable alternative in this patient where potency is less of an issue. Where greater potency is required, atorvastatin (starting at a dosage of 10–20 mg daily and increasing as required to control lipids) or rosuvastatin is a possibility.
- Switching to an alternative agent, such as ezetimibe: Non-statin agents could be used to lower cholesterol but should be reserved for patients who are unable to tolerate statins. Ezetimibe monotherapy may be a suitable alternative if Mr JT cannot tolerate statin therapy after dose reduction and a change in agent.
- Using a low dose of statin plus an alternative agent, such as ezetimibe: This may be a suitable option if this patient can tolerate only small doses of statins and the ezetimibe is introduced to increase the degree of cholesterol lowering achieved. This is a useful combination in some patients, but every effort should be made to maximise the statin dose before adding ezetimibe to ensure maximal outcome benefits.

- For Mr JT, a good starting point would be a reduction in the dosage of simvastatin to 20 mg daily, providing he is willing to continue to take this drug. Myalgia appears to be dose related, and the symptoms may resolve with the lower dose. An alternative is to try pravastatin, perhaps at a starting dosage of 20 mg daily, to see whether it is better tolerated. The dosage will probably need increasing to give adequate control of lipid levels. The use of ezetimibe should be reserved as an additional medicine if only low doses of statins can be tolerated or for monotherapy if that patient cannot be persuaded to take any statin at all. Mr JT should be reviewed regularly over the next few months, until his concerns regarding his lipid-lowering therapy have been addressed, to encourage ongoing adherence.

Case 24.6

Mrs RS is a 36-year-old care assistant from the Philippines with heterozygous FH. She has diffuse, symptomatic coronary artery disease and is currently taking rosuvastatin 20 mg daily and ezetimibe 10 mg daily. Her lipid levels are: TC 8.6 mmol/L (12.3 mmol/L before statin therapy), non-HDL-C 7.7 mmol/L, HDL-C 0.9 mmol/L and LDL-C 7.0 mmol/L.

Questions

- What treatment options would you consider next for Mrs RS?
- How would you monitor therapy?
- What other issues should you consider?

Answers

- Mrs RS needs a significantly greater reduction in her lipid levels than is currently being achieved with statin and ezetimibe. A higher statin dose is contraindicated in view of the ethnicity of Mrs RS. Whilst other classes of oral lipid-lowering therapies could be considered, they are unlikely to deliver a significant further

reduction in LDL. In this case, a lipid specialist may consider the use of a PCSK9 inhibitor, because it is the only drug class able to deliver the significant drop in cholesterol required here. Mrs RS meets the NICE criteria for use of a PCSK9 inhibitor (NICE, 2016b, 2016c); she has heterozygous FH and evidence of CVD, is at high risk of events and her LDL-C level remains greater than the 3.5 mmol/L threshold for use, despite statin and ezetimibe therapy.

- Mrs RS will need to be willing to inject the PCSK9 inhibitor at two weekly intervals and will need adequate training to feel confident in doing this procedure. In the UK, supplies of these drugs are usually delivered by a homecare provider, and the companies offer nursing support to patients at home who require additional support with the injections. Mrs RS should also be followed up by

the lipid specialist within 4–6 weeks of initiation to check she is managing the injections and is not experiencing significant side effects. Her lipid levels will fall rapidly on a PCSK9 inhibitor with a reduction in LDL-C of at least 30% expected within the first 3 months of therapy. If this is not achieved, injection technique and adherence should be checked initially, but if a poor response persists, ongoing treatment should be reviewed.

- Lifestyle issues, particularly diet and physical activity, should be regularly reviewed with appropriate advice, support and/or signposting to enable Mrs RS to make any necessary changes. In view of the presence of heterozygous FH, her first-degree relatives should be screened for FH and offered appropriate advice and treatment.

25 Asthma

Kelly Atack and Ian Clifton

Key points

- Asthma is a common chronic inflammatory disorder of the airways.
- The common symptoms of asthma are breathlessness, wheeze and cough.
- Reversible airflow obstruction is the main physiological measure used in the diagnosis of asthma.
- Asthma triggers should be identified and avoided where possible.
- Poorly controlled asthma remains a significant health burden despite effective therapy.
- The keystone of pharmacological therapy in people with asthma is the delivery of effective anti-inflammatory drugs.
- Well-established national and international guidelines should be used to direct therapy.
- Asthma therapy should be titrated to the lowest effective dose to ensure control with minimal side effects.
- Inhaler technique is crucial to ensure that drug delivery is effective.
- People with asthma should be offered asthma education and self-management plans.

Introduction

Asthma is a chronic inflammatory condition of the airways. The airway inflammation is associated with hyper-responsiveness of the airways and variable airflow obstruction ([Global Initiative for Asthma 2012](#)). These physiological changes result in the classic symptoms of intermittent breathlessness, cough and wheeze.

Asthma was first formally described by Hippocrates approximately 2500 years ago. The term *asthma* is derived from the Greek word *aazein*, which describes panting or laboured breathing.

The modern treatment of asthma began with the use of epinephrine at the turn of the 20th century, followed by the introduction of xanthines, such as theophylline, in the 1920s. During the 1950s oral corticosteroids were introduced, with subsequent introduction of chromoglycate, inhaled corticosteroids and short-acting β -agonists in the 1960s. Subsequently, during the 1980s and 1990s long-acting β -agonists and leukotriene antagonists were introduced, respectively. Therapies, particularly for people with severe asthma, have advanced during the early 21st century with the introduction of targeted biological therapy such as omalizumab (anti-immunoglobulin E [IgE]) and mepolizumab (anti-interleukin-5 [IL-5]).

Epidemiology

Asthma is a common condition, with an estimated 300 million people affected worldwide. The prevalence of the condition varies widely in different populations, and it appears to lie in the range of 1–18% ([Global Initiative for Asthma, 2012](#)). One of the reasons for this variation in prevalence would appear to be the lack of a strict definition. There may also be overlap with other conditions, such as chronic obstructive pulmonary disease. During childhood, asthma tends to be commoner in boys; however, during adulthood, the condition tends to be more frequent in women ([Global Initiative for Asthma, 2012](#)).

Within the UK, the prevalence of asthma is thought to amongst the highest in the world, with an estimated 5.4 million people receiving asthma treatment. Asthma is estimated to affect 1 in 12 adults and 1 in 11 children in the UK. Approximately 900 individuals die from asthma each year in the UK. The National Review of Asthma Deaths identified that the majority of deaths occurred outside of the hospital environment, with only approximately a third (30%) occurring in hospital ([Royal College of Physicians, 2014](#)). A common theme in many studies examining asthma deaths is the underuse of personal asthma action plans (PAAPs), overuse of bronchodilators and underuse of corticosteroids.

Aetiology

The aetiology of asthma is complex and not fully elucidated. It is recognised that there is a complex interaction between multiple genetic and environmental factors. There is evidence for a hereditary component to asthma, and current data suggest that multiple genes are involved in the development of asthma. Numerous environmental factors have been identified as potential factors that influence the risk of developing asthma. These include exposure to allergens, infectious agents, occupational substances, air pollution and diet.

One hypothesis for the increasing prevalence of asthma is the ‘hygiene hypothesis’, which postulates that reduction in early childhood exposure to infectious agents increases the susceptibility to allergic diseases. There are other potential explanations for the increased incidence of asthma in the developing world, including air pollution.

Pathophysiology

Asthma is an inflammatory disorder of the airways, and various inflammatory cells and mediators have been identified as playing an important role in the pathophysiology of asthma.

Bronchial hyper-reactivity is recognised as a key feature of asthma pathophysiology. This results in the airways of people with asthma responding to exposure to particular triggers, which vary from person to person. Exposure to triggers causes constriction of the airway smooth muscle, resulting in bronchoconstriction.

Bronchoconstriction is a result of activation of the parasympathetic pathways of the autonomic nervous system. The release of acetylcholine by the postganglionic nerve fibres activates the M3 muscarinic receptors within the airway smooth muscle. Activation of these receptors results in contraction of the smooth muscle and, consequently, constriction of the diameter of the airway.

The inflammatory process follows the bronchoconstriction, resulting in the production of excess mucus and oedema within the airway. The combination of bronchoconstriction and inflammatory process leads to narrowing of the airway calibre and the classic symptoms of breathlessness, wheeze and cough.

Some people with asthma have brittle asthma, which is classified into two types. Type I brittle asthma is defined by periods of prolonged peak flow variability, whereas type II is characterised by sudden deteriorations on a background of good control and relatively normal lung function.

Over the last few years there has been a paradigm shift in the understanding of asthma pathophysiology. This has led to asthma no longer describing a single disease but a collection of multiple subgroups referred to as phenotypes (Wenzel, 2012).

The majority of people with asthma have an inflammatory process driven by T_H2 processes that tend to be associated with atopy, allergy, type I hypersensitivity and eosinophilic inflammation. Asthma associated with an inflammatory process driven by eosinophilic inflammation has long been recognised to be responsive to treatment with corticosteroids (Brown, 1958). The understanding of non- T_H2 -driven asthma is much less established than that of asthma driven by T_H2 pathways. This subgroup of people with asthma can be associated with a later age of onset, obesity and neutrophilic inflammation. Lack of response to treatment with corticosteroids tends to be a feature of non- T_H2 -driven asthma.

Clinical signs and symptoms

Asthma can present with a number of different symptoms but classically presents with cough, wheeze and breathlessness, often induced by exposure to a wide variety of trigger factors. Individuals with asthma will commonly describe exposure to certain triggers resulting in an increase in symptoms (Table 25.1). The frequency and severity of these symptoms is highly variable between individuals and also within individuals. At times the person with asthma may be asymptomatic, whereas at other times the person may have a high level of symptoms potentially requiring hospital admission. Asthma tends to demonstrate diurnal variation, generally with increased symptoms at night and early in the morning.

Table 25.1 Potential triggers for asthma symptoms

Type of potential trigger	Trigger
Allergens	House dust mite Animal dander Moulds Pollens
Infectious agents	Influenza Rhinovirus
Drugs	Non-steroidal anti-inflammatory drugs Beta blockers Prostaglandins
Occupational	Isocyanates Wheat flour Soy caster bean Latex Formaldehydes Hair colourants
Other	Sulphites Nitrogen oxides Sulphur dioxide Exercise Cold air Stress

There are a number of signs of acute asthma, including tachypnoea (increased rate of respiration), wheeze on expiration and use of accessory muscles of respiration. In children there may also be indrawing of the intercostal muscles.

Investigations

The diagnosis of asthma is a clinical one; there is no standardised definition of the type, severity or frequency of symptoms, nor of the findings on investigation (British Thoracic Society [BTS] and Scottish Intercollegiate Guidelines Network [SIGN], 2016). A key part of the diagnostic process is to identify the characteristic symptoms of asthma from the patient. Due to the long-term nature of the condition, the history obtained from the patient is not sufficient to make the diagnosis, and it is important to use diagnostic tests to provide objective evidence of asthma.

Lung function testing

Lung function testing is a key part of the diagnosis and monitoring for people with asthma. Lung function testing in asthma aims to demonstrate the presence of reversible airflow obstruction. It can also provide a guide to response to treatment and detect deterioration in asthma control. There are a number of different methods for testing lung function, all of which have particular strengths and weaknesses.

Peak expiratory flow rate (PEFR) is the maximum airflow rate during forced expiration. A peak flow meter can measure

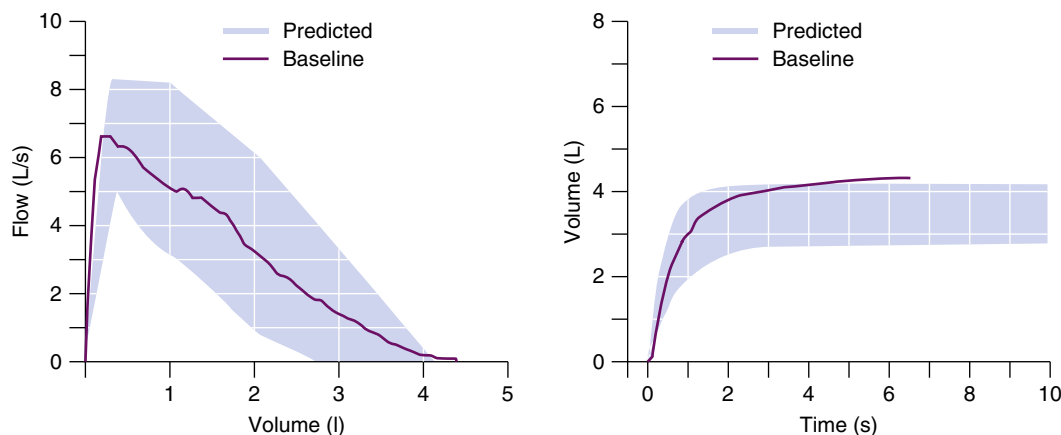

Fig. 25.1 Example flow–volume loop (A) and volume–time curve (B).
FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.

Table 25.2 Spirometry parameters

Abbreviation	Term	Definition
FEV ₁	Forced expiratory volume in 1 second	Volume of air forcibly expired in 1 second
FVC	Forced vital capacity	Total volume of air forcibly expired at maximum expiration
FEV ₁ %	Percent of predicted FEV ₁	Calculated from normal values for gender, age, height and ethnic origin
FVC%	Percent of predicted FVC	
FEV ₁ /FVC	Ratio between FEV ₁ and FVC	Normal ratio >0.7, if ratio <0.7, then spirometry in keeping with airflow obstruction

FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.

PEFR in a simple portable device that provides a simple and useful method for patients to monitor their asthma. When using a peak flow meter, the patient undertakes three forced expirations through the device and records the highest of the three values.

Measurements of spirometry provide a measure of lung function that is more reproducible than PEFR. Spirometry is preferable to PEFR because it provides a more accurate measure of airflow obstruction. When performing spirometry, an individual inhales to maximal inspiration, then exhales maximally to complete expiration. The spirometry provides a graphical representation of the manoeuvre as a volume–time curve and/or a flow–volume loop (Fig. 25.1). Examination of the spirometry trace as well as review of the spirometry values is important to ensure that the procedure has been performed appropriately. When performing spirometry, the forced expiratory volume in 1 second (FEV₁) and forced vital capacity (FVC) are recorded (see Table 25.2 for definitions of spirometry parameters). This then allows for calculation of the FEV₁/FVC ratio and also the percentage of predicted values.

Further investigations

Sometimes the combination of clinical assessment and measurement of lung function is not sufficient to confirm the diagnosis of asthma, and further investigations are required.

Reversibility testing

Reversibility testing measures the response to bronchodilators or corticosteroids to determine whether there is an improvement in lung function as demonstrated by a change in FEV₁ or PEFR. The use of reversibility testing in individuals with normal or near-normal lung function is limited because there is limited scope for improvement. Salbutamol reversibility is assessed by repeating spirometry after 20 minutes following the administration of 400 micrograms salbutamol. Corticosteroid reversibility can be undertaken by using oral prednisolone for 2 weeks or inhaled beclometasone for 6–8 weeks.

There are a number of definitions of a positive reversibility trial. The European Respiratory Society/American Thoracic Society (ERS/ATS) guidelines define a positive test as greater than 200 mL or 12% improvement in FEV₁ and/or FVC in response to treatment with bronchodilators or corticosteroids (Pellegrino et al., 2005). The National Institute for Health and Care Excellence (NICE) uses a higher threshold requiring greater than 400 mL improvement in FEV₁ (NICE, 2010).

Measurement of airway hyper-responsiveness

Testing of airway hyper-responsiveness has long been established as a research tool, and such testing is now starting to become more routine in clinical practice. These tests are generally more useful in patients with normal or near-normal spirometry. The tests aim to demonstrate bronchoconstriction in response to administration

of an inhaled challenge. A number of substances can be used as challenges, including histamine, methacholine and mannitol.

Measures of airway inflammation

Eosinophilic airway inflammation can be determined using induced sputum differential counts or measurement of the fraction of exhaled nitric oxide (FeNO). Evidence of active eosinophilic airway inflammation is seen more commonly in people with asthma but also would seem to predict an increased response rate to corticosteroids (Green et al., 2002a).

Other tests

Other tests that can be useful in supporting the diagnosis include measurement of blood eosinophil count, measurement of serum IgE and testing for atopy through either skin-prick testing or IgE testing for specific allergens. For individuals with atypical features, consideration should be undertaken for a chest X-ray (BTS and SIGN, 2016).

Treatment

Chronic treatment

The aim of asthma management is to have complete control and have no exacerbations of the disease. The BTS defines

complete asthma control as the following (BTS and SIGN, 2016):

- no daytime symptoms,
- no night-time waking due to asthma symptoms,
- no requirement for rescue medication,
- no asthma attacks/exacerbations,
- no limitations on activity,
- normal lung function – FEV₁ and/or peak expiratory flow (PEF) greater than 80% predicted or best,
- minimal adverse effects from medication.

BTS guidelines recommend that treatment should begin at the most appropriate step to improve symptoms and lung function as quickly as possible (Fig. 25.2; BTS and SIGN, 2016).

Treatment must be balanced against the risk of adverse effects and should be titrated down where possible whilst keeping good control of asthma. Prior to moving treatment up a step, adherence and inhaler technique must be assessed and any triggers should be removed.

Inhaled corticosteroids

Corticosteroids bind to glucocorticoid receptors within the lung and decrease the formation of cytokines, which produce IgE and promote the expression of IgE receptors. They also inhibit the influx of eosinophils into the lung, therefore reducing overall inflammation. Inhaled corticosteroids (ICSs) are recommended as the second step as a regular preventative therapy in the BTS guidelines

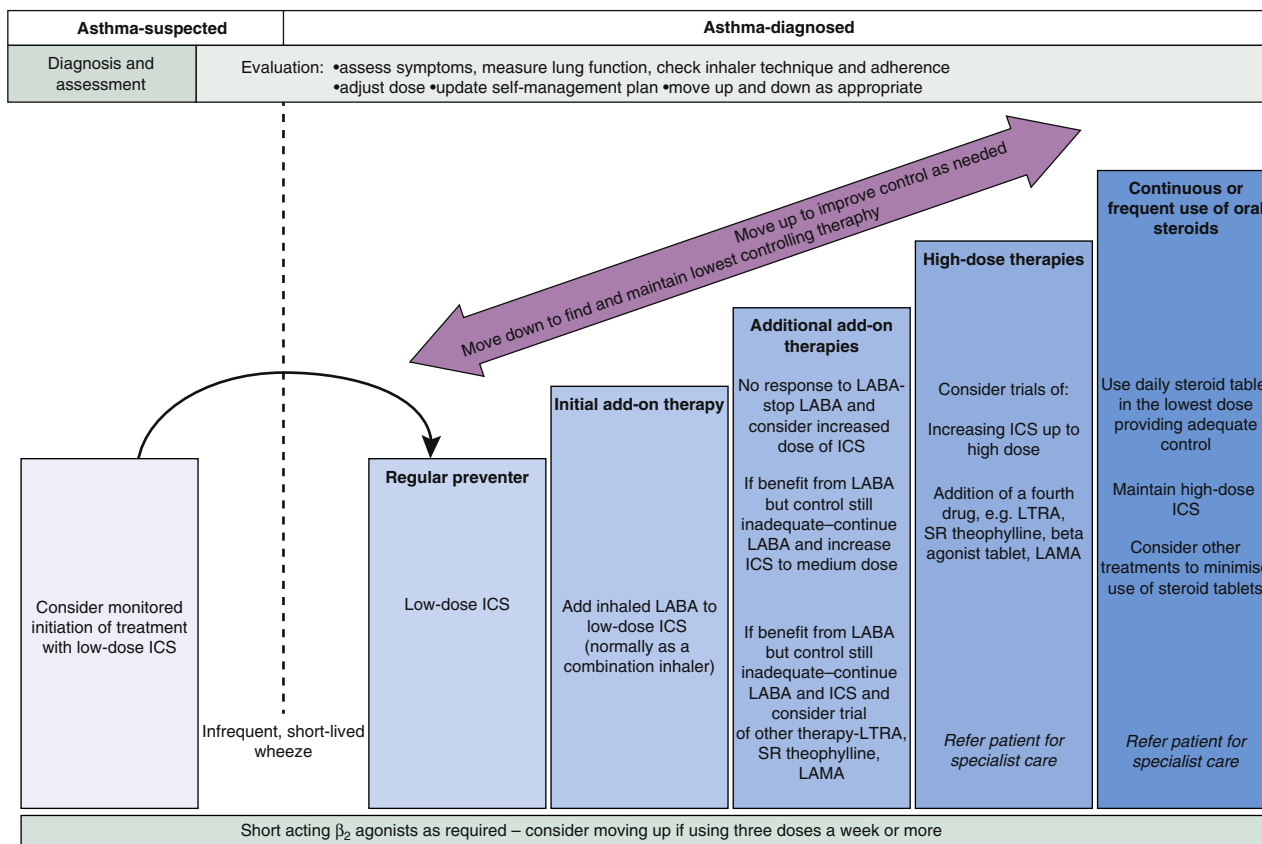

Fig. 25.2 Summary of stepwise management of asthma in adults (BTS and SIGN, 2016).

ICS, Inhaled corticosteroids; LABA, long-acting β -agonist; LAMA, long-acting antimuscarinics; LTRA, leukotriene antagonists; SR, sustained release.

Reproduced from BTS/SIGN British Guideline on the management of asthma by kind permission of the British Thoracic Society.

(BTS and SIGN, 2016), for all people with asthma, except those with very mild and occasional symptoms, where ‘as-required’ symptomatic treatment with short-acting β_2 -agonists alone may be sufficient. Standard doses of ICSs are suggested as 200–400 micrograms/day of beclometasone dipropionate (BDP) or equivalent in 24 hours. For adults, it is recommended that patients commence treatment at a dose of 200–800 micrograms/day of BDP or equivalent. This can be increased to up to 2000 micrograms/day of BDP or equivalent as a fourth step if patients have no response to the addition of a long-acting β -agonist (LABA) or a trial of alternative agents (BTS and SIGN, 2016). It should be noted, however, that at doses of 800 micrograms/day of BDP or equivalent, this will achieve 90% clinical benefit for the patient. At doses higher than this there is a significant increase in adverse effects (Holt et al., 2001). Budesonide, ciclesonide, fluticasone and mometasone are other ICSs that are available and widely used.

Administering drugs via the inhalation route allows the drug to be delivered directly into the lungs, allowing it to take action in the target organ and reducing systemic absorption and therefore the risk of adverse effects. It is imperative to note, however, that using corticosteroids in the inhaled form is not without risk. Patients on long-term, high-dose ICSs (i.e. at a dose of more than 1000 micrograms/day of beclometasone or equivalent) are encouraged to carry a steroid card with them and should be educated of the potential serious adverse effects (BTS and SIGN, 2016). ICSs can cause oral candidiasis and dysphonia; hence, encouraging patients to rinse the mouth after use is important. Long-term, high-dose ICS use will result in some of the steroid being absorbed systemically, potentially leading to adverse effects, including increased blood glucose and susceptibility to diabetes. ICSs can also lead to osteoporosis, increasing the risk of fractures, muscle wasting and impaired wound healing. They can also cause psychiatric reactions and mood disorders, as well as adrenal suppression, which may lead to the patient requiring steroid replacement therapy. Consequently, it is important to inform the patients of the risks associated with ICSs and consider the risk versus benefit of them, particularly in patients with medical conditions that may be exacerbated by the use of steroids.

ICSs are available in a variety of devices, in combination with a LABA or as individual agents. In some circumstances they are used in conjunction with a LABA as a reliever, such as in the ‘Maintenance and Reliever Therapy’ regimen. Traditionally, there were few devices containing ICSs available to patients. More recently there has been an influx of new devices into the UK market. This gives patients and healthcare professionals more choice with regard to selecting the most appropriate device. Care needs to be taken, however, when changing a patient’s inhaled therapy due to the variety of different devices and doses currently available (Table 25.3).

Because there is some systemic absorption, ICSs also have interactions with other medicines. Itraconazole and ritonavir, in particular, interact significantly by inhibiting the metabolism of ICSs and can increase levels enough to induce adrenal suppression.

Short-acting β -agonists

Short-acting β -agonists (SABAs), such as salbutamol and terbutaline, are the first-line step and should be prescribed for all asthma patients and should be used on a when-required basis

(BTS and SIGN, 2016). Patients with very infrequent signs and symptoms of asthma may require only a SABA. Excessive use of SABAs, defined as more than one canister per month, has been associated with an increased risk of asthma death.

Additionally, oral SABAs are not recommended due their higher risk of systemic side effects compared with administration via inhalation.

Long-acting β -agonists

LABAs act on the β_2 -receptors in the smooth muscle of the bronchi, aiding bronchodilation. Inhaled LABAs are a first-line addition to ICSs and can be administered as an individual ingredient or in a combination inhaler with an ICS. The addition of a LABA to a low-dose ICS has been shown to be as effective as increasing the ICS dose and may be associated with fewer side effects. LABAs, such as salmeterol, formoterol fumarate and vilanterol, are designed to be used regularly but have different characteristics in terms of onset and duration of action (Table 25.4). Indacaterol and olodaterol are LABAs designed for once-daily administration; however, they are not currently licensed for use in asthma.

LABAs can exert an effect on β -receptors elsewhere and are not completely selective to β_2 -receptors. Consequently, they also affect the β_1 -receptors in the cardiac muscle, increasing cardiac output and stimulation, leading to tachycardia and arrhythmias. Additionally, they can cause tremor and hypokalaemia. LABAs used alone have been associated with an increased risk of death and therefore should not be used without an ICS (Royal College of Physicians, 2014). The Medicines and Healthcare Products Regulatory Agency (MHRA) recommends that LABAs should ideally be administered in a combination inhaler to aid adherence (MHRA, 2008). There are not many interactions with LABAs, but care must be taken when using LABAs with other agents that cause hypokalaemia. Due to the cardiac risks associated with the use of LABAs, it is important to step down treatment where possible for safety.

The use of LABAs as monotherapy in asthma is associated with significantly worse asthma outcomes and increased asthma mortality compared with treatment with ICSs. This increased mortality is not seen when LABAs and ICSs are used concurrently. Consequently, national (BTS and SIGN, 2016) and international (Global Initiative for Asthma, 2012) guidelines are very clear that long-acting relievers should not be prescribed without an ICS and where possible should be prescribed as a combination ICS/LABA inhaler to prevent people inadvertently taking only the LABA. Table 25.5 demonstrates that there are a large number of ICS/LABA preparations and devices currently on the market and that it is important to be aware of the different strengths when swapping between devices. Some patients may require a regimen requiring the separate components in separate inhaler devices, for example, if ciclesonide is prescribed as an alternative to other ICSs due to oropharyngeal side effects. However, patients in this situation must be made aware of the importance of adhering to both the LABA and the ICS.

When added to an existing ICS, LABAs are used in preference to leukotriene receptor antagonists because they provide greater control and reduce exacerbation rates (Chauhan and Ducharme, 2014).

Table 25.3 Equivalent steroid doses for inhaled corticosteroids

Name	Device	Equivalence to 400 micrograms of beclometasone dipropionate
Beclometasone dipropionate

BD, Twice daily; OD, once daily; pMDI, pressurised metered dose inhaler.

Leukotriene antagonists

Leukotriene antagonists work by reducing the inflammation in the bronchi, by inhibiting leukotriene receptors in the respiratory mucosa and reducing sputum eosinophilia. Leukotriene antagonists such as montelukast and zafirlukast are recommended for use in the UK when patients are not responding to a LABA or as an addition to an ICS/LABA combination inhaler in someone with persistent poor control.

There is some evidence for their use in addition to ICSs, and they have been shown to be particularly useful for people with exercise-induced asthma (Malmstrom et al., 1999) and potentially for patients with allergic rhinitis (Nathan, 2003). They can be taken orally, and there are a number of preparations available, including granules if patients have problems with swallowing solid oral dosage forms.

Leukotriene antagonists are commonly associated with relatively mild side effects of headaches and gastro-intestinal side effects. However, they are also rarely associated with the more serious eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome). This is characterised by vasculitis and eosinophilia, and care should be taken to inform patients of this rare adverse effect. There are minimal drug interactions associated with the leukotriene antagonists.

Long-acting antimuscarinics

Long-acting antimuscarinics (LAMAs) work by binding to the muscarinic M3 receptors in the smooth muscle of the lung to aid bronchodilation. LAMAs may also be trialled in patients who have not responded to an ICS/LABA combination in the fourth step of the BTS guidelines (BTS and SIGN, 2016). Tiotropium

has been demonstrated to improve asthma control and quality of life as well as reduce exacerbation frequency in patients with severe asthma (Rodrigo and Castro-Rodriguez, 2015). The other currently marketed LAMAs – aclidinium, glycopyrronium and umeclidinium – are not currently licensed for use in asthma. It should be noted that they have antimuscarinic side effects throughout the body and can cause dry mouth, constipation, urinary retention and angle-closure glaucoma.

Theophylline preparations

Theophylline and aminophylline are methylxanthines and work as bronchodilators and stimulate respiration. The exact mechanism of action is unclear, and their effect is not specific to the lung. Oral theophylline and aminophylline can be used as an alternative in the same way as the leukotriene antagonists when patients are unresponsive to LABAs or as an addition to an ICS/LABA combination inhaler (BTS and SIGN, 2016).

Methylxanthines have a narrow therapeutic window and require close monitoring of serum theophylline levels to ensure a therapeutic dose and avoid toxicity. Levels should be taken 5 days after commencing treatment or changing doses and annually, with the aim of achieving a serum level of 10–20 mg/L. At toxic levels methylxanthines have effects on the central nervous system, causing tremor and action on cardiac muscle α -receptors that results in increased cardiac output and tachycardia, as well as constricting cerebral blood vessels. Because theophylline may also cause convulsions, care must be taken when prescribing for people with epilepsy. The use of theophylline should be reviewed regularly. The risk of cardiotoxicity and high plasma concentrations should be taken into consideration to ensure that the benefit outweighs the risk.

Table 25.6 Drug interactions with theophylline

Drug	Interaction
Azole antifungals (itraconazole, fluconazole)	May increase theophylline levels
Calcium-channel antagonists (diltiazem, verapamil)	May increase theophylline levels
Carbamazepine	May decrease theophylline levels
Cimetidine	May increase theophylline levels
Fluvoxamine	May increase theophylline levels
Isoniazid	May increase theophylline levels
Lithium carbonate	Increased lithium levels
Macrolide antibiotics (azithromycin, clarithromycin, erythromycin)	May increase theophylline levels
Phenytoin	May reduce theophylline and phenytoin levels
Primidone	Decreased theophylline levels
Quinolone antibiotics (ciprofloxacin, norfloxacin)	May increase theophylline levels
Rifampicin	Decreased theophylline levels
Ritonavir	May increase theophylline levels
St John's wort	May reduce theophylline levels

Theophylline is metabolised using the cytochrome P450 pathway; therefore, its plasma concentration can be decreased by enzyme inducers and increased by drugs that inhibit cytochrome P450 (Table 25.6). Unfortunately, antimicrobials that may be used for the treatment of respiratory tract infections, such as ciprofloxacin and clarithromycin, inhibit cytochrome P450. Therefore, patients should be informed to halve the dose of theophylline whilst taking these medicines, to ensure levels are not increased and cause toxicity. Care should be taken when prescribing medicines concurrently with theophylline, and interactions should be checked to assess the risk of toxicity.

Biological therapies

Biological therapies are slowly being introduced into the UK for treatment of allergic asthma. Omalizumab is a humanised monoclonal anti-IgE antibody. It works to reduce the amount of circulating IgE and reduce the inflammatory response. Omalizumab is being more widely used in particular and is licensed for use in patients with uncontrolled asthma where their asthma is mediated by the presence of IgE. In the UK, it is approved for people with allergic asthma who need continuous or frequent treatment with oral corticosteroids and had at least four courses in the last

year (NICE, 2013). It has been shown to significantly reduce the number of exacerbations in patients with severe asthma who have not improved on standard treatments.

Omalizumab is administered as a subcutaneous injection two to four times weekly, and it can take up to 12–16 weeks before an effect is felt. The dose of omalizumab is calculated according to the individual's weight and serum IgE levels.

Mepolizumab is another humanised monoclonal antibody. It targets IL-5, which is responsible for activating eosinophils, and is used for patients with severe refractory eosinophilic asthma. It has recently been approved for use in the UK for people with severe eosinophilic asthma requiring frequent or daily oral corticosteroids (NICE, 2017).

Because biological therapies are not metabolised, there are minimal drug interactions, although there are concerns regarding the possibility of an anaphylactic reaction during therapy. Patients are therefore expected to have these injections administered in a specialist hospital setting (BTS and SIGN, 2016).

More biological therapies targeted at specific parts of the inflammatory response are being developed to reduce the need for oral steroids and their associated side effects. However, such therapies are likely to be expensive and therefore only used in specialist centres.

Oral corticosteroids

Oral corticosteroids, such as prednisolone, can be used for the treatment of both exacerbations and chronic asthma. A maintenance dose of oral corticosteroids is occasionally used for chronic asthma treatment for individuals requiring multiple courses of oral steroids who are on the fifth step of treatment (BTS and SIGN, 2016). Individuals who may require long-term oral corticosteroids should be referred to a specialist clinic for review of their asthma and treatment plan. These drugs should be used at the lowest dose possible and regularly reviewed, and patients should be monitored for risk of adverse effects. Corticosteroids will reduce lung inflammation; however, they also have systemic adverse effects. The risk of these serious adverse effects must be thoroughly considered to ensure that patients are gaining benefit from oral corticosteroid use. Patients should be fully informed of the risks of long-term oral steroids. Other treatments, such as calcium and vitamin D, bisphosphonates for bone protection and medicines for gastric protection, may also be required when the patient is prescribed oral corticosteroids.

Care must also be taken to consider interactions with oral corticosteroids because they can increase the risk of gastro-intestinal bleeding. Other medicines that increase the risk of this (e.g. non-steroidal anti-inflammatory drugs [NSAIDs] and selective serotonin re-uptake inhibitors [SSRIs]) should be used with caution.

Steroid-sparing agents

Steroid-sparing agents, such as methotrexate, ciclosporin and oral gold, have been used in some patients with difficult-to-treat asthma to reduce the risk of adverse effects from prolonged use of corticosteroids, despite a limited evidence base (Davies et al., 1998; Evans et al., 2000a,b). When used, they are prescribed on a 3-month trial after discussion with the patient about the potential

Table 25.7 Classification of acute asthma severity (BTS and SIGN, 2016)

Severity of exacerbation	Characteristics
Moderate asthma	Increased symptoms PEFR 50–75% of best or predicted No features of acute severe asthma
Acute severe asthma	Any one of the following features: <ul style="list-style-type: none"> • PEFR 33–50% of best or predicted • ≥ 25 breaths/min • Heart rate ≥ 110 beats/min • Inability to complete sentences in one breath
Life-threatening asthma	One of the following features in a patient with acute severe asthma: <ul style="list-style-type: none"> • PEFR $< 33\%$ of best or predicted • $\text{PaO}_2 \leq 8$ kPa • Normal PaCO_2 (4.6–6.0 kPa) • $\text{sO}_2 < 92\%$ • Altered consciousness level • Exhaustion or poor respiratory effort • Haemodynamic instability as defined by cardiac arrhythmias or hypotension • Cyanosis • Silent chest
Near-fatal asthma	One of the following features: <ul style="list-style-type: none"> • $\text{PaCO}_2 > 6.0$ kPa • Need for mechanical ventilation with raised inflation pressures

PaCO_2 , Partial pressure of carbon dioxide in arterial blood; PaO_2 , partial pressure of oxygen in arterial blood; PEFR, peak expiratory forced reserve.

risks. It is recommended they are only used under the supervision of a specialist severe asthma service (BTS and SIGN, 2016).

Cromones

Inhaled sodium cromoglicate and nedocromil have a limited role in the management of asthma, and they are significantly less effective than ICS therapy (BTS and SIGN, 2016). They are rarely used in current practice.

Acute treatment

When assessing a person with an acute exacerbation of asthma, it is important to ask about possible trigger factors, such as recent allergen exposure or upper respiratory tract viral infections (Green et al., 2002b). An acute exacerbation of asthma needs prompt assessment and appropriate treatment because it represents a potentially life-threatening condition.

Risk stratification and assessment

The severity of an acute exacerbation of asthma is determined by a number of different clinical factors and is categorised as moderate, acute severe, life-threatening or near-fatal (Table 25.7). This risk stratification provides guidance on the need for admission to

Box 25.1 Factors lowering the threshold for admission to hospital

- People younger than 18 years
- Poor adherence to medication
- Person living alone
- Psychological problems, such as depression, and alcohol or drug misuse
- Physical or learning disability
- Previous near-fatal attack or brittle asthma
- Persistent exacerbation despite an adequate dose of oral corticosteroids before presentation
- Presentation at night or in the afternoon
- Pregnancy

hospital. Patients with life-threatening or near-fatal asthma should be admitted to hospital for assessment and treatment. Patients with acute severe asthma who have responded to initial therapy and have no other concerning features do not need to be admitted to hospital. Patients should be assessed for a number of other factors because these may influence the threshold for referral for admission to hospital (see Box 25.1).

Treatment

Acute asthma can be life-threatening, and treatment aims to relieve immediate symptoms, improve bronchoconstriction and address airway inflammation. Acute asthma is stratified according to clinical observations and investigations (see Table 25.7). Acute severe asthma is defined as the patient's peak flow reduced to between 33–50% of the patient's best or predicted, increased respiratory rate of more than 25 breaths per minute, heart rate of more than 110 beats per minute and the patient is unable to complete a sentence in one breath. Life-threatening asthma is defined as the peak flow being less than 33% of the patient's best or predicted, oxygen saturation of less than 92%, silent chest, reduced respiratory effort, hypotension and an altered state of consciousness. Sufficient treatment with steroids and monitoring of the patient's condition are key factors in ensuring the patient's recovery. Overuse of β -agonist therapy has been associated with asthma death; therefore, care must be taken and monitoring undertaken.

Oxygen. Patients with severe or life-threatening acute asthma should have their oxygen saturation maintained at 94–98% to treat hypoxia. These patients should be administered oxygen via a face mask, Venturi mask or nasal cannulae as a matter of urgency. Pulse oximetry should be used to measure oxygen saturation where possible; however, this should not be a barrier to the use of oxygen in this situation if unavailable (BTS and SIGN, 2016; O'Driscoll et al., 2008).

Bronchodilators. Inhaled β -agonists should also be administered in emergency situations to treat bronchoconstriction. High doses should be given via the nebulised route where possible. However, if the patient is at home, they can administer 4–6 puffs at one time of a SABA into a large-volume spacer and take multiple breaths in and out of this device. Patients should have their potassium and heart rate monitored due to the potential adverse effects of hypokalaemia and tachycardia associated with nebulised β -agonist use (BTS and SIGN, 2016).

If their response to nebulised β -agonists is poor, or in cases of severe exacerbations, then there is evidence for the addition of nebulised ipratropium for increased bronchodilation (Lanes et al., 1998). Ipratropium is an antimuscarinic and works on the M3 receptors to relax the smooth muscle of the bronchi to induce bronchodilation.

Intravenous salbutamol and terbutaline have also been used; however, these are no longer recommended because nebulised salbutamol is a safer option. The only scenario where they could be considered would be where a patient was not responding to β -agonists via an inhaled route (BTS and SIGN, 2016; Travers et al., 2012).

Corticosteroids. Oral corticosteroids should be administered after an acute asthma attack at the earliest stage possible for the most benefit (Rowe et al., 2007). There is much evidence suggesting they will reduce the risk of another attack and aid recovery time, as well as decrease mortality (Rowe et al., 2007). Oral prednisolone should be administered at a dose of 40–50 mg daily, preferably in the morning to mimic the body's natural cortisol production and reduce adverse effects, including insomnia. If the oral route is unavailable, then intravenous hydrocortisone may be administered at a dose of 100 mg four times daily until the oral route is available again.

Corticosteroid therapy should be continued for at least 5 days but can be extended until the patient's condition has improved. Additionally, corticosteroids can be stopped without needing to wean down the dose unless they have been prescribed for longer than 2 weeks or if the patient is already taking maintenance corticosteroids because this poses a risk of adrenal suppression. The shortest course length possible should be used to protect patients from the adverse effects of corticosteroids (BTS and SIGN, 2016).

Intravenous magnesium. Patients who have not responded well to initial bronchodilator therapy can be administered a dose of intravenous magnesium at a dose of 1.2–2 g over 20 minutes. This can aid bronchodilation and reduce the requirement for admission to hospital (Rowe et al., 2000). It has minimal adverse effects unless repeated doses are administered and hypermagnesaemia develops. Blood pressure, respiratory rate and urine output should be monitored whilst intravenous magnesium is administered. Signs of toxicity, including weakness, nausea, drowsiness and slurred speech, should also be monitored.

Intravenous aminophylline. Intravenous aminophylline may be commenced in severe acute asthma to aid with bronchodilation, although evidence suggests it does not provide additional bronchodilation compared with SABAs (Travers et al., 2012). Care should be taken with regards to the dosing of intravenous aminophylline. A loading dose should be administered to patients who are not taking oral theophylline or aminophylline already. Smoking status also needs to be obtained because patients who smoke require a higher maintenance dose; conversely, patients with heart failure require lower loading doses as per Table 25.8. The risk of arrhythmias and toxicity due to high plasma concentrations should be taken into consideration before commencement. Patients require daily plasma concentration levels to ensure safety. Due

Table 25.8 Dosing of intravenous aminophylline

Patient characteristics	Loading dose
Adult already taking oral theophylline/aminophylline	No loading dose required
Adult not taking oral theophylline/aminophylline	5 mg/kg over 20 min
Maintenance dose	
Elderly adult/adult with heart failure	0.3 mg/kg/h
Nonsmoking adult	0.5 mg/kg/h
Smoking adult	0.7 mg/kg/h

to the risks involved with intravenous aminophylline and also the monitoring involved, this should not be commenced without specialist medical input.

Antibiotics. Acute asthma exacerbations are mostly caused by exposure to allergens or viruses. Consequently, antibiotics are not indicated and should not be commenced without clear evidence of a bacterial cause (Graham et al., 2001).

Patient care

Structure of an asthma review

There are a number of issues that should be addressed during an asthma review to ensure that it is as effective as possible. Firstly the degree of asthma control needs to be assessed. If the person's asthma symptoms are controlled, then potentially a step down in therapy may be indicated. Conversely, when the person's asthma is not at the appropriate level of control, a number of factors will need to be assessed prior to stepping up pharmacological therapy. These include assessment of trigger factors, concordance and inhaler technique (Fig. 25.3).

Assessment of asthma control

One key aspect of an asthma review is determining the level of control. The degree of asthma control can be assessed using a number of different methodologies.

There are several different definitions used to report symptoms in clinical practice. These include:

- Global Initiative for Asthma definition (Global Initiative for Asthma, 2012; Table 25.9),
- Royal College of Physicians 3 questions (Pearson and Bucknall, 1999),
- Asthma Control Questionnaire (Juniper et al., 1999),
- Asthma Control Test (Nathan et al., 2004).

Other physiological tests can be useful to help to monitor asthma control, including lung function (PEFR or FEV₁) or measures of eosinophilic airway inflammation (Green et al., 2002a).

Patient education

It is important to provide high-quality and accurate information to people with asthma. This information is crucial for achievement of adherence with therapy and improving patient outcomes. There are a number of organisations that can help provide information for patients (see [Box 25.2](#)).

Inhaler technique

Good inhaler technique is imperative in optimising asthma treatment. Many new devices are now available. This allows for more patient choice but also requires healthcare professionals to be trained in their use so that they can provide accurate patient training. Optimal inhaler technique is paramount in ensuring the drug is delivered into the lung for it to exert its action. Errors

in inhaler technique have been associated with reduced asthma control ([Giraud and Roche, 2002](#)). Inhaler technique should be reassessed during regular asthma reviews and should also be reassessed after an exacerbation. Inhaler devices should be chosen based on patient choice and the patient’s ability to use them ([BTS and SIGN, 2016](#)). It should be appreciated that every inhaler has a different number of steps that need to be achieved to allow the drug to be accurately delivered. Simplifying information is a good approach to helping patients retain the correct technique.

The most common inhaler device prescribed in the UK is the pressurised metered dose inhaler (pMDI), which contains an aerosol, yet it has been shown that only 21% of patients are able to use pMDIs correctly even after expert training ([Lenney et al., 2000](#)). In stable patients, their inhaler technique should be checked at every asthma review. Patients should also be checked after an

Fig. 25.3 Structure of an asthma review. (Adapted from [Crompton et al., 2006](#).)

Table 25.9 Definition of asthma control

Characteristic	Controlled asthma	Partly controlled asthma	Uncontrolled
	All characteristics present	Any characteristic present	
Daytime symptoms	<2 per week	>2 per week	
Limitations of daily activity	None	Any	
Night-time symptoms or awakening from sleep	None	Any	3 or more characteristics of partly controlled asthma present in any week
Lung function as measured by PEFR or FEV ₁	Normal	<80%	
Use of reliever inhaler	<2 per week	>2 per week	

FEV₁, Forced expiratory volume in 1 second; PEFR, peak expiratory flow rate. Adapted from Global Initiative for Asthma (2012).

exacerbation and each time there is a decision made to switch inhalers. Inhalers should not be changed or the dose increased without ensuring that the patient can use the inhaler optimally. Additionally, using inhalers correctly will reduce waste, improve patient outcomes and reduce the risk of adverse effects such as oral candidiasis (Basheti et al., 2007; Capstick and Clifton, 2012).

Particle size, inspiratory flow and resistance all affect lung deposition of the inhaled drug. The particle size of the drug decides the location in which it will be deposited. Ideally, inhaled drugs should have a particle size of 1–5 micrometres for them to be deposited within the airways and have an effect on the receptors within the bronchi. There are some pMDIs that have been developed with extra-fine particles, allowing a reduced dose of corticosteroid to be used, and these have been shown to have improved lung deposition compared with standard pMDIs (Basheti et al., 2007; Capstick and Clifton, 2012).

Inspiratory flow also has an impact on lung deposition, and each device requires a different level. Dry powder inhalers (DPIs) require a quick inspiratory flow so that the dose is broken up into small enough particles to penetrate the airways, whereas pMDIs require a slower inspiratory flow. Failing to achieve the desired inspiratory flow for any device increases the likelihood that the drug will deposit into the mouth and oropharynx rather than the lungs, leading to a lack of efficacy and an increased risk of oral side effects. The inspiratory flow is determined by the effort of the patient during inspiration and the resistance to airflow within the device. pMDIs have a low resistance to airflow, meaning they require less effort on inhalation, whereas DPIs

have a high resistance to airflow, requiring more effort on inhalation (Capstick and Clifton, 2012).

Inhaler devices can be split into pMDIs, DPIs, breath-actuated metered-dose inhalers (BA-MDIs) and soft-mist inhalers (SMIs), with each device requiring a different technique (Table 25.10). Many patients using pMDIs find the coordination of pressing the canister down to deliver the dose whilst inhaling difficult. BA-MDIs or DPIs may be more appropriate for use in these patients, or the use of a spacer may be beneficial. These strategies remove the need for coordination. Additionally, spacer devices reduce the amount of resistance and decrease particle size, thus allowing improved drug deposition (Capstick and Clifton, 2012).

DPIs may involve the loading of a single capsule manually by the patient or be multiple-dose devices, which may require other manipulation by the patient to load the dose. The only SMI device available in the UK is the Respimat device. This device requires multiple steps to prepare the dose and administer the drug, but it removes the reliance on the patient's inspiratory flow to deliver the drug (Capstick and Clifton, 2012).

Prior to prescribing an inhaler, healthcare professionals must check the patient's inspiratory flow and inhaler technique. The In-Check Dial Inspiratory Flow Meter or inhaler device whistles can be used to test inspiratory flow. Placebo inhalers are also available to help train patients on how to use new devices (Capstick and Clifton, 2012).

Different inhaler devices

Pressurised metered dose inhaler

The pMDI (Fig. 25.4) is a cost-effective device used widely. It is a pressurised aerosol device and can be used with spacer devices if needed. It is available for several drugs, although a popular choice can be difficult to use due to the coordination required. Inhalation should be slow and deep for this device; if patients inhale too quickly using this device, the aerosol will hit the back of the pharynx rather than travel to the lungs and deposit in the desired area.

Breath-actuated metered dose inhaler

Easi-Breathe. The Easi-Breathe device is a BA-MDI and is an aerosol inhaler. The Easi-Breathe device may be favourable for those patients who struggle with the coordination aspect of the pMDI. This device again requires slow and deep inhalation.

Autohaler. The Autohaler device is another type of breath-actuated inhaler that requires priming by pushing a lever into the vertical position prior to inhalation. Slow and steady inhalation is required for this device.

Dry powder inhalers

Ellipta. The Ellipta is a new, simple DPI that is primed by opening the cover completely until a click is heard. It has a dose counter; however, doses may be wasted if the cap is opened multiple times or if the device is not held upright. It requires deep and strong inhalation to achieve drug deposition into the lungs.

Nexthaler. The Nexthaler is a new DPI device (Fig. 25.5) that also requires priming by opening the cap completely. It requires strong and deep inhalation, and if this is achieved, a click should be heard. It has a dose counter and cannot be multi-dosed.

Novolizer. The Novolizer device is a DPI that requires priming by pressing the button down until it clicks. It has a coloured control window that patients may find useful; it changes from red to green as the inhaler is primed, then back to red once the dose is inhaled. It requires deep and strong inhalation, and patients cannot multi-dose using this device.

Fig. 25.5 Nexthaler device. (Reproduced by kind permission of T. Capstick.)

Fig. 25.6 Turbohaler device. (Reproduced by kind permission of T. Capstick.)

Spiromax. The Spiromax is a DPI and requires loading by opening the cap. It requires strong and deep inhalation, has a dose counter and patients cannot multi-dose when using this device.

Turbohaler. The Turbohaler device is another DPI (Fig. 25.6) that requires strong and deep inhalation to achieve deposition of the dose into the lungs. It has a dose counter and requires priming by twisting the bottom of the device to load it prior to inhalation. Fortunately, patients are unable to multi-dose because the counter will continue to count down but will not actually load multiple doses.

Twisthaler. The Twisthaler device is a DPI requiring strong and deep inhalation. It is primed by twisting the cap anticlockwise to remove it and ensuring the pointers on the device and the counter are aligned. It has a dose counter, which will count down with multiple actuations; however, the dose is not loaded multiple times.

Fig. 25.7 Accuhaler device. (Reproduced by kind permission of T. Capstick.)

Fig. 25.8 Easyhaler device. (Reproduced by kind permission of T. Capstick.)

Accuhaler. The Accuhaler is a DPI (Fig. 25.7) that does not require coordination. It has a dose counter; therefore, it can aid patients in ensuring they do not run out of their inhaler. It has increased lung deposition compared with a pMDI and is useful for patients with poor dexterity. The Accuhaler does require loading by pushing down a lever; however, if this dose is loaded several times, there is potential to waste the dose if these doses are not inhaled. There is also potential to take too many doses if the lever has been pushed down multiple times. Inhalation should be strong and deep with this device.

Clickhaler. The Clickhaler device is a DPI and is primed by pushing the button down prior to inhaling; it does not require coordination. There is a risk of multi-dosing with this device if the button is pushed multiple times prior to inhalation.

Easyhaler. The Easyhaler is a DPI (Fig. 25.8) very similar to the Autohaler. It requires priming by pushing the button down in the upright position; however, patients are unable to load multiple doses, as with the Clickhaler. The dose may be lost if the device is not kept upright.

Fig. 25.9 RespiMAT device. (Reproduced by kind permission of T. Capstick.)

Soft-mist metered dose inhaler

RespiMAT. RespiMAT is a soft-mist metered dose inhaler (Fig. 25.9) that requires multiple steps to use efficiently. It requires slow and steady inhalation. Those with dexterity issues may find this device difficult to use due to the cartridge requiring insertion into the device and the requirement to then turn the base of the device and push the button during inhalation.

Adherence

Good adherence to asthma treatment is imperative in improving asthma outcomes and reducing exacerbations. A concordant decision must be made between the healthcare professional and the patient with regards to prescribing medicines. Adherence to treatment for any long-term condition has been shown to be poor, and there are a number of barriers to adherence. Consequently, patient adherence should be monitored regularly and interventions made if patients are having difficulty adhering to their medicines. Time should be taken to discuss barriers with patients, whether these are physical or psychological, intentional or unintentional, and concordant decisions made with regards to overcoming these. Treatment should not be stepped up with regard to treating asthma without assessing and improving adherence where possible.

Management plans

Self-management is a long-established practice in the care of people with asthma. When self-management is delivered to people (and/or their carers) with asthma, there is good evidence for reduced emergency healthcare utilisation, particularly emergency department attendance, hospital admission and unscheduled primary care consultations. From a patient perspective, self-management has been demonstrated to improve asthma control and quality of life, as well as reducing absenteeism from work and school (BTS and SIGN, 2016).

The key aspects of self-management are education that is strengthened by written PAAPs. The PAAPs include advice about recognising the loss of asthma control as defined by symptoms and peak flow. In response to recognition of deteriorating asthma control, there are then two or three action points. These action points can include increasing ICS dose, starting an oral corticosteroid and seeking immediate medical attention.

Case studies

Case 25.1

Mr DM is a 25-year-old man with a history of asthma since childhood. He has a background of poor asthma control; he uses his reliever most days and wakes at night approximately twice per week. He works full-time in a garage, smokes 10 cigarettes per day and has a pet dog at home. He has been admitted to hospital in January with an acute severe exacerbation of asthma. During his hospital stay his regular inhalers were changed from Symbicort 200/6 Turbohaler two puffs twice a day to Seretide 500/50 Accuhaler one puff twice a day.

Questions

1. What asthma reviews should Mr DM have following this exacerbation of his asthma?
2. What components are key to each asthma review?
3. What are the potential causes of Mr DM's poor asthma control?
4. What is the increase in Mr DM's inhaled steroid dose?

Answers

1. Mr DM should be reviewed by a respiratory specialist prior to discharge from hospital. He should also be seen by his primary care doctor or specialist primary care nurse two days following discharge. Subsequent to this he should be seen in a hospital asthma clinic 4 weeks following discharge.
2. At each review Mr DM's asthma control should be assessed, adherence with therapy should be reviewed, aggravating factors identified and inhaler technique checked.
3. Mr DM has a number of factors that may be worsening his asthma, including his smoking and exposure to pets. In view of the time of the year, the most likely cause of his exacerbation may be a viral infection. More information about his job should be elicited because exposure to isocyanates in car-paint fumes can be an asthma trigger.
4. Mr DM was initially taking Symbicort 200/6 Turbohaler two puffs twice daily. This is equivalent to 800 micrograms of beclomethasone per day. His dose has been increased to Seretide 500/50 Accuhaler one puff twice daily, which is equivalent to 2000 micrograms beclomethasone per day.

Case 25.2

Mrs ES is 36 years old. She weighs 76 kg, and her height is 170 cm. Her usual PEFR is 440 L/min. She does not smoke. Mrs ES is prescribed a Fostair 100/6 pMDI two puffs twice a day and salbutamol 100 micrograms/dose pMDI two puffs to be taken as required. She is admitted to hospital with an exacerbation of asthma. Mrs ES's initial observations demonstrate a PEFR of 100 L/min, respiratory rate of 30 breaths/min and sO_2 of 92% on room air.

She is started on nebulised bronchodilators and a steroid but fails to improve.

Questions

1. What severity of asthma exacerbation does Mrs ES have?
2. What bronchodilators and at what dose would be recommended?
3. What dose of steroid would be recommended?
4. Because she is failing to improve, what two other therapies could be considered, and at what dose?

Answers

1. Mrs ES has a life-threatening exacerbation as determined by her oxygen saturation and PEFR. Her oxygen saturation is $\leq 92\%$, and her PEFR is less than 33% of her normal value.
2. Mrs ES should be started on nebulised salbutamol 5 mg and ipratropium 500 micrograms as an immediate response. If she fails to respond clinically to the initial therapy, then repeated (or 'back-to-back') administration of salbutamol can be used until clinical improvement is seen in terms of routine observations and/or PEFR. Once she is more stable, the nebulised bronchodilators should be administered 6 hourly and stopped 24 hours prior to discharge from hospital.
3. She should receive 40–50 mg of oral prednisolone immediately, then once daily for a minimum of 5 days. Because her asthma exacerbation is life-threatening, she should be monitored in hospital until clinically stable for discharge. If she is unable to take the tablets orally, then an alternative would be hydrocortisone 100 micrograms intravenously. Once she is able to take medication orally, then the intravenous hydrocortisone should be swapped to oral prednisolone as previously described.
4. Mrs ES could be considered for intravenous magnesium 1.2–2 g over 20 minutes. Alternatively, she could receive intravenous aminophylline. Aminophylline would require a loading dose of 5 mg/kg (380 mg) over 20 minutes, followed by a maintenance infusion of 0.5 mg/kg/h (38 mg/h). If Mrs ES received intravenous aminophylline, then therapeutic drug monitoring would need to be undertaken daily.

Case 25.3

Mr CM is a 56-year-old man with a history of asthma over the preceding 5 years. His height is 177 cm and weight is 80 kg. He had one exacerbation of his asthma 3 years ago that required hospital admission, and he is currently prescribed Symbicort 200/6 Turbohaler two puffs twice daily. At his asthma review today, Mr CM reported minimal symptoms from his asthma and could not remember the last time he used his reliever inhaler. His peak flow was 580 L/min, which is at his best.

Questions

1. Is Mr CM's asthma controlled?
2. Should Mr CM's asthma treatment be altered?
3. What potential alterations could be used in Mr CM's treatment?

Answers

1. Mr CM's asthma is controlled because he is reporting minimal symptoms, has not had an exacerbation in the last 12 months and has a normal peak flow. He would fulfil the [Global Initiative for Asthma \(2012\)](#) definition of controlled asthma.

- Mr CM's asthma treatment should be considered for a step down in treatment because he meets the current guideline definition for asthma control. He is currently on step 3 of the BTS guideline treatment.
- Mr CM is currently taking Symbicort 200/6 two puffs twice daily. This is a medium-dose combination inhaled steroid and LABA inhaler. Potential changes to his therapy would be either to continue the LABA and reduce his ICS dose (i.e. change to Symbicort 100/6 Turbohaler two puffs twice a day) or, alternatively, to change his inhaler to an equivalent ICS dose as monotherapy.

Case 25.4

Miss CM is 45 years old. She presents with a 6-month history of intermittent breathlessness, wheeze and cough. Miss CM has found that she gets symptoms at least three or four times each week. She has also noticed that her symptoms are worse first thing in the morning, also significantly during the winter when she had a minor upper respiratory tract infection.

She is currently taking no regular medication. Apart from seasonal allergic rhinitis, Miss CM has no other health problems.

Questions

- What is the likely diagnosis?
- What investigations should be undertaken?
- What treatment should be started?
- What non-pharmacological measures should be considered?

Answers

- Miss CM's history is suggestive of a diagnosis of asthma. The intermittent symptoms, diurnal variation and previous atopy (seasonal allergic rhinitis) would all be supportive of this diagnosis.
- Miss CM should undertake a lung function test to confirm the presence of airflow obstruction. Ideally this should be spirometry measurements, although an alternative would be serial peak flow measurements. These measurements should be taken morning and evening for 2 weeks. If these investigations were not conclusive, then Miss CM may need to proceed to reversibility testing or be considered for referral to a hospital specialist for further investigation.
- Initial therapy would be a regular ICS at a starting dose equivalent to beclomethasone 400 micrograms per day.
- The other key non-pharmacological interventions are to provide Miss CM with a PAAP. She should also receive education regarding her condition and training in the use of her inhaler device.

26 Chronic Obstructive Pulmonary Disease

Trevor Rogers and Helen Meynell

Key points

- Chronic obstructive pulmonary disease (COPD) is a leading cause of morbidity and mortality worldwide.
- Reducing exposure to tobacco smoke as well as other recreational drugs, including cannabis, cocaine and heroin; occupational dusts; chemicals and pollutants is an important goal to prevent the onset and progression of COPD.
- Smoking cessation is the single most important intervention to reduce the risk of developing COPD and slow disease progression.
- Risk factors for COPD include host factors (α_1 -antitrypsin deficiency and airway hyper-responsiveness) and exposure to tobacco smoke as well as socio-economic status.
- Pulmonary rehabilitation, incorporating exercise and education, is the intervention that has the greatest impact on quality of life.
- Drugs have an important role in maximising lung function and reducing exacerbations.

Definitions

Chronic obstructive pulmonary disease (COPD) is defined on the basis of airflow obstruction that is not fully reversible. Certainly, this clinical entity is highly prevalent and familiar, usually in older patients with a significant smoking history. It is associated with largely irreversible damage to the airways and lung parenchyma (emphysema). However, based as it is on physiology, this definition is likely also to include other pathologies. For example, there is a subset of patients who meet this definition who have varying degrees of eosinophilia and who share the important characteristic of corticosteroid responsiveness with the other highly prevalent condition in which airflow obstruction is a key feature: asthma. A diagnostic label is only of use if it is helpful in practice, and in this important aspect of corticosteroid responsiveness, the use of the unqualified terms of COPD, and indeed asthma, fail. Reflecting this, there has recently been a move away from these umbrella terms, instead identifying 'treatable traits', such as eosinophilic, steroid-responsive airway disease and those in which it is absent when the emphasis is on bronchodilatation. The term COPD is so firmly entrenched that its use will undoubtedly continue for the foreseeable future, but its limitations do need to be borne in mind.

Epidemiology

COPD is a leading cause of morbidity and mortality. In the UK an estimated 3 million people have the condition (a prevalence of about 5%), of whom only about 900,000 have been diagnosed; a substantial majority, an estimated 2 million people, have not. The diagnosis is usually not made before patients reach their 50s, with prevalence increasing with age. Worldwide prevalence is likely to vary between about 5% and 10%, with estimates varying according to the methods employed in identifying disease.

Aetiology

Whilst smoking is overwhelmingly the commonest cause, it is now well established that dust and fume exposure can also cause the condition. In the developed world this is most often seen in subjects exposed occupationally, as in mining, steel working and similar occupations. Globally, cooking using biomass in poorly ventilated houses is an important cause, especially in women. The rare homozygous α_1 -antitrypsin deficiency predisposes to early-onset emphysema, mostly in smokers, revealing the importance of the balance between neutrophil-derived proteases and anti-proteases in the development of the condition. The major risk factors are summarised in [Table 26.1](#).

Pathology and pathophysiology

The two pathological components of COPD are chronic bronchitis and emphysema, existing in the individual in greater or lesser proportions. Emphysema means dilatation of the airways distal to the terminal bronchiole, with loss of alveolar walls and consequent reduction in the surface area of the alveolar membrane. This impairs gas transfer and can be measured in the laboratory by a reduction in the carbon monoxide gas transfer coefficient (DL_{CO}). Another effect of this tissue damage is a reduction in the traction on airways, increasing lung compliance and making airways prone to collapse during expiration. The tendency is for emphysematous areas to coalesce, which can lead to the formation of large air cysts, called bullae. These are most commonly located in the upper

Table 26.1 Risk factors for the development of chronic obstructive pulmonary disease

Risk factor	Comment
Smoking (including tobacco, heroin, cannabis)	Risk increases with increasing consumption, but there is large inter-individual variation in susceptibility.
Age	Lung function impairment progresses with age.
Gender	Male gender was previously thought to be a risk factor, but this may be due to historical higher rates of smoking in men.
Occupation	Development of COPD is associated with occupational dust and fume exposure, including coal mining, farming, grain-handling and the cement and cotton industries.
Genetic factors	Alpha-1 antitrypsin deficiency is the strongest single genetic risk factor, accounting for 1–2% of COPD.
Air pollution	Death rates are higher in urban areas than in rural areas. Indoor air pollution from burning biomass fuel is also a risk factor, particularly in the developing world.
Socio-economic status	COPD has increased prevalence in individuals of low socio-economic status.
COPD, Chronic obstructive pulmonary disease.	

zones, whereas in α_1 -antitrypsin deficiency, emphysematous areas are more basally distributed. Occasionally giant bullae can develop and occupy over half of the volume of a lung.

The other pathological component is chronic bronchitis. This has been defined clinically, largely in epidemiologic studies, as a chronic cough with sputum production for at least 3 months per year for 2 consecutive years. Pathologically, chronic bronchitis refers to hypertrophy of the mucus-secreting goblet cells in airway walls. This in turn leads to worsening airflow obstruction by luminal obstruction of small airways, epithelial remodelling and alteration of airway surface tension, predisposing to collapse.

At a microscopic level the inflammation is predominantly neutrophilic, and as is usual, this is not responsive to corticosteroids. A relatively small proportion of COPD patients, however, have a significant eosinophilic component to their disease, which is steroid responsive (see later discussion).

Repeated bronchial infections can cause damage to bronchial walls, leading to loss of elasticity, and dilatation, a condition called bronchiectasis, which develops in a proportion of COPD patients. This tends to be associated with copious sputum production, with repeated infective exacerbations and frequently with the emergence of pathogens more resistant to first-line antibiotics.

Both emphysema and bronchitis combine to impair the ability to expel air from the lungs, leading to hyperinflation of the thorax. The consequent overstretching of intercostal muscles and diaphragm places them at a mechanical disadvantage, reducing

their efficiency. Hyperinflation can be exacerbated by exercise, leading to further reduction in efficiency of the respiratory pump, a process known as dynamic hyperinflation.

The syndrome known as hypoxic cor pulmonale is widely misunderstood. It refers to peripheral oedema occurring in COPD with type 2 respiratory failure. It is not, as widely thought, due to simple right ventricular failure and pressure overload: pulmonary artery pressures are similar to those tolerated by many millions of people living at high altitude without difficulty over lifetimes, and right ventricular hypertrophy is rarely found at autopsy. In fact, cardiac output increases during acute episodes. It is likely that the systemic vasodilation caused by elevated carbon dioxide levels causes blood pressure to fall. Renal salt and fluid retention mediated by neurohumoral mechanisms are utilised by the body to maintain blood pressure, as in other forms of high-output cardiac failure. The onset of oedema is an important milestone in the natural history of COPD, suggesting a poor prognosis, albeit much improved by long-term oxygen therapy (LTOT). Whilst loop diuretics are necessary to control oedema, the improvement in gas exchange by optimal medical management is the real key to its treatment.

Clinical manifestations

Symptoms, signs and natural history

The earliest symptoms of COPD are cough and expectoration of sputum. These develop insidiously, often being disregarded as a 'smoker's cough'. Acute infections may lead to episodic breathlessness and increased expectoration, frequently with wheezing, which may be appreciated by the patient and by the clinician on auscultation of the chest. Lung function usually continues to decline at an accelerated rate, particularly whilst smoking continues, although it is likely that many COPD patients start from a lower baseline with reduced lung function from an early age. Due to the substantial reserve of respiratory function, which is only called on at times of stress, such as heavy exertion or respiratory tract infection, more persistent symptoms of breathlessness only occur when large amounts of lung have been destroyed. This is the explanation for the gross underdiagnosis of the condition, especially in its earlier stages. When pulmonary reserve is exhausted, patients often perceive that they have fairly suddenly developed a problem with persistent breathlessness. Thus, identification of early intermittent symptoms and performing spirometry to identify and quantify airflow obstruction can be helpful in concentrating efforts on smoking cessation, at a time when severe disability is completely avoidable.

If emphysema is prominent, the chest becomes visibly hyperinflated, which can also be appreciated by a hyper-resonant percussion note, as part of the clinical examination.

Other symptoms that may be experienced are sleep disturbance, dry mouth, lethargy and weight loss, the last of which is a poor prognostic sign, independent of lung function but more common in advanced disease. If respiratory failure develops, ankle oedema appears, comprising the clinical syndrome of hypoxic cor pulmonale. This may be associated with headache and drowsiness and is clinically associated with a bluish complexion ('cyanosis'), warm peripheries, a bounding pulse and flapping tremor.

Table 26.2 Assessment of severity of airflow obstruction

FEV ₁	Severity
Greater than 80% predicted	GOLD stage 1: Mild
50–79% predicted	GOLD stage 2: Moderate
30–49% predicted	GOLD stage 3: Severe
<30% predicted	GOLD stage 4: Very severe

FEV₁, Forced expiratory volume in 1 second.
Adapted from GOLD (2017).

Two COPD stereotypes have been recognised, the so-called ‘pink puffer’ and ‘blue bloater’. Pink puffers tend to have a more emphysematous phenotype, with marked hyperinflation. They maintain normal blood gases at the expense of a high work of breathing and severe breathlessness. These patients are typically thin. The blue bloater, in contrast, tends to have less obvious hyperinflation and slips into respiratory failure and hypoxic cor pulmonale. These patients are less breathless and tend to be obese. It should be emphasised that whilst these caricatures do exist, they are opposite ends of a spectrum, with many patients having elements of both. Interestingly, pathologically, the lungs of these two stereotypes are very similar, suggesting that the cause for the difference lies in the central respiratory control of breathing.

Investigations

Airflow obstruction is readily measured by spirometry, now conventionally performed, in the assessment of COPD, 10–20 minutes after bronchodilator treatment. Airflow obstruction is present when the ratio of the volume expired in the first second (FEV₁) to the total volume expired (FVC) falls below 70%. The severity of airflow obstruction is assessed by the post-bronchodilator FEV₁ expressed as the percentage of the predicted, according to age and height, and can be graded as shown in Table 26.2.

More detailed physiological evaluation is not usually required, but lung volume measurements and carbon monoxide gas transfer (DL_{CO}) can more precisely quantify the severity of air trapping and emphysema, respectively. When the diagnosis remains in doubt, including when lung function testing reveals features that may indicate interstitial lung disease (pulmonary fibrosis), computed tomography (CT) scanning can be helpful in identifying emphysema, and this is also useful when lung volume reduction treatment is being considered, including the surgical removal of giant bullae. CT scanning can also be useful in identifying the not infrequent co-existence of bronchiectasis. Plain chest radiography has both poor sensitivity and specificity for COPD but is recommended when the diagnosis is first being considered to exclude other pathologies. COPD is a strong risk factor for lung cancer, even after correction for smoking has been included. Therefore, when a smoker presents with persistent new

Table 26.3 Modified Medical Research Council dyspnoea scale

Grade	Degree of breathlessness related to activities
1	Not troubled by breathlessness except on strenuous exercise
2	Short of breath when hurrying or walking up a slight hill
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath when walking at own pace
4	Stops for breath after walking about 100 m or after a few minutes on level ground
5	Too breathless to leave the house, or breathless when dressing or undressing

Adapted from Fletcher et al. (1959).

respiratory symptoms, this is an important differential diagnosis in which the chest X-ray is useful. In COPD the chest X-ray can be normal but often shows hyperinflated lungs, increased lung markings due to bronchial wall thickening and regions of lucency corresponding to areas of emphysema/bullae.

Symptoms can be quantified with differing levels of precision. One of the simplest is the modified Medical Research Council (mMRC) dyspnoea score (Table 26.3), which is readily usable in clinical practice.

More complex and multidimensional instruments exist, generating indices of quality of life, the most widely used of which is the St George Respiratory Questionnaire (SGRQ), which was developed specifically for COPD and is mostly used in clinical trials (Jones et al., 1991). Functional assessments can also be used, including exercise tests, including the 6-minute walk and shuttle walks. Body mass index (BMI) is also prognostically important, with weight loss and cachexia being associated with a poor prognosis. Indeed, a combination of BMI, the severity of airflow obstruction, severity of breathlessness and walking distance can be used to assess prognosis having been incorporated into the Body-Mass Index, Airflow Obstruction, Dyspnoea, and Exercise (BODE) index (Celli et al., 2004).

Classification

COPD has historically been graded in severity according to the degree of airflow obstruction (see Table 26.2). Symptom severity correlates poorly with lung function. The Global Strategy for the Diagnosis, Management, and Prevention of Chronic Obstructive Pulmonary Disease guidelines (GOLD, 2017) have been updated to introduce the ‘ABCD’ algorithm. This is the first classification to combine risk assessment with symptoms to help determine the most effective treatments. This generates a 2 × 2 matrix (Fig. 26.1). It is important to note that there are two ways of qualifying as high risk: higher GOLD score (equating to poor lung function) or frequent exacerbations.

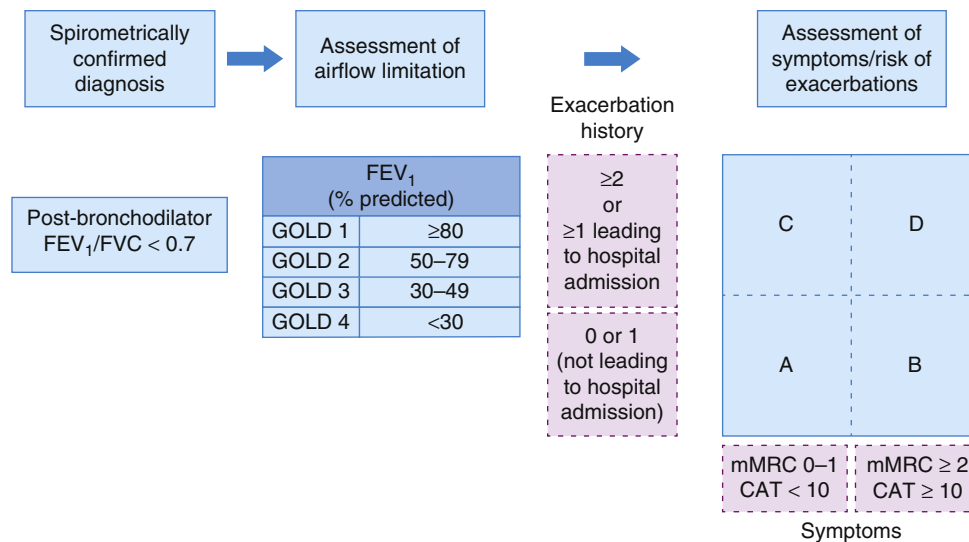

Fig. 26.1 GOLD refined ABC assessment tool. For mMRC definitions, see Table 26.3. The CAT score refers to the COPD Assessment Test (GlaxoSmithKline, 2009). COPD, Chronic obstructive pulmonary disease; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; mMRC, Modified Medical Research Council. Treatment

Managing stable chronic obstructive pulmonary disease

The National Institute for Health and Care Excellence (NICE, 2010) guidance for the management of COPD has largely been superseded by the body of evidence that is outlined in the GOLD (2017) guidelines. As such, NICE is no longer favoured for the management of COPD, and GOLD (2017) is a comprehensive document that respiratory professionals should be referring to when managing these patients. The rate of progression of COPD does not change despite medication or rehabilitation, but the measures in the guidance can significantly improve a patient's quality of life and reduce the symptom burden. If the treatment plan is optimised, then this is likely to reduce symptoms, exacerbations and admissions to hospital. The aims of treatment with the pharmacological agents are shown in Box 26.1.

Fig. 26.1 outlines assessment of COPD dependent on symptom burden and exacerbation frequency.

A group A patient is one who is relatively symptom-free (mMRC 0–1 or CAT score <10) with no exacerbations in the previous year. For these patients, who are most likely to present in primary care, a bronchodilator should be prescribed. An as-required bronchodilator would only be recommended for those patients with very occasional breathlessness: it is preferable to use a long-acting bronchodilator in these circumstances. Once initiation with a bronchodilator has occurred, the patient should be re-assessed and an alternative bronchodilator prescribed if symptoms remain an issue.

Group B patients are those patients who are more symptomatic (mMRC >2 or CAT score >10) who also have not exacerbated in the previous year. For these patients, GOLD (2017) guidelines recommend the use of a long-acting β -agonist (LABA) or long-acting anti-muscarinic antagonists (LAMAs). This is very similar to the management of category A patients, with a step up in

Box 26.1 Treatment aims for patients with chronic obstructive pulmonary disease

- Prevent disease progression
- Relieve symptoms
- Improve exercise tolerance
- Improve quality of life and health status
- Prevent and treat complications such as hypoxaemia
- Prevent and treat exacerbations
- Reduce mortality

therapy to a dual LABA-LAMA combination should symptoms continue. GOLD (2017) guidelines also give the flexibility to initiate treatment straight away with a LABA-LAMA combination.

Group C patients are those who are not particularly symptomatic but have experienced more than two exacerbations requiring antibiotics and/or steroids or more than one exacerbation requiring hospital admission in the previous year. For these patients, GOLD (2017) guidelines recommend a LAMA, escalating to a LABA-LAMA combination if further exacerbations occur. In this group, there is an option to add in a LABA/inhaled corticosteroid (ICS), but this is not the preferred choice of agent.

Group D patients are those with frequent exacerbations and severe symptoms. For these patients, the options are very flexible and would be based on individual patients. Ultimately, for these patients, so-called 'triple therapy' may be appropriate (i.e. LAMA plus LABA/ICS). Roflumilast has recently been approved by NICE (2017) as an add-on bronchodilator in this group of patients. It is generally thought that ICSs should be reserved for these patients with very debilitating symptoms and frequent exacerbations.

Pharmacological treatments do not change the underlying pathology. The common therapeutic problems associated with COPD are shown in Box 26.2.

Box 26.2 Common therapeutic problems associated with chronic obstructive pulmonary disease

- Failure of patient to stop smoking
- Inadequate inhaler technique, leading to subtherapeutic dosing and medicine wastage
- Poor adherence to the treatment regimen
- Inappropriate prescribing (or lack of prescribing) of antibiotics in an acute exacerbation of chronic obstructive pulmonary disease
- Failure to properly assess a patient for home nebulisation
- Failure to properly assess adherence to at least 15 h/day of oxygen therapy
- Failure to discontinue current inhalers when switching to new devices/regimens

Surgical treatments

Intervention to reduce lung volume can improve lung function and breathlessness in appropriately selected patients, with severe air trapping. This can be achieved by surgical removal of emphysematous regions, especially when these are located primarily in the upper zones, or more recently by the placement of endobronchial valves.

Lung transplantation is an option when lung function and quality of life become severely impaired, but the rigorous criteria applied in selection and the paucity of donor organ availability limit this to a very small proportion of patients.

Smoking cessation

Smoking is the most important and modifiable factor in the development of COPD. Smoking cessation interventions are effective in reducing ill health and prolonging life. All COPD patients who continue to smoke, regardless of age, should be given encouragement to stop smoking and be offered help to do so at every opportunity (GOLD, 2017). Even brief conversations between the patient and the healthcare professional can lead to quitting and, as a result, are one of the most cost-effective of all healthcare interventions. Once a quit date has been determined, it is the level of dependence rather than the motivation that influences the success rate, and this is where having professional support can help the individual to maintain his or her smoke-free status. For example, in the first few days after quitting, the cough and sputum production increase as the cilia start to recover from their paralysis due to the toxic effects of the smoke.

Fig. 26.2 summarises how lung function and symptoms are believed to be affected by continuing to smoke or stopping at any age. Estimates suggest that stopping smoking leads to a sustained 50% reduction in the rate of lung function decline; however, it should be remembered that the damage already sustained cannot be reversed.

Bronchodilators

Short-acting β -agonists and short-acting antimuscarinics. Bronchodilators in COPD are used to reverse airflow limitation. They are useful for easing symptoms such as wheeze and

improve exercise tolerance. GOLD (2017) guidance recommends that the once the diagnosis of COPD is confirmed, the patient is assessed for symptom severity, either using the CAT score or mMRC dyspnoea score. In addition, the number of exacerbations in the past year should also be determined. Once these have been assessed, the patient can be initiated on appropriate treatment using the modified ABCD algorithm (see Fig. 26.1). Patients should be provided with a short-acting β_2 -agonist (SABA) for use when required. Salbutamol and terbutaline are the principal SABAs available, although formoterol, which is long-acting, has an equally swift onset of action of approximately 5 minutes. Ipratropium, the only short-acting anti-muscarinic available (SAMA), is another option, provided the patient is not taking a LAMA, although its rate of onset is slower.

Long-acting bronchodilators. LAMAs and LABAs are the mainstay of treatment for patients with stable COPD. The evidence base is rapidly growing, and the role of bronchodilators and their position in therapy is also rapidly changing. The recent FLAME study (Jadwiga et al., 2016) has demonstrated that a combination product of indacaterol and glycopyrronium is superior to salmeterol plus fluticasone for all exacerbations, lung function and health-related quality of life in patients with a history of exacerbations. In addition, there was a lower incidence of pneumonia in the LABA/LAMA arm.

Long-acting muscarinic antagonists. Tiotropium has been a cornerstone of treatment and provides the most robust evidence of efficacy. The landmark trial UPLIFT showed that treatment with tiotropium in mild to severe disease can significantly sustain improvements in lung function over 4 years. It was also shown to delay time to first exacerbation, reduce the number of exacerbations per year and reduce the risk of exacerbations leading to hospital admission (Tashkin et al., 2008).

There was controversy over the cardiovascular safety of Tiotropium Respimat, which has been largely discounted following publication of TIOSPIR in 2013 (Wise et al., 2013), a randomised, double-blind, parallel group trial of around 17,000 patients. Patients were randomised to either tiotropium Respimat 2.5 micrograms, tiotropium Respimat 5 micrograms or tiotropium 18 micrograms in the HandiHaler device. End points were risk of death and time to first exacerbation, but cardiovascular safety was also assessed. The trial showed that 2.5-microgram and 5-microgram doses via the Respimat device had a similar safety profile and exacerbation rate to the HandiHaler mode of delivery. Other, newer LAMAs include aclidinium, umeclidinium and glycopyrronium, and new trial data are emerging regarding quality of life, exacerbations and improvement in lung function (Jones et al., 2012; Kerwin et al., 2012; Trivedi et al., 2014). Choice of LAMA is made by consideration of the patient's ability to use the device, adherence and tolerability.

Long-acting β_2 -adrenergic agonists. Salmeterol, indacaterol, olodaterol and formoterol are all available in the UK in a range of different inhaler devices and in combination with LAMAs or ICSs. There is emerging evidence that LABAs are also effective in reducing exacerbations and improving symptoms; however, asthma must be confidently excluded before initiating a LABA without an ICS. The TORCH study (Calverley et al., 2007) demonstrated that salmeterol significantly reduced exacerbation frequency.

Fig. 26.2 Diagrammatic representation of the effects of smoking and smoking cessation in a man who is likely to develop COPD if he smokes. (Reproduced from Fletcher and Peto, 1977, with permission.)

Nebulised bronchodilator therapy. For those patients who suffer debilitating breathlessness, a home nebuliser has traditionally been offered for SABA and/or ipratropium bromide therapy. However, with the evidence of longer-term benefits conferred by the newer long-acting inhaler-delivered drugs, there has been a marked reduction in long-term nebuliser use. Very occasionally patients do seem to benefit from high-dose nebuliser treatment, and motivated patients are generally loaned a device to explore this aspect. Further consideration should be given to the very time-consuming nature of regular nebulisation on the patient's social well-being and fitness.

Combination long-acting β -agonist and long-acting muscarinic antagonist therapy. Numerous LABA-LAMA combinations have been introduced into the UK market. Available options are Anoro (umeclidinium/vilanterol), Spiolto (tiotropium/olodaterol), Duaklir (aclidinium/formoterol) and Ultibro Breezhaler (glycopyrronium/indacaterol). SPARK was a 64-week, double-blind, randomised, parallel group study comparing glycopyrronium/indacaterol versus tiotropium versus glycopyrronium (Wedzicha et al., 2013). SPARK showed that the dual combination decreased moderate to severe exacerbations compared with both tiotropium and glycopyrronium alone. The LABA-LAMA combinations offer value for money in comparison to the separate components and short-acting drugs, so it is reasonable to use a LABA-LAMA combination inhaler from the outset rather than to use monotherapy and add in a different inhaler at a later date. Thus, the availability of these LABA-LAMA combinations along with recognition that an identifiable (non-eosinophilic) majority do not benefit from inhaled steroids has effectively made the previous complex NICE (2010) guidance on escalation

of therapy redundant. This also stratifies the treatment according to inhaler device rather than changing devices at each step of the guideline.

There is some concern around the use of these agents in patients who may have an asthmatic component to their disease. This is because the use of a LABA without an ICS increases the risk of death in asthma (Spitzer et al., 1992). It is, therefore, imperative that a firm diagnosis of COPD is made when considering these agents. The absence of eosinophilia may be helpful in identifying patients who are unlikely to require inhaled steroids, although the role of blood eosinophils has yet to be firmly established in clinical practice. Evidence for the so-called 'triple therapy' (LABA-LAMA-ICS) is limited, and cost per quality-adjusted life-year (QALY) is very high.

Long-acting β_2 -adrenergic agonists and inhaled corticosteroid therapy

Several preparations are now available on the UK market and include Relvar Ellipta (vilanterol and fluticasone furoate), Seretide Accuhaler and AirFluSal Forspiro (salmeterol and fluticasone propionate), Symbicort Turbohaler and DuoResp Spiromax (formoterol and budesonide), and Fostair (formoterol and ultrafine beclometasone). One of the pivotal trials was the TORCH study (Calverley et al., 2007), which compared salmeterol to fluticasone to salmeterol/fluticasone and placebo. The primary end point of reduced mortality was not reached, despite a non-significant trend toward benefit. This was also important as being the first study to identify an increased risk of pneumonia in patients using ICSs, whether as monotherapy

or in combination with a LABA. At this time, trials had not been designed to assess the risk of pneumonia, and where pneumonia was reported, there was variation in methods for diagnosis and how it was distinguished from COPD exacerbations. Patient demographics (e.g. smoking or vaccination status, concurrent or previous use of oral corticosteroids) were not recorded. It has now become clear that ICSs, alone or in combination with a LABA, can increase the number of serious pneumonias that require hospitalisation. Because patients receiving an ICS are no more likely to die overall compared with controls, the clinical implication of these findings is yet to be established (Kew and Seniukovich, 2014). There is also debate whether the increased risk of pneumonia is a class effect or if a particular ICS is implicated. An increased risk of pneumonia with Relvar Ellipta of approximately double compared with the LABA monotherapy arm (6% vs 3%) has been identified (Dransfield et al., 2013). The trial was designed to detect pneumonia as a primary end point and used radiographic techniques for diagnosis, which means that the diagnosis was robustly established. More information was also available with regard to participants' smoking status, pneumonia history and body mass index (which is a risk factor for pneumonia).

It is advised that the corticosteroid dose prescribed is the minimum to maintain symptom control and/or decrease exacerbations. A recent review by the European Medicines Agency (EMA) Pharmacovigilance Risk Assessment Committee (EMA, 2016) has concluded that ICSs in the treatment of COPD do significantly increase the risk of pneumonia, but the benefits of using ICSs continue to outweigh the risks overall. The committee also concludes that there is insufficient evidence to distinguish between different ICSs with regard to risk of pneumonia.

Triple therapy combination inhalers. Trimbow pMDI (ultra-fine beclometasone/formoterol/glycopyrronium) and Trelegy (fluticasone furoate/vilanterol/umeclidinium) have recently been licensed for the management of COPD in patients who continue to experience symptoms despite treatment with ICS/LABA.

Two efficacy studies using Trimbow have been completed. The TRILOGY study compared Trimbow to Fostair 100/6 over a 26 week period. This study identified that Trimbow improved pre- and post-dose FEV₁ compared to Fostair and also reduced the annual rate of exacerbations by 23% as a secondary end point (Singh et al., 2016). The TRINITY study compared Fostair plus tiotropium to Trimbow over a 52 week study period. As expected, Trimbow was superior to tiotropium alone for reduction in exacerbations and improvement in FEV₁. Trimbow was shown to be non-inferior (or equivalent) to the triple combination with regard to exacerbations and FEV₁ (Vestbo et al., 2017). In these studies pneumonia was seen in a small proportion of patients, similar to other ICS studies.

These combination inhalers may offer a simplified regimen for those patients that benefit from ICS, combined with a significant cost saving. It is important to recognise that existing patients on so-called triple therapy need a therapeutic review before switching to a combination inhaler device to assess inhaler technique and to review whether the ICS can be withdrawn safely from therapy for that individual.

Withdrawal of inhaled corticosteroids in patients with chronic obstructive pulmonary disease

From the emerging literature (Magnussen et al., 2014), there is increasing confidence that there is overuse of ICSs in the COPD patient population. It is far easier to change the therapy strategy in those patients newly diagnosed. How this is managed in the existing population is more challenging because of the evidence suggesting bronchodilation rather than suppression of inflammation is important in patients with a low eosinophil count. The recent WISDOM study by Magnussen et al. (2014) showed that in a severe to very severe COPD population without a tendency to exacerbate, gradual withdrawal of ICS did not increase exacerbation rates or result in loss of symptom control. Although the evidence is beginning to point toward ICS withdrawal in this phenotype, the practicalities of how this should be undertaken are yet to be determined, and there are many factors to be considered: for example, how this would be communicated across the primary/secondary care interface; how the patient would be counselled when being switched from one inhaler type to another; whether the patient should be switched to a LABA-LAMA device and a monotherapy (off-license) ICS to gradually reduce the steroid. The WISDOM study does provide a basis on which withdrawal regimens can be based (Magnussen et al., 2014), but it should be noted that the role of ICSs in these patients is currently very much debated within the respiratory community.

Roflumilast

Roflumilast is a PDE-4 inhibitor recommended by NICE (2017) for use in patients with severe or very severe COPD with a chronic bronchitic phenotype. These patients should have had two or more exacerbations in the last 12 months despite receiving treatment with triple inhaled therapy, that is, LABA/LAMA/ICS during that period. The evidence considered by NICE was based on two clinical trials REACT (Martinez et al., 2015) and RE(2) SPOND (Martinez et al., 2016). The primary endpoints, rates of moderate or severe exacerbations, did not reach statistical significance versus placebo in the intention to treat analysis. However, it did in a pre-defined sensitivity analysis using negative binomial regression and approval has been given by NICE (2017).

Roflumilast may have a role in those patients who are obese and of a chronic bronchitic phenotype. Currently roflumilast is considered to generally provide only a modest benefit in a small cohort of patients, rather than the whole population as recommended by NICE (2017). Moreover, not only is there small clinical benefit, roflumilast is associated with significant side effects: notably weight loss, diarrhoea and nausea. These would not be appropriate in an already cachectic patient meeting the treatment criteria. In addition, more patients taking roflumilast withdrew in both trials due to adverse effects (Martinez et al., 2015, 2016). There is also an increased risk of psychiatric disorders in patients with or without a history of depression, including suicidal ideation.

Controversy with the NICE (2017) guidance lies with the definition of triple therapy. To be eligible for roflumilast, a patient must demonstrate that triple therapy is entirely clinically appropriate.

There is a view that ICS is overused and that maximal bronchodilation is sufficient for symptom management and reduction in exacerbation rates for many patients. In addition, a patient has to have been adherent with the triple therapy for 12 months to be eligible. In the UK there are practical problems implementing the guidance because of challenges associated with assessing adherence to the triple therapy. This is coupled with difficulties in assessment of the number of exacerbations, particularly in those patients who have rescue packs at home. This, together with the equivocal evidence and side effect profile for roflumilast reduces the incentive for secondary care prescribers to adopt the [NICE \(2017\)](#) guidance. There is also debate about when to stop roflumilast, if the patient still exacerbates. Currently NICE has not provided practical advice on this management aspect.

Theophylline and aminophylline

Methylxanthines are weak bronchodilators with a narrow therapeutic index. It appears that the benefits of these compounds in COPD may involve other mechanisms, including increasing respiratory drive and exercise tolerance as well as some steroid-sparing and anti-inflammatory effects. These drugs are now being superseded due to their relative lack of effect and poor tolerability. If used, patients should be given a therapeutic trial of 6–8 weeks to see if there is any clinical benefit. Treatment should be discontinued if there is no improvement in breathlessness or lung function testing.

Care must be taken to ensure theophylline levels are measured, particularly if the patient is prescribed interacting medications such as ciprofloxacin or clarithromycin. Other comorbidities that can also affect the clearance of theophylline include heart failure and smoking.

Mucolytics

Carbocysteine, the most commonly prescribed mucolytic, provides some symptomatic benefit in those patients with a productive cough. Upon initiation, the carbocysteine should be trialled for 6–8 weeks and then assessed for clinical improvement (e.g. reduction in cough frequency and/or sputum production). If there is no perceived benefit, then the mucolytic should be stopped. A systematic review has shown that patients who take mucolytics are less likely to exacerbate ([Poole et al., 2015](#)). The benefit appears to be greatest in those patients who exacerbate frequently and/or who have prolonged exacerbations. There is little evidence to support the initiation of mucolytics in the acute phase.

Prophylactic antibiotics

Currently, prophylactic antibiotic therapy with azithromycin is not currently recommended in the [GOLD \(2017\)](#) guidance unless the patient is a former smoker with recurrent exacerbations despite optimal pharmacological therapy. Macrolide antibiotics appear to have immunomodulatory and anti-inflammatory effects. One study has shown that azithromycin in a dose of 250 mg daily (in addition to usual COPD medication) reduced

exacerbation rates from 1.83 per patient-year in the placebo group to 1.48 per patient-year ([Albert et al., 2011](#)). However, azithromycin has been associated with prolonged QT intervals and ventricular arrhythmias. Probably more importantly, there is real concern regarding antibiotic resistance and the effect on the microbial flora in the community. Unfortunately, azithromycin appears to be particularly prone to causing transmissible antibiotic resistance, even when compared to other macrolides. Whilst the routine use of prophylactic azithromycin is not recommended, it may be considered in very severe patients who have a history of frequent exacerbations, whose medication regimens have been fully optimised, who are not at risk of ventricular arrhythmias and who have a normal QT interval on electrocardiography.

Pharmacological management of exacerbations of chronic obstructive pulmonary disease

Exacerbations of COPD are an acute deterioration beyond the day-to-day variation in symptoms, often precipitated by viral or bacterial infection. This can result in episodes of respiratory failure and may require admission to hospital, although patients can often be safely managed at home, with appropriate support and self-management plans.

Bronchodilators

These are used to treat the acute wheeze and breathlessness. After acute admission, hand-held inhalers plus spacer device is recommended where possible, but in practice, it is more pragmatic from a nursing workload perspective to administer bronchodilators via a nebuliser at least for the first day. Salbutamol 2.5 mg four times daily is usually adequate with the addition of ipratropium 500 micrograms four times daily as an adjunct. Doses above 1 mg of salbutamol confer small additional benefits and increase cost and side effects. It is usually preferable to use a mouthpiece for delivery of nebulisers where possible to decrease adverse effects and to improve lung deposition. This is particularly important with the use of ipratropium in patients with glaucoma. LAMAs and LABA-LAMAs should be suspended whilst on nebuliser therapy.

Antibiotics

Acute infective exacerbations may be bacterial or viral in origin. If the exacerbation is bacterial in origin, suggested by purulent sputum, then antibiotics should be prescribed. Common bacteria include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. First-line antibiotics include amoxicillin, doxycycline and clarithromycin, but local antibiotic policy should be followed. Antibiotic therapy is not indicated if sputum is non-purulent (or similar in colour to normal) unless there is other evidence of infection, such as infective consolidation, high fever or acute-phase response (i.e. a markedly raised C-reactive protein [CRP] or erythrocyte sedimentation rate [ESR]). Patients admitted to hospital should have sputum sent for culture and sensitivity to optimise therapy. Usually a 5- to 7-day course is

Table 26.4 Comparison of type 1 and type 2 respiratory failure

	Type 1 respiratory failure	Type 2 respiratory failure
PaO ₂ level	Low	Low
PaCO ₂ level	Low or normal	Raised
Pathophysiological cause	Impaired gas exchange (ventilation/perfusion mismatch)	Hypoventilation (may also be impaired gas exchange)
Common associated diseases	'Pink-puffer' variant of COPD Pneumonia Pulmonary embolism Asthma (unless moribund)	'Blue-bloater' variant of COPD Morbid obesity Neuromuscular diseases including respiratory muscle weakness, kyphoscoliosis
Treatment	Whatever concentration of oxygen needed (FiO ₂) to achieve SaO ₂ of 94–98% Treatment of the underlying cause	Controlled oxygen to achieve SaO ₂ 88–92% If PaCO ₂ climbs, causing pH to fall below 7.35, consideration of non-invasive ventilation
COPD, Chronic obstructive pulmonary disease; FiO ₂ , fraction of inspired oxygen; PaCO ₂ , arterial carbon dioxide tension; PaO ₂ , arterial oxygen tension; SaO ₂ , percentage of oxygen saturation of arterial blood.		

effective. It is prudent to monitor sputum volume and colour and temperature to ensure resolution of infection prior to discontinuing antibiotics. If the exacerbation follows influenza, then there is a risk of *Staphylococcal aureus* infection, when an agent with anti-staphylococcal properties should be used (e.g. flucloxacillin or co-amoxiclav).

Corticosteroids

GOLD (2017) recommends a course of prednisolone 30 mg for 5–7 days only. There is evidence to suggest that a shorter course of steroids does not increase the risk of relapse and minimises risk to the patient. Many clinicians favour the use of a 5-day course (Leuppi et al., 2013). ICSs are usually continued during this phase. Increasingly, an absence of eosinophilia is used to identify patients who may not benefit, but this is not presently supported by guidelines.

Aminophylline

On occasion, intravenous aminophylline may be used if there is an inadequate response to bronchodilators. If the patient is already on a theophylline compound, then the loading dose is not required. If the patient is unsure if he or she is on a theophylline and that information is not available, then it is best to omit the loading dose and give the maintenance dose only. Smoking status should be established because smoking increases the metabolism of theophylline. Once smoking stops, then continuing a patient on his or her usual theophylline dose will likely result in toxicity.

Thromboprophylaxis

All acutely unwell medical patients admitted to hospital should receive a prophylactic dose of low-molecular-weight heparin if there is no known contraindication.

Physiotherapy

When bronchiectasis complicates COPD, physiotherapy instruction on daily sputum clearance exercise is the mainstay of control, along with antibiotics for infective exacerbations. Otherwise, the input of the physiotherapist is generally limited to pulmonary rehabilitation, which is now widely available.

Management of acute respiratory failure in chronic obstructive pulmonary disease

The type of respiratory failure is important in the management of the acute exacerbation: patients with type 1 respiratory failure (that is, a low oxygen level without an increased carbon dioxide level) are not at risk of developing elevated carbon dioxide levels when receiving supplemental oxygen therapy and can safely be treated with whatever oxygen concentration is required to achieve normal oxygen saturation (94–98%). In contrast, patients with type 2 respiratory failure (when the carbon dioxide level is increased) can develop severe carbon dioxide retention with attendant narcosis, especially if treated with injudicious concentrations of oxygen; a target of 88–92% is sufficient. These two forms of respiratory failure are compared in Table 26.4.

Some patients live with undiagnosed type 2 respiratory failure, and its longstanding nature can be identified when the pH is normal. The respiratory acidosis is fully compensated by a metabolic alkalosis, reflected by a high standard bicarbonate level observed on arterial blood gas analysis.

When patients present acutely with a respiratory acidosis (i.e. the pH is less than 7.35 despite appropriate oxygen and bronchodilator therapy), the introduction of non-invasive ventilation (NIV) can be life-saving and may obviate invasive positive pressure ventilation (IPPV). It is important that a ceiling of escalation of treatment is established in the acute setting because severely disabled patients are unlikely to survive or benefit from IPPV and indeed would often decline this when its implications are explained.

Doxapram, a respiratory stimulant, has largely been superseded by NIV and is no longer recommended as a routine treatment. Doxapram must be infused at a rate of 1.5–4 mg/min in those patients where NIV is contraindicated and in patients with hypercapnic respiratory failure who are comatose. It can sometimes enable the patient to become more rousable and more able to cooperate with therapy. Clinicians should be aware that doxapram can also be harmful in respiratory failure because it stimulates both respiratory and nonrespiratory muscles. As a consequence it must only be used under expert medical advice and in a suitably supervised clinical area to minimise risk. Overall, the recommendation is to avoid doxapram due to its very limited benefits.

Patient care

Pulmonary rehabilitation

The most effective treatment for improving quality of life and ameliorating breathlessness is pulmonary rehabilitation. It is composed of multiple interventions, not just exercise training. Thus, subjects receive education on self-management, nutrition, home exercise and medication use. Programmes typically run from 6–8 weeks, usually with two visits per week. Pharmacists are well placed to contribute to this programme of education regarding pharmacological management, including introducing the concept of medicines in the palliation of symptoms.

Vaccination

Whilst pneumococcal and influenza vaccinations are not 100% effective, all patients diagnosed with COPD should be offered them. Influenza vaccination is annual, and a single pneumococcal inoculation is advised unless there is another reason to be vaccinated more frequently (e.g. nephrotic syndrome). Patients should be reassured that the influenza vaccine is inactive and that they are not able to contract the illness from the vaccination itself.

Stopping smoking

The effects of smoking on health are well known and well publicised. As described previously, stopping smoking is the most important intervention patients can achieve no matter their age or how advanced their lung disease is. There are a number of therapeutic options to aid a quit attempt.

Nicotine replacement therapy

Nicotine replacement therapy (NRT) can be used to aid abrupt smoking cessation (e.g. whilst on a ward as an in-patient) or, alternatively, to reduce the number of cigarettes smoked in the lead-up to a specified quit date.

There are many different formulations available that can be prescribed. Many of these are now licensed to be used in combination with other NRT products with or without smoking and also in pregnancy. These are shown in [Table 26.5](#).

The mode of action is directly on nicotine receptors in the brain, which release dopamine. This has the effect of reducing the nicotine withdrawal symptoms (e.g. agitation). Another

significant influencing factor is the habit of putting a cigarette to the lips, and the use of some of the products that mimic this action can also be helpful, especially in social situations. NRT does not completely eliminate the effects of withdrawal because none of the available products can accurately reproduce the rapid and high levels of nicotine obtained from cigarettes.

There is no clear evidence that one formulation is more effective than another, and the effectiveness of any of these products will lie with the individual and his or her trigger points and habits. Choices are influenced by the number of cigarettes smoked, personal preference/previous/experience and tolerance of side effects. Another factor to consider, although unlikely with a diagnosis of COPD, is if the patient is pregnant. Patches should be avoided where possible due to the continuous level of nicotine in the plasma. As with any pharmacological therapy, the benefits should always outweigh the risks, and the use of nicotine patches is not contraindicated in pregnancy if the patient is able to maintain her smoke-free status as a result of using the product. For information on formulations available and their usage/side effects, please see [Table 26.5](#).

Bupropion

Bupropion (amfebutamone hydrochloride) is licensed for smoking cessation and works by inhibiting uptake of noradrenaline and dopamine within the neuronal synapses. This reduces the withdrawal symptoms by increasing synaptic dopamine levels. Treatment is started 2 weeks prior to the quit date, and cigarettes should be stopped in the second week of treatment. If abstinence is not achieved or maintained by week 7 of treatment, it should be discontinued. Bupropion is contraindicated in epilepsy, acute alcohol or benzodiazepine withdrawal, bipolar disorder, central nervous system (CNS) tumour, eating disorders and hepatic cirrhosis. The main side effects include agitation, anxiety, dry mouth, allergic reactions and insomnia.

Varenicline

Varenicline is a selective nicotine receptor partial agonist at the $\alpha 4\beta 2$ acetylcholine receptor. It alleviates the craving and withdrawal whilst reducing the rewarding and reinforcing effects of smoking by preventing binding of nicotine to $\alpha 4\beta 2$ receptors if a cigarette is smoked. A recent trial, EAGLES, compared varenicline with bupropion, NRT patches and placebo. The trial showed that at weeks 12 and 24, varenicline provided superior abstinence rates in both psychiatric and nonpsychiatric patients ([Anthenelli et al., 2016](#)). Varenicline is usually started 1–2 weeks before quitting smoking and comprises a 12-week course. Medicines and Healthcare Products Regulatory Agency (MHRA)/Commission on Human Medicines (CHM) advice states that varenicline may be associated with increased risk of suicide, and patients should be counselled to discontinue treatment if they develop agitation, depression or suicidal thoughts. Any patient with a history of psychiatric illness should be monitored closely.

Electronic cigarettes

The use of electronic cigarettes has also received attention, with controversy over effectiveness and regulation. Initially, the

Table 26.5 Comparison of nicotine replacement products

Formulation	Use and comments	Specific side-effects
Patch 24 h: 7, 14, 21 mg 16 h: 5, 10, 15, 25 mg	Apply on waking to dry, clean and non-hairy skin on the hip, trunk or upper arm and held in position for 10–20 s. Remove the 16-h patch prior to bed. Place next patch on a different area and avoid using the same site for several days. Licensed for use over 12 years of age. Patch therapy can be useful in pregnancy if patient vomiting, otherwise intermittent therapy is preferable.	Local skin irritation and rash, insomnia. Do not use on broken skin or in patients with skin disorders.
Chewing gum: 2, 4 mg	Chew one piece of gum when urge to smoke occurs or to prevent cravings. No more than 15 pieces of 4 mg gum should be used in one day. The gum should be chewed until the taste becomes strong then should be rested between gum and cheek until taste has faded. The gum should then be chewed again. Repeat for 30 min or until taste dissipates. Avoid acidic drinks (e.g. coffee, fruit juice) for 15 min before and during treatment.	Gum may stick to dentures. Jaw ache, headache and mild burning in mouth and throat may occur.
Sublingual tablets: 2 mg	Place tablet under the tongue and allow to dissolve. Acidic drinks should be avoided for 15 min before and during treatment. Maximum 40 tablets per day.	Gastritis, oesophagitis and peptic ulcers can be aggravated by swallowing nicotine
Inhalator: 10, 15 mg cartridge	Inhale as required up to 5 min per session. Helps to satisfy the hand-to-mouth habit. The nicotine is absorbed through the oral mucosa rather than the lungs. No more than 12 cartridges of the 10 mg strength or 6 cartridges of the 15 mg strength per day. A 10 mg cartridge lasts approximately 20 min of intense use; a 15 mg cartridge lasts approximately 40 min of intense use.	Caution with asthmatics because can cause bronchospasm. Nasal irritation, rhinorrhea, sneezing, throat irritation and cough may occur.
Lozenges: 1, 1.5, 2, 4 mg	One lozenge every 1–2 h as required. Slowly allow the lozenge to dissolve in the mouth; periodically move the lozenge from one side of the mouth to the other. Lozenges last 10–30 min depending on their size. Maximum of 15 lozenges per day. Patients who smoke less than 20 cigarettes per day should use the lower-strength lozenges; patients who smoke more than 20 cigarettes per day or who have failed to quit on the low-strength should use the high-strength lozenge. Avoid acidic drinks for 15 min before and during treatment.	Gastritis, oesophagitis and peptic ulcers can be aggravated by swallowing nicotine. Nasal irritation, rhinorrhea, sneezing, throat irritation and cough may occur.
Oromucosal spray: 500 micrograms and 1 mg per actuation	One to two sprays when cravings occur, do not exceed 2 sprays per episode. Maximum 64 sprays per day. Avoid acidic drinks for 15 min before and during treatment. Spray should be released into the mouth by holding the spray as close to the mouth as possible and avoiding the lips. Do not inhale while spraying and avoid swallowing for a few seconds after use.	Gastritis, oesophagitis and peptic ulcers can be aggravated by swallowing nicotine.
Intranasal spray	One spray as required; can spray into each nostril when craving occurs. Maximum 64 sprays per day. More rapidly absorbed than other forms of nicotine replacement therapy.	Caution in asthma, nasal/sinus conditions or allergies.
Orodispersible film: 2.5 mg	Suitable for smokers who have their first cigarette of the day more than 30 min after waking up. Place one film on the tongue. Close the mouth and press the tongue gently to the roof of the mouth until the nicotine film dissolves (approximately 3 min). The film should not be chewed or swallowed whole. Users should not eat or drink while a nicotine film is in the mouth.	Gastritis, oesophagitis and peptic ulcers can be aggravated by swallowing nicotine.

Information taken from British National Formulary (2017).

stance from the professional bodies such as the MHRA was that electronic cigarettes could not be recommended due to the variation in product quality, although anecdotal reports do suggest that these are effective in helping to support a quit programme. Subsequently, there have been several papers published that appear to endorse the use of e-cigarettes ([Public Health England, 2015a](#)). [Public Health England \(2015b\)](#) issued a press release that concluded that e-cigarettes are 95% less harmful than tobacco

with no evidence that they encourage children or nonsmokers to start smoking tobacco. However, there is no long-term information about the solvents used in the process of ‘vaping’ and the long-term clinical impact that this may have on the patient. There are also very real concerns around the risk of fire if the electronic cigarette is left charging, particularly with a non-compatible charger from a different brand. The use of an electronic cigarette is not considered safe in patients on long-term oxygen

therapy (LTOT), and so electronic cigarettes are not permitted on hospital premises or in any area that may be oxygen enriched, for example, in the home of a patient with LTOT in place.

Effect of smoking on concomitant medications

When smoking is discontinued, this can have significant impact on how concomitant medications are metabolised. Areas of high risk include the previously common respiratory medication theophylline. Theophylline is a narrow-therapeutic-index medication that interacts with antibiotics such as clarithromycin and ciprofloxacin, causing the theophylline levels to significantly increase. It is imperative that an accurate smoking history is taken for patients prescribed theophylline because smoking increases its metabolism. Admission to hospital for an exacerbation of COPD means the patient is no longer able to smoke whilst an in-patient; therefore, theophylline metabolism is reduced, and the theophylline levels will become raised. Tachycardia and tremor are often attributed to salbutamol nebuliser therapy, but these should be recognised as a potential sign of likely theophylline toxicity. For patients who smoke, theophylline levels should be taken on admission to hospital and the doses reduced as appropriate.

Oxygen therapy

Large studies in the USA and Britain performed in the 1970s showed an important improvement in prognosis when LTOT is used for substantial proportions of the day in patients with stable hypoxaemia (Cooper et al., 1987; Medical Research Council Working Party, 1981; Nocturnal Oxygen Therapy Trial Group, 1980). The accepted criteria are as follows: patients with stable COPD and a resting $\text{PaO}_2 \leq 7.3$ kPa or patients with stable COPD with a resting $\text{PaO}_2 \leq 8$ kPa plus evidence of peripheral oedema, polycythaemia or pulmonary hypertension (British Thoracic Society [BTS], 2015). Oxygen is delivered via an oxygen concentrator, which is usually piped to the living room and bedroom so that the patient can use oxygen for at least 15 hours/day at a flow rate sufficient to raise PaO_2 above 8 kPa.

Outside this setting, oxygen is usually unhelpful: there is no evidence that short-burst oxygen therapy improves breathlessness, despite its powerful placebo effect. Occasionally patients are sufficiently motivated and benefit from portable oxygen to enable increased exercise capacity, but these are exceptions.

Patients with the typical 'pink-puffing' form of COPD tend to maintain normal blood gases until very late in the disease and so rarely meet the criteria for LTOT. Neither are they at risk of adverse effects from high concentrations of oxygen. In contrast, the 'blue-bloating' patients develop type 2 respiratory failure, meaning that they develop elevated carbon dioxide levels and accommodate to surprisingly low oxygen levels. This group is the one that tends to benefit from LTOT. They are also, however, susceptible to developing acute rises in carbon dioxide levels in response to acute exacerbations, especially when high concentrations of oxygen are administered. This life-threatening complication can cause initial headache and drowsiness, leading on to coma and ultimately respiratory arrest. As a result, the BTS (2008) emergency oxygen guidelines recommend relatively low target oxygen saturation in the management of acute

exacerbations, measured by pulse oximetry, of 88–92% in such patients, whereas those with normal or low carbon dioxide levels should have a normal target of 94–98%.

Acute episodes of type 2 respiratory failure may occur, with development of a respiratory acidosis as acute elevations of carbon dioxide overtake the relatively slow process of compensation by renal metabolic alkalosis. Oxygen and drug therapy alone are often insufficient; indeed, even low flow rates of oxygen may make acidosis worse. It has been shown that non-invasive ventilation can be life-saving and can avoid the need for invasive ventilation in the relatively small proportion of patients who are otherwise fit enough to be eligible. It is recommended when the pH is less than 7.35. During the first 48 hours of therapy, the patient is encouraged to adhere to the therapy for as long as possible to maximise the effectiveness of the intervention.

Some patients are prone to recurrent severe episodes of type 2 respiratory failure despite long-term oxygen therapy. They often have severe nocturnal hypoventilation and sleep poorly. Such patients may benefit from long-term domiciliary non-invasive ventilation as well as LTOT.

Antidepressants

It is widely recognised that depression is prevalent within the COPD population. It is also recognised that it is underdiagnosed, as it is in many chronic medical conditions. The selection of antidepressant should be made according to comorbidities, side-effect profile, interaction profile and patient choice. For example, for a cachectic patient, mirtazapine may be preferable because it can cause appetite stimulation. Likewise, if insomnia is a problem, then tricyclic antidepressants, trazodone or mirtazapine are good choices. For patients with a cardiac history, sertraline is the safest option.

Palliative care

Palliative care is defined by the World Health Organization (WHO, 2015) as follows:

an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual.

Palliative care for COPD patients should start at the point of diagnosis: it is a progressive disease, and most patients continue to deteriorate despite maximising pharmacological and non-pharmacological treatments. COPD contributes to the increasing population of patients diagnosed with life-limiting illnesses not related to malignancy. Any patient deemed to be in the last year of life is entitled to be managed symptomatically through the palliative route, but resources are currently limited for these patients. Often the most debilitating symptoms are breathlessness, depression and anxiety. It is seen as best practice to discuss preferred place of care, resuscitation status and the patient wishes as they approach the last year of life. For example, the patient's wish to have antibiotics and/or invasive

and non-invasive ventilation in the event of a future severe exacerbation should be determined.

Management of breathlessness

Breathlessness is the primary symptom in the patient with COPD, reported in 90–95% of the COPD population. Breathlessness is not always related to exertion and correlates poorly with lung function. Other causes of breathlessness also frequently coexist. Heart failure, angina and dysfunctional breathing/panic should be diagnosed and treated appropriately. Unfortunately, the dyspnoea of COPD can be refractory to conventional treatment in up to 50% of patients.

Non-pharmacological methods are outlined as follows:

- addressing fear and anxiety through education and psychological support;
- use of a hand-held fan, or sitting near an open window, to stimulate the second and third trigeminal nerves, which reduces the sensation of breathlessness;
- activity-pacing advice;
- breathing exercises (e.g. pursed-lip breathing);
- complementary therapies (e.g. acupuncture, hypnosis, massage).

Opioids are the mainstay of treatment for breathlessness. The evidence base for the management of dyspnoea is not as established as for pain management, but patients do derive benefit. A Cochrane review has concluded that opioids can reduce dyspnoea irrespective of route of administration (Jennings et al., 2002). The mechanism is believed to be a central action on the respiratory control centre: it is well known that in higher doses opioids can reduce minute ventilation. They can reduce the perception of breathlessness in the same way as the perception of pain. It seems paradoxical to be giving a medication known to depress respiratory drive to a patient with an already-compromised respiratory function, but it is understood that the response to chronic hypoxia results in an abnormal perception of the symptom of breathlessness. This practice is also regarded as safe. No reports of respiratory depression were found in a study of the use of opioids for relief of dyspnoea in heart failure (Oxberry et al., 2011). To initiate opioids, the first-line choice is morphine sulfate. Often, very small doses are effective (e.g. 1.25–2.5 mg at night) initially, but it is also entirely appropriate to follow the NICE (2012) guidance for the management of pain (i.e. 2.5–5 mg every 4–6 hours or morphine sulfate MR 10 mg twice a day with 2.5 mg as required). There is no upper limit for dosing, provided relief is obtained and there are no signs of opiate toxicity, such as myoclonus, pinpoint pupils or respiratory depression. As with the initiation of any medication, it is very important that the patient understands the reason for prescribing opiates and that any misperceptions are explored. Patient should also be advised that drowsiness, especially when these drugs have recently been started, may affect fitness to drive; however, there is no restriction on driving in the UK (Department for Transport, 2013).

Benzodiazepines

There is a paucity of evidence to support the use of benzodiazepines for management of breathlessness, but it has been

reported anecdotally that they are effective, and there is a trend towards benefit (Simon et al., 2010). Opioids would be first line, but benzodiazepines are used particularly in patients who suffer with panic/anxiety during an acute episode of breathlessness. Lorazepam is widely used, 0.5 mg when required up to a maximum of 4 mg daily in divided doses.

Case studies

Case 26.1

Mr B is a 67-year-old retired miner who presents to hospital as an emergency with acute shortness of breath and a cough productive of green sputum. Mr B has a past medical history of COPD and had a myocardial infarction 10 years ago. He smokes 35 cigarettes per day and has done so for the last 45 years. Spirometry has shown that his FEV₁ is 58% of predicted. He weighs 45 kg. When he is well his CAT score is 8. There are no known drug allergies.

Mr B's regular medication is:

- aspirin 75 mg daily,
- bisoprolol 10 mg daily,
- simvastatin 20 mg at night,
- salmeterol 25 microgram pressurised metered dose inhaler (pMDI) two puffs twice daily.

On examination:

- blood pressure (BP) 130/75 mmHg,
- temperature 38.6 °C,
- pulse 98 bpm,
- respiratory rate 28 breaths/min.

Investigations:

- white blood cell count 20.8 × 10⁹ L,
- creatinine 140 mmol/L – his baseline was 93 mmol/L 3 months ago,
- Hb – normal,
- oxygen saturation 84% on 28% oxygen via Venturi mask,
- chest X-ray – no consolidation seen.

Arterial blood gases on 28% oxygen:

pH	7.30	(7.35–7.45)
pO ₂	7.26 kPa	(10–13 kPa)
pCO ₂	8.3 kPa	(4.7–6.0 kPa)
HCO ₃	24 mmol/L	(22–26 mmol/L)

Questions

1. What is the diagnosis, and how was this determined?
2. What do the arterial blood gases show, and how would you suggest this is managed?
3. What would you expect to see on Mr B's prescription chart for acute management of his condition?
Mr B shows no clinical improvement and appears to be tiring. He is transferred to the intensive care unit (ICU) in case ventilation (invasive or non-invasive) may be needed. In the ICU, the intensivists wish to increase his medical treatment.
4. What options are there?
5. How should aminophylline be administered?
6. What treatment options would you recommend for Mr B once he has recovered from his acute illness?
7. Are there any other medications that require optimisation?

Answers

- Mr B has an infective exacerbation of COPD. The patient has a cough productive of green sputum and elevated temperature and white blood cell count. He is also tachypnoeic and has deranged arterial blood gases. Other potential diagnoses include anaemia, which has been excluded because his haemoglobin level is normal, community-acquired pneumonia and acute heart failure, which have also been excluded because the chest X-ray is currently clear. The patient has also developed an acute kidney injury, which should be considered when prescribing any new medications.
- The low PaO₂ indicates significant hypoxia. The reduced pH and raised carbon dioxide constitute a respiratory acidosis and indicate hypoventilation. The normal bicarbonate indicates there has not yet been any metabolic compensation and that the condition has deteriorated in the last 1–2 days.
The acidosis indicates a need for non-invasive ventilation. Administering higher concentrations of oxygen alone will exacerbate carbon dioxide retention and may precipitate narcosis. His arterial blood gases should be checked every 30–60 minutes after any change in oxygen therapy, and the carbon dioxide levels should be closely monitored. If there is any increase in the carbon dioxide concentration, then this may indicate a clinical deterioration.
- In the acute phase, the aim of treatment is to optimise oxygen levels, bronchodilate to improve symptoms and treat any underlying infection. Other interventions include thromboprophylaxis at appropriate doses and frequencies according to local policy. The prescription should therefore include oxygen at a flow rate to maintain oxygen saturation between 88% and 92%. A salbutamol nebuliser 2.5 mg four times daily (or 10 puffs of salbutamol 100 micrograms/actuation via a spacer device four times daily) plus ipratropium 500 micrograms nebuliser four times daily will provide bronchodilation. An appropriate antibiotic such as amoxicillin or doxycycline should be prescribed for a total of 5–7 days (or as per local policy) given the green sputum and 30 mg oral prednisolone for a total of 5 days. There is no benefit in giving i.v. hydrocortisone if the patient is able to swallow; therefore, oral steroids will suffice.
- The dose of nebulised salbutamol can be increased, but the main limitation is the side effects, including tremor, tachycardia and hypokalaemia. Ordinarily, if there has been an inadequate response to bronchodilators, then intravenous aminophylline may be considered.
- Aminophylline is available in 250 mg/10 mL vials. The loading dose required is 5 mg/kg (i.e. 225 mg in his case). To make the dose practical for administration it should be rounded to the nearest millilitre. In this case, either 250 mg (10 mL) or 200 mg (9 mL) should be added to a 50 to 100 mL bag of either sodium chloride 0.9% or glucose 5% and given over 20 minutes. Immediately after giving the loading dose, the maintenance infusion must be started.
 - To calculate the maintenance dose = 500 microgram/kg/h. Convert to milligrams first so that everything is in the same units (i.e. 0.5 mg/kg/h). Dose to be given is therefore 22.5 mg/h.
 - Check if the patient is fluid restricted because this may dictate which fluid volume to use. In Mr B's case there is no evidence that fluid restriction is required. Add 500 mg of aminophylline to a 500 mL bag of compatible i.v. fluid. This gives a 1 mg/mL solution, which should be infused at 22.5 mL/h through an infusion pump.
 - To check aminophylline levels, the infusion should be stopped after 4–6 hours. After waiting 20 minutes a blood sample can be taken from a cannula different from the one the infusion

is running through. The infusion should then immediately be restarted. It is not necessary to wait for the result before restarting the infusion.

- The rate should be adjusted according to level obtained.
- Because Mr B has exacerbated, he would benefit from a full medication review. Mr B has continued to be symptomatic despite demonstrated adherence to his salmeterol therapy. GOLD (2017) guidelines suggest that a LAMA should be added to his current prescription. Mr B would fall in GOLD group C because he has had an exacerbation requiring hospital admission and his CAT score is less than 10 when he is feeling well. Alternatively, once inhaler technique has been assessed and recorded, a LABA-LAMA combination could be prescribed to maintain cost-effectiveness, for example, Anoro, Spiolto, Duaklir or Ultibro. Mr B's salmeterol should be discontinued, and this should be communicated to him and his primary care doctor.
Whilst Mr B is an in-patient, it would be a good opportunity to offer him smoking cessation advice and pharmacological intervention to support his quit attempt. He should also be referred into the pulmonary rehabilitation service and be seen by a dietician, as he is underweight at 45 kg.
Mr B should be offered a routine pneumococcal and annual flu vaccination and be given a self-management plan with reserve antibiotics and steroids with clear instruction on when to start these. Finally, at least 12 hours prior to discharge, he should be weaned from the oxygen and nebulisers and converted back to regular inhalers.
 - Mr B suffered a myocardial infarction 10 years ago. His medication could be reviewed. His simvastatin should be increased to a minimum of 40 mg at night. β -Blockers are not contra-indicated in COPD, and indeed, there is evidence to suggest that β -blockers may decrease mortality in patients with this condition, so this medicine should be continued. Addition of an angiotensin-converting enzyme (ACE) inhibitor should be considered once the acute kidney injury has resolved.

Case 26.2

Ms M is a 54-year-old woman who presents to hospital as an emergency, with shortness of breath and coughing up green sputum. She has a history of COPD and an FEV₁ of 44% of predicted. She smokes 50 cigarettes per day and has done so for the past 34 years. She normally finds it difficult to get herself dressed in the morning without becoming breathless. She is allergic to penicillin, which causes her tongue to swell. She has had antibiotics and steroids from her primary care doctor 5 times in the past 8 months.

Her usual medication is:

- Anoro Ellipta 55/22 micrograms one puff daily, started 6 months ago;
 - salbutamol 100 micrograms pMDI two puffs when required (has been using this every 2 hours in the past 2 days);
 - Uniphyllin 600 mg twice daily.
- The doctor diagnoses Ms M with an infective exacerbation of COPD and prescribes:
- oxygen – target saturation 88–92%;
 - dalteparin 5000 units daily;
 - doxycycline 200 mg as a single stat dose followed by 100 mg daily, total course 5 days;
 - salbutamol nebuliser 5 mg four times daily;
 - ipratropium 500 micrograms four times daily;
 - Anoro Ellipta 55 micrograms/22 micrograms one puff daily;
 - Uniphyllin 600 mg twice daily;
 - Prednisolone 30 mg daily for 5 days.

Questions

1. What is Ms M's MRC dyspnoea score?
2. What monitoring parameters would need to be measured, and why?

Ms M is admitted to a respiratory ward and appears to be doing well. On day 2, she starts to vomit, and the medical team prescribes i.v. cyclizine 50 mg three times daily to try to control this. Her BP has dropped to 90/52 mmHg, and her pulse is elevated at 135 bpm. She is tremulous, and her respiratory rate has increased to 40 breaths/min.

3. What is the cause of Ms M's vomiting, how can this be managed and why has this occurred?

Potassium levels come back as 3.0 mmol/L with no electrocardiogram (ECG) changes other than sinus tachycardia. After giving Ms M a bolus of 250 mL sodium chloride 0.9%, her BP improves to 110/60 mmHg. The medical team prescribes 40 mmol/L potassium in 1 litre sodium chloride 0.9% over 4 hours via an infusion pump with a plan to recheck potassium at the end of this period. All other electrolytes are within the normal range. The theophylline level comes back as 30 mg/L (range 10–20 mg/L). The plan is to continue to monitor Ms M on the cardiac monitor for 24 hours, repeat electrolytes and blood glucose every 6 hours and give i.v. potassium as and when required.

4. What pharmaceutical care planning should be made prior to Ms M's discharge?

Answers

1. 5, breathless whilst getting washed/dressed
2. Temperature, blood pressure, respiratory rate, pulse and arterial blood gases should be monitored to indicate if Ms M is clinically improving or deteriorating. WCC should be measured to monitor improvement in infection in conjunction with the basic observations outlined previously. The pulse rate and potassium level are important because the patient is receiving salbutamol, prednisolone and theophylline, all of which can lower potassium levels significantly. In addition, potassium is likely to drop further with her profuse and protracted vomiting. Platelets and creatinine need to be monitored because dalteparin can cause heparin-induced thrombocytopenia, and the dose is affected by renal function. Theophylline levels should be monitored on admission to hospital, particularly because Ms M is prescribed salbutamol nebulas concurrently, which predisposes the patient to theophylline toxicity.
3. The most likely cause of Ms M's vomiting is theophylline toxicity. A theophylline level (even if one was taken on admission) should now be requested. Administration of theophylline should be stopped until the result is known. The most likely cause of theophylline toxicity is that Ms M has been unable to smoke whilst an in-patient. Stopping smoking reduces the metabolism of theophylline, so the patient requires a lower dose when smoking has stopped. This had not been identified as a risk factor when Ms M was admitted to hospital. Potassium, magnesium, calcium, blood glucose and phosphate levels need to be measured because profound and rapid hypokalaemia can develop with theophylline toxicity, particularly if salbutamol is being administered concurrently; i.v. replacement may be required. In the immediate situation, Ms M needs fluid resuscitation because her blood pressure is currently low; an arterial blood gas needs to be analysed to exclude metabolic acidosis or respiratory alkalosis. Salbutamol nebulas need to be discontinued due to the tachycardia and likely hypokalaemia. Ms M needs to be placed on a cardiac monitor and a 12-lead ECG performed. Monitor for restlessness, agitation and convulsions. Ensure 4 mg i.v. lorazepam is prescribed as required in the event of convulsions. Beta blockers

can be considered if severe tachycardia persists. Monitor theophylline levels every 2 to 4 hours to ensure they are falling. Activated charcoal is not usually indicated if theophylline levels are less than 40 mg/L, but treatment of theophylline toxicity should be considered if symptoms do not resolve rapidly. Toxbase (www.toxbase.org) should be accessed for more detailed information.

Ondansetron is an alternative antiemetic should cyclizine be ineffective; therefore, 8 mg when required should be prescribed proactively.

4. Smoking cessation should be discussed with Ms M. She should be offered advice on support available and the pharmacological therapies that may aid her quit attempt. She should be referred to the smoking cessation team. If Ms M decides to quit, then the theophylline dose will need to be adjusted. Initially the theophylline dose should be halved to 300 mg twice daily and a level taken within a week, 4–6 hours post-dose. Ms M should also be offered pulmonary rehabilitation. She has also had five courses of oral prednisolone in the last 8 months, which increases the risk for osteoporosis. Osteoporosis prophylaxis should therefore be considered. For a patient of 54 years of age, a bone scan would usually need to be arranged. Ms M is already on Anoro, but due to her exacerbation history, she may benefit from ICS/LABA, particularly if her blood eosinophil levels are elevated. This would mean switching Anoro to a different inhaler. If her inhaler technique is good with the Ellipta device, then a suitable ICS/LABA would be Relvar 92 micrograms/22 micrograms one puff daily plus Incore 55 micrograms one puff daily. Ms M would need to understand that the Anoro has been discontinued. Ms M should be provided with a self-management plan together with reserve steroids and antibiotics. Her vaccinations should also be checked to ensure they are up to date.

Case 26.3

Mrs K is a well-known COPD patient who has had very frequent admissions to hospital due to the symptoms related to end-stage COPD. She has no family support at home and is severely disabled by breathlessness. She is on LTOT and complies with the 15 h/day prescription. She is an ex-smoker. Mrs K is cachectic and extremely anxious, especially when she is acutely unwell and more breathless than usual. She finds it hard to sleep at night. She is adherent to her medications and knows precisely what each item is for and how often to take them. She is very reluctant for these medicines to be changed or altered. In the last few admissions, Mrs K has required non-invasive ventilation and prolonged courses of antibiotics. Mrs K has recognised herself that recently she has been more symptomatic and has been struggling to cope at home. She has decided that she does not want any more antibiotics or respiratory support should her condition acutely deteriorate once more. It has been recognised by the medical team that Ms K is entering into the last few weeks of her life, and a Do Not Attempt Cardiopulmonary Resuscitation form has been discussed with Mrs K and has been signed to be valid to the end of life.

Her regular medications are as follows:

- alendronic acid 70 mg weekly,
- betahistine 16 mg three times daily,
- carbocysteine 750 mg three times daily,
- domperidone 10 mg three times daily,
- furosemide 40 mg daily,
- gabapentin 800 mg three times daily,
- lansoprazole 30 mg daily,
- prochlorperazine 5 mg three times daily,
- quinine sulfate 300 mg at night,
- salbutamol 2.5 mg nebulas four times daily,
- senna 15 mg at night,
- Seretide 500 Accuhaler one puff twice daily.

Questions

1. How would you rationalise Mrs K's current medication, and how would you persuade her to stop unnecessary medications?

Upon talking to Mrs K, it becomes apparent that she is extremely low in mood. You suggest to her that an antidepressant may help her feel better, although it will not change her physical situation. She agrees that she feels 'down in the dumps', and she says she is willing to try a new tablet if it makes her feel better about herself.

2. Which antidepressants would you consider suitable?
3. Mrs K is breathless and anxious at rest. What suggestions could you make to help control these symptoms?

Next time Mrs K is admitted, she is extremely unwell. Her opioid usage is equivalent to 60 mg morphine sulfate per day. She is confused and in type 2 respiratory failure. Her wish was not for further intervention, and reversible causes for the confusion are ruled out. There is no evidence of opioid toxicity (e.g. pinpoint pupils/myoclonic jerks). Mrs K is breathless, scared and agitated. She is now unable to take oral medication. Her doctor decides that she is progressing to the last few hours/days of life.

4. What would you suggest to manage her symptoms?

Answers

1. Alendronic acid, betahistine, prochlorperazine, domperidone and quinine should be stopped because these are now nonessential medications that will not significantly contribute to symptom management at this stage of her condition. A trusting relationship needs to be established with Mrs K and the risks and benefits of stopping all the medications discussed with her. Mrs K needs gentle support to understand that the medicines will not cause her symptoms to become worse and indeed may contribute to unnecessary side effects. It may be that one medicine at a time is stopped, with perhaps either the betahistine or the prochlorperazine being a suitable starting point. Betahistine and prochlorperazine are both used for vertigo, and therapeutic duplication is unnecessary, so a pragmatic starting point would be to stop one of these in the first instance. She should not take regular salbutamol in the nebuliser on top of Seretide, and instead this should be changed to as required.
2. Selective serotonin reuptake inhibitors such as citalopram would be suitable for Mrs K; mirtazapine or duloxetine would be other appropriate choices. Choosing which option is better will depend on side effects, interactions with her current medications and cost. Citalopram is licensed for panic disorder, whereas duloxetine is licensed for depression and generalised anxiety disorder. Mirtazapine is licensed for depression. Mrs K is cachectic and finds it hard to sleep at night because of her anxiety, so a suitable choice for Mrs K would be mirtazapine because this is an appetite stimulant and causes some drowsiness. It should be started at 15 mg at night and then titrated if tolerated.
3. A hand-held fan could be tried to relieve the breathlessness. Mrs K should be referred to physiotherapy to be taught coping techniques and to ensure there is no element of dysfunctional breathing. Opioids are an option to control breathlessness. Mrs K could

be started on small doses of morphine sulfate solution (e.g. 2.5 mg every 4–6 hours). Often patients are initiated with morphine sulfate modified-release (MR) tablets/capsules 10 mg twice daily with 2.5 mg as a breakthrough dose to be taken if breathlessness occurs during the day. This is calculated by dividing the total daily dose of morphine by six. Laxatives and anti-emetics should also be prescribed as required. The 'as-required usage' of the breakthrough morphine should be monitored and the maintenance dose increased as appropriate dependent on clinical effect and side effects. This is calculated by adding up how much breakthrough morphine the patient has taken in the last 24 hours and adding this to the current maintenance dose. For example, if Mrs K had taken an additional 10 mg of morphine in the last 24 hours, then the total daily dose of morphine is added to the 10 mg twice-daily maintenance prescription. This makes the total daily dose of morphine 30 mg, which is then divided by 2 for the MR preparations (i.e. 15 mg twice daily). The use of benzodiazepines is also an alternative option to morphine, with lorazepam being the drug of choice. Mrs K could be started on 0.5 mg as required (max 4 mg/day). This can be used regularly if a good effect is seen. It is also appropriate to combine benzodiazepines with opioids for symptom control. Information should be provided on the hospital discharge letter to inform the primary care doctor of the newly started medications and their indications.

4. Ms K should be started on a continuous subcutaneous syringe driver containing both diamorphine (or morphine) and midazolam. Administration of midazolam and opioids via the subcutaneous route is off-license, and mixing of these products is also unlicensed. It is standard practice within palliative care to administer these medications in this manner. To calculate the equivalent dose of subcutaneous diamorphine, divide the total daily dose of oral morphine by 3. In Mrs K's case, she is taking a total daily dose of 60 mg oral morphine. To calculate the dose of diamorphine to add into the syringe driver, this total daily dose should be divided by 3. So, for Mrs K, the equivalent dose of diamorphine is 20 mg over 24 hours. If subcutaneous morphine is to be added to the syringe driver, then the total daily dose of oral morphine is divided by 2, so Mrs K would need 30 mg of subcutaneous morphine in the syringe driver over 24 hours. A small dose of midazolam should be added to the syringe driver (e.g. 5–10 mg over 24 hours). Appropriate breakthrough doses of both opioid and midazolam should be prescribed. In Mrs K's case, this would be 20 mg of diamorphine divided by 6, which is 3 mg or 30 mg of morphine divided by 6, which is 5 mg. Midazolam 2.5 mg should also be prescribed as required. Hyoscine butylbromide 20 mg subcutaneously every hour as required should be added to the prescription to reduce respiratory secretions. An anti-emetic (e.g. subcutaneous haloperidol 1.5–2.5 mg every 4 hours as required) should also be prescribed. During the dying phase, the usage of 'as-required medications' should be monitored daily as a minimum. Any medication that has been administered twice in the preceding 24 hours should be added to the syringe driver to maintain adequate symptom control. Compatibilities should be checked prior to mixing. At the end of life, it is not appropriate to continue with routine monitoring, such as blood pressure and temperature or blood glucose testing, because this does not add to the clinical management of the patient and can be distressing and uncomfortable.

27 Insomnia

Deborah Baidoo and Michele Sie

Key points

- Hypnotic medicines do not cure insomnia but can provide useful short-term symptomatic treatment.
- Before starting medication, the primary cause of insomnia should be investigated and treated appropriately where possible.
- Non-pharmacological approaches should be considered first line.
- Hypnotic medicines should only be used short-term (2–4 weeks); long-term regular use leads to tolerance, dependence and other adverse effects.
- Sleep hygiene, relaxation techniques and psychological methods are more appropriate than hypnotics as long-term treatment for patients with insomnia.
- Nonbenzodiazepine hypnotics, such as zopiclone, zolpidem and zaleplon, have similar pharmacological and adverse effects to benzodiazepines.
- Promethazine, an antihistamine, can be used for the short-term management of insomnia in adults, but tolerance to its hypnotic effects can occur.
- A melatonin preparation is available for primary insomnia licensed in those older than 55 years. It is a naturally occurring hormone that stimulates sleep initiation but does not cause tolerance or dependence.

Definitions and epidemiology

Insomnia refers to difficulty in either falling asleep, remaining asleep or feeling refreshed from sleep. It is the most common sleep disorder and in the UK adult population; an annual prevalence of around 35% has been reported (Ellis et al., 2012). Insomnia has been significantly associated with increasing age, female gender, comorbid anxiety, depression and pain. By age 50, a quarter of the population is dissatisfied with their experience of sleep, rising to 30–40% (two-thirds of them women) among individuals older than 65 years (Sateia and Nowell, 2004).

Pathophysiology

The pathophysiology of insomnia is related to the overactivity of the arousal, emotional regulatory and cognitive sleep systems in the brain (Riemann et al., 2015). These systems are functionally

interrelated, and their activity determines the degree and type of alertness during wakefulness and the depth and quality of sleep.

Sleep systems

The phenomenon of sleep is actively induced and maintained by neural mechanisms in several brain areas, including the lower brainstem, pons and parts of the limbic system. These mechanisms have reciprocal inhibitory connections with arousal systems so that the activation of sleep systems inhibits waking and vice versa. Normal sleep includes two distinct levels of consciousness, nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep, which are promoted from separate neural centres.

NREM sleep normally takes up about 80% of sleeping time. It is divided into three stages (N1–N3), which merge into each other, forming a continuum of decreasing cortical and behavioural arousal (Fig. 27.1). Stage N3 represents the deepest phase of sleep and is also termed delta sleep (DS) due to the production of delta waves in the brain during this stage. Historically NREM sleep was defined as four stages (1–4) until 2007 when the American Academy of Sleep Medicine reclassified the sleep–wake cycle and changed the stages by amalgamating NREM stages 3 and 4 into stage N3 (Schulz, 2008).

REM sleep normally takes up about 20% of sleeping time and has characteristics quite different from NREM sleep. The electroencephalogram (EEG) shows desynchronised fast activity similar to that found in the alert conscious state, and the eyes show rapid, jerky movements. Peripheral autonomic activity is increased during REM sleep, which may result in changes in blood pressure, heart rate and respiration as well as sexual arousal. Atonia occurs, causing a temporary paralysis. Heightened cognition, resulting in vivid dreams and nightmares, most often occurs during REM sleep, although brief frightening dreams (hypnagogic hallucinations) can occur in NREM sleep, especially at the transition between sleeping and waking. Normally stage N3 sleep occurs primarily in the first few hours of the night, whereas REM sleep is most prominent towards the morning. Brief awakenings during the night are normal. Both DS and REM sleep are thought to be essential for brain function, and both show a rebound after a period of deprivation, usually at the expense of lighter (stage N1 and N2) sleep, which appears to be expendable. Many medicines can affect the different stages of sleep. Benzodiazepines suppress stage N3 of sleep but cause only a slight decrease in REM sleep.

Fig. 27.1 The stages of sleep across a single night in adults.

N1, N2, N3, nonrapid eye movement sleep stages 1, 2 and 3; R, rapid eye movement sleep; W, wake. (Keenan and Hirshkowitz, 2011, *Principles and Practice of Sleep Medicine*. Reprinted with permission from Elsevier.)

Z-hypnotics shorten stage N1 of sleep and prolong stage N2 of sleep but have little effect on stage N3 and REM sleep. Sedating antihistamines cause a reduction in the duration of REM sleep.

Aetiology and clinical manifestations

Insomnia may be caused by any factor that increases activity in arousal systems, which leads to decreased activity in sleep systems. Increased sensory stimulation (e.g. electronic media use) activates arousal systems, resulting in difficulty in falling asleep. Common physical health causes include chronic pain, gastric reflux, uncontrolled asthma and external stimuli such as noise, bright lights and extremes of temperature.

Mental health conditions often affect sleep. Anxiety may delay sleep onset as a result of increased emotional arousal. Difficulty in staying asleep is characteristic of depression. Patients typically complain of early waking, but sleep records show frequent awakenings, early onset of REM sleep and reduced NREM sleep. Alteration of sleep stages, increased dreaming and nightmares may also occur in schizophrenia, and recurring nightmares are a feature of posttraumatic stress disorder (PTSD). Interference with circadian rhythms, as in shift work or rapid travel across time zones, can cause difficulty in falling asleep or early waking.

Frequent arousals from sleep are associated with myoclonus, 'restless legs syndrome', muscle cramps, bruxism (tooth grinding), head banging and sleep apnoea syndromes. Reversal of the sleep pattern, with a tendency for poor nocturnal sleep but a need for daytime naps, is common in the elderly, in whom it may be associated with cerebrovascular disease or dementia. In general, decreased duration of sleep has been shown to increase the future risk of musculoskeletal pain conditions and myocardial infarction. Associations have also previously been identified with an increased risk of obesity and diabetes, but in larger studies, these have been shown not to be significant (Sivertsen et al., 2014). Sleep disturbances in the elderly are also associated with increased falls, cognitive decline and a higher rate of mortality (Cohen et al., 2009). There is growing concern that daytime sleepiness resulting from insomnia increases the risk of industrial, traffic and other accidents, medical errors and a general decrease in performance and functioning.

Difficulty in falling asleep may result directly from the action of stimulants, including caffeine, nicotine, theophylline, sympathomimetic amines, some antidepressants, levothyroxine and antimuscarinics. Some illicit substances, cocaine, amphetamines and anabolic steroids can also cause insomnia. Withdrawal after chronic use of central nervous system depressants, including hypnotics, anxiolytics and alcohol, commonly causes rebound insomnia with delayed or interrupted sleep, increased REM sleep and nightmares. With rapidly metabolised drugs, such as alcohol or short-acting benzodiazepines, duration of action is limited, which may result in early waking. Certain medicines, including antipsychotics, tricyclic antidepressants and propranolol, occasionally cause nightmares, which may result in insomnia.

Investigations and differential diagnosis

Many patients complaining of insomnia overestimate their sleep requirements. Although most people sleep for 7–8 hours daily, some healthy subjects require as little as 3 hours of sleep, and sleep requirements decline with age. Such 'physiological insomnia' does not usually cause daytime fatigue, although the elderly may take daytime naps. If insomnia is causing distress, primary causes such as pain, medicines that disturb sleep, psychiatric disturbance including anxiety and depression and organic causes such as sleep apnoea should be identified and treated before hypnotic therapy is prescribed.

Treatment

Non-pharmacological therapies

Explanation of sleep requirements, attention to sleep hygiene (Box 27.1), reduction in caffeine or alcohol intake and the use of analgesics where indicated may obviate the need for hypnotics. Medications that cause insomnia should also be avoided if possible. Sleep restriction, stimulus control and psychological techniques such as relaxation therapy and cognitive behavioural therapy (CBT) are also beneficial (Siebern et al., 2012). However, studies comparing psychological approaches to hypnotics are scarce (Riemann and Perlis, 2009).

Box 27.1 Principles of typical advice for good sleep hygiene

- Have a good bedtime routine; go to bed and get up at the same time every day, and avoid daytime naps.
- Avoid stimulants such as caffeine, nicotine, chocolate and alcohol 6 h before bedtime.
- Take regular exercise during the day, but avoid strenuous exercise within 4 h of bedtime.
- Avoid large meals close to bedtime.
- Associate bed with sleep. Do not watch TV or listen to music when retiring to bed.
- The bedroom should be a quiet, relaxing place to sleep; make sure the room is not too hot or too cold.
- If after 30 min you cannot get off to sleep, then get up. Leave the bedroom and try to do something else; return to bed when sleepy. This can be repeated as often as necessary until you are asleep.

Hypnotic medicines

Hypnotic medicines provide only symptomatic treatment for insomnia. Although often efficacious in the short-term they do little to alter the underlying cause, which should be sought and treated where possible. About 9 million prescriptions for hypnotics are issued each year in primary care in England, and there is a trend that prescribing of these medicines is reducing year on year. These medicines can improve the quality of life if used rationally.

The ideal hypnotic would:

- gently suppress brain arousal systems while activating systems that promote deep and satisfying sleep,
- have a rapid onset of action with no residual effects,
- have no ataxic or memory effects,
- not induce tolerance or dependence if used long-term
- not cause withdrawal effects when stopped,
- not depress respiration,
- be safe for use in the elderly patient.

Unfortunately, most available hypnotics are general central nervous system depressants which inhibit both arousal and sleep mechanisms. Thus, they do not induce normal sleep and often have adverse effects, including daytime sedation ('hangover') and rebound insomnia on withdrawal. They are unsuitable for long-term use because of the development of tolerance and dependence.

Benzodiazepines

By far the most commonly prescribed hypnotics are the benzodiazepines. Various benzodiazepines are available (Table 27.1). These medicines differ considerably in potency (equivalent dosage) and in rate of elimination but only slightly in clinical effects. All benzodiazepines have sedative/hypnotic, anxiolytic, amnesic, muscular relaxant and anticonvulsant actions, with minor differences in the relative potency of these effects.

Pharmacokinetics. Most benzodiazepines marketed as hypnotics are well absorbed and rapidly penetrate the brain, producing hypnotic effects within half an hour after oral administration. Rates of elimination vary, however, with elimination half-lives from 6 to 100 hours (see Table 27.1). These medicines undergo hepatic metabolism via oxidation or conjugation and some form pharmacologically active metabolites with even longer elimination half-lives.

Oxidation of benzodiazepines is decreased in the elderly, in patients with hepatic impairment and in the presence of some medication, for example, oral contraception, disulfiram and propranolol.

Pharmacokinetic characteristics are important in selecting a hypnotic medicine. A rapid onset of action combined with a medium duration of action (elimination half-life about 6–8 hours) is usually desirable. Too short a duration of action may lead to, or fail to control, early morning waking, whereas a long duration of action (e.g. nitrazepam) may produce residual effects the next day and may lead to accumulation if the medication is used regularly. However, frequency of use and dosage are also important. For example, diazepam (5–10 mg) produces few residual effects when used occasionally, despite its slow elimination, although chronic use impairs daytime performance. Large doses of short-acting medicines may produce hangover effects, whereas small doses of longer-acting medicines may cause little or no hangover.

Mechanism of action. Most of the effects of benzodiazepines result from their interaction with specific binding sites associated with postsynaptic GABA_A receptors in the brain. All benzodiazepines bind to these sites, although with varying degrees of affinity, and potentiate the inhibitory actions of GABA at these sites.

GABA_A receptors are the major inhibitory transmitter receptor in the brain. They are multi-molecular complexes (Figs. 27.2 and 27.3) that control a chloride ion channel and contain specific binding sites for gamma aminobutyric acid (GABA), benzodiazepines and several other medicines, including many nonbenzodiazepine hypnotics and some anticonvulsant medicines (Richter et al., 2012). The various effects of benzodiazepines (hypnotic, anxiolytic, anticonvulsant, amnesic, muscle relaxant) result from GABA potentiation in specific brain sites and at different types of GABA_A receptor. There are multiple subtypes of GABA_A receptor, which may contain different combinations of at least 19 subunits (including α_{1-6} , β_{1-3} , γ_{1-3} and others), and the subtypes are differentially distributed in the brain.

Benzodiazepines predominantly bind to receptors containing α , β , and γ subunits, and it appears that their combination with α_1 -containing subtypes mediates their sedative, amnesic and anticonvulsant effects whilst α_2 -containing subtypes mediate their anxiolytic effects (Möhler, 2006).

Zopiclone

Zopiclone, a cyclopyrrolone, was the first nonbenzodiazepine to be approved for the treatment of insomnia in the European market. Although classed as a nonbenzodiazepine, it still binds to benzodiazepine receptors and is more selective for the α_1 subtype. It has been shown to be effective in promoting sleep initiation and sleep maintenance and is licensed in the UK for up to 4 weeks of use. It has an elimination half-life of approximately 5 hours. This medicine appears to have no particular advantages over benzodiazepines, although it may cause less alteration of sleep stages.

It has hypnotic effects similar to benzodiazepines and carries a similar potential for adverse effects including tolerance, dependence and abstinence effects on withdrawal. Psychiatric reactions, including hallucinations, behavioural disturbances and nightmares, have been reported to occur shortly after the first dose. Other common adverse reactions include a bitter taste, a dry mouth and difficulty arising in the morning (Zammit, 2009).

Table 27.1 Overview of the medication used for insomnia

Drug	Usual dose at night (adult) (mg)	Half-life in adults (h)	Licensed indication	Tolerance	Dependence
Benzodiazepines					
Diazepam	5–15	24–36	Insomnia (short-term use)	Yes	Yes
Loprazolam	1	11	Insomnia (short-term use)	Yes	Yes
Lorazepam	1–2	12–16	Insomnia (short-term use)	Yes	Yes
Lormetazepam	0.5–1.5	10	Insomnia (short-term use)	Yes	Yes
Nitrazepam	5–10	18–36	Insomnia (short-term use)	Yes	Yes
Temazepam	10–20	5–11	Insomnia (short-term use)	Yes	Yes
Z-Hypnotics					
Zaleplon	5–10	2	Insomnia (short-term use up to 2 weeks)	Yes	Yes
Zolpidem	5–10	2–3	Insomnia (short-term use up to 4 weeks)	Yes	Yes
Zopiclone	3.75–7.5	3.5–6	Insomnia (short-term use up to 4 weeks)	Yes	Yes
Orexin receptor antagonist					
Suvorexant	10	10–22	Insomnia up to 3 months	Yes	Yes
Chloral and derivatives (rarely used)					
Chloral betaine ^a	707–1414	Unclear	Insomnia (short-term use)	Yes	Yes
Clomethiazole					
Clomethiazole	192–384	4–5	Severe insomnia in elderly (short-term use)	Yes	Yes
Antihistamines					
Promethazine	25–50	10–19	Insomnia (short-term use)	Yes	No
Diphenhydramine	50	2.5–9	Relief of temporary sleep disturbance (short-term use up to 2 weeks)	Yes	No
Melatonin					
Melatonin (Circadin) Unlicensed products also available	2	3.5–4	Insomnia in adults older than 55 years (up to 13 weeks)	No	No

^aChloral betaine 707 mg is equivalent to 414 mg chloral hydrate tablets.

Eszopiclone

The *S*(+) enantiomer of zopiclone is available in the USA, but there are no current plans for it to be launched in the UK. The advantage that the isomer incurs over zopiclone is unclear. Eszopiclone has been shown to promote sleep onset and sleep maintenance. It has a mean elimination half-life of approximately 7 hours. There is no evidence of tolerance, rebound insomnia or serious withdrawal effects (Hair et al., 2008; Zammit, 2009).

Zolpidem

Zolpidem is an imidazopyridine that binds preferentially to the α_1 benzodiazepine receptor subunit thought to mediate hypnotic effects. It is an effective hypnotic with only weak anticonvulsant and muscle relaxant properties. It has a short elimination half-life (2–3.5 hours), reducing the risk of hangover effects, but rebound effects may occur in the later part of the night, causing early morning waking and daytime anxiety. Zolpidem can cause tolerance and a pharmacodependence, leading to a withdrawal

GABA_A receptor

6 different α subunits

4 different β subunits

3 different γ subunits

Most common mammalian structure (α_1)₂(β_2)₂(γ_1)

Fig. 27.2 The GABA_A receptor and subunits. The GABA_A receptor is a heteropentameric glycoprotein. A total of five distinct polypeptide subunits have been cloned to date— α , β , γ , δ , and ϵ —and multiple isoforms of these subunits are reported in the literature. Different conformations of the GABA_A receptor are found throughout the brain, and the most common mammalian arrangements of subunits is (α_1)₂(β_2)₂(γ_1). The specific subunits in the GABA_A receptor confer functional diversity on the receptor. For example, the γ subunit needs to be co-expressed with the α and β subunits to observe the potentiation of the GABA_A receptor by benzodiazepines.

Fig. 27.3 Schematic representation of the GABA_A receptor. GABA is the major inhibitory neurotransmitter in the central nervous system. The GABA_A receptor is composed of five subunits—two α , two β and one γ subunit. Two molecules of GABA activate the receptor by binding to the α subunits. Once activated the receptor allows the passage of negatively charged ions (Cl^-) into the cytoplasm, which results in hyperpolarisation and the inhibition of neurotransmission. (Source: www.CNSforum.com.)

syndrome and causing irritability, agitation, nervousness and, in severe cases, seizures. Anecdotal case reports have also associated zolpidem with complex sleep-related behaviours. These have included sleep-walking, ‘sleep-driving’, ‘sleep self-intoxication’, amnesia, making phone calls, preparing food and eating while asleep. Long-term use of zolpidem has been shown to increase the risk of major injury (head trauma or fracture). In the USA in 2013 zolpidem became the first medication to be prescribed

differently according to gender following evidence that women were more susceptible to next-day impaired alertness due to slower elimination (Farkas et al., 2013). A controlled-release version of zolpidem (zolpidem-CR) is available in some countries.

Zaleplon

Zaleplon is a pyrazolopyrimidine which, like zolpidem, binds selectively to the α_1 benzodiazepine receptor. It has been shown to effectively promote sleep initiation but is less effective in promoting sleep maintenance. It has a very short elimination half-life of 1 hour and appears to cause minimal residual effects on psychomotor or cognitive function after 5 hours.

There is little evidence of tolerance or withdrawal effects in short-term use, and the medicine appears suitable for use in the elderly.

Suvorexant

Suvorexant, a novel hypnotic, is a dual orexin-1 receptor and orexin-2 receptor antagonist. Suvorexant is structurally unrelated to benzodiazepines and other hypnotic agents. It has been shown to be effective in promoting sleep initiation and maintaining sleep and can be used for periods of up to 3 months. It has an elimination half-life of approximately 15 hours (range of 10–22 hours).

Clinical trial data showed no evidence of rebound insomnia on discontinuation, no evidence of physical dependence with prolonged use and no reports of withdrawal symptoms. However, further clinical trials may be required to determine tolerance and withdrawal effects in long-term use (Yang, 2014).

Other hypnotic medicines

The risk of adverse effects, including dependence and dangerous respiratory depression in overdose, generally outweighs the potential benefits of the older hypnotics – chloral derivatives, clomethiazole and barbiturates. Therefore, these treatments are best avoided. Antidepressants with sedative properties, such as mirtazapine or agomelatine, may be helpful if sleep disturbance is secondary to depression. Sedative antipsychotics are not recommended for the management of insomnia due to their adverse effects.

Antihistamines

Diphenhydramine and promethazine

Diphenhydramine and promethazine are H-1 receptor antagonists. Activating H-1 receptors promotes wakefulness, and therefore H-1 receptor antagonists promote sedation. The evidence for the efficacy in the management of acute or chronic insomnia is sparse. Diphenhydramine and promethazine have an elimination half-life of approximately 2–9 hours and 5–14 hours, respectively.

The long duration of action may lead to hangover effects, and antihistamines are associated with a potential for tolerance and abuse. Abrupt discontinuation can be associated with activation, insomnia and mild antimuscarinic withdrawal symptoms such as nausea, sweating and headache. Many antihistamines have potent anticholinergic activity, leading to adverse effects of

sedation, dizziness, dry mouth, constipation, urinary retention, blurred vision and weight gain.

Melatonin

Melatonin is a naturally occurring hormone, produced by the pineal gland, which regulates the circadian rhythm of sleep. It begins to be released once it becomes dark and continues to be released until the first light of day. Melatonin release decreases with age, which may in part explain why older adults require less sleep. Melatonin supplementation promotes sleep initiation and helps reset the circadian clock, allowing uninterrupted sleep. It has also been shown to improve next-day functioning. Contrary to most other hypnotics, melatonin shows no abuse or tolerance potential and appears to have no next-day sedation problems (Riemann et al., 2015). Prolonged-release melatonin (Circadin) was launched in June 2008 and is available at a dose of 2 mg at night for up to 13 weeks. It is licensed as monotherapy in primary insomnia for adults older than 55 years old. Although the adverse-effect profile looks advantageous, there are currently no trials comparing melatonin against psychological or other hypnotic treatments. Circadin is also much more expensive than other currently prescribed hypnotics

Potential adverse effects of hypnotic use

Tolerance and dependence

Tolerance to the hypnotic effects of benzodiazepines, z-hypnotics and antihistamines develops rapidly and may lead to unprescribed dose escalation by users. Nevertheless, poor sleepers may report continued efficacy. Physical and psychological dependence are common with benzodiazepines and z-hypnotics, and despite safety recommendations for short-term use, these medicines are often used long-term because of difficulties on withdrawal. Prescribing hypnotics beyond limited short courses brings potential hazards, of dependence, adverse effects and adverse events, for example, falls. Targeted deprescribing of hypnotic medicines can lead to better health outcomes.

Rebound insomnia

Rebound insomnia, in which sleep is poorer than before pharmacological treatment, is common on withdrawal of benzodiazepines. Sleep latency (time to onset of sleep) is prolonged, intra-sleep awakenings become more frequent and REM sleep duration and intensity are increased, with vivid dreams or nightmares which may add to frequent awakenings. These symptoms are most marked when the medicines have been taken in high doses or for long periods but can occur after only a week of low dose administration. They are prominent with moderately rapidly eliminated benzodiazepines (temazepam, lorazepam) and may last for many weeks. With slowly eliminated benzodiazepines (diazepam), DS and REM sleep may remain depressed for some weeks and then slowly return to the baseline, sometimes without a rebound effect. Tolerance and rebound effects are reflections of a complex homeostatic response to regular use of medicines, involving desensitisation, uncoupling and internalisation

of certain GABA/benzodiazepine receptors and sensitisation of receptors for excitatory neurotransmitters (Allison and Pratt, 2003). These changes encourage continued hypnotic usage and contribute to the development of dependence.

Oversedation and hangover effects

Many benzodiazepines and z-hypnotics used to treat insomnia can give rise to a subjective 'hangover' effect, and after most of them, even those with short elimination half-lives, psychomotor performance, including driving ability and memory, may be impaired on the following day. Oversedation is most likely with slowly eliminated medicines, especially if used chronically, and is most marked in the elderly in whom drowsiness, incoordination and ataxia, leading to falls and fractures, and acute confusional states may result, even from small doses. Chronic use can cause considerable cognitive impairment, sometimes suggesting dementia. Paradoxical excitement may occasionally occur.

These medicines may also decrease alveolar ventilation and depress the respiratory response to hypercapnia, increasing the risk of cerebral hypoxia, especially in the elderly and in patients with chronic respiratory disease.

Drug interactions

Concomitant use of two or more medicines that cause central nervous system (CNS) depression result in additive effects that can increase drowsiness, cause marked sedation and reduce alertness, which may lead to accidents and severe respiratory depression. Medicines that can cause CNS depression include antidepressants, antiepileptics, antihistamines, antipsychotics, anxiolytics, benzodiazepines, barbiturates, hypnotics, opioid analgesics and skeletal muscle relaxants as well as alcohol (all amounts). (Zammit, 2009).

Suvorexant is metabolised via cytochrome P450 isoenzyme CYP3A, and therefore use with potent inhibitors of these enzymes (e.g. ketoconazole) is not recommended. Dose adjustment may be required when used with moderate inhibitors (e.g. fluconazole); conversely, concomitant use with potent CYP3A inducers (e.g. rifampicin) is likely to reduce efficacy of suvorexant (Yang, 2014).

Rational pharmacological treatment of insomnia

A hypnotic may be indicated for insomnia when it is severe, disabling, unresponsive to other measures or likely to be temporary. In choosing an appropriate agent, individual variables relating to the patient and to the medicine need to be considered (see Table 27.1).

Patient care

Type of insomnia

The duration of insomnia is important in deciding on a hypnotic regimen. Transient insomnia may be caused by changes of routine such as overnight travel, change in time zone, alteration of shift work or temporary admission to hospital. In these circumstances, a hypnotic with a rapid onset, medium duration of action and few residual effects could be used on one or two occasions.

Short-term insomnia may result from temporary environmental stress. In this case, a hypnotic may occasionally be indicated but should be prescribed in low dosage for 1 or 2 weeks only, preferably intermittently, on alternate nights or one night in three to prevent tolerance and dependence.

Chronic insomnia presents a much greater therapeutic problem. It is usually secondary to other conditions (organic or psychiatric) at which treatment should initially be aimed. In selected cases, a hypnotic may be helpful, but it is recommended that such medicines should be prescribed at the minimal effective dosage and administered intermittently (one night in three) or temporarily (not more than 2 or 3 weeks). Occasionally it is necessary to repeat short, intermittent courses at intervals of a few months.

The elderly

The elderly are especially vulnerable both to insomnia and to adverse effects from hypnotic medicines. They may have reduced metabolism of some medicines and may be at risk of cumulative effects. They are also more susceptible than younger people to CNS depression, including cognitive impairment and ataxia (which may lead to falls and fractures). They are sensitive to respiratory depression, prone to sleep apnoea and other sleep disorders and are more likely to have 'sociological', psychiatric and somatic illnesses which both disturb sleep and may be aggravated by hypnotics. For some of these elderly patients, hypnotics can improve the quality of life, but the dosage should be adjusted (usually half the recommended adult dose), and hypnotics with long elimination half-lives or active metabolites should be avoided.

A considerable number of elderly patients give a history of regular hypnotic use going back for 20 or 30 years. In many of these patients, gradual reduction of hypnotic dosage or even withdrawal may be indicated and can be carried out successfully, resulting in improved cognition and general health with no impairment of sleep or escalation of other symptoms.

The young

Traditional benzodiazepine-like hypnotics are generally contraindicated for children. Promethazine is the only licensed paediatric sedative for use in those aged 5 years or older. The use of promethazine in young children is usually unjustified, and there have been reports of a possible association between the use of phenothiazine antihistamines and sudden infant death syndrome (SIDS), although this has not been confirmed. The off-label use of melatonin is common particularly in those with attention-deficit/hyperactivity disorder (ADHD).

Disease states

Hypnotics are contraindicated in patients with acute pulmonary insufficiency, significant respiratory depression, marked neuromuscular respiratory weakness, sleep apnoea syndrome or severe hepatic impairment. In terminal conditions, the possibility of pharmacodependence becomes a less important issue, and regular use of hypnotics with a medium duration of action should not be denied if they provide symptomatic relief of insomnia.

Choice of pharmacological treatment

There is little difference in hypnotic efficacy between most of the available agents. The main factors to consider in the rational choice of a hypnotic regimen are duration of action and the risk of adverse effects, especially oversedation and the development of tolerance and dependence. There is no compelling evidence to distinguish z-hypnotics from the shorter-acting benzodiazepine hypnotics ([National Institute for Health and Care Excellence, 2004](#)). Patients who do not respond to either a benzodiazepine or z-hypnotic should not be prescribed the other. Cost may also be a factor when prescribing melatonin.

Rate of elimination

Slowly eliminated medicines should be avoided because of the risk of oversedation and hangover effects. Very short-acting drugs such as zaleplon carry the risk of late-night rebound insomnia and daytime anxiety. Medicines with a medium elimination half-life (6–8 hours) appear to have the most suitable profile for hypnotic use. These include temazepam and zopiclone, and as such, these are the medicines of first choice in most situations where hypnotics are indicated in adults. Sedative antihistamines are a reasonable second choice, followed by melatonin.

Duration and timing of administration

To prevent the development of tolerance and dependence, the maximum duration of treatment should be limited to between 2 and 4 weeks, and treatment should, where possible, be intermittent (one night in two or three). Dosage should be tapered slowly if hypnotics have been taken regularly for more than a few weeks to prevent potential withdrawal effects such as rebound insomnia, anxiety, loss of appetite, tremor, perspiration and seizures (Tapering advice is available in the *British National Formulary*). Doses should be taken 20 minutes before retiring in order to allow dissolution in the stomach and absorption to commence before the patient lies down in bed.

Medicines and driving

In the UK the Department for Transport has introduced a new offence of driving with certain controlled drugs above specified limits in the blood. The new law came into force on 2 March 2015 and outlaws driving while under the influence of drugs. As well as illegal drugs, the new legislation also includes some prescription medicines. Medicines included in the new offence that might be used for insomnia include benzodiazepines (e.g. temazepam and diazepam). The legislation provides for a statutory 'medical defence', if patients are taking medicines in accordance with instructions and their driving is not impaired. Patients who are unsure about the effects of their medication or how the new legislation may affect them are advised to seek the advice of their doctor or pharmacist. Drivers who are taking prescribed medication at high doses are advised to carry evidence with them, such as prescriptions slips, when driving in order to minimise any inconvenience should they be asked to take a test by the police ([Department for Transport, 2014](#)).

Case studies

Case 27.1

Mr PH, aged 24, was hospitalised for 3 months after a serious motorcycle injury followed by painful complications. While in hospital he developed panic attacks and insomnia. He received no psychological support but was prescribed temazepam, initially in 20 mg doses but later increased to 60 mg because of continued insomnia. After discharge from hospital Mr PH continued to receive temazepam from his primary care doctor, and the dosage was increased over a period of years until he was taking 80 mg temazepam each night and 40–80 mg during the day. At the age of 30, Mr PH was removed from the practice list of his doctor after he altered a prescription. He later attended several different primary care doctors, obtaining multiple temazepam prescriptions. When he could no longer satisfy his need from prescriptions, he took to obtaining temazepam on the street, taking large and irregular doses by mouth. All this time, his anxiety levels increased. His behaviour became chaotic, and he was twice imprisoned for credit card fraud, but he was able to obtain temazepam and other drugs from his co-prisoners. When last heard of, Mr PH, aged 35, was again buying temazepam illicitly, as well as other addictive drugs, had started injecting intravenously and was involved in a court case for obtaining money under false pretences.

Question

How could the risk of creating dependence and subsequent personal tragedy have been avoided?

Answer

Mr PH's problematic situation could have been averted by judicial prescribing, supply and management of medicines likely to cause dependence or substance misuse.

- The risk of creating dependence could be reduced by not introducing medicines with an abuse potential unless absolutely necessary. Non-pharmacological approaches (e.g. sleep hygiene and/or cognitive behavioural therapy) should have been considered in the first instance.
- Rapid and large dose escalation of temazepam should be avoided, and the lowest effective therapeutic dose for hypnotics should be used. The appropriate dose of hypnotic should be reviewed at each opportunity because the signs of dependence, its effects, and withdrawal from medicines with abuse potential are not always obvious, so timely recognition and assessment may be difficult.
- The treatment and management of the underlying cause for insomnia should be investigated because Mr PH may have been experiencing PTSD or panic disorder. Along with psychological approaches, an antidepressant with sedative effects may have been a more appropriate prescription choice, instead of prolonged treatment with excessive doses of temazepam.
- A slow reducing-dose schedule for hypnotics should be implemented when the acute episode for insomnia has been managed. On discharge from hospital, Mr PH's primary care doctor should have been warned about his temazepam intake and a slow withdrawal schedule communicated.

- Signs of drug-seeking behaviour, such as visiting more than one doctor, fabricating stories and forging prescriptions, should be addressed. The series of primary care doctors who gave Mr PH prescriptions should have been aware that he was likely to attempt to obtain illicit supplies and should have referred him to a withdrawal clinic or substance misuse unit. Doses should be reduced steadily and/or weekly or even daily prescriptions issued for small amounts if dependence is suspected.
- Prescribers should closely monitor amounts prescribed for medicines with abuse potential to prevent patients or their carers from accumulating stocks. A minimal amount should be prescribed in the first instance, or when seeing a new patient for the first time. Patients seen by temporary care services should be given small amounts of medicines unless they present an unequivocal letter from their own primary care doctor.

Case 27.2

Mrs RS, a recently widowed woman aged 75, had difficulty sleeping after her bereavement. She was initially prescribed temazepam 10 mg at night, which was changed following reports of next-day hangover effect to zopiclone in a bedtime dose of 7.5 mg. This was very effective and was continued for over 4 weeks. Mrs RS lived alone but was visited occasionally by her daughter. On a visit 2 weeks after the zopiclone was started, Mrs RS seemed calm and said that she was sleeping well, but the daughter noticed her mother was unsteady on her feet. A few weeks later the daughter visited again and found her mother lying on the bedroom floor, in pain and unable to move. She said that she had lost her balance on getting out of bed. An ambulance was called, and it was found in hospital that Mrs RS had broken her hip.

Question

Should the doctor have prescribed temazepam or zopiclone for this patient, and what other treatment options are available?

Answer

- First-line treatment for insomnia should be non-pharmacological, such as sleep hygiene and relaxation techniques. The doctor should have completed a healthy sleep assessment to identify any contributory factors to Mrs RS's insomnia, such as using stimulant substances (e.g. caffeine) or taking other medicines that may have affected her sleep (e.g. diuretics in the evening).
- Benzodiazepines and z-hypnotics should be avoided in the elderly. If used, a medication with a short duration of action should be selected, and the dose of hypnotic should be reduced to ¼–½ of the adult dose. Zopiclone starting dose in the elderly is 3.75 mg at night.
- Hypnotics should be used on alternate nights or one night in three to prevent tolerance and dependence.
- The elderly are particularly prone to ataxia and light-headedness with benzodiazepines and z-hypnotics, and this can lead to falls and fractures.
- Benzodiazepines and z-hypnotics are not recommended, except acutely, for bereavement. Their amnesic effects may interfere with subsequent psychological adjustment.
- If a hypnotic was indicated, melatonin would have been a better option for Mrs RS because it has less adverse effects, has no tolerance or dependence risks, does not exhibit the increased risk of falls observed with other hypnotics and can be used for up to 13 weeks.

28 Anxiety Disorders

Stephen Bleakley and David S. Baldwin

Key points

- Benzodiazepines should typically only be used short-term (2–4 weeks) because long-term regular use can lead to tolerance, dependence and other adverse effects in some patients.
- If benzodiazepines are indicated, the smallest effective dose should be used along with intermittent dosing where possible. Start with small doses; increase if necessary. Use half the adult dose in elderly patients.
- Psychological therapies ('talking therapies') are generally considered first-line treatments in all anxiety disorders because they may provide lower relapse rates than pharmacotherapy.
- Some antidepressants are appropriate as long-term treatment for anxiety disorders.
- Selective serotonin reuptake inhibitors (SSRIs) are the recommended antidepressants in anxiety disorders but can worsen symptoms at the beginning of treatment, so patients should be monitored carefully in the first weeks.
- When antidepressants are used, they often require higher therapeutic doses in anxiety disorders than those used in patients with depression.

Definitions and epidemiology

Anxiety is a normal, protective, psychological response to an unpleasant or threatening situation. Mild to moderate anxiety can improve performance and ensure appropriate action is taken. However, excessive or prolonged anxiety can be disabling, lead to severe distress and cause much impairment in social functioning. Fig. 28.1 shows that as anxiety levels increase, performance and actions initially increase; however, as the anxiety level increases beyond acceptable or tolerated levels, performance declines.

The term *anxiety disorder* encompasses a variety of conditions that can either exist on their own or in conjunction with another psychiatric or physical illness. Symptoms of anxiety vary, but patients generally present with a combination of psychological, physical and behavioural symptoms (Fig. 28.2). Some of these symptoms are common to many anxiety disorders, whereas others are distinctive to a particular disorder. Anxiety disorders are broadly divided into generalised anxiety disorder (GAD), panic disorder, social anxiety disorder, specific phobias, separation anxiety disorder and illness anxiety disorder. Posttraumatic stress disorder (PTSD) and obsessive-compulsive disorder (OCD) were previously classified under the umbrella of anxiety disorders but

Fig. 28.1 The Yerkes–Dodson curve.

Fig. 28.2 The symptoms of anxiety.

Table 28.1 A brief description of anxiety and related disorders

Symptoms common to all anxiety disorders	Fear or worry, sleep disturbances, concentration problems, dry mouth, sweating, palpitations, GI discomfort, restlessness, shortness of breath, avoidance behaviour
Generalised anxiety disorder (GAD)	Persistent (free-floating), excessive and inappropriate anxiety on most days for at least 6 months. The anxiety is not restricted to a specific situation.
Panic disorder (with or without agoraphobia)	Recurrent, unexplained surges of severe anxiety (panic attack). Most patients develop a fear of repeat attacks or the implications of an attack. Often seen in agoraphobia (fear in places or situations from which escape might be difficult).
Social anxiety disorder (or social phobia)	A marked, persistent and unreasonable fear of being observed, embarrassed or humiliated in a social or performance situation (e.g. public speaking or eating in front of others)
Specific phobia	Marked and persistent fear that is excessive or unrealistic, precipitated by the presence (or anticipation) of a specific object or situation (e.g. flying, spiders). Sufferers avoid the feared object/subject or endure it with intense anxiety.
Posttraumatic stress disorder (PTSD)	Can occur after an exposure to a traumatic event which involved actual or threatened death or serious injury or threats to the physical integrity of self or others. The person responds with intense fear, helplessness or horror. Sufferers can re-experience symptoms (flashbacks) and avoid situations associated with the trauma. Usually occurs within 6 months of the traumatic event.
Obsessive-compulsive disorder (OCD)	Persistent thoughts, impulses or images (obsessions) that are intrusive and cause distress. The person attempts to get rid of these obsessions by completing repetitive, time-consuming purposeful behaviours or actions (compulsions). Common obsessions include contamination, and the compulsion may be repetitive washing or cleaning.
GI, Gastro-intestinal.	

are now considered to be separate illnesses. For completeness, though, these will also be discussed here. [Table 28.1](#) presents a brief description of anxiety and related disorders. Patient testimonials are presented in [Box 28.1](#). Approximately two-thirds of sufferers of an anxiety disorder will have another psychiatric illness. This is most commonly depression, and often successful treatment of an underlying depression will significantly improve the symptoms of anxiety. Many patients also present with symptoms

Box 28.1 Patient testimonies (NICE, 2005a, 2005b)

Symptoms described by a sufferer of posttraumatic stress disorder:

I would feel angry at the way the crash happened and that there was nothing I could do to stop it or help. I was physically exhausted, but was finding it hard to sleep. As soon as the bedroom light went out at night a light would come on in my head and all I could do was lie there and think. When I would eventually fall asleep, I would wake up with nightmares of the crash. I could not get away from it. It was all I could think about in the day and all I would dream about at night.

Thoughts from a sufferer of obsessive-compulsive disorder:

I've just arrived home from work. Tired and tense, I'm convinced my hands are contaminated with some hazardous substance and my primary concern now is to ensure that I don't spread that contamination to anything that I, or others, may subsequently touch. I will wash my hands, but first I will need to put a hand in my pocket to get my door keys, contaminating these, the pocket's other contents, and everything else I touch on my way to the sink. It will be late evening before I will have completed the whole decontamination ritual.

A slow recovery described by a posttraumatic stress disorder and panic attack sufferer:

Slowly I gained ground and as each new insight came I was able to see my symptoms diminish. The panic attacks tapered off, the intensity of the flashbacks dwindled, and my irritable bowel began to loosen some of its hold on me. I was able to breathe again.

of more than one anxiety disorder at the same time, which can further complicate treatment. Anxiety disorders are the most commonly reported mental disorders and as a whole have a lifetime prevalence of approximately 21% ([Baldwin et al., 2014](#)), with specific phobias the most commonly reported.

For all anxiety disorders together, the overall female-to-male ratio is 2:1. The age of onset of most anxiety disorders is in young adulthood (20s and 30s), although the maximum prevalence of generalised anxiety and agoraphobia in the general population is in the 50- to 64-year-old age group.

Pathophysiology

Anxiety occurs when there is a disturbance of the arousal systems in the brain. Arousal is maintained by at least three interconnected systems: a general arousal system, an 'emotional' arousal system and an endocrine/autonomic arousal system ([Fig. 28.3](#)). The general arousal system, mediated by the brainstem reticular formation, thalamic nuclei and basal forebrain bundle, serves to link the cerebral cortex with incoming sensory stimuli and provides a tonic influence on cortical reactivity or alertness. Excessive activity in this system, due to internal or external stresses, can lead to a state of hyperarousal as seen in anxiety. Emotional aspects of arousal, such as fear and anxiety, are contributed by the limbic system, which also serves to focus attention on selected aspects of the environment. There is evidence that increased activity in certain limbic pathways is associated with anxiety and panic attacks.

These arousal systems activate physical responses to arousal, such as increased muscle tone, increased sympathetic activity

Fig. 28.3 Diagram of arousal and sleep systems. Arousal systems receive environmental and internal stimuli, cause cortical activation and mediate motor, autonomic and endocrine responses to arousal. Reciprocally connected sleep systems generate slow-wave sleep (SWS) and rapid eye movement sleep (REMS). Either system can be excited or inhibited by cognitive activity generated in the cortex.

and increased output of anterior and posterior pituitary hormones. Inappropriate increases in autonomic activity are often associated with anxiety states; the resulting symptoms (palpitations, sweating, tremor, etc.) may initiate a vicious circle that increases the anxiety.

Several neurotransmitters have been implicated in the arousal systems. Acetylcholine is the main transmitter maintaining general arousal, but there is evidence that heightened emotional arousal is particularly associated with noradrenergic and serotonergic activity. Drugs which antagonise such activity have anxiolytic effects. In addition, the inhibitory neurotransmitter γ -aminobutyric acid (GABA) exerts an inhibitory control on other transmitter pathways, and increased GABA activity may have a protective effect against excessive stress reactions. Many drugs which increase GABA activity, such as the benzodiazepines, are potent anxiolytics.

Aetiology and clinical manifestations

Anxiety is commonly precipitated by stress or adverse life events, but vulnerability to stress and trait anxiety also appear to be

linked to genetic factors. Many patients presenting for the first time with anxiety symptoms have a long history of high anxiety levels going back to childhood. Anxiety may also be induced by central stimulant drugs (e.g. caffeine, amphetamines), withdrawal from chronic use of central nervous system depressant drugs (e.g. alcohol, hypnotics, anxiolytics) and metabolic or endocrine disturbances (e.g. hyperventilation, hypoglycaemia, thyrotoxicosis). Anxiety may form part of a depressive disorder or psychosis and may occur in temporal lobe lesions and in rare hormone-secreting tumours such as phaeochromocytoma or carcinoid syndrome.

Apart from the psychological symptoms of apprehension and fear, somatic symptoms may be prominent in anxiety and include palpitations, chest pain, shortness of breath, dizziness, dysphagia, gastro-intestinal disturbances, loss of libido, headaches and tremor. Panic attacks are experienced as storms of increased autonomic activity combined with a fear of imminent death or loss of control. If panic becomes associated with a particular environment, commonly a crowded place with no easy escape route, the patient may actively avoid similar situations and eventually become agoraphobic. When anxiety is precipitated by a specific cause, then behaviour can become altered to ensure the sufferer avoids the cause. This avoidance behaviour

can maintain the often-irrational fear and strengthen the desire to avoid the threat.

Investigations and differential diagnosis

In patients presenting with symptoms and clinical signs of anxiety, it is important to exclude organic causes such as thyrotoxicosis, excessive use of stimulant drugs such as caffeine and the possibility of alcohol dependence or withdrawal effects from benzodiazepines. However, unnecessary investigations should generally be avoided if possible. Extensive gastroenterological, cardiological and neurological tests may increase anxiety by reinforcing the patient's fear of a serious underlying physical disease.

Treatment

Treatment for anxiety disorders often requires multiple approaches. The patient may need short-term treatment with an anxiolytic, such as a benzodiazepine, to help reduce the immediate symptoms combined with psychological therapies and an antidepressant for longer-term treatment and to prevent relapse of symptoms.

Psychological interventions

Psychological therapies ('talking therapies') are generally considered first-line treatments in all anxiety disorders because they may provide lower relapse rates than pharmacotherapy. Psychotherapy, however, is less readily available, is more emotionally demanding and takes longer to work than pharmacotherapy. If the patient is unable to tolerate the anxiety or associated distress, then medicines are often used before psychotherapy or while awaiting psychotherapy. The ideal treatment should be tailored to the individual and optimised treatment may involve the combination of psychotherapy and pharmacotherapy. The type of treatment should depend on symptoms, type of anxiety disorder, speed of response required, long-term goals and patient preference.

The specific psychotherapy with the most supporting evidence in anxiety disorders is cognitive behavioural therapy (CBT). CBT focuses on the 'here and now' and explores how individuals feel about themselves and others and how behaviour is related to these thoughts. Through individual therapy or group work, the patient and therapist identify and question maladaptive thoughts and help develop an alternative perspective. Individual goals and strategies are developed and evaluated with patients, who are encouraged to practise what they have learned between sessions. Therapy usually lasts for around 60–90 minutes every week for 8–16 weeks, or longer in more resistant cases. Cognitive behavioural therapists are usually health professionals such as mental health nurses, psychologists, primary care doctors, social workers, counsellors or occupational therapists who have undertaken specific training and supervision.

In PTSD, CBT is trauma focused, with the therapist helping patients confront their traumatic memories and people or objects associated with the trauma. At the same time, patients are taught skills to help them cope with the emotional or physical response to the trauma. One such skill includes relaxation training, which may involve systematically relaxing major muscle groups in a way that decreases anxiety. Another psychotherapy sometimes recommended in PTSD is eye movement desensitisation and reprocessing (EMDR). This involves briefly recounting the trauma or objects associated with the trauma to the therapist, who will then simultaneously initiate another stimulus, for example, moving a finger continuously in front of the patient's eyes or hand tapping. Over time, it enables the patient to focus on alternative thoughts when associations with the trauma occur. Routinely applied single- or multiple-session 'debriefing' following a traumatic event is not thought effective to prevent PTSD and, therefore, not recommended.

In OCD, CBT includes exposure and response prevention (ERP). This involves the therapist and the patient repeatedly facing the fears, beginning with the easiest situations and progressing until all the fears have been faced. At the same time the person must not perform any rituals or checks.

Specific phobias, illness anxiety disorder and separation anxiety disorder are also almost exclusively treated using psychological therapies. Only a few patients will require additional drug therapy, which is usually a selective serotonin reuptake inhibitor (SSRI).

Other psychotherapies (excluding those based on CBT techniques) are occasionally tried, but these have a poorer evidence base and are, therefore, not usually recommended. Self-help approaches are recommended ([National Institute for Health and Care Excellence \[NICE\], 2011](#)) for GAD and panic disorder. They usually involve using materials either alone or in part under professional guidance to learn skills to help cope with the anxiety. The materials, such as books, tapes or computer packages, can be accessed at home and at the patient's convenience. Some self-help material, however, is of poor quality, so it is probably best used in those who have mild symptoms and who do not need more intensive treatments.

Pharmacotherapy

Benzodiazepines

Benzodiazepines are often prescribed to provide an immediate reduction in the symptoms of severe anxiety. Various benzodiazepines are available ([Table 28.2](#)). These drugs differ considerably in potency (equivalent dosage) and in the rate of elimination but only slightly in clinical effects. All benzodiazepines have sedative/hypnotic, anxiolytic, amnesic, muscular relaxant and anti-convulsant actions, with minor differences in the relative potency of these effects.

Pharmacokinetics. Most benzodiazepines are well absorbed and rapidly penetrate the brain, producing an effect within half an hour after oral administration. Rates of elimination vary, however, with elimination half-lives from 8 to 35 hours (see [Table 28.2](#)). The drugs undergo hepatic metabolism via oxidation or conjugation and some form pharmacologically active metabolites with shorter

or even longer elimination half-lives. An example of this effect is diazepam, which has active metabolites including temazepam and oxazepam. Oxidation of benzodiazepines is decreased in the elderly, in patients with hepatic impairment and in the presence of some drugs, including alcohol. Benzodiazepines are metabolised mostly through the cytochrome P450 3A4/3 enzyme system in the liver, so significant enzyme inducers (e.g. carbamazepine) may reduce levels, whereas enzyme inhibitors (e.g. erythromycin) may increase levels (Bazire, 2014).

Mechanism of action. Most of the effects of benzodiazepines result from their interaction with specific binding sites associated with postsynaptic GABA_A receptors in the brain. All

benzodiazepines bind to these sites, although with varying degrees of affinity, and potentiate the inhibitory actions of GABA at these sites. GABA is the most important inhibitory neurotransmitter in the central nervous system (CNS). Neuronal activity in the CNS is regulated by the balance between GABA inhibitory activity and excitatory neurotransmitters such as glutamate. If the balance swings towards more GABA activity, sedation, ataxia and amnesia occur. Conversely, when GABA is reduced arousal, anxiety and restlessness occur. GABA_A receptors are multimolecular complexes that control a chloride ion channel and contain specific binding sites for GABA, benzodiazepines and several other drugs, including many nonbenzodiazepine hypnotics and some anticonvulsant drugs (Haefely, 1990) (Fig. 28.4). The various effects of benzodiazepines (hypnotic, anxiolytic, anticonvulsant, amnesic, muscle-relaxant) result from GABA potentiation in specific brain sites and at different GABA_A receptor types. There are multiple subtypes of GABA_A receptor which may contain different combinations of at least 17 subunits (including α_{1-6} , β_{1-3} , γ_{1-3} , and others), and the subtypes are differentially distributed in the brain (Christmas et al., 2008). Benzodiazepines bind to two or more subtypes, and it appears that combination with α_2 -containing subtypes mediates their anxiolytic effects and α_1 -containing subtypes their sedative and amnesic effects. There is some evidence that patients with anxiety disorders have reduced numbers of benzodiazepine receptors in key brain areas that regulate anxiety responses (Roy-Byrne, 2005). Secondary suppression of noradrenergic and/or serotonergic and other excitatory systems may also be of importance in relation to the anxiolytic effects of benzodiazepines.

Role in treating anxiety. Benzodiazepines have been used for more than 50 years in the treatment of anxiety and can provide rapid symptomatic relief from acute anxiety states.

Drug	Usual daily dose (mg)	Half-life hours (range)	Equivalent dose to diazepam 10 mg
Alprazolam	0.5–1.5	13 (12–15)	Unknown
Chlordiazepoxide	30	12 (6–30)	30 mg
Clonazepam	2–4	35 (20–60)	1–2 mg
Diazepam	5–30	32 (21–50)	—
Lorazepam	1–4	12 (8–25)	1 mg
Oxazepam	30	8 (5–15)	30 mg
Temazepam	10–20	8 (5–11)	20 mg

Fig. 28.4 Schematic diagram of the GABA_A receptor. This consists of five subunits arranged around a central chloride ion channel (one subunit has been removed in the diagram to reveal the ion channel, shown in the closed position). Some of the subunits have binding sites for benzodiazepines (B) and other hypnotics and anticonvulsants. Activation of the receptor by GABA opens the chloride channel, allowing chloride ions (Cl⁻) to enter the cell, resulting in hyperpolarisation (inhibition) of the neuron. Occupation of the benzodiazepine site, along with GABA, potentiates the inhibitory actions of GABA.

Concerns about dependence and tolerance largely restrict use to short-term treatment (Baldwin et al., 2013a). Many clinical trials have shown short-term efficacy in patients with anxiety disorders, although the efficacy shown is in part dependent on the year of publication of the study. Older randomised controlled trials appear to show a larger effect than more recent ones (Martin et al., 2007). Anxiolytic effects have also been reported in normal volunteers with high trait anxiety and in patients with anticipatory anxiety before surgery. However, in subjects with low trait anxiety and in nonstressful conditions, benzodiazepines may paradoxically increase anxiety and impair psychomotor performance.

Although useful for many anxiety disorders, benzodiazepines are not generally recommended for those with panic disorder (NICE, 2011). Some patients report worse panic attacks after the benzodiazepines are stopped. Benzodiazepines are also useful at the start of SSRI treatment in OCD and as hypnotics in PTSD (NICE, 2005a, 2005b). They should, however, be used at the lowest effective dose, prescribed intermittently where possible and used for no longer than 2–4 weeks.

Choice of benzodiazepine in anxiety. The choice of benzodiazepine depends largely on pharmacokinetic characteristics. Potent benzodiazepines such as lorazepam and alprazolam (Table 28.2) have been widely used for anxiety disorders but are probably inappropriate. Both are rapidly eliminated and need to be taken multiple times a day. Declining blood concentrations may lead to interdose anxiety as the anxiolytic effect of each tablet wears off. The high potency of lorazepam (~10 times that of diazepam), and the fact that it is available only in 1- and 2.5 mg tablet strengths, has often led to excessive dosage. Similarly, alprazolam (~20 times more potent than diazepam) has often been used in excessive dosage, particularly in the USA. Such doses lead to adverse effects, a high probability of dependence and difficulties in withdrawal.

A slowly eliminated benzodiazepine such as diazepam is more appropriate in most cases. Diazepam has a rapid onset of action, and its slow elimination ensures a steady blood concentration. Clonazepam, although long acting, is more potent than diazepam and in practice is often difficult to withdraw from. It is only indicated for epilepsy in the UK but is commonly used as an anxiolytic.

Parenteral administration of lorazepam or diazepam may occasionally be indicated for severely agitated patients.

Adverse effects. Adverse effects include drowsiness, light-headedness, confusion, ataxia, amnesia, a paradoxical increase in aggression, an increased risk of falls and of road traffic accidents. They are also widely acknowledged as addictive and cause tolerance after more than 2–4 weeks of continuous use (Taylor et al., 2015). Respiratory depression is rare but possible following high oral doses or parenteral use. Flumazenil, a benzodiazepine receptor antagonist, can reverse the effects of severe reactions but requires repeated dosing and close monitoring because of its short half-life.

Psychomotor and cognitive impairment. Although over-sedation is not usually a problem in anxious patients, there is evidence that long-term use of benzodiazepines can result in psychomotor and memory impairment in some patients. Some

patients on long-term benzodiazepines complain of poor memory, and incidents of shoplifting have been attributed to memory lapses associated with benzodiazepine use. In elderly patients, the amnesic effects may falsely suggest the development of dementia. There is some evidence that benzodiazepines also inhibit the learning of alternative stress-coping strategies, such as behavioural treatments for agoraphobia. Additive effects with other CNS depressants, including alcohol, occur and may contribute to road traffic and other accidents.

Disinhibition, paradoxical effects. Rarely, benzodiazepines produce paradoxical stimulant effects. These effects are most marked in impulsive individuals and include excitement, increased anxiety, irritability and outbursts of rage. Violent behaviour has sometimes been attributed to disinhibition by benzodiazepines. This behaviour is normally suppressed by social restraints, fear or anxiety. Increased daytime anxiety can also occur with rapidly eliminated benzodiazepines and may be a withdrawal effect.

Affective reactions. Chronic use of benzodiazepines can worsen depression and may possibly provoke suicide attempts in impulsive patients. Aggravation of depression is a particular risk in anxious patients who often have mixed anxiety/depression. Benzodiazepines are taken alone or in combination with other drugs in 40% of self-poisoning incidents. Although relatively nontoxic in overdose, they can cause fatalities as a result of drug interactions and in those with respiratory disease.

Some patients on long-term benzodiazepines complain of ‘emotional anaesthesia’, the inability to experience either pleasure or distress. However, in some patients, benzodiazepines induce euphoria, and they are occasionally used as drugs of abuse.

Dependence. The greatest drawback of chronic benzodiazepine use is the risk of drug dependence. It is generally agreed that the regular use of therapeutic doses of benzodiazepines as hypnotics or anxiolytics for more than a few weeks (2–4 weeks) can give rise to dependence, with withdrawal symptoms on cessation of drug use in around 40% of patients. It is estimated that there are about 1 million long-term benzodiazepine users in the UK, and many of these are likely to be dependent. People with substance misuse histories or anxious or ‘passive-dependent’ personalities seem to be most vulnerable to dependence and withdrawal symptoms. Such individuals make up a large proportion of anxious patients in psychiatric practice, are often described as suffering from ‘chronic anxiety’ and are the type of patient for whom benzodiazepines are most likely to be prescribed. Such patients often continue to take benzodiazepines for many years because attempts at dosage reduction or drug withdrawal result in intolerable abstinence symptoms. Nevertheless, these patients continue to suffer from anxiety symptoms despite continued benzodiazepine use, possibly because they have become tolerant to the anxiolytic effects and may also suffer from other adverse effects of long-term benzodiazepine use such as depression or psychomotor impairment.

Abuse. Over the last 30 years, there has been much concern about benzodiazepine abuse. Some patients escalate their prescribed dosage and may obtain prescriptions from several

doctors. These tend to be anxious patients with ‘passive-dependent’ personalities who may have a history of alcohol misuse; they may combine large doses of benzodiazepines with excessive alcohol consumption. In addition, a high proportion (30–90%) of illicit recreational drug abusers also use benzodiazepines, and some take them as euphorants in their own right. Recreational use of most benzodiazepines has been reported in various countries; in the UK, temazepam is the most commonly abused anxiolytic drug. Exceedingly large doses (over 1g) may be taken and sometimes injected intravenously. Benzodiazepines became easily available due to widespread prescribing, which favoured their entrance into the illicit drug scene. Abusers can become dependent and suffer the same adverse effects and withdrawal symptoms as prescribed-dose users.

Benzodiazepine withdrawal. Many patients on long-term benzodiazepines seek help with drug withdrawal. Clinical experience shows that withdrawal is feasible in most patients if carried out with care. Abrupt withdrawal in dependent subjects is dangerous and can induce acute anxiety, psychosis or convulsions. However, gradual withdrawal, coupled where necessary with psychological treatments, can be successful in the majority of patients. The duration of withdrawal should be tailored to individual needs and may last many months. Dosage reductions may be of the order of 1–2 mg of diazepam per month. Even with slow dosage reduction, a variety of withdrawal symptoms may be experienced, including increased anxiety, insomnia, hypersensitivity to sensory stimuli, perceptual distortions, paraesthesia, muscle twitching, depression and many others (Box 28.2). These may last for many weeks, although diminishing in intensity, but occasionally, the withdrawal syndrome is protracted for a year or more. Transfer to diazepam, because of its slow elimination and availability as a liquid and in low-dosage forms, may be indicated for patients taking other benzodiazepines. Useful guidelines for benzodiazepine withdrawal are given in the British National Formulary, and detailed withdrawal schedules are also available (Lader et al., 2009).

Box 28.2 Benzodiazepine withdrawal symptoms

Symptoms common to anxiety states	Symptoms relatively specific to benzodiazepine withdrawal
Anxiety, panic	Perceptual distortions, sense of movement
Agoraphobia	Depersonalisation, derealisation
Insomnia, nightmares	Hallucinations
Depression, dysphoria	Distortion of body image
Excitability, restlessness	Tingling, numbness, altered sensation
Poor memory and concentration	Skin prickling (formication)
Dizziness, light-headedness	Sensory hypersensitivity
Weakness, ‘jelly legs’	Muscle twitches, jerks
Tremor	Tinnitus
Muscle pain, stiffness	Psychosis ^a
Sweating, night sweats	Confusion, delirium ^a
Palpitations	Convulsions ^a
Blurred or double vision	
Gastro-intestinal and urinary symptoms	

^aUsually only on rapid or abrupt withdrawal from high doses.

The eventual outcome does not appear to be influenced by dosage, type of benzodiazepine, duration of use, psychiatric history, age, severity of withdrawal symptoms or rate of withdrawal. Hence, benzodiazepine withdrawal is worth attempting in patients who are motivated to stop, and most patients report that they feel better after withdrawal than when they were taking the benzodiazepine. Community pharmacists may be ideally suited to advise doctors and patients on the management of benzodiazepine withdrawal. Leading a benzodiazepine withdrawal clinic may also be a useful role for non-medical prescribers.

Drug interactions. In addition to the pharmacokinetic interactions listed earlier, benzodiazepines have additive effects with other CNS depressants. Combinations of benzodiazepines with alcohol, other hypnotics, tricyclic antidepressants (TCAs), sedative antipsychotics, antihistamines or opioids can cause marked sedation and may lead to accidents, collapse or severe respiratory depression.

Pregnancy and lactation. The regular use of benzodiazepines is not recommended in pregnancy because the drugs are concentrated in fetal tissue where hepatic metabolism is minimal. They have been associated with an increased risk of oral clefts following first-trimester exposure, a low birth weight, neonatal depression, feeding difficulties and withdrawal symptoms if given in late pregnancy. They also enter breast milk and may cause sedation, lethargy and weight loss in the infant. Long-acting benzodiazepines should particularly be avoided during lactation because of the potential for the infant to accumulate the drug. Short- to medium-acting benzodiazepines are occasionally used with enhanced monitoring of the infant.

Antidepressant drugs

Antidepressants can provide a long-term treatment option for those with an anxiety disorder. They are generally recommended for those who are unable to commit to or have not responded to psychological therapies. In addition, antidepressants are considered first-line treatment option either alone or in combination with CBT in patients suffering from OCD with moderate or severe impairment (NICE, 2005a). The number needed to treat (NNT) to see one benefit with antidepressants is around five in PTSD and GAD (NICE, 2005b, 2011).

The response rate to antidepressants in anxiety is often lower and takes longer than that seen in depression. Initial worsening of symptoms can occur, and high therapeutic doses are often required to improve response (Baldwin et al., 2014).

Selective serotonin reuptake inhibitors. The SSRIs have a broad anxiolytic effect and are considered the first drug option in GAD, panic disorder, social anxiety disorder, PTSD and OCD (Baldwin et al., 2014; NICE, 2005a, 2005b, 2011, 2013). Individual SSRIs have varying licensed indications across the anxiety disorders, but this does not necessarily mean others have no supporting evidence. Where more than one SSRI is licensed in a particular disorder, it is not possible to conclude which SSRI would be more effective because of the lack of direct head-to-head trials. The SSRIs differ in their interaction potential, side-effect profile and ease of discontinuation. Initial worsening of symptoms is common when starting an SSRI in anxiety,

so beginning with half the dose than that used in depression is recommended, as is reassuring the patient that this is usually only experienced for the first few weeks of treatment. In view of these concerns, the NICE guidelines for GAD and panic disorder recommend that patients are reviewed every 2 weeks for the first 6 weeks of treatment to monitor for efficacy and tolerability (NICE, 2011). Although unlicensed, sertraline was recommended by NICE (2011) as the first-line SSRI in GAD because it was the most cost-effective drug. Sertraline and escitalopram are highlighted as appropriate first-choice SSRIs in social anxiety disorder (NICE, 2013).

Tricyclic antidepressants. Certain TCAs, such as clomipramine, imipramine and amitriptyline, are efficacious in some anxiety disorders. They are, however, associated with a greater burden of adverse reactions, such as antimuscarinic effects, hypotension and weight gain. Of particular concern is the TCAs' cardiac toxicity in overdose, which relegates their position to second line following the failure of an SSRI. They should be avoided in any patient at risk of suicide or those with an underlying cardiac disease. TCAs commonly cause sedation, which occasionally can prove useful in anxiety disorders. Clomipramine may also be slightly more effective in OCD compared with SSRIs.

Monoamine-oxidase inhibitors. The monoamine-oxidase inhibitors (MAOIs) are rarely used in practice because of their potentially severe interactions with other medicines and tyramine in the diet. Moclobemide is a reversible MAOI, so it causes fewer problematic interactions. Phenelzine and moclobemide are occasionally used by specialists in social anxiety disorder following the failure of an SSRI. Phenelzine is also recommended as a third-line treatment option in PTSD (NICE, 2005b).

Other antidepressants. The selective and noradrenaline reuptake inhibitor (SNRI) venlafaxine has some evidence to support its use in almost all the anxiety disorders but is only licensed for use in GAD, OCD and social anxiety disorder. Discontinuation symptoms are common following venlafaxine withdrawal and can be experienced after missing a single dose. Patients prescribed venlafaxine should be reminded of the importance of a slow withdrawal (over at least 4 weeks, sometimes longer) when discontinuation is necessary. Venlafaxine can increase blood pressure at higher doses in some patients and so is contraindicated in patients with a high risk of cardiac ventricular arrhythmia or uncontrolled hypertension. Duloxetine, another SNRI, is also licensed in GAD and can similarly increase blood pressure; withdrawal symptoms are also reported after abrupt discontinuation.

Mirtazapine, an α_2 -adrenoreceptor antagonist, is recommended as an option for PTSD if patients do not wish to participate in trauma-focused CBT (NICE, 2005b). Mirtazapine has a lower incidence of nausea, vomiting and sexual dysfunction than the SSRIs but can commonly cause weight gain and sedation.

Agomelatine, a melatonin agonist and specific serotonin receptor antagonist, has proven efficacy in the acute treatment and prevention of relapse in GAD (Baldwin et al., 2014), although it is currently unlicensed for these conditions.

No other antidepressants are routinely recommended for anxiety disorders, although some, such as vortioxetine, have been evaluated in GAD to investigate potential future uses. To reduce

the risk of symptoms returning, patients should be advised to continue the antidepressant for at least 6 months following improvement of symptoms in panic disorder and for 12 months in GAD, PTSD, OCD and social anxiety disorder (Baldwin et al., 2014; NICE, 2005a, 2011). Those with an enduring and recurrent illness, however, may continue for many years, depending on the risk of relapse and severity of symptoms.

For a complete review of the antidepressants, including adverse effects and interactions, see Chapter 29.

Other medications occasionally used in anxiety

Hydroxyzine, a sedating antihistamine, is licensed for the short-term treatment of anxiety in adults at a dose of 50–100 mg four times a day. The clinical evidence only supports its use in GAD (for up to 4 weeks) if sedation is required (Baldwin et al., 2014).

Antipsychotics have limited evidence and a high side effect burden when used in anxiety disorders. The first-generation (typical) antipsychotics are associated with movement disorders such as akathisia and tardive dyskinesia and so are rarely used in anxiety. The second-generation (atypical) antipsychotics are less likely to cause movement disorders but can have other physical health concerns. Antipsychotics (most commonly risperidone, olanzapine and quetiapine) are occasionally used by specialists for those with resistant symptoms in OCD, GAD, PTSD and social anxiety disorder (Baldwin et al., 2014).

Pregabalin has robust evidence and is licensed for GAD and has shown an anxiolytic effect over placebo after 1 week in adults or 2 weeks in the elderly (Montgomery et al., 2008). Two short-term studies in GAD (4 and 6 weeks) suggest that pregabalin 400–600 mg/day is as effective but better tolerated than venlafaxine 75 mg/day XL or lorazepam 6 mg/day. Pregabalin is most commonly used in GAD in combination with an SSRI or SNRI when initial treatments have failed (Baldwin et al., 2014). Emerging evidence also supports pregabalin in social anxiety disorders. Adverse effects of pregabalin include dizziness, somnolence and nausea, and there have been concerns raised over its abuse potential (Baldwin et al., 2013b; Schnerring et al., 2016).

Buspirone, a 5HT_{1A} partial agonist, is licensed for short-term use in anxiety. It is not a benzodiazepine and so does not treat or prevent benzodiazepine-withdrawal problems. In GAD, buspirone and other azapirones are superior to placebo in short-term studies (4–9 weeks) but less effective or acceptable than benzodiazepines (Chessick et al., 2006). Buspirone is occasionally used in GAD after nonresponse to the first-line treatments.

Propranolol and oxprenolol are both licensed for anxiety symptoms but are probably only useful for physical symptoms such as palpitations, tremor, sweating and shortness of breath. Beta blockers do not have sufficient evidence to support their inclusion in NICE guidelines, but intriguingly, small pilot studies indicate that giving an immediate course of propranolol following a traumatic event may prevent emerging PTSD (Pitman et al., 2002; Vaiva et al., 2003).

An overview of the recommended drug treatments in anxiety is provided in Table 28.3.

Table 28.3 Overview of the recommended drug treatments in anxiety

	Generalised anxiety disorder	Panic disorder	Social anxiety disorder (social phobia)	Obsessive-compulsive disorder	Posttraumatic stress disorder
Immediate management/short-term treatment	Benzodiazepines (2–4 weeks only)	Benzodiazepines not recommended by NICE	Benzodiazepines (2–4 weeks only)	Benzodiazepines (only to counter initial worsening of symptoms with SSRIs)	Hypnotics may be considered for short-term use for insomnia
First-line pharmacotherapy ^a	SSRI Escitalopram Paroxetine	SSRI Citalopram Escitalopram– Paroxetine Sertraline	SSRI Citalopram– Escitalopram– Paroxetine	SSRI Escitalopram Fluoxetine Sertraline ^b	SSRI Escitalopram Fluoxetine– Fluvoxamine Paroxetine–Sertraline
Other drug treatments with supporting evidence	Agomelatine Buspirone Duloxetine Imipramine Pregabalin ^c Venlafaxine Quetiapine Vilazodone Vortioxetine	Clomipramine ^b Imipramine ^b Mirtazapine Moclobemide Venlafaxine	Moclobemide ^c Phenelzine ^c Venlafaxine Pregabalin ^c	Clomipramine Augmentation with aripiprazole, quetiapine or risperidone ^c	Amitriptyline ^c Augmentation with olanzapine or risperidone ^c Imipramine Mirtazapine ^b Phenelzine ^c Venlafaxine Prazosin ^c

^aThe licensed SSRI is indicated but other SSRIs may also be beneficial.

^bUnlicensed but recommended by NICE (2005a, 2005b, 2011, 2013).

^cUsually prescribed by mental health specialists only.

SSRI, Selective serotonin reuptake inhibitor.

Case studies

Case 28.1

Mrs DW is a 32-year-old with a 10-year history of 'emotional problems'. These have largely been dealt with by her primary care doctor, who has prescribed low-dose TCAs for the last 3 years. Mrs DW's life is severely restricted by a number of rituals which she obsessively carries out. They include washing of sinks, baths and toilets; disinfection of kitchen surfaces; and vacuuming. These activities occupy her up to 8 hours a day.

Current prescribed medication:

- diazepam 10 mg three times a day,
- amitriptyline 25 mg twice a day.

Both have been prescribed for 3 years.

Mrs DW is concerned about possible addiction to her medication, as previous attempts to stop it have been unsuccessful. In addition, both she and her family feel that more can be achieved and are willing to work at solving the problems faced by Mrs DW.

Questions

1. Is this appropriate therapy for OCD, and if not, what would be a better first choice?
2. Suggest possible drug therapies for Mrs DW and indicate for how long they should be continued.
3. Provided an alternative therapy is commenced, recommend an appropriate scheme for withdrawal of the diazepam.

Answers

1. Benzodiazepines are not recommended in OCD. The first choice is CBT or an SSRI.
2. Potential drug treatments include high-dose SSRIs or clomipramine. Augmentation strategies (e.g. antipsychotics) would also be a possibility. Treatment may need to be continued for a year before a dose reduction is tried.
3. Because Mrs DW is on a dose of 30 mg diazepam daily, it would be appropriate to consider reducing the diazepam by 2 mg/day every 1–2 weeks until a 20 mg/day dose is reached. Further reductions may need to be 1 mg every 1–2 weeks until stopped. Longer intervals between dose reduction may be necessary as the dose reduces towards zero. The patient may wish to adopt faster withdrawal and accept the consequences. All patients should be monitored for increased anxiety, restlessness, agitation and other effects, and may need slow withdrawal.

Case 28.2

Mrs AB, a previously well 30-year-old woman, had been treated with paroxetine 40 mg daily for anxiety/depression which had been precipitated by a traumatic marriage breakup. After taking paroxetine for 18 months, Mrs AB's problems had mainly resolved, and she was feeling well. She decided that she no longer needed the drug and stopped taking it. Within 3 days, her anxiety/depression returned, with insomnia and nightmares. Her mood lowered, and she became irritable and found herself weeping for no reason. A week later she returned to her doctor complaining of these symptoms, as well as depersonalisation and electric

shock sensations. The doctor thought the original depression had returned and reinstated paroxetine, which cleared up her symptoms within a few days.

Questions

1. What alternative explanation could there be for Mrs AB's symptoms, and what other decision could the doctor have made?
2. What would be a suitable withdrawal schedule for her paroxetine?

Answers

1. All antidepressants can cause a discontinuation reaction. Mrs AB's symptoms are typical of SSRI withdrawal. This occurs most commonly with paroxetine, perhaps partly due to its rapid rate of elimination (half-life around 21 hours in chronic users).
2. In this previously well patient, who is no longer under marital stress, the doctor, after reinstating paroxetine, could have supplied a gradual tapering schedule of drug withdrawal – that is, reducing the dose by 10 mg/week, aiming to withdrawal in 4 weeks or longer depending on patient preference.

Case 28.3

Mr SB is a 22-year-old soldier. He has recently returned from his second active tour, where he was injured by a roadside bomb. Two of his squad were killed in the same blast, and although his physical injuries healed quickly, he has persistent and intense episodes of panic and flashbacks. He is especially aroused at night and has great difficulty getting to sleep. An initial prescription of an SSRI has proved ineffective, and he is currently on the waiting list for psychological therapies.

Question

1. What alternative drug treatment may be appropriate?

Answer

1. A sedating antidepressant such as mirtazapine or amitriptyline may be appropriate, ensuring adequate duration of therapy and effective dose. A short course of a benzodiazepine may prove useful but for no longer than 2–4 weeks. Alternatively, augmenting the antidepressant with a sedating antipsychotic such as olanzapine may be useful. For prolonged symptom treatment and relapse prevention, it is likely that the patient will need to fully engage with psychological therapies.

Case 28.4

Ms AC is a 32-year-old personal assistant to a director of a leading investment company. She has recently been promoted to this role and is now expected to entertain potential clients by dining out with the director at local restaurants. She has always preferred eating alone in the comfort of her own home, and the thought of eating in public while promoting the business fills her with dread, which brings on palpitations and shortness of breath.

Questions

1. What drug therapy is available which may provide some immediate relief of her anxiety symptoms?
2. What would be an appropriate choice of treatment for long-term control and prevention of symptoms?

Answers

1. β -Blockers such as propranolol may help with the shortness of breath and palpitations but will not treat the fear and dread. Benzodiazepines may be appropriate but may affect her performance and cause other adverse reactions.
2. For long-term control, a course of CBT including exposure techniques is appropriate or treatment with an SSRI such as escitalopram or sertraline.

29 Affective Disorders

Alan Pollard

Key points

- Diagnosis of affective disorders should be made using standardised criteria, for example, *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, and *International Classification of Diseases*, 10th Revision.
- Target symptoms should be recorded and response to treatment monitored against these symptoms.
- In patients with mild depression, non-pharmacological strategies should be considered as first-line intervention.
- The evidence base for determining the choice of a particular antidepressant in an individual patient does not exist. For most patients, when an antidepressant is indicated, a generic selective serotonin reuptake inhibitor should be considered as a first-line treatment option.
- Currently, all antidepressants are considered equally effective but differ in their side effect profile, toxicity in overdose, need for dose titration, and monitoring.
- In the absence of a previous response or contraindication, antidepressant choice should be guided by evidence-based clinical guidelines and the clinician and patient's perception of the risks and benefits of available options. Resource implications should not be ignored.
- Emerging evidence and a greater understanding of the clinical application of pharmacogenomics may lead to the ability to individualise treatments in the future.
- Comprehensive assessment, accurate diagnosis, adequate duration of pharmacotherapy, and involvement of the patient in the treatment regimen are the cornerstones of effective medicines management of affective disorders.
- Valproate, antipsychotics, and benzodiazepines, sometimes in combination, are the treatments of choice in acute mania.
- Either lithium, valproate, or specific antipsychotics may be considered to be the first-line prophylactic agent of choice in bipolar I disorder.

The term *affect* relates to mood or emotional state, and this chapter therefore analyses mood disorders. These consist in clinical practice of depression and bipolar disorder. Within bipolar disorder, mood swings predominate so at times the person may present as 'high' or manic, which led to the historical description of manic depression for this condition. The issues addressed in this chapter relate to adults. Affective disorders in children and adolescents are more complex and are beyond the scope of this chapter.

Classification

Depression

The term *depression* is often used by people to describe a general feeling of being low in mood and negative, but in clinical practice, depression is more than just sadness or unhappiness in response to a life event. A diagnosis of depression is only made when key signs and symptoms are present. *International Classification of Diseases*, 10th Revision (ICD 10; World Health Organization [WHO]) and *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5; American classification system) list their relevant diagnostic criteria. Much overlap exists, and both require a cluster of presenting features to be present for a defined period.

Depression is subclassified as mild, moderate or severe according to the intensity of presenting symptoms. This classification has implications for treatment options with milder forms of depression amenable to psychological-based interventions, whereas more severe forms of depression are likely to require more medically focused interventions, such as antidepressants or at the most severe end electroconvulsive therapy (ECT).

Mania and hypomania

When mood becomes abnormally elated, the terms *hypomania* or *mania* may be applied. Mania is the more extreme form and is often distinguished from hypomania by the presence of psychotic symptoms (see [Chapter 30](#) for further information on psychosis) and the potential need for hospitalisation. In the early stages of hypomania, irritability may be more evident than overt symptoms of overactivity and elation.

Bipolar and unipolar disorders

Depression on its own is a unipolar disorder. Mania or hypomania on its own could also be defined as a unipolar disorder, but in the UK the term *bipolar disorder* is used from the outset because at some point it is expected that a depressive episode will ensue. Bipolar I identifies mania as the first episode that brought the patient in for treatment. Bipolar II is applied when depressive episodes dominate the presentation. Between episodes, patients may have a relatively level state of mood and can be clinically described as euthymic, although many will say that subjectively they may feel on the subdued side. Mood cycles are very

Fig. 29.1 Mood swings in bipolar disorder.

individual and often asymmetric, with the majority of patients having far more depressive episodes than manic episodes. Fig. 29.1 shows a diagrammatic representation of a pattern of mood swings in bipolar disorder. The time interval between mood episodes is also very variable, but to be identified as a rapid cycling as few as four episodes per year are needed.

Bipolar disorder is a cyclical mood disorder. Abnormally elevated mood or irritability alternates with depressed mood, but mood fluctuations are often asymmetric and for much of the time patients are never truly ‘euthymic’.

Epidemiology

Nearly one-fifth of adults experience anxiety or depression, with the conditions affecting a higher proportion of women than men. Reported in 2012, the World Mental Health Survey, conducted in 17 countries, found that on average about 1 in 20 people reported having an episode of depression in the previous year. Depressive disorders may start at a young age; they reduce people’s functioning and often are recurring. For these reasons, depression remains the leading cause of disability worldwide. In contrast, bipolar disorder is quite different. The aggregate lifetime prevalence rates have been identified as 0.6% for bipolar I disorder, 0.4% for bipolar II disorder, 1.4% for subthreshold bipolar and 2.4% for bipolar spectrum disorder. Twelve-month prevalence rates were 0.4% for bipolar I, 0.3% for bipolar II, 0.8% for subthreshold bipolar and 1.5% for bipolar spectrum disorder (Merikangas et al., 2011).

The incidence of bipolar I is generally reported to be the same for both men and women, whereas some studies suggest that bipolar II may be slightly more common in women. Although depression may occur at any age, including childhood, it is estimated that the average age of onset of depression is in the mid-20s. Some earlier studies found the incidence and prevalence of depression in women peaking at the age of 35–45 years. In bipolar disorder an earlier age of onset is suggested, perhaps in late adolescence, with most people experiencing their first episodes before 30 years of age.

Aetiology

Like most other psychiatric disorders, the causes of affective disorders remain unknown. In depression it is likely that genetic,

environmental, biochemical, hormonal and social factors all have some role in determining an individual’s susceptibility to development of the disorder, with major life events sometimes acting as a trigger for a particular episode. Although pharmacological treatments are clearly effective, there is no simple relationship between biochemical abnormalities and affective disorders.

Genetic causes

Evidence for a genetic component to mood disorders has been documented consistently using family, twin and adoption studies. The first genetic studies of mood disorders were conducted more than 70 years ago and included assessment of concordance rates for monozygotic and dizygotic twins with mood disorders. These early studies did not distinguish between bipolar depression and unipolar depression. A review in 2000 of twin studies in recurrent unipolar depression estimated heritability at 37%, with a substantial component of unique individual environmental risk but little shared environmental risk (Sullivan et al., 2000).

In depression one theory suggests that a variant of the gene responsible for encoding the serotonin transporter protein could account for early childhood experiences being translated into an increased risk of depression through stress sensitivity in adulthood. In bipolar disorder some genetic linkage has been proposed, but a precise marker remains elusive.

Following a large, comparative study of bipolar patients and healthy control subjects, five DNA regions were identified as risk regions associated with bipolar disorder. Of particular interest is the ADCY2 region because it codes an enzyme that has a role in sending signals to nerve cells.

The discovery of the ADCY2 risk region provides new insight into the biological mechanisms involved in the development of bipolar disorder (Muhleisen et al., 2014).

The incidence of affective disorder in first-degree relatives of someone with severe depression may be about 20%, which is almost three times the risk of relatives in control groups. Comparisons of the risk of affective disorder in the children of both parents with an affective disorder show a four times greater risk, and the risk is doubled in children with one parent with an affective disorder. Studies evaluating twins have found fairly strong evidence for a genetic factor. Evidence of a genetic link has also been found in studies of children from parents with affective disorder who were adopted by healthy parents. A higher incidence of affective disorder was found in the biological parents of adopted children with affective disorder than in the adoptive parents.

Fig. 29.2 Amine transmitters and association with behavioural response.

Environmental factors

Although environmental stresses can often be identified before an episode of mania or depression, a causal relationship between a major event in someone's life and the development of an affective disorder has not been firmly established. It may be that life events described as 'threatening' are more likely to be associated with depression. The lack of prospective studies makes it difficult to interpret data linking early life events, such as loss of a parent, to the development of an affective disorder. The fact that specific environmental stresses have not been identified should not lead to the conclusion that the environment or lifestyle is irrelevant to the course or development of affective disorders. Employment, higher socio-economic status and the existence of a close and confiding relationship have been consistently noted to offer some protection against the development of an episode.

Biochemical factors

In its simplistic form the biochemical theory of depression postulates a deficiency of neurotransmitter amines in certain areas of the brain. This theory has been developed to suggest that receptor sensitivity changes may be important. Alternative propositions suggest a central role of acetylcholine arising from dysregulation of the cholinergic and noradrenergic neurotransmitter systems. Although many neurotransmitters may be implicated, the theory focuses on an involvement of the neurotransmitters noradrenaline (norepinephrine), serotonin (5-hydroxytryptamine [5-HT]) and dopamine. This theory emerged from the findings that both monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs) appeared to increase neurotransmitter amines, particularly noradrenaline (norepinephrine), at important sites in the brain. When it was found that reserpine, previously used as an antihypertensive, caused both a depletion of neurotransmitter and also induced depression, this was taken as further evidence of the monoamine theory. Newer antidepressants continue to pharmacologically promote serotonin and noradrenaline activity, albeit in more subtle ways. However, the amine transmitters do not work in isolation, and modifying the

serotonin system will impact on noradrenergic (norepinephrine) and dopaminergic systems.

Fig. 29.2 shows the actions of each monoamine transmitter and their inter-relationship. Because the transmitters do not work in isolation, modification of one transmitter will impact across numerous behavioural domains. The overlap between transmitters linked to discrete behaviours helps account for why a single transmitter-focused antidepressant may produce a broad improvement in a range of depressive symptoms. Although less attention has been paid to dopaminergic activity, some studies have found reduced activity in patients with depression, and an overactivity has been postulated in mania. There remains no clear biochemical model to explain mania.

Endocrine factors

Stress triggers the hypothalamus to release corticotrophin-releasing factor. Corticotrophin-releasing factor interacts with the pituitary gland to release adrenocorticotrophic hormone. Adrenocorticotrophic hormone binds to adrenal glands on the kidney and releases stress hormones including cortisol. There is negative feedback under short-lived healthy conditions, but chronic stress may damage the switch off process (**Fig. 29.3**).

Patients with depression often have higher baseline cortisol levels and larger adrenal glands (the source of cortisol). Dexamethasone mimics cortisol, and it was postulated that this agent could provide a diagnostic marker for depression. Failure of a test dose of dexamethasone to suppress cortisol levels in the so-called dexamethasone suppression test was once thought to be a robust marker of depression. However, all severe and enduring mental health conditions chronically stress the hypothalamic-pituitary-adrenal axis, switch off the negative feedback and can result in failure of dexamethasone to suppress cortisol production.

Physical illness and side effects of medication

Disorders of mood, particularly depression, have been associated with several types of medication and a number of physical

Fig. 29.3 The hypothalamic–pituitary–adrenal axis, key hormones and feedback mechanisms involved in regulating the body’s response to stress.

illnesses (Box 29.1). Depression can affect the outcome in people with a range of physical problems. An increase in mortality rates has been found in those patients with comorbid depression. Many drugs can affect mood states and other risk factors such as underlying physical health condition that contribute to a syndromal episode. This is why in any patient assessment it is important to always look for any organic factors that may contribute to an altered mental state. For many long-term physical conditions (e.g. diabetes), the incidence of depression is higher than in controls. Altered or abnormal biochemistry may be another factor, particularly as presentation is more acute in onset. When medication is a main driver for mood-related changes, then a few drugs (e.g. interferon-alfa, corticosteroids and digoxin) can be identified as potentially more problematic with associated evidence to support this risk (Preda, 2012).

Clinical manifestations

Depression

A low mood is the central feature of depression. This is often accompanied by a loss of interest or pleasure in normally enjoyable activities. Thinking is pessimistic and in some cases suicidal. A depressed person may complain he or she has little or no energy. In severe cases psychotic symptoms such as mood-congruent hallucinations or delusions may be present. Anxiety or agitation frequently accompanies the disorder, and the so-called biological features of sleep disturbances, weight loss and loss of appetite are often present. Sexual drive is often reduced, and some people may lose interest in sex altogether. Depression in an older adult may present with more somatic symptoms, particularly gastric problems,

and non-specific aches and pains. In some cases, known as atypical depression, the biological symptoms are reversed and excessive eating and sleeping may occur. In contrast with anxiety and agitation, psychomotor retardation may be a presenting feature.

The following mnemonic may be useful in helping to identify the key signs and symptoms that present in depression. INSADCAGES describes the sense of being trapped in a prison of sadness (Box 29.2).

Bipolar disorder

Standardised diagnostic criteria vary. For an ICD 10 diagnosis of bipolar disorder, at least two mood episodes must occur, one of which must be manic or hypomanic (Box 29.3). According to DSM 5, at least one episode of mania must have occurred for a diagnosis of bipolar I disorder to be made; depression may also occur, but it is not essential.

Mania/Hypomania

In hypomanic states the mood is described as elated or irritable, and the accompanying overactivity is usually unproductive. Disinhibition may result in excessive spending sprees, inappropriate sexual activity and other high-risk behaviours. Driving may be particularly dangerous. Manic people may describe their thoughts as racing, with ideas rapidly changing from one topic to another. Speech may be very rapid or indeed stop as the rapid flow of thoughts is not able to be vocalised. Ideas may become grandiose, with patients embarking on expansive projects which lead nowhere and usually their projects are left incomplete and disjointed. Clothing may become flamboyant, and if makeup is

Box 29.1 Physical illnesses and drugs implicated in disorders of mood

Biochemical change	Effect on mental state	Mental health link
Hyperthyroid state	Overactivity, poor sleep	Hypomania
Hypothyroid state	Lethargy, reduced energy levels	Depression
Hypoglycaemia	Confusion, disorientation, tremor and unsteadiness	Alcohol intoxication

Drug group	Comment
Anticonvulsants	More prone to induce depressive episodes, but some agents can trigger a manic presentation and psychotic symptoms
Antidepressants	In bipolar patients unopposed antidepressants may trigger a manic episode
Antimalarials	Mefloquine carries a risk of depression, anxiety and psychosis
β-Blockers	Propranolol and some other β-blockers may contribute to depression
Corticosteroids	Long-term treatment reported to contribute to depression but also known in short-term and high doses to induce euphoria and manic presentations
HIV medicines	Non-nucleoside reverse transcriptase inhibitors may increase the risk of depression
Interferons	As many as 40% of people who are receiving interferon-alfa may experience depression
Isotretinoin	Has been associated with depression and proactive monitoring for signs of depression recommended
Methylodopa	An antihypertensive that may be used during pregnancy but has been associated with depression

worn it may become excessive and will often involve bright colours. Hypomania and mania are on a continuum, and in clinical practice mania is applied when the patient experiences psychotic symptoms and cannot be managed outside of a hospital environment or equivalent intervention.

Severity

The severity of depression may vary from mild through moderate to severe. In the UK more than 90% of depression cases are managed in primary care, and in most circumstances it is not necessary for people with milder forms of depression to be seen by specialist services. In the absence of a risk of serious self-harm, or other complex comorbidities, patients should be entirely managed by the primary healthcare team. Guidelines advise that a stepwise approach is taken on the management of depression; evidence supports antidepressant therapy as more effective in the moderate-to-severe cases ([National Institute of Health and Care Excellence \[NICE\], 2009a, 2009b](#)).

If left untreated, it is important to remember that affective disorders carry a risk of mortality. In addition to suicidal attempts by someone who is depressed, the lack of self-care and physical exhaustion resulting from mania may become life-threatening.

Box 29.2 Mnemonic describing the key signs and symptoms present in depression

Insomnia – typically early morning waking
 Neurotic symptoms – anxiety/agitation with ruminations
 Suicidality – thoughts/plans around self-harm
 Appetite ↓ – leading to weight loss
 Depressed mood – tearfulness, feeling low
 Concentration ↓ – reading and staying focused, retaining information, concentrating on television more difficult
 Anhedonia – loss of pleasure in usually rewarding pastimes
 Guilt/worthlessness – pessimistic around the future; may not believe in being worthy of receiving help; exaggerated negativity around past misdemeanours
 Energy ↓ – poor self-care, lack of motivation
 Sex – loss of libido; amenorrhoea

Box 29.3 ICD 10 diagnostic criteria for bipolar affective disorder (WHO, 1992)

Bipolar affective disorder is characterised by repeated (at least two) episodes in which the patient's mood and activity levels are significantly disturbed. This disturbance consists on some occasions of an elevation in mood and increased energy and activity (mania or hypomania), and on others of a lowering of mood and decreased energy and activity (depression).

Manic episodes usually begin abruptly and last for between 2 weeks and 4–6 months (median 4 months). Depression tends to last longer (median about 6 months). Episodes of both kinds often follow stressful life events or other mental trauma, but the presence of such stress is not essential for the diagnosis.

The social and financial consequences can have a devastating effect on both the patient with mania or hypomania and his or her family. Depression may also contribute to poorer outcomes of physical problems such as increased pain and worsening outcomes from cardiac disease and diabetes.

Investigations

No universally accepted biochemical or genetic tests exist that will confirm the presence of an affective disorder. Various rating scales have been developed that may help to demonstrate the severity of depressive disorder or distinguish a predominantly anxious patient from a depressed patient. In an older adult, distinguishing depression from early stages of dementia can also pose a challenge (see [Chapter 33](#)). Within the limits of our current understanding of the technology, biochemical or genetic tests are unlikely to be helpful in determining the treatment plan or management of affective disorders.

In the UK, mental and behavioural disorders are commonly classified using the ICD 10 (WHO, 1992). The [American Psychiatric Association \(2013\)](#) has developed a precise system of diagnosis based on the description of symptoms in the DSM 5.

A systematic approach to the diagnosis of affective disorders is important when considering the effectiveness of medication.

Box 29.4 ICD 10 diagnostic criteria for depressive disorder (WHO, 1992)

Usual symptoms

Depressed mood, loss of interest and enjoyment, and reduced energy leading to increased fatigability and diminished activity

Common symptoms

Reduced concentration and attention
 Reduced self-esteem and self-confidence
 Ideas of guilt and unworthiness (even in a mild type of episode)
 Bleak and pessimistic views of the future
 Ideas or acts of self-harm or suicide
 Disturbed sleep
 Diminished appetite

In a depressive episode the mood varies little from day to day and is often unresponsive to circumstances, yet may show characteristic diurnal variation as the day goes on. The clinical picture shows marked individual variations, and atypical presentations are particularly common in adolescence. In some cases anxiety, distress and motor agitation may be more prominent at times than the depression.

For depressive episodes of all grades of severity, a duration of 2 weeks is usually required for diagnosis, but shorter periods may be reasonable if symptoms are unusually severe and of rapid onset.

Mild depressive episode: For at least 2 weeks, at least two of the usual symptoms of a depressive episode plus at least two of the common symptoms listed earlier must be present. An individual with a mild depressive episode is usually distressed by the symptoms and has some difficulty in continuing with ordinary work and social activities, but will probably not cease to function completely.

Moderate depressive episode: For at least 2 weeks, at least two or three of the usual symptoms of a depressive episode plus at least three (preferably four) of the common symptoms listed earlier must be present. An individual with moderately severe depressive episode will have these symptoms to a marked degree, but this is not essential if a particularly wide variety of symptoms are present overall. These individuals will usually have considerable difficulties in continuing with social, work or domestic activities.

Severe depressive episode: For at least 2 weeks, all three of the usual symptoms of a depressive episode plus at least four of the common symptoms listed earlier, some of which should be of severe intensity, must be present. An individual with severe depressive episode may be unable or unwilling to describe many symptoms in detail, but an overall grading of severe may still be justified. These individuals will usually show considerable distress or agitation, unless retardation is a marked feature. Loss of self-esteem or feelings of uselessness or guilt are likely to be prominent. Suicide is a distinct danger, particularly in severe cases.

Most new clinical trials for antidepressants or antipsychotics require a DSM diagnosis as an entry criterion. In the UK the ICD 10 classification is commonly used, with the severity of depression determined by the presence of the number of symptoms (see [Boxes 29.3 and 29.4](#)). More recently, use of the symptom count as a single factor upon which to base treatment decisions has been cautioned against ([NICE, 2009a, 2009b](#)). Account should also be taken of the extent of impairment and disability associated with depression. Recognition of enduring subsyndromal symptoms of

low mood and other depression-related symptoms is acknowledged by NICE as significant enough to warrant intervention.

National guidelines provide a sound framework for the management of depression ([NICE, 2009a, 2009b](#)) and bipolar disorder ([NICE, 2014](#)). It is important that people with depression are identified. A simple screening process for the presence of depression could involve asking the patient two questions about his or her mood and interest. For example, the patient could be asked: 'During the last month, have you often been bothered by feeling down, depressed or hopeless?' and 'During the last month, have you often been bothered by having little interest or pleasure in doing things?' If the answer to either question is no, it is unlikely the patient will be considered to have a depressive disorder. Patients who answer yes warrant further investigation. A follow-up question asking about any unusual periods of elation or overactivity is recommended to detect potential for bipolar disorder.

Identification of target symptoms may be useful in evaluating the response to treatment. In routine clinical practice, antidepressant medication should not generally be used to treat patients with mild depression. Non-pharmacological strategies are preferable in this group.

Rating scales

Various rating scales can be used to assist with the assessment of the severity of the disorder. Two of the more commonly used rating scales are the Beck Depression Inventory and the Hamilton Depression Rating Scale.

Beck depression inventory

This is a self-reporting scale that evaluates 21 depressive symptoms. Subjects are asked to read a series of statements and mark on a scale of 1–4 the severity of their symptoms. The higher the score, the more severely depressed a person may be.

Hamilton depression rating scale

This rating scale is used by a healthcare professional at the end of an interview to rate the severity of depression. It scores on 17 items, although 21 items are listed. The higher the score is, the more severe the depression. Moderate depression starts at 14, with severe depression scoring greater than 19.

Treatment

The aim of treatment is to promote recovery, and in unipolar depression a return to premorbid state is a realistic goal. In bipolar disorder the focus shifts to reducing intensity and duration of mood swings. In all cases quality of life is an important consideration. Pharmacological interventions alongside psychological interventions will be utilised in most patients.

Pharmacological management of unipolar depression, bipolar disorder (including bipolar depression) and manic states are quite distinct. In some cases medication used will be outside

of its product licence but supported by a strong evidence base. Clinicians should be aware of the licensed indication of treatments, so that any off-label use is done knowingly and in line with current best practice.

Treatment of depression

In moderate and severe depression, pharmacological intervention is important, but this should never be considered in isolation from the social, cultural and environmental influences on the patient. Non-pharmacological therapies are effective, and in mild depression they are considered preferable to drug treatment. Non-drug treatments and antidepressant medication are not mutually exclusive, and in some cases it is preferable to use both in combination. Cognitive behavioural therapy (CBT) is frequently employed to support changes to unhelpful patterns of thinking that occur in depression.

The basis of CBT was developed more than 50 years ago and subsequently refined into a specific therapy in the 1970s. This type of treatment helps patients to address their unhelpful thoughts and actions associated with depression. Over a series of up to 20 sessions, the CBT therapist works with the patient either alone or in groups, to replace negative or self-critical thoughts and actions with more positive and helpful ones. CBT is not a 'quick fix' solution to depression; patients are often given 'homework' between sessions to try and put their positive actions into practice. Interpersonal psychotherapy is another form of psychotherapy which may help patients deal with more social aspects of their depression. This type of therapy explores relationships and their effect on mental health and well-being.

Drug treatment

In the treatment of depression all of the antidepressants currently available in the UK may be considered to be equally effective. [Table 29.1](#) defines terminology often used when reporting outcomes of antidepressant treatment in the literature. A strong response to placebo is found in most of the studies of antidepressants. Tolerability is, therefore, an important factor in the choice of drug; patients who are unable to tolerate the side effects of antidepressants are likely to discontinue taking these drugs. Overall, the selective serotonin reuptake inhibitors (SSRIs) antidepressants appear to be better tolerated than tricyclics, and their improved safety profile in overdose may be an important consideration for use.

For most patients first-line treatment is a generic SSRI. For these agents the starting dose is often the treatment dose because these agents have a flat dose–response curve. This means increasing the dose serves only to increase adverse effects. Patients should notice some discernible improvement in symptoms by week 2, although full benefit is often not seen until 4–6 weeks into treatment. This delay is probably due to adaptive neurochemical changes that need to take place but are not fully understood. Some effects which are directly linked to primary transmitter effects will occur quickly. These are often side effects. Some such as increased sedation may be helpful, particularly if poor sleep is improved, whereas others such as dry mouth, blurred vision and constipation will not be welcome. In older adults and with MAOIs, this full benefit time frame may be extended to 12

Table 29.1 Different terms employed in reporting interventions in depression management

Term	Definition
Onset	A 20% improvement in depressive symptoms
Response	A 50% improvement in depressive symptoms
Remission	A return to premorbid baseline with minimal or no residual symptoms
Recovery	Usually declared when the patient has been in sustained remission for between 4 and 6 months

weeks. In monitoring a patient's progress, failure to see any onset of benefit at week 2 should prompt a review of treatment, and often this will be a change to an alternative agent. Patients may also switch antidepressants because of tolerability issues. When considering an antidepressant for a particular patient, many factors are likely to influence the choice of agent.

- Previous experience or response to treatment: If this is not the first occasion of taking an antidepressant, then it is useful to explore past outcomes with treatment, and if positive consider a previously successful antidepressant as first line.
- Dosing regimen: A big advantage of SSRIs is the once-daily dosing which often requires no further titration.
- Other medications or comorbidities: Patients with epilepsy and receiving anticonvulsant medication may be exposed to interactions with some antidepressants. All antidepressants lower seizure threshold, but this per se is not usually a problem in clinical practice for patients well stabilised on their anticonvulsant treatment. Those at risk of QTc prolongation may need to avoid antidepressants that carry a larger impact on QT prolongation. Any significant renal or hepatic impairment may also need to be taken into consideration.
- Formulary constraints: The local health economy may add its own additional formulary and prescribing restrictions.
- Cost: Resource implications are important because the volume of prescribing in depression means that small price differences can equate with significant savings.

For patients who obtain a partial response to a chosen antidepressant, augmentation options, as opposed to a switch to an alternative treatment, are available. The most common and universal antidepressant treatment used in augmentation is lithium. Evidenced-based antidepressant combinations have also been identified ([NICE, 2009a, 2009b](#)) and also included in the updated evidence based British Association for Psychopharmacology 2015 guidelines for treating depressive disorders with antidepressants ([Cleare et al., 2015](#)). Specialist texts such as Maudsley Prescribing Guidelines and Bazire's Psychotropic Drug Directory provide details of less commonly prescribed combinations.

Once a patient is in remission, then the question of when to stop treatment is likely to arise. For a first episode of depression, where the patient is well supported psychosocially, the evidence-based recommendation is to continue for a minimum of 6 months. Where patient support is less favourable or this is not the patient's first episode of depression, maintenance treatment

should continue for 2 years. Any patient who has experienced three or more episodes within a 5-year period is likely to benefit from ongoing antidepressant treatment.

Given these time frames many patients express concerns about becoming addicted to antidepressants. It can be accurately stated that antidepressants are not addictive. Antidepressants do not cause the cravings associated with drugs of addiction. In addition the dose does not need to be increased to preserve ongoing benefit. Patients are also unlikely to become preoccupied with where the next dose is obtained, so addiction criteria are unmet. However, abrupt cessation of a course of antidepressant treatment can lead to unpleasant discontinuation effects. Patients may interpret such discontinuation effects as withdrawal. However, healthcare professionals can advise that a 4-week dose reduction strategy should minimise any adverse events resulting from discontinuation of treatment.

Monoamine oxidase inhibitors

Traditional monoamine oxidase inhibitors. The traditional MAOI group contains the earliest recognised antidepressants comprising isocarboxazid, phenelzine and tranylcypromine. Their antidepressant effect is understood to come about from promoting levels of biogenic amines serotonin, noradrenaline (norepinephrine) and dopamine, by blocking enzyme breakdown of these transmitters in key brain synapses. These agents are no longer early choices in depression for several reasons. Clinically they can be slow to provide noticeable benefit and do not provide any early symptom relief of associated anxiety or poor sleep. However, the main concern is the risk they introduce alongside tyramine-containing foods and medicines that may similarly release noradrenaline (norepinephrine) from peripheral nerve terminals, that is, indirectly acting sympathomimetics. These traditional MAOI agents block both MAO-A and MAO-B enzyme subtypes, rendering the patient vulnerable to the pressor effects of such compounds. MAO enzyme is present in many areas of the body including the gut, and normally tyramine found in cheese would be broken down by MAO in the gut. With no gut MAO available, the tyramine passes unhindered into the circulation, where it displaces noradrenaline on to peripheral target sites. The cardiovascular system is most at risk, increasing heart rate with a vasoconstriction which leads to a dramatic rise in blood pressure. This hypertensive crisis, sometimes referred to as a 'cheese' reaction, is a medical emergency and is one of the few situations where hypertension produces key symptoms for the patient. Symptoms of a hypertensive crisis are likely to include pain and stiffness in the neck, an occipital headache and angina-like chest pain. In an emergency department, treatment is likely to involve the administration of a noradrenergic (norepinepheric) α receptor blocker such as phentolamine or phenoxybenzamine.

Therefore, patients should be aware of the dietary precautions and need to avoid purchasable medicines that carry similar risk. MAOI warning cards were produced, but these have now been discontinued. However, the patient leaflet contained with the medicines provides this written advice. Most patients receiving these treatments are likely to have been receiving them for some time and will be fully aware of food restrictions and the need to check the safety of any bought medicines with the pharmacist. As well as being used for depression, these agents may be in place as part of treatment for phobic disorders.

Of the three drugs in this category, tranylcypromine carries the highest risk of hypertensive crisis, whereas isocarboxazid is the weakest and safest. Although tranylcypromine is a reversible inhibitor of MAO and enzyme recovery may be seen in as little as 5 days following cessation of treatment, in clinical practice MAOI precautions should be maintained for a full 2 weeks after stopping treatment regardless of which MAOI has been taken.

Reversible inhibitors of monoamine oxidase. Monoamine oxidase exists in two forms, MAO-A and MAO-B. MAO-A is the major form found in monoamine neurones. MAO-A inhibition appears necessary for an antidepressant response. MAO-B inhibition helps preserve dopamine and has an anti-parkinsonian effect. MAO-A is also found in the gut and liver, where it acts to metabolise ingested tyramine. Moclobemide is a competitive reversible inhibitor of MAO-A and is displaced by large amounts of tyramine. There is therefore little risk of a potentially fatal hypertensive crisis, and the need for dietary caution or the avoidance of other medicines is reduced. MAO-B can also compensate physiologically for some loss of MAO-A activity. Moclobemide was introduced into clinical practice in the early 1990s as a safer option over traditional MAOIs. Patients can be reassured that dietary and medicinal restrictions associated with original MAOIs are not required. If an MAOI antidepressant is initiated, this is likely to be the agent of choice. In terms of clinical efficacy, timescales and unwanted effects, it shares many of the traditional MAOI characteristics.

Tricyclic antidepressants. Pharmacologically, tricyclic agents act as serotonin, noradrenaline (norepinephrine) reuptake inhibitors, but with the additional property of blocking acetylcholine at muscarinic receptors. This additional antimuscarinic property is not believed to confer any therapeutic benefit but accounts for many predictable unwanted effects of this class of drugs.

Predictable antimuscarinic side effects are:

- Dry mouth: Caused by reduced saliva production. This is best countered by sips of cool water, chewing sugar-free gum or the application of saliva-enhancing sprays.
- Blurred vision: Accommodation is impaired early on in treatment, and patients should be reassured that this will settle and is not an indication of sight problems.
- Constipation: Reduced peristalsis may occur. Most patients are likely to require a laxative early on in treatment and this should be proactively managed. Depression itself caused by reduced mobility and poor diet may separately contribute.
- Difficulty passing urine: Reducing sphincter activity. Male patients with enlarged prostate may find this problematic, and in rare instances urinary retention may ensue.
- Confusion: Confusion is a central antimuscarinic effect. Older adults are more overtly vulnerable, but subtler effects in other patients may lead to reduced reaction times and pose increased driving risks. Depression itself will already have lowered reaction time. Doses of tricyclics should be titrated over several days to full treatment dose with these factors in mind.

A number of TCAs are in current clinical use. The basic chemical structures of these compounds are similar, but there are differences between them. All of the TCAs require dose titration to achieve optimum antidepressant dose. Most are significantly sedating and with central antimuscarinic effects; therefore,

starting a patient on the full treatment dose would predictably induce a confusional state alongside unwanted sedation. Furthermore, the common property of postural hypotension and blurred vision further adds to an unpleasant experience and increases the risk of falls or other accidents.

Tricyclics can be taken as single daily doses because of their long half-lives and often at night so that peak levels occur during sleep. Tricyclics are toxic in overdose. The antimuscarinic effects on the vagus nerve can lead to the development of cardiac arrhythmias and these, in turn, may prove fatal. Children and older adults are especially vulnerable.

In low doses some tricyclics have other uses in clinical practice. For example, those with significant noradrenergic (norepinephrine) reuptake properties may be used to help with neuropathic pain. Low doses of particularly sedating agents are sometimes used for hypnotic purposes. This should not be supported because it represents unlicensed use and is employing an agent with many adverse properties to substitute for a single need.

Amitriptyline. Amitriptyline is one of the more sedating agents and in low doses is often employed to manage neuropathic pain. Its use in depression continues to decline because it is no longer a recommended first-line treatment option.

Imipramine. Imipramine is similar to amitriptyline, but less sedating. This agent may be employed in children to help manage nocturnal enuresis or again in children as part of attention-deficit/hyperactivity disorder treatment. Again use as an antidepressant is declining for the same reasons as amitriptyline.

Clomipramine. Pharmacologically clomipramine is a potent serotonin reuptake inhibitor with minimal noradrenergic (norepinephrine) reuptake inhibition, and this leads to some differences in clinical application outside of depression. For example, it has little or no value in neuropathic pain management, but as a serotonin-rich drug it has an established role in the management of obsessive-compulsive disorder (OCD).

Dosulepin. Formerly known as dothiepin (British Approved Name), dosulepin is the most cardiotoxic of the tricyclic agents and should now not be initiated in any new patients. Patients already established on this agent should not be automatically switched to another antidepressant. Instalment dispensing (i.e. dispensing only small quantities at a time) may be put in place if there are concerns about self-harming through overdosing.

Lofepamine. Within the tricyclic group, lofepramine carries a much-reduced toxicity profile. Antimuscarinic effects do occur with lofepramine, but these are less severe than with other tricyclics. Lofepamine does not have a significant sedative effect. For new patients who require a TCA to manage their depression, this is likely to be the drug of choice.

Selective serotonin reuptake inhibitors. In the mid-1980s these agents were developed in an attempt to reduce some of the problems associated with the TCAs. Overall, the SSRIs are better tolerated by most patients, and they are considerably less toxic in overdose; this means that they should be the first-line choice for the pharmacological management of moderate or severe depression (NICE, 2009a, 2009b). Compared with TCAs, they have less impairment on reaction time and there is less additional sedation if alcohol is consumed. Because generic versions of the drugs are available, the financial impact of using SSRIs first line is considerably reduced. The SSRIs have a broadly similar range of side

effects, but there are variations in the intensity or duration. The degree of specificity for serotonin reuptake differs between the SSRIs, but this does not correlate with clinical efficacy. When given in adequate doses for an adequate period of time, all of the drugs in this class appear to be equally effective. The two main clinical issues with SSRIs are nausea and their early alerting effects whereby patients are likely to feel more anxious or on edge during the first 2 weeks of treatment. Nausea is best addressed by advising patients to take their daily dose after breakfast. Nausea should decline within a few days, but for some patients it remains an intolerable adverse event and an alternative class of agent is required. Alerting effects may be addressed by exploring non-pharmacological strategies to promote relaxation (e.g. yoga or music). Alternatively, a short course (maximum 2 weeks) of a benzodiazepine such as diazepam could be prescribed. A hypnotic agent such as zopiclone or zolpidem could be prescribed if alerting effects occur at nighttime.

Some years ago the SSRI paroxetine was subject to media attention in the UK, and this led to the identification of three important medicines management issues with use of antidepressants: unpleasant events occurring on abrupt cessation of treatment, sexual dysfunction and increased risk of suicide.

It has now become standard practice to stop antidepressant treatment over a 4-week period by gradually reducing the dose. Patients who abruptly stop antidepressants may feel acutely quite unwell, and this should not be taken to indicate a recurrence of the depression. Left unchecked, symptoms will remit after some days, but a short-term reinstatement of dose and review of the discontinuation strategy is often all that is required.

Sexual dysfunction has now been identified as a feature of many other classes of antidepressant, linked to agonist effect on serotonin 5-HT₂ receptors. There are various pharmacological strategies identified in the literature to manage this, and some of the newer antidepressants carry less sexual dysfunction. It should also be remembered that depression itself reduces libido, but antidepressant impairment is more often associated with ejaculatory ability.

Self-harm and suicide are aspects of depression itself, and the suggestion that this class of antidepressants actually contributed to this mortality outcome was subject to much debate and review of evidence. The early alerting effects of SSRIs may allow a patient to carry out a suicidal intent. With the older TCAs, many patients receiving treatment experience significant sedation and are unable to act on these impulses. As the depression remits, the suicidal ideation reduces with effective treatment.

Since their launch as antidepressants, SSRIs have become treatment options for a range of anxiety-based disorders (e.g. panic disorder, OCD, general anxiety disorder, eating disorders, post-traumatic stress disorder), but generally the doses required are much higher than those employed in depression.

Fluvoxamine. The first SSRI launched in the mid-1980s, fluvoxamine was marketed at a high dose requiring a three times a day dosing. Many patients experienced severe nausea, and the drug has many interactions because it is a potent inhibitor of the cytochrome P450 drug metabolising system. It is unlikely to be seen very often in clinical practice today.

Fluoxetine. The main difference between fluoxetine and the other SSRIs is its long half-life. In the initial stages of treatment, some

patients may experience a greater feeling of nervousness with fluoxetine than with the other SSRIs. The long half-life of fluoxetine, mediated through its major metabolite norfluoxetine, can be a problem if severe side effects develop. In other situations, the long half-life means that the risk of a patient experiencing discontinuation symptoms is minimal. This SSRI may be abruptly stopped because it will take about 5 weeks to clear from the body. Formulations of fluoxetine that can be taken on a weekly basis are available in some parts of the world.

Paroxetine. In contrast with fluoxetine, paroxetine has a relatively short half-life and no active metabolites. Therefore, this drug requires gradual dose reduction prior to stopping. It has some inhibitory activity at CYP4502D6, which may need to be considered in patients who are taking other medications.

Sertraline. The SSRI sertraline is preferred where a patient has comorbid cardiac disease because it does not increase the burden of the underlying condition and has very few drug interactions. It is also a popular choice within perinatal mental health because it does not independently add to any baseline risk of taking SSRIs. In pregnancy all SSRIs carry a slightly increased risk of neonatal septal heart defect. From week 20 there is an increased risk of the respiratory syndrome persistent pulmonary hypertension of the neonate. However, the absolute risk remains small at 0.3%, although subsyndromal respiratory states are more common. Exposure to SSRIs during the third trimester is likely to produce mild neonatal withdrawal reactions (e.g. irritability or tremor). These are minimal with sertraline but may be more problematic with paroxetine.

Citalopram and Escitalopram. Citalopram is a racemic mixture of *R*- and *S*-citalopram and predates escitalopram, the active *S* enantiomer of citalopram. Escitalopram was launched on the basis that the *R* enantiomer has no antidepressant effect, and it may even counteract some of the antidepressant effects of the *S* enantiomer of escitalopram. Citalopram carries a greater risk of clinically significant QT prolongation, prompting restrictions to be placed on doses especially in older adults. The QT prolongation effect is much less with escitalopram. In clinical practice several patients do find escitalopram much more tolerable, and now that escitalopram is available generically, the economic pressure to avoid using this SSRI as first-line treatment is much less.

Other Antidepressants

Trazodone. Trazodone is a little used antidepressant which requires adult dosages of 300 mg daily and above to treat depression. It is rapidly absorbed on an empty stomach, leading to profound dizziness, so it should always be taken with food. Its mechanism of action remains unclear. It does have some helpful anxiolytic properties and occasionally is used in older adults more for this property than to manage depression. Compared with the tricyclics it is much safer in overdose and lacks significant antimuscarinic properties. Priapism has also been noted as a rare but distressing side effect. This is almost certainly due to its potent α receptor-blocking properties.

In an attempt to improve on the benefits gained with SSRIs over TCAs, newer antidepressants were introduced from the late 1990s onward. These antidepressants include venlafaxine, duloxetine, reboxetine, mirtazapine, agomelatine and vortioxetine. **Table 29.2** summarises the key practice points associated with these newer agents.

Venlafaxine. Venlafaxine possesses minimal antimuscarinic properties and greatly reduced toxicity compared with TCAs. At low doses the drug behaves more like an SSRI, but as the dose is increased venlafaxine adopts its serotonin noradrenaline reuptake inhibitor (SNRI) profile. Across all doses there is weak dopamine reuptake inhibition. Dose titration therefore is indicated. There is a low potential for postural hypotension, although the drug carries a risk of hypertension at higher doses. Discontinuation effects can be problematic, and careful gradual dosage reduction is required when stopping treatment.

Duloxetine. The SNRI profile of duloxetine remains constant and equal between the two transmitters, serotonin and noradrenaline (norepinephrine). This means that dose titration is not routinely indicated.

Medicine management issues including adverse events closely resemble SSRIs. In the UK duloxetine is also licensed separately for neuropathic pain and stress incontinence; this latter indication is under a different brand.

Reboxetine. Reboxetine is indicated for more reclusive and presentations where the patient is particularly lacking energy. The main side effects are dry mouth and insomnia. The drug is considered to have a low evidence base of independent effectiveness.

Mirtazapine. Compared with SSRIs, the antidepressant mirtazapine represents an agent with reduced alerting effects, minimal nausea and low incidence of sexual dysfunction. However, both sedation, which is more prominent at lower dose, and weight gain are significant. Use of mirtazapine has superseded mianserin to which it is chemically related.

Agomelatine. Advantages of agomelatine include restoration of sleep pattern without residual sedation and impaired reaction time, as well as minimal weight gain, gastro-intestinal upset and sexual dysfunction. Abnormal liver function tests are common and require regular liver function monitoring in accordance with the Summary of Product Characteristics. Variable efficacy has been seen in clinical trials.

Vortioxetine. The mechanism of action of vortioxetine is described descriptively, but the focus is on promoting serotonin activity. Nausea is the most common adverse effect. Sexual dysfunction is present but only at higher doses. Early alerting effects are likely to be less pronounced, and in remission patients appear to be less residually cognitively impaired with this agent. There is no evidence of QT prolongation. Patients show minimal weight gain and no evidence of significant discontinuation symptoms following abrupt cessation of treatment. **NICE (2015)** supports its use as a third-line option for the treatment of major depression.

Other treatments

Electroconvulsive therapy. When urgent intervention is indicated to manage severe depression, ECT may be considered. ECT involves inducing a seizure under controlled conditions. Unless a patient lacks capacity it requires their agreement and is prescribed by a psychiatrist. ECT involves the administration of an anaesthetic and muscle relaxant before the application of the treatment and thus is carried out under theatre-like conditions with full resuscitation facilities present. ECT is often delivered twice weekly as a course of six to eight treatments and for some patients provides a rapid resolution of the most severe symptoms,

Table 29.2 Newer antidepressants and key practice points

Name	Type	Practice points
Venlafaxine	SNRI	<ul style="list-style-type: none"> • Reduced toxicity compared with TCAs • At low doses, drug behaves like SSRI, adopting SNRI profile as dose increases; across all doses there is additional dopamine reuptake inhibition • Dose titration applicable • Low risk of postural hypotension, but risk of hypertension at high dose • Marked discontinuation effects
Duloxetine	SNRI	<ul style="list-style-type: none"> • A fixed ratio of serotonin to noradrenaline (norepinephrine) reuptake inhibition • Dose titration rarely indicated • Resembles SSRIs in clinical practice • Also licensed for neuropathic pain and for stress incontinence; in the UK duloxetine is marketed under a different brand name when prescribed for stress incontinence
Reboxetine	NARI	<ul style="list-style-type: none"> • Indicated for more reclusive and anergic presentations • Key side effects are dry mouth and insomnia • Low evidence base of independent effectiveness
Mirtazapine	NaSSA	<ul style="list-style-type: none"> • Reduced alerting effects • Minimal nausea • Low incidence of sexual dysfunction • Sedation is more prominent at lower dose • Weight gain is significant
Agomelatine	MT ₁ MT ₂ agonist 5-HT _{2c} antagonist	<ul style="list-style-type: none"> • Restoration of sleep pattern without residual sedation and impaired reaction time • Minimal weight gain, GI upset and sexual dysfunction • Abnormal LFTs are common and require regular monitoring • Variable efficacy in trials
Vortioxetine	Direct modulation of receptor activity and inhibition of the serotonin transporter	<ul style="list-style-type: none"> • Nausea is most common adverse effect • Sexual dysfunction present at higher doses only • Alerting effects less pronounced • Less residual cognitive impairment • No evidence of QT prolongation • Minimal weight gain • No significant discontinuation symptoms

GI, Gastro-intestinal; LFT, liver function test; NARI, noradrenaline reuptake inhibitor; NaSSA, noradrenaline-specific serotonin agonist; SNRI, serotonin noradrenaline reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

promoting enough improvement to provide ongoing treatment via pharmacological and non-pharmacological means. Although the treatment itself is very safe, patients must be risk assessed for safe receipt of an anaesthetic, and many patients experience short-term memory loss following treatment.

ECT remains controversial, but its speed of effect is not currently matched by any antidepressant medication. This situation may change because recently the immediate and beneficial effects of ketamine in treating depression have been identified.

St John's wort (*Hypericum perforatum*). In the UK herbal remedies such as St John's wort do not feature in prescribing guidelines, but this agent has become a popular option for self-medication. Extracts of hypericum have been shown to be as effective as standard antidepressants in the management of major depression (Linde et al., 2008). Herbal remedies can appear attractive because they sound and feel 'natural', and some patients assume that this exempts them from the serious side effects or interactions that characterise prescribed medicines. In reality St. John's wort has been identified as a cytochrome P450 enzyme inducer

responsible for oral contraceptive failure, breakthrough seizures and reducing the effectiveness of antirejection medication. Mental health stigma may lead some patients to self-medicate for anonymity of treatment. St John's wort is readily accessible, but information provided with the herbal medication will not provide specific information about use in depression. As a herbal product there is some variance in the quality and content of various active ingredients, which indicates inconsistency of dosing is likely. As with prescription antidepressants, treatment should continue for 6 months to minimise the risk of relapse. Once a patient is feeling better this may prove financially challenging if he or she is buying the product. Encouraging people to be aware of mental health issues together with the signs and symptoms of depression is beneficial. However, management of depression without professional support severely limits the options for other interventions (e.g. psychological support) and also objective monitoring.

Ketamine. Ketamine predominantly exerts its effect through an antagonist action on the glutamate *N*-methyl-D-aspartate receptor. Researchers are now looking for an alternative oral preparation

with the same therapeutic effect but fewer of the adverse effects, less abuse potential and fewer problems of administration seen with ketamine. It also means that antidepressants of the future may depart from the traditional biogenic amines and focus on the glutamate pathway.

Treatment of mania

The treatment of acute mania often requires urgent intervention to reduce high arousal states and associated risks. Pharmacological agents employed include benzodiazepines, valproate, antipsychotics and lithium. Combinations of these agents may be used in the early management of such episodes. Lithium is now rarely used in the management of acute mania because it has a slow onset of effect and the dose required can result in high levels which are close to toxic. From a patient perspective, an early unpleasant experience with lithium is likely to deter a patient to agree to this agent being used as a longer-term strategy to help protect against further mood swings. At the same time any agents that could be exacerbating a manic episode should be reviewed. Depression associated with bipolar disorder should not be managed by using antidepressants in isolation because there is a risk of prompting a switch to a manic episode. Agents such as quetiapine or lamotrigine with or without lithium represent evidence-based preferred options. Therefore, antidepressants in bipolar patients should be urgently reviewed and strong consideration given to their withdrawal. Sometimes non-psychotropic drugs such as high-dose steroids (e.g. prednisolone) may precipitate an episode. Prescribing prednisolone in divided doses, as well as reducing the overall daily dose, may help mitigate the situation.

Benzodiazepines

Lorazepam, because of its high potency and availability in both tablet and injection form, is often the agent of choice for prompt sedation. As with other members of this group it works quickly to lower high arousal states and on its own may be enough to interrupt an emergent episode. Some patients have small quantities of benzodiazepine, or related agents, available to self-manage any early signs of such mood swings. In more urgent cases lorazepam may need to be given parenterally to a patient by a healthcare professional to effect treatment. In the UK this may be under the provision of the Mental Health Act legislation if the patient does not consent and there are clear risks of not treating the episode. An alternative parenteral agent to lorazepam is midazolam, which has the advantage of not requiring refrigeration or dilution 1:1 with water for injection prior to intramuscular injection. However, in the UK midazolam is a Schedule 3 Controlled Drug, and this requires additional processes relating to ordering, recording and auditing of stock levels.

Valproate semisodium

Valproate semisodium (divalproate) is licensed in the UK as a specific treatment for mania associated with bipolar disorder. This distinguishes it from the original sodium valproate which,

introduced into the UK in the 1970s, remains licensed only for the management of epilepsy.

Valproate semisodium is a 1:1 molar combination of sodium valproate and valproic acid. Following administration, valproate ion is released and subsequently absorbed. Any meaningful therapeutic differences between sodium valproate and valproate semisodium have not been established. The mechanism of action of valproate in mania is unclear but may be related to increased levels of γ -aminobutyric acid. The antimanic effects of valproate are seen within 3 days, but the full benefit of treatment may not be apparent for up to 3 weeks. Doses should be rapidly titrated to between 1000 and 2000 mg/day. Routine valproate serum levels are not necessary, but levels between 50 and 100 mg/L have been reported to be associated with optimal response in some patients. Although the risks for liver damage are greater in young children, liver function tests should be performed prior to initiation of therapy and periodically thereafter in all patients. In addition, the patient must be instructed to report any problems, such as unexplained bruising, that may indicate abnormalities in coagulation. Although valproate is well established as a prophylactic treatment to prevent relapse, this is an off-label use across all formulations. Valproate should not be used in women of childbearing potential because of its high risk of teratogenicity. These warnings have been strengthened in the UK through amended NICE guidance.

Antipsychotics

All antipsychotics are acknowledged as being intrinsically antimanic, although not all have this utility formally listed within their licensed indications. Most of the second-generation (atypical) antipsychotics, for example, olanzapine, risperidone, quetiapine, aripiprazole and asenapine, are licensed for use in the management of acute mania and in most cases prevention of new manic episodes.

Haloperidol is still commonly prescribed as part of the acute management of mania. It is less sedating than other antipsychotics, but because of its potent dopamine D_2 receptor blockade it carries a much higher risk of inducing acute extrapyramidal side effects. See [Chapter 30](#) for more details around management of extrapyramidal side effects.

Longer-term management

Second-generation antipsychotics also have an established role in the longer-term management of bipolar disorder. Quetiapine in particular is now recognised as an evidence-based choice for management of bipolar depression. This paradox of an antipsychotic playing a key role in managing depression associated with bipolar disorder is linked to the limited understanding of the pharmacological mechanisms of newer antipsychotics in the management of affective disorders.

Continuation therapy with a prophylactic mood stabiliser should be considered in all bipolar patients who have had two or more acute episodes within 2–4 years. It may also be reasonable to consider prophylaxis in any patient following a severe manic

episode. Because treatment is long-term the cooperation of the patient is essential; therefore, a thorough explanation of the risks and benefits of the treatment is vital.

Lithium. Lithium has two distinct roles within affective disorders:

- In unipolar depression it can augment the partial effect of an antidepressant. Adding lithium to the regimen can lead to remission within a few weeks.
- In bipolar disorder lithium remains for the UK the first-choice mood stabiliser.

It has a greater impact on manic episodes, but in bipolar depression its effectiveness can be improved when used alongside lamotrigine. Lithium has a significant impact on reducing suicide rates in bipolar disorder. The mechanism of action remains to be fully elucidated, but since its discovery lithium has been shown to act upon various neurotransmitter systems at multiple levels of signalling in the brain. It is suggested that lithium restores the balance among faulty signalling pathways in critical brain regions. Such effects are thought to trigger long-term changes in neuronal signalling patterns that account for the prophylactic properties of lithium in the treatment of bipolar disorder. Through its inhibitory effects on glycogen synthase kinase-3beta (GSK-3 β) and β -arrestin-2, lithium may alter the level of phosphorylation of cytoskeletal proteins, which leads to neuroplastic changes associated with mood stabilisation (Malhi et al., 2013).

Lithium has a number of medicines management issues because it has a narrow therapeutic range, a low therapeutic index, a wide range of unpleasant side effects and may be involved in several clinically significant drug interactions. It is potentially very toxic, with a clear correlation between serum levels and efficacy, as well as toxicity. It was made the subject of a national patient safety alert in 2009 requiring all healthcare services to implement a five-point action plan. Before initiating treatment with lithium, certain tests should be performed:

- Check serum urea and electrolytes to identify fluid and salt balance.
- Measure serum creatinine to generate an estimate of glomerular filtration rate and assess renal function.
- Undertake thyroid function test and measure calcium levels to check on baseline activity of thyroid and parathyroid glands.
- Where clinically indicated, perform a full blood count. This would include patients with a history of blood disorders because lithium is likely to induce a benign increase in white cells.
- Conduct an electrocardiogram if cardiovascular risk factors are present or the patient has existing cardiovascular disease.

If no abnormalities are found in these parameters, lithium can then be initiated based on the premise that 1 g lithium carbonate produces a steady-state level of around 1.0 mmol/L.

Serum levels. At steady state, which is usually 7 days following initiation of treatment, blood samples are taken 12 hours after the last dose. The 12-hour standard lithium level range is routinely 0.4–1.0 mmol/L. For prophylaxis a plasma lithium level of 0.6–0.8 mmol/L is considered optimum

whether lithium is being used in unipolar depression or within bipolar disorder management. The majority of a dose of lithium is excreted unchanged in the urine, making renal function the primary determinant of the treatment dose. The target range for prophylaxis should be routinely around 0.6 mmol/L, and so a dosage of around 600 mg daily for adult patients is appropriate. Older adults, who will invariably have some age-related reduced renal function, may be initiated at 200 mg daily, but target levels are the same, so under-dosing should be avoided.

When initiating lithium, or making a dose adjustment, it takes around 7 days for a revised steady state to develop. Therefore, unless assessment is required for toxicity, blood levels should not be measured any sooner because dosing adjustments would be based on inaccurate levels. Dose adjustments with lithium are straightforward because at steady-state lithium levels vary in direct proportion to dose; that is, a doubling of dose will double the blood level. However, should this empirical dosing lead to predictive doses above 1600 mg daily, adherence should be thoroughly assessed.

Doses are likely to need adjusting during the early stages of treatment according to patient response and measured serum levels. A number of predictable and unwanted effects can occur, such as polydipsia (increased thirst), polyuria (increased urine output of up to 3 L/day), mild stomach discomfort with some looseness of the bowels and fine tremor of the hands.

However, with the exception of polyuria, these early adverse effects usually resolve within 1–2 weeks. Patients usually adapt to the increased urine output. Monitoring should initially include routine lithium levels on a 3 monthly basis which may be reduced to 6 monthly after a year in patients who continue with stable levels and have no other comorbidities that could affect the body's handling of lithium. Assessment of renal function and thyroid status should be carried out 6 monthly or at least annually. A lithium treatment pack (National Patient Safety Agency [2009] lithium resource pack) should be made available to all patients who are prescribed lithium.

Some patients may notice a swelling in the neck (goitre). Lithium can reduce the output of thyroid hormone, but this is easily corrected with levothyroxine. Often any reduction in thyroid activity is identified in blood tests before the patient notices any discomfort. Weight gain is a significant side effect of lithium therapy.

Lithium toxicity. When lithium levels exceed 1.5 mmol/L signs of lithium toxicity begin to develop. Lithium toxicity is characterised by severe shaking of the hands, giddiness or loss of balance, slurred speech, unusual drowsiness or sleepiness, vomiting and/or diarrhoea. These symptoms should be seen as a medical emergency. Lithium levels may become high unintentionally and usually because of dehydration, diet and drugs. It is important to educate the patient on recognising and avoiding lithium toxicity.

Dehydration arising from extreme fluid loss because of feverish illness, sickness and diarrhoea should prompt a stopping of the lithium until the situation is improved. This will avoid high concentrations of lithium developing. In relation to diet, extreme changes to salt intake, particularly the exclusion of salt from the diet, may lead to the body retaining more lithium to

compensate for the salt loss. Some medicines taken alongside lithium may interact. Patients should be advised to ask their pharmacist before purchasing any over-the-counter medicines. Some medications may push lithium levels into the toxic range. This applies not just to prescription drugs, where the diuretic bendroflumethiazide is a classic example, but also to some over-the-counter medications such as ibuprofen; this analgesic is best avoided unless there is good access to close monitoring of the lithium.

Formulation. As the absorption and bioavailability of lithium may vary from brand to brand, it is important that patients do not inadvertently change brands or dosage forms without levels being checked. Failing to correctly convert a tablet dose to the correct equivalent of the liquid formulations can also lead to dosing errors. The poor aqueous solubility of lithium carbonate (soluble 1 part in 100 parts water) compared with lithium citrate means that the citrate salt is used in all liquid formulations of lithium.

When converting from citrate formulations to carbonate, it should be noted that:

520 mg of lithium citrate = 200 mg of lithium carbonate.

Other anticonvulsants in bipolar disorder. Carbamazepine is a second-line prophylactic treatment which is likely to be prescribed when lithium is ineffective, contraindicated or not tolerated. The medicines management issues that apply when carbamazepine is employed as an anticonvulsant are the same as when it is used as an anticonvulsant. However, there is no robust evidence to confirm that such carbamazepine target serum levels are applicable for use in bipolar disorder.

There is a good evidence base to support the use of lamotrigine in bipolar depression. Specific drug-related monitoring is also not required. Lamotrigine should always be initiated slowly and at half the standard incremental regimen when valproate is also being taken. This is because valproate elevates lamotrigine levels and through this process increases the risk of development of serious skin reactions to lamotrigine. The use of lamotrigine in bipolar disorder remains unlicensed in the UK.

Patient care

Adherence to medication in patients with affective disorders may prove challenging. A patient with severe depression may feel that no treatment can help. At the height of a manic episode anything that will subdue great elation and well-being may be resisted. In these circumstances patients may be described as lacking insight, and in the UK their choice to refuse treatment overridden by the processes within the Mental Health Act. However, outside of an acute phase, good therapeutic discussions around treatment options can take place. Pharmacists are ideally placed to present balanced information on the medicines available to help patients identify treatments and regimens.

It is good practice to provide written information about the medicines. One source is the Choice and Medication website (<http://www.choiceandmedication.org/cms/?lang=en>) which provides access via subscription to independent medicines information on psychotropic agents. It is not restricted by licensed indications and is a resource for both healthcare professionals and patients.

In any patient consultation it should be remembered that concerns around stigma associated with a mental health condition and adherence to treatment may need to be addressed. During treatment selection shared decision making is likely to be much more successful than a unilateral decision made by a healthcare professional. The nature of bipolar disorder means that some patients value the option of advance decisions. This is encouraged as best practice with patients identifying and recording their preference(s) and dislikes for acute intervention which allow, unless circumstances dictate otherwise, their preferences to be honoured in a relapse situation. Exploring with patients their hopes and expectations around medication and actively listening to their concerns about treatment should help to ensure that rewarding conversations take place.

Many of the drugs used in the treatment of affective disorders have the potential to interact with other drugs that have been prescribed or purchased. Some of these are summarised in Table 29.3. Common therapeutic problems in the management of affective disorder are outlined in Table 29.4.

Table 29.3 Examples of important drug interactions with drugs used in the management of affective disorders

Drug group	Interacting drugs	Effects
Tricyclics	Adrenaline (epinephrine) and other directly acting sympathomimetics	Increased risk of hypertension and arrhythmias
	Alcohol Antiarrhythmics Anticonvulsants MAOIs	Enhanced sedation Risk of ventricular arrhythmias Lowered seizure threshold and possible lowered tricyclic levels
	Fluoxetine Paroxetine	Severe hypertension, although some combinations are relatively safe and have been used in augmentation strategies Increased tricyclic serum levels Increased tricyclic serum levels
SSRIs	Anticoagulants MAOIs	Enhanced anticoagulant effects Central nervous system effects of SSRIs increased and risk of serotonin syndrome
	Lithium	Possible serotonin syndrome

Table 29.3 Examples of important drug interactions with drugs used in the management of affective disorders—cont'd

Drug group	Interacting drugs	Effects
MAOIs	Fermented beverages, tyramine-rich foods Antihypertensives Anticonvulsants Levodopa Sympathomimetics	Hypertensive crisis; nonfermented alcoholic beverages will not induce hypertensive event Increased hypotensive effect Lowered seizure threshold Hypertensive crisis Hypertensive crisis
Antipsychotics	Anaesthetic agents Anticonvulsants Drugs that prolong QT interval	Hypotension Lowered seizure threshold Risk of ventricular arrhythmias
Lithium	Non-steroidal anti-inflammatory drugs SSRIs Diuretics Angiotensin-converting enzyme inhibitors Sumatriptan	Enhanced lithium serum levels Possible serotonin syndrome Enhanced lithium serum levels particularly with thiazides Enhanced lithium serum levels Possible central nervous system toxicity; notably, some other triptans are cautioned alongside SSRIs and MAOIs for the same reason
St John's wort	Induces cytochrome P450 enzymes, particularly 1A2, 2C9 and 3A4 Indinavir Warfarin SSRIs Carbamazepine (and other anticonvulsants) Digoxin Oestrogens and progestogens Theophylline Ciclosporin	Reduced indinavir serum concentration (avoid) Reduced anticoagulant effect (avoid) Increased serotonergic effect (avoid) Reduced serum concentrations (avoid) Reduced digoxin serum concentration (avoid) Reduced contraceptive effect (avoid) Reduced theophylline serum concentration (avoid) Reduced ciclosporin serum concentration (avoid)
Always check latest British National Formulary or other reference source for specific drug interaction information. MAOI, Monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.		

Table 29.4 Common therapeutic problems in the management of affective disorder

Problem	Possible solution
Antidepressants	
Treatment failure (30–40% of patients will not respond to first antidepressant)	Ensure adequate dose and duration of treatment Check adherence, engage the patient and develop therapeutic alliance Reassess response against target symptoms
Risk of self-harm	Reconfirm diagnosis and identify other risk factors, e.g. high levels of alcohol consumption in unsupervised situations
Discontinuation reactions	Re-introduce antidepressant and adopt slower tapering of dose
True relapse which develops much later than acute discontinuation events	Consider long-term treatment
Intolerance	Consider changing to a different class
Antimanic agents	
Treatment failure	Ensure adequate dose, check serum levels and adherence; consider drug combinations
Toxicity adverse effects	Determine dose by clinical response, guided by serum levels Ensure patient is well informed and able to recognise impending toxicity and adverse effects of treatment
Problematic weight gain	Dietary advice; structured exercise programmes; consider alternative pharmacotherapy, noting that most drugs used in affective disorders will cause some degree of weight gain
Lithium levels	Ensure serum levels are 12 h post-dose. This is facilitated by single night time dosing and a blood sample taken the following morning

Case studies

Case 29.1

Ms PS is a 21-year-old woman who presented to her primary care doctor with a 2-month history of difficulty in getting to sleep. She described herself as feeling generally unhappy. She was socialising much less but was able to perform most of her usual daily routines. She sometimes felt as though she had little energy and was spending more time just watching the television.

Question

What other questions would you want to ask of Ms PS before a diagnosis is made? What treatment options are indicated?

Answer

Firstly, it is important to explore with the patient if there are any other changes, especially with regard to signs and symptoms that present in depression. In a discussion with Ms PS it would be important to look for other symptoms of anxiety such as worrying thoughts, appetite changes and associated weight loss, suicidality, reduced concentration, loss of interest in hobbies and reduced libido (see mnemonic in main text).

On further questioning by her primary care doctor, Ms PS does not reveal any indicators of self-harm. She does not identify any significant weight loss, and her appetite has not reduced significantly. She does not demonstrate any signs of poor self-care, is in a supportive relationship, and although she has some financial concerns, these are not excessive.

It is likely that her depression is subthreshold or of mild severity. Referral to specialist services is not appropriate. Ms PS could be given advice on sleep hygiene. Sleep hygiene strategies include ensuring that the sleeping environment is comfortable and at an acceptable temperature and not too bright. Ms PS herself should be advised to avoid heavy meals, excessive exercise and stimulant (e.g. caffeine-based drinks) prior to bedtime. Associating bed with sleep and avoiding reading, watching TV or listening to the radio in bed is also recommended.

Active monitoring should be adopted and Ms PS asked to attend for a follow-up appointment in around 2 weeks.

At this stage antidepressants are not indicated. Non-pharmacological interventions to consider would be a structured group exercise programme, guided self-help based on the principles of CBT or computerised CBT. The specific intervention should be guided by Ms PS's preferences.

Case 29.2

Mr DD is a 50-year-old unemployed man with a long-standing history of bipolar disorder. He has been prescribed lithium for some time. His admission into hospital was prompted by a short period of increasingly disturbed behaviour. Mr DD's daughter had contacted the mental health services when she discovered that her father had just spent over £5000 on scientific instruments from an Internet auction site. Over the same period she had noticed that her father had lost interest in his self-care and become elated at the prospect of being on the verge of developing a special formula to solve the fuel crisis. On assessment Mr DD said he felt 'fine, fine all the time'. He told the visiting team that he did not need to be in hospital and it would keep him away from his top-secret mission. He also said that they could not admit him. Mr DD's speech was sometimes very rapid, and it was sometimes difficult to understand what he was saying. His

records showed that on his last admission he had been treated with haloperidol. He was not keen to take any medication offered and it was decided that admission to hospital was appropriate.

Question

What treatment is appropriate for Mr DD?

Answer

Although Mr DD has an established psychiatric diagnosis, it is still important to rule out any organic or physical causes or drivers for his presentation. Following a thorough physical and psychiatric examination, it was established that Mr DD had been relatively well since commencing treatment with lithium almost 4 years previously. However, it was identified that a few months ago he decided to stop taking lithium. It is important that symptoms of mania are promptly brought under control. Haloperidol would be a suitable choice, in view of his previous response. However, a review of Mr DD's medication history revealed that he had experienced several acute dystonic reactions to haloperidol during previous admissions. His daughter also reported that her father had commented on how awful it felt being given haloperidol during his last admission. Mr DD was, therefore, given the option to discuss alternative antipsychotic treatment. He agreed to take olanzapine which was prescribed at a dosage of 15 mg daily. When Mr DD's manic symptoms are controlled, prophylactic treatment should be discussed with him. This should include a discussion about why he had discontinued lithium several months earlier. The opportunity should be taken to provide written information with the offer of a further discussion that should include his daughter.

Mr DD had stopped lithium because he felt he no longer needed it, but after discussion he was prepared to restart treatment. In line with results from renal and thyroid function tests, lithium carbonate may be re-introduced. A suitable starting dose is likely to be of the order 400 mg lithium carbonate at night.

One week later, a 12-hour standard serum lithium level should be performed and the dose of lithium adjusted to achieve the same lithium levels as before (0.6 mmol/L).

The side effects and signs of impending toxicity from lithium should be explained to Mr DD and, if possible, his daughter. They should be provided with the National Patient Safety Agency lithium resource booklet or any local hospital equivalent publication. In the UK this resource is used to provide important safety information around medicines management of lithium and includes the importance of regular lithium levels and other blood tests such as kidney and thyroid function, signs and symptoms of lithium toxicity, and actions that can be taken to avoid lithium toxicity. Once Mr DD is more settled, the olanzapine can be reduced with a view to discontinuation. This may take several weeks and can be done after he has been discharged from hospital. Further discussion with the patient and prescriber about having a supply of medication to help with any breakthrough symptoms that may occur in the future would be helpful and promote insight into the condition. This medication might be olanzapine or could be an agreed benzodiazepine or related sedative agent.

Case 29.3

Mr MA is a 49-year-old unemployed man. He was admitted to a psychiatric unit as an emergency admission. Mr MA had been prescribed fluoxetine 20 mg daily 2 months ago, and after no apparent response the prescriber had changed this to citalopram 20 mg daily 4 weeks earlier. On admission he was noted to be withdrawn, lacking motivation and just gave yes or no in response to questioning. He reported no interests in his life, and it was noted that he had attempted to harm himself in the past. Two weeks after

admission there was no significant improvement in his symptoms. Mr MA is a non-smoker and takes no other medications. He has lost some weight but remains still mildly obese with a body mass index of 32 kg/m².

Question

What treatment options would you consider for Mr MA?

Answer

Mr MA demonstrates symptoms of severe depression with some risk factors, and ECT may be considered an early intervention pending review of antidepressant treatment. Mr MA must give his consent to this treatment because he is an informal patient and retains capacity to make treatment decisions.

Before considering a change in antidepressant treatment, previous adherence should be checked. Review of the medicine charts and discussion with nursing staff, relatives, key workers and the patient should enable a reasonable judgement to be reached. A dose increase is unlikely to be helpful unless the patient is a fast metaboliser or smoker because SSRIs have a flat dose–response curve. In this case, the patient had taken the majority of prescribed doses, is a non-smoker, and having received no apparent benefit, a change in treatment is warranted.

An in-depth review of his physical condition and previous medication should be undertaken. This should include discussion about any previous antidepressant treatment found to be particularly effective, or troublesome.

This review revealed that Mr MA had received several different antidepressants over the past 20 years. Three years ago he was treated with venlafaxine modified release 75 mg twice daily. The medical records confirmed Mr MA's view that this medication had helped him in the past, but on further questioning he stated that he had not taken medication for long after discharge from hospital because he did not want to get 'hooked' on it.

The importance of long-term treatment and the proposed treatment plan should be discussed with Mr MA. Particular issues to be addressed include an assessment of physical health including baseline blood pressure and the need for ongoing periodic monitoring. In view of Mr MA's concerns about dependence, particular attention should be given to discussion around 'antidepressant addiction'. Based on Mr MA's agreement to the treatment plan, his previous response, the lack of any physical contraindication and the ability to organise ongoing, periodic blood pressure monitoring, venlafaxine would be an appropriate treatment option.

Case 29.4

Ms YS is a 28-year-old student with a history of bipolar disorder. She recently moved to the area in the hope of continuing her studies. She was urgently assessed at the request of her key worker, who reported that Ms YS had recently become increasingly elated and her partner was very concerned about the increased credit card bills she was incurring. In the past Ms YS had been prescribed lithium but had refused to continue with it because of significant weight gain. She had been switched to valproate. Prescribed medication was valproate semisodium 1500 mg daily. However, Ms YS had become aware that this agent was very toxic in pregnancy. Being keen to start a family with her partner, Ms YS had stopped taking this treatment.

Question

Describe the treatment options available for Ms YS.

Answer

Cautions around the use of valproate in pregnancy have recently been strengthened in national guidance (NICE, 2016). However, in any perinatal mental health situation the wellness of the mother and the treatment(s) needed must be balanced against individualised risks of effective treatment. The fetal malformation risk of valproate use in pregnancy is dose dependent and non-linear (Eadie, 2016). Valproate semisodium at a dose of 1500 mg daily has a risk of around 18%. The risk is fetal malformation. At higher valproate doses of around 2000 mg/day the incidence of spina bifida is increased. The risk to Ms YS could be reduced by identifying a lower effective dose; for example, at 1000 mg daily the risk is around 10%.

Alternative agents for managing manic episodes include lithium, carbamazepine and antipsychotics. Carbamazepine is inherently less teratogenic, and at a dosage of 1000 mg daily fetal malformation risk is around 8%. However, because Ms YS has not previously been prescribed this drug its effectiveness for her bipolar management is unknown.

For both carbamazepine and valproate, supplementary high-dose folate (5 mg folic acid daily) might help mitigate some of the risk to the developing foetus including development of neural tube defect, but the protective effect of folate has recently been questioned if used pre-conception (Eadie, 2016).

Lithium, outside of first-trimester use, where there is a risk of around 1 in 1000 of causing a heart defect (Ebstein's anomaly), is now considered a suitable option with careful medicines management. Ms YS stopped treatment because of weight gain, not because of lack of efficacy, and her priorities may now be different. As part of pregnancy planning lithium is sometimes stopped during a low-risk period of relapse and this is timed to coincide with first trimester. For Ms YS and her hypomanic state, re-establishing lithium may take too long.

Second-generation antipsychotics with a license for use in and prevention of further manic episodes remain another option. There is no one particular agent to recommend and in line with the US Food and Drug Administration category C classification, benefits are considered to outweigh risks when used in pregnancy. If this option is selected, then choice of agent is best determined by consideration of other properties of each agent. Drugs that may be considered include aripiprazole, olanzapine and risperidone.

Benzodiazepines may also be considered as a short-term adjunct if additional sedation is required.

Case 29.5

Ms AB is a 55-year-old unemployed lady with a long-standing history of depression. She has been treated with several antidepressants over the years and is currently under the care of the community mental health team. The only treatment that appears to have had any effect on her depressive episodes has been dosulepin. She has taken several overdoses in the past, and her psychiatrist is reluctant to prescribe this drug.

Question

What measures could be taken to enable Ms AB to be treated effectively?

Answer

Ms AB does not have treatment-resistant depression. She has been successfully treated with dosulepin in the past, but seemingly impulsively takes an overdose from time to time. This case requires management of the overdose risk and exploring any triggers that prompt such action, or moving to an alternative untried regimen which carries a lower toxicity profile.

Although current guidelines (NICE, 2009a, 2009b) now advocate that no new patients should be commenced on dosulepin, this is not the same as switching patients for whom the drug is effective to an alternative agent.

If Ms AB is going to continue to take dosulepin, then practical measures for controlling the quantities of medication should be introduced. This could be ensuring she receives sufficient medication

for only a few days' treatment at a time. An instalment dispensing arrangement requires good communication among all those involved in her care. When individualising the supply of medication in this way, all of those involved must be alert to the possibility that the system of supply may break down. In this case, an apparently routine prescription for 1 month's supply of medication may have fatal consequences.

30 Schizophrenia

Caroline Parker

Key points

- Schizophrenia is a complex chronic illness which varies greatly in presentation (positive and negative symptoms).
- Positive symptoms such as hallucinations, delusions and thought disorder, which commonly occur in the acute phase of the illness, usually respond to treatment with antipsychotics.
- Negative symptoms such as apathy, social withdrawal and lack of drive, which occur commonly in the chronic phase of the illness, are more resistant to medication.
- The term 'atypical' or 'second generation' is used to describe the newer antipsychotics that generally do not cause the extrapyramidal side effects (EPSE) or hyperprolactinaemia.
- However, the second generation antipsychotics are associated with a range of metabolic side effects including weight gain and diabetes, which in turn may have long-term effects on morbidity and mortality.
- The older 'typical' or 'first generation' antipsychotics are often associated with anticholinergic, sedative and cardiovascular side effects, in addition to EPSE.
- Long-term treatment with first generation antipsychotics is associated with the development of the movement disorder tardive dyskinesia.
- Most first generation and second generation antipsychotics have similar efficacy in the treatment of schizophrenia. The exception is clozapine, which has greater efficacy than all other antipsychotics and is therefore indicated for treatment-resistant schizophrenia. Its use is hampered by the mandatory requirement for regular full blood count checkups.
- Decisions about which antipsychotic to use should be a shared decision between patient and the prescriber, based on an informed discussion involving individual preference, previous efficacy of medication and potential side effects.

The concept of schizophrenia can be difficult to understand. People who do not suffer from schizophrenia can have little idea of what the experience of hallucinations and delusions is like. The presentation of schizophrenia can be extremely varied, with a great range of possible symptoms. It is a chronic disorder with a lifetime prevalence of 1 in 100 people. There are also many misconceptions about the condition of schizophrenia that have led to prejudice against sufferers of the illness. People with schizophrenia are commonly thought to have low intelligence and to be dangerous. In fact, only a minority shows violent behaviour, with social withdrawal being a more common picture. Up to 10% of people with schizophrenia commit suicide.

Classification

Since the late 19th century there have been frequent attempts to define the illness we now call schizophrenia. Kraepelin, in the late 1890s, coined the term 'dementia praecox' (early madness) to describe an illness where there was a deterioration of the personality at a young age. Kraepelin also coined the terms 'catatonic' (where motor symptoms are prevalent and changes in activity vary), 'hebephrenic' (silly, childish behaviour, affective symptoms and thought disorder prominence) and 'paranoid' (clinical picture dominated by paranoid delusions). A few years later Bleuler, a Swiss psychiatrist, introduced the term 'schizophrenia', derived from the Greek words *skhizo* ('to split') and *phren* ('mind'), meaning the split between the emotions and the intellect.

Two systems for the classification of schizophrenia are widely used: *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM 5) ([American Psychiatric Association, 2013](#)) and the *International Classification of Diseases and Related Health Problems*, 10th Edition (ICD 10) ([World Health Organization, 1992](#)).

Symptoms and diagnosis

Schizophrenia is a chronic illness; the exact nature of the symptoms varies greatly in presentation between individuals. It comprises 'positive' and 'negative' symptoms. Positive symptoms include hallucinations (these may be auditory, visual or visceral), delusions, thought disorder (including thought insertion or deletion), paranoia, and grandiosity. Negative symptoms include apathy, social withdrawal and lack of drive and interest.

The intensity of an individual's positive and negative symptoms may vary over time. As with most chronic illness, a person with schizophrenia may always have some of these symptoms to some degree, but during an acute relapse they will be worse, and it is usually the positive symptoms that are more obvious to other people and may be problematic. During periods of remission between acute episodes, it is often the negative symptoms that are more problematic, and these are generally less responsive to treatment with antipsychotics.

Acute psychotic illness

An acute psychotic episode may occur in a number of disease states and for a range of reasons, and a single psychotic episode

does not constitute the disease schizophrenia. Symptoms which commonly occur in an acute psychotic episode include:

- awkward social behaviour, appearing preoccupied, perplexed and withdrawn, or showing unexpected changes in behaviour;
- initial vagueness in speech which can progress to disorders of the stream of thought or poverty of thought;
- abnormality of mood such as anxiety, depression, irritability or euphoria;
- auditory hallucinations, the most common of which are referred to as ‘voices’; such voices can give commands to patients or may discuss the person in the third person, or comment on their actions;
- delusions, of which those relating to control of thoughts are the most diagnostic; for example, patients feel that thoughts are being inserted into or withdrawn from their mind;
- lack of insight (understanding or self-awareness) into the illness.

These symptoms are commonly called positive symptoms and generally respond to treatment with antipsychotics.

Factors that affect diagnosis and prognosis

A definite diagnosis of schizophrenia is established according to the diagnostic criteria in either DSM 5 or ICD 10. It would not generally be made after a single psychotic episode, especially if it is brief. It is more likely to be made after a repeated psychotic episode. A number of features aid prediction of whether an acute illness will become chronic. These features include:

- age of onset, which, typically for schizophrenia, is late teenage to 30 years;
- reports of a childhood which indicate the individual did not mix or was a rather shy and withdrawn personality;
- a poor work record;
- a desire for social isolation;
- being single and not seeming to have sexual relationships;
- a gradual onset of the illness and deterioration from the previous level of functioning;
- grossly disorganised behaviour.

A person with schizophrenia may well have periods of relapse with acute psychotic symptoms, and in between there may be a general underlying trend towards ‘negative’ symptoms, for example, lack of drive, social withdrawal and emotional apathy. Unfortunately negative symptoms respond poorly to most antipsychotics.

Causes of schizophrenia

Although the cause of schizophrenia remains unknown, there are many theories and models.

Developmental model

The developmental model postulates that there are critical periods in the development of neuronal cells which, if adversely affected, may result in schizophrenia. Two such critical periods are postulated to occur when migrant neural cells do not reach

their goal in fetal development and when supernumerary neural cells slough off at adolescence. This model is supported by neuroimaging studies which show structural brain abnormalities in patients with schizophrenia.

Environmental factors

Multiple external environmental factors may influence the development of the disorder including the social, cultural and family environments; the population density; living in an urban environment; individual space; family dysfunction; socio-economic status; social isolation; racial status; immigration; substance misuse; and prenatal stressors. Childhood trauma, death of a parent, and being bullied or abused also increase the risk of psychosis.

Genetic model

There is undoubtedly a genetic component to schizophrenia, with a higher incidence in the siblings of people with schizophrenia and in those with a first-degree relative with schizophrenia. However, even in monozygotic twins there are many cases where schizophrenia developed in only one sibling. It can often be difficult to separate the effects of genetics and the environment.

Transmitter abnormality model

Based on the research that shows that all effective antipsychotics are active at dopamine receptors and, in particular, D₂ receptors, the hypothesis is that schizophrenia is due to an overactivity of dopamine (the dopamine hypothesis). However, such a theory is increasingly being questioned as newer research emerges regarding efficacy of antipsychotics relating to activity at other receptors.

Vulnerability model

The vulnerability model postulates that the persistent characteristic of schizophrenia is not the acute episode itself, but the vulnerability to the development of such episodes. The episodes are time limited, but the vulnerability remains, awaiting the trigger such as stress. The vulnerability can depend on the premorbid personality, the individual’s social network or the environment. Manipulation and avoidance of stress can abort a potential psychotic episode.

Other factors

Numerous other factors have been implicated in the development and cause of schizophrenia. These include perinatal insult, infections, season of birth (people with schizophrenia are more likely to have been born in winter or spring, at least in the northern hemisphere), viruses and toxins.

In reality, all of the above factors may influence both the development and the progression of schizophrenia. Social, familial and biological factors may lead to premorbid vulnerability and subsequently influence both the acute psychosis and the progression to

chronic states. What is then likely is that the illness will feed back to influence social, familial and biological factors, thus leading to future vulnerability.

Pharmacological treatment

Antipsychotics

Antipsychotics have been widely available in the UK since the 1950s. They are an essential treatment for most individuals with schizophrenia and are considered first-line pharmacotherapy. Antipsychotics can help treat acute symptoms and maintain remission from the illness. In fact, the main aim of antipsychotic treatment is to prevent acute relapse and to help keep the person well and stable. Although antipsychotics are a core treatment in the management of schizophrenia, they are just one part of the package of care that contributes towards this aim.

A wide range of antipsychotics is available. Overall most antipsychotics are equally effective for the treatment of psychotic symptoms (Leucht et al., 2013); however, some individuals respond much better to one than another and they are not effective in all cases. There is no way of predicting to which antipsychotic an individual person will respond.

Mode of action of antipsychotics

Although the cause of schizophrenia is the subject of controversy, an understanding of the mode of action of antipsychotics has led to the dopamine hypothesis of schizophrenia. This postulates that the psychotic symptoms in schizophrenia are caused by an alteration in the level of dopamine activity in the brain. It is known that dopamine receptor antagonists are often effective at treating psychotic symptoms, whilst drugs which increase dopamine activity, such as amphetamine, can either induce psychosis or exacerbate schizophrenia.

At least six dopamine receptors exist in the brain, with much interest being focused on antagonism of the D₂ receptor as being responsible for the antipsychotic effect. However, some

antipsychotics have a more specific effect on D₂ receptors alone, yet they do not appear to have superior antipsychotic effect when compared with other agents.

Even today, all the known antipsychotics have an effect via the D₂ receptors. However, additionally most second generation antipsychotics also target serotonin (5-HT_{2A}) receptors, and the balance between the activity at these two receptors types is thought to be important to their mechanism of action.

'Typical' or 'first generation' and 'atypical' or 'second generation' antipsychotics

The antipsychotics that were first available were known to commonly cause extrapyramidal movement disorders. It was not until the development of clozapine in the 1980s that it was established that antipsychotic efficacy could be achieved without inducing extrapyramidal side effects (EPSE). Thereafter, development of antipsychotics aimed to ensure antipsychotic efficacy without EPSE.

The older antipsychotics developed before clozapine and which 'typically' caused EPSE became known as 'typical' antipsychotics, with the new antipsychotics developed after clozapine, which caused no or fewer EPSE, termed 'atypical'. These two groups are now more often termed 'first' and 'second' generation antipsychotics, as in the British National Formulary (BNF). Although there are no definitive criteria for this classification, it is generally accepted that when used at therapeutic doses second generation antipsychotics tend not to cause EPSE and tend not to raise prolactin. Importantly this is not without exception, because some second generation antipsychotics (e.g. risperidone, amisulpride) can cause EPSE and hyperprolactinaemia even at therapeutic doses. Therefore, these two classifications are better viewed as principles, and it is helpful not to consider antipsychotics as being in two discrete groups, but rather on a continuum (refer to Fig. 30.1).

Although the reason for the superiority of clozapine in schizophrenia treatment remains an enigma, a variety of theories have led to the development of newer antipsychotics.

Fig. 30.1 Classification of antipsychotics. EPSE, Extrapyramidal side effects.

Some mimic the impact of clozapine on a wide range of dopamine and serotonin receptors (e.g. olanzapine), some mimic the impact on particular receptors (e.g. 5-HT₂/D₂ receptor antagonists such as risperidone), others focus on limited occupancy of D₂ receptors (e.g. quetiapine), and still others focus on alternative theories such as partial agonism (e.g. aripiprazole).

Selecting an antipsychotic and dose

Despite a wide selection of antipsychotics with different chemical structures, different suggested variation in mechanisms of action and different safety profiles, a number of studies and meta-analyses in recent years have demonstrated that all antipsychotics are of similar efficacy for the treatment of positive symptoms of schizophrenia, with the exception of clozapine which has superior efficacy, being effective for people with schizophrenia who did not successfully respond to treatment with other antipsychotics (Kane et al., 1988; Lieberman et al., 1994). There is no clear advantage of a second generation antipsychotic over a first generation antipsychotic (Hartling et al., 2012; Jones et al., 2006; Leucht et al., 2009, 2013; Lieberman et al., 2005; Stroup et al., 2007). They do, however, vary significantly in terms of potential side effects.

The choice of antipsychotic should always be informed by a patient's previous response to treatment, past experiences, including side effects, and preference, as well as any concurrent medical comorbidity and medication (National Institute for Health and Care Excellence [NICE], 2014).

Side effects

A large number of adverse effects are associated with antipsychotic medicines. In general the frequent or troublesome side effects of the older first generation antipsychotics include EPSE, tardive dyskinesia (TD), anticholinergic effects, cardiac effects and hypotension, hyperprolactinaemia and sexual dysfunction. In contrast, in general the frequent or troublesome side effects of the newer second generation antipsychotics, including metabolic changes such as diabetes, weight gain and sexual dysfunction, can affect adherence in many patients. Sedation remains a factor for many antipsychotics.

Beyond these generalisations there is great variation in side effects with each antipsychotic. Some effects, such as sedation and weight gain, may be beneficial for particular patients, but not for others. The susceptibility of individual patients to such adverse effects can vary significantly and is often a major factor in determining the choice of antipsychotic. When deciding on the most suitable antipsychotic for an individual patient, the relative potential of the individual antipsychotics to cause specific side effects such as EPSE, akathisia, metabolic side effects, weight gain and other unpleasant subjective experiences should be considered (NICE, 2014).

Extensive prescribing guidelines are available (Barnes et al., 2011; Bazire, 2016; Procyshyn et al., 2015; Taylor et al., 2015) providing detailed comparisons of the relative likelihood of side effects with the various antipsychotics. The major side effects are set out below.

Sedation. Of the commonly used antipsychotics, sedation is most prominent with olanzapine and clozapine, even when used at moderate doses. However, it is seen to a lesser extent with many other antipsychotics. Patients may become accustomed to the sedation after the initial period (i.e. the first few weeks of treatment), although for some individuals it may make that particular antipsychotic an unfeasible maintenance option.

Weight gain and diabetes. Weight gain was a common feature with the first generation phenothiazine antipsychotics, but is now seen to a greater extent with certain second generation antipsychotics, particularly olanzapine and clozapine. Weight gain is generally related to increased food intake driven by increased appetite and lack of satiation. In addition to weight gain, these two second generation antipsychotics have also been associated with increased incidence of diabetes and hyperlipidaemia. This is seen with some other second generation antipsychotics (e.g. quetiapine), but to a much lesser extent.

Schizophrenia itself is associated with increased incidence of diabetes and cardiovascular disease; therefore, any additional effect from an antipsychotic on increasing weight gain, lipids and adversely affecting glucose control is a significant concern. People with schizophrenia often suffer poorer physical health in addition to poor mental health and require regular and often proactive monitoring of physical health risk factors.

Cardiac side effects and QT prolongation. Postural hypotension may be relatively common with a number of antipsychotics. This is part of the rationale for slow-dose titrations when initiating treatment (e.g. olanzapine, risperidone, quetiapine, clozapine, chlorpromazine).

Some antipsychotics, particularly haloperidol, are associated with changes to the QTc interval measured on the electrocardiogram (ECG) and, if given in high doses, may increase the risk of sudden cardiac death. Although overall the risk is very low, monitoring the ECG has become part of normal practice. Maximum licensed doses should not be exceeded.

Extrapyramidal side effects and tardive dyskinesia. The EPSE such as akathisia, dystonia and parkinsonian symptoms are frequently associated with first generation antipsychotics, particularly trifluoperazine, fluphenazine and haloperidol (see Box 30.1). They are also seen with certain second generation antipsychotics, especially at higher doses (e.g. risperidone, amisulpride). These side effects can be managed by dosage reduction or by giving anticholinergics such as procyclidine or orphenadrine.

Attempts to treat TD have been many and varied. These strategies are rarely successful and the focus should be on avoiding development rather than treatment. Currently, the most successful strategies involve a gradual withdrawal of the causal first generation antipsychotic and replacement with a second generation antipsychotic.

Anticholinergics may be prescribed to counter the EPSE of antipsychotics. A number of studies have investigated the discontinuation of anticholinergic agents and reported re-emergence of the EPSE. The anticholinergics are not without problems, having their own range of side effects including dry mouth, constipation and blurred vision. They can cause euphoria and, therefore,

Box 30.1 Movement disorders associated with antipsychotics

Extrapyramidal symptoms consist of:

- *Parkinsonian symptoms* (usually present as tremor, rigidity, bradykinesia, stooping gait and poverty of facial expression): may appear gradually. These may remit if the antipsychotic is withdrawn and may be suppressed by the administration of anticholinergics; however, routine co-administration of anticholinergics is not justified because not all patients are affected. Anticholinergics are also associated with adverse effects and may unmask or worsen *tardive dyskinesia*.
- *Acute dystonic reactions* (abnormal face and body movements as a result of sustained muscle contraction) and *dyskinesia*: occurs more commonly in children or young adults and may appear after only a few doses. These are acute and painful and need immediate treatment with an anticholinergic, often in the parenteral form.
- *Akathisia* (inner restlessness): patients may pace up and down, constantly shifting their leg position or tapping their feet.
- *Tardive dyskinesia* (rhythmic, involuntary movements that usually affect the tongue, face, neck and jaw muscles, but can also affect extremities): usually develops after long-term use of antipsychotics or with high doses. It is of particular concern because it may be irreversible and there is no effective treatment. Withdrawal of the causal antipsychotic at the earliest signs may halt its full development.

have the potential for misuse. Withdrawal problems can include cholinergic rebound. One of the benefits of most second generation antipsychotics is the reduced need for co-prescription of anticholinergics.

Hormonal effects and sexual dysfunction. The side effects of hormonal effects and sexual dysfunction are primarily influenced by the effect of antipsychotics on inhibiting prolactin regulation leading to hyperprolactinaemia. This may become symptomatic; symptoms include amenorrhoea, galactorrhoea, gynaecomastia and loss of libido. Such effects are relatively common with the older first generation antipsychotics, as well as with certain second generation antipsychotics such as risperidone, paliperidone and amisulpride.

Neuroleptic malignant syndrome. The neuroleptic malignant syndrome is a rare but serious idiosyncratic adverse effect that can occur with any antipsychotic and with a few other related medicines (e.g. metoclopramide). The primary symptoms are related to loss of autonomic control (e.g. rigidity, fever, diaphoresis, confusion and fluctuating consciousness). There may also be a significant rise in creatinine kinase, although this is not a specific diagnostic indicator. Although unpredictable, the onset is particularly associated with the use of high-potency first generation antipsychotics such as haloperidol, recent and rapid-dose increases, and abrupt withdrawal of anticholinergics. Treatment usually requires urgent admission to a medical ward and immediate withdrawal of all antipsychotics.

Clozapine and refractory illness

Clozapine was developed as an antipsychotic during the 1960s. Unfortunately, it was associated with a 1–2% incidence rate of neutropenia, and this initially resulted in its withdrawal.

However, it was noted even at an early stage in trials that it was completely free from causing the debilitating extrapyramidal symptoms frequently seen with all the other existing antipsychotics. In the 1980s, clozapine was demonstrated to have a greater efficacy than other antipsychotics because it was effective for some patients for whom other antipsychotics had failed (Kane et al., 1988; Lieberman et al., 1994). It was subsequently reintroduced into clinical practice but with mandatory routine blood monitoring.

Clozapine is now established as the antipsychotic of choice in treatment-resistant schizophrenia (NICE, 2014), but it is not without problems (Bleakley and Taylor, 2013). Treatment-resistant schizophrenia is generally defined as a failure to respond to two antipsychotics used (in succession) at therapeutic doses for a reasonable period of time. The use of clozapine should not be delayed or viewed as a treatment option of ‘last resort’. The earlier it is used the better is the patient’s prognosis.

In addition to neutropenia, clozapine is associated with a greater risk of seizures, particularly at higher dosages (>600 mg daily); therefore, careful dose titration is required, as well as regular adherence to the daily doses. Other problematic side effects include initial hypotension and sedation. Later, significant weight gain, mediated through increased food intake driven by food craving, disturbed glucose control, and potentially the development of diabetes and excessive drooling can also present.

A regimen of gradual dose titration starting at 12.5 mg twice daily aiming to reach 300 mg in 2–3 weeks is normally recommended. If the titration is too rapid, tachycardia, sedation and seizures may be problems. Although tachycardia is a common and usually benign problem during the initiation, if it is associated with fever, chest pain or hypotension this may indicate a high risk of myocarditis, and clozapine should be stopped (Bleakley and Taylor, 2013).

When treatment with clozapine is perceived to be inadequate, or dose optimisation is limited due to side effects, the treatment plan can become complex. The theory behind the addition of a further medication is either to enhance the plasma concentration of clozapine, or for the second medication to enhance a particular receptor blockade which may be considered necessary in a specific patient (Barber et al., 2017; Paton et al., 2007). The augmentation strategy with the best evidence to support its use is the addition of sulpiride or amisulpride to clozapine. Other strategies include the addition of risperidone, lamotrigine or omega-3 fatty acids. However, many of the trials that support these augmentation strategies are small scale. A meta-analysis concluded that no single strategy was superior to another (Paton et al., 2007).

Using antipsychotics

As a general rule, a patient should be prescribed only one antipsychotic at a time. Exceptions would include the short periods of time when changing from one antipsychotic to another, because an antipsychotic should not be stopped abruptly, and the new one is likely to require titration to a therapeutic dose; therefore, there will often be a period of a few weeks of crossover. Another exception is augmentation of clozapine as described earlier.

If a person is being treated with an antipsychotic and it is not thought to be working sufficiently the following steps are recommended:

- consider the patient's adherence to the prescribed dose;
- optimise the dose;
- review the symptoms and diagnosis in case it has changed;
- consider changing to another antipsychotic;
- consider using clozapine if the patient has not responded successfully to two antipsychotics.

Prescribers should not keep increasing the dose of the existing antipsychotic beyond the BNF maximum or simply add a second antipsychotic for use alongside the first.

Maximum and equivalent doses

The consensus is that higher than licensed doses of antipsychotics do not improve the overall level of response which tends to plateau. Higher doses only increase the number and severity of side effects, because many are dose related; therefore, both acute and longer-term risks are increased (Royal College of Psychiatrists, 2014).

If more than one antipsychotic is used regularly, then prescribers should consider the total cumulative daily dose of antipsychotics and the BNF maximum should not be exceeded.

Antipsychotics vary in potency of D₂ receptor activity. However, this is known to be only part of the explanation for their efficacy. There is no definitive list of equivalent doses in terms of efficacy, but in terms of safety a standardised concept has been developed for calculating maximum doses. This widely accepted method is to calculate what proportion the current dose is of the maximum dose stated in the BNF. For example, a daily dose of 15 mg of olanzapine is 75% of the maximum dose of 20 mg a day. This method is not without its drawbacks because it generally reflects the maximum doses manufacturers used in trials, but not all manufacturers conducted dose ranging trials to establish the maximum beneficial dose.

Onset of effect

The full antipsychotic effect is not evident immediately. For the more sedating antipsychotics the sedating effects may be evident within hours and generally wears off after 2–3 weeks (Kapur et al., 2005). The actual antipsychotic effects on thought disorder, hallucinations and delusions may begin to be noticed within a week, but it may take several more weeks for full effects to be seen. If there has been no response at all within 2–3 weeks of adherence, then a change of antipsychotic or change of dose is probably indicated.

Long-acting formulations of antipsychotics

Oral antipsychotic medication should be offered to people with newly diagnosed schizophrenia. There may be circumstances where oral formulations of antipsychotics may not be suitable for an individual patient, for example, for those who struggle to remember to take medicines regularly and for those with

swallowing problems. For such patients a 'depot' intramuscular formulation may be an alternative strategy for maintenance treatment (Fig. 30.2). Some patients also prefer to have a depot because this avoids the daily routine of taking oral medicines. Non-adherence with oral medicines is a major problem in patients with any long-term illness, and the administration of a depot formulation guarantees drug delivery.

Antipsychotics have been available in depot formulations since the 1960s; there are now a number available and they are widely used. Despite this increasing range of options in terms of treatment efficacy and overall adverse effects, there is minimal discernable difference between the depot formulations; however, there are notable practical differences (Shajahan et al., 2010).

Disadvantages of depots include reduced flexibility of dosage because it may be necessary to wait a few weeks until the next dose is due before any dose amendment can be made. Other disadvantages are the potentially painful nature of intramuscular injections and, for some antipsychotics, a high incidence of EPSE. In addition, risperidone long-acting injection has a considerable delay in onset, because there is no release of the active drug from the microsphere formulation until 3 weeks after injection. The olanzapine depot is associated with a post-injection syndrome consistent with olanzapine overdose; there is a requirement for patients to be observed for 3 hours after every injection.

Most long-acting (depot) formulations are esters which are lipophilic and soluble. These are dissolved in an oily vehicle such as sesame oil or a thin vegetable oil (Viscoleo). Once injected into muscle it is slowly released from the oil vehicle. Active drug becomes available following hydrolysis for distribution to the site of the action.

Although the ideal long-acting antipsychotic formulation should release the drug at a constant rate so that plasma level fluctuations are kept to a minimum, all of the available products produce significant variations. This can result in increased side effects at the time of peak plasma concentrations, usually after 5–7 days for oil-based depots after which plasma concentrations decline.

Four first generation and four second generation antipsychotics are currently licensed in the UK as long-acting depot formulations for intramuscular injection. The first generation depots are oily injections given every 1–5 weeks; the second generation depots (or long-acting injections) are aqueous suspensions, given every 2–4 weeks (Table 30.1).

Interactions and antipsychotics

There are claimed to be many interactions involving antipsychotics, but few appear to be clinically significant. Carbamazepine accelerates the metabolism of haloperidol, risperidone and olanzapine, and should not be used with clozapine because of the additional risk of neutropenia. Most antipsychotics increase the sedative effect of alcohol. The selective serotonin reuptake inhibitors fluoxetine, paroxetine and fluvoxamine interact with clozapine, resulting in increases in clozapine plasma concentration. Smoking tobacco increases the rate of metabolism of

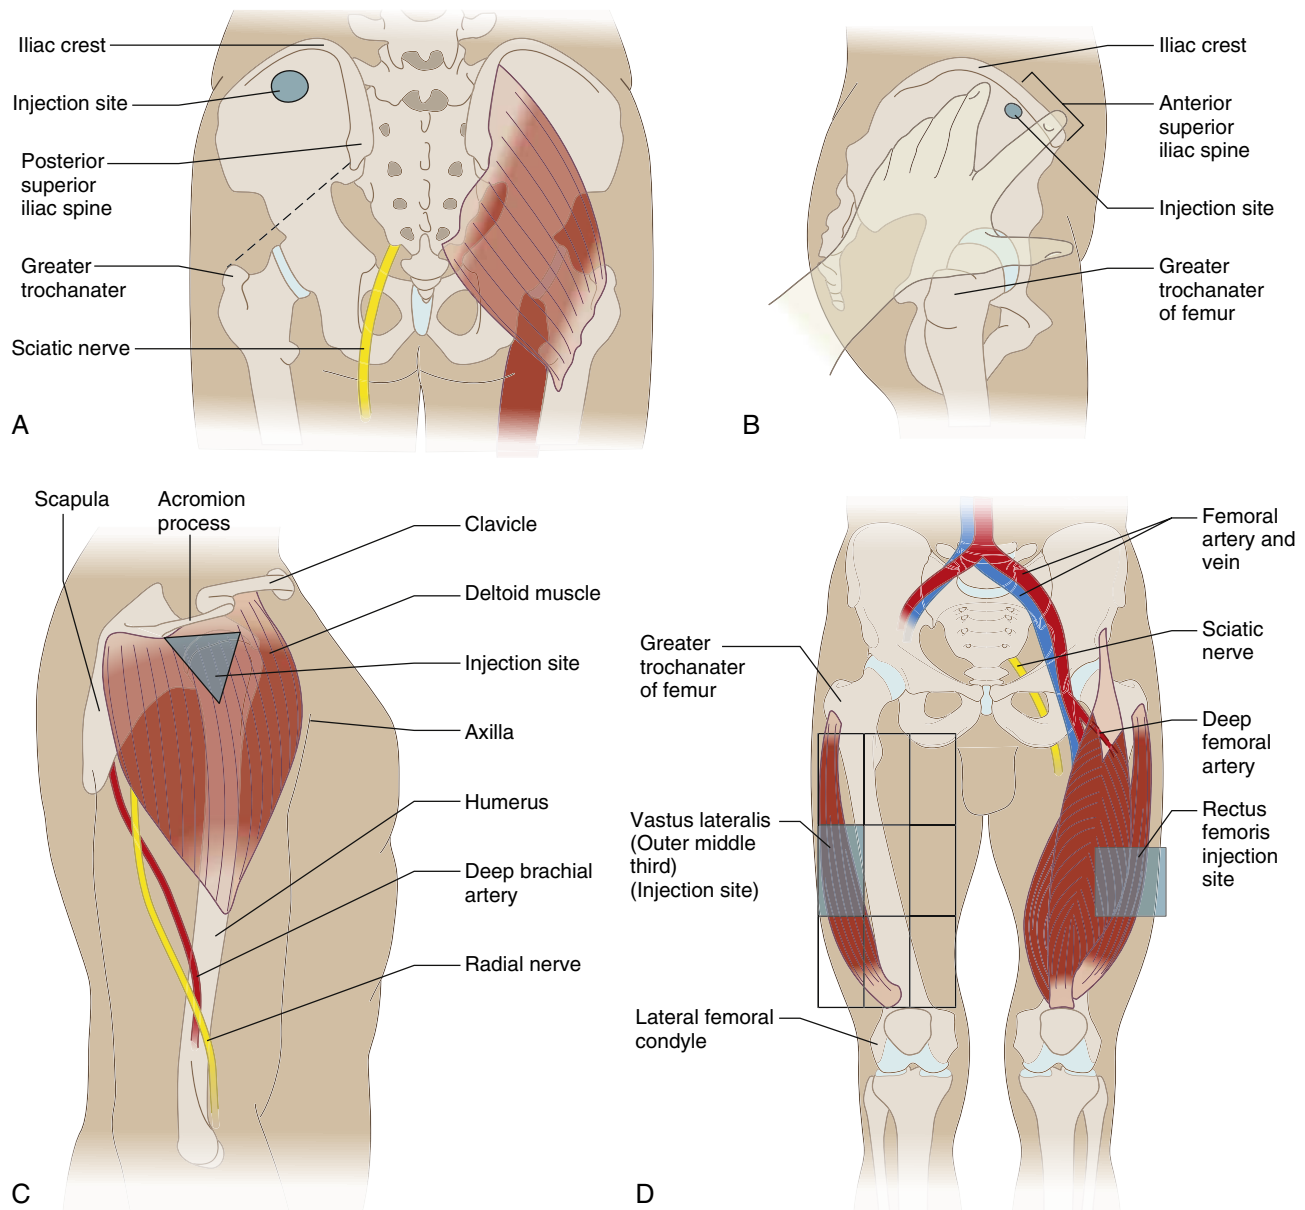

Fig. 30.2 Location of intramuscular injection site (deltoid and gluteal). A and B are both gluteal injection sites, viewed from different angles. C is a deltoid injection site. D is vastus lateralis and rectus femoris injection sites.

olanzapine and clozapine, and regular doses may need to be reduced if a person stops smoking. Clozapine levels should also be checked if a patient changes his or her smoking habits.

Therapeutic drug monitoring

Therapeutic drug monitoring is only of value if there is a reliable laboratory assay and a correlation exists between the concentration of the drug in any particular body compartment, usually blood/plasma, and its clinical effectiveness. Unfortunately, this is not the case for most antipsychotics, and the measurement

of drug concentrations is not a part of routine clinical practice except with clozapine, although even with clozapine there is only a weak correlation between plasma levels and clinical effect. The general guidance is that individuals who have not adequately responded to clozapine and have a plasma level less than 350–500 micrograms/L may benefit from a dose increase. Those who suffer side effects and have a plasma level above this range may benefit from a dose reduction. Those with a plasma level greater than 1000 micrograms/L are more likely to suffer seizures, and antiepileptic cover using sodium valproate should be considered.

Table 30.1 Depot antipsychotics available in the UK

Trade name	Generic name	Formulation and vehicle	Administration (intramuscular) and comments	Time to peak (days)	Half-life (days)	Available since
First generation						
Clopixol	Zuclopenthixol decanoate	Thin vegetable oil	Upper outer buttock (gluteal) or upper lateral thigh, every 1–4 weeks	4–7	19	1978
Depixol	Flupentixol decanoate	Thin vegetable oil	Upper outer buttock (gluteal) or upper lateral thigh, every 1–4 weeks	7	17	1972
Haldol	Haloperidol decanoate	Sesame oil	Gluteal, every 4 weeks	3–9	21	1982
Modecate	Fluphenazine decanoate	Sesame oil	Gluteal, every 2–5 weeks	0.3–1.5	6–9	1968
Second generation						
Risperdal Consta	Risperidone	Powder for reconstitution with aqueous solution in a prefilled syringe, forms a suspension	Gluteal or deltoid, every 2 weeks Requires refrigeration	32	8–9	2002
Abilify Maintena	Aripiprazole	Prefilled syringe of aqueous prolonged-release suspension	Gluteal or deltoid, every month	7 after gluteal, and 4 after deltoid administration	47	2015
Xeplion	Paliperidone palmitate	Prefilled syringe of aqueous prolonged-release suspension	Gluteal or deltoid, every month (no refrigeration), active metabolite of risperidone	13	25–49	2011
ZypAdhera	Olanzapine pamoate	Powder for reconstitution with aqueous fluid, forms a suspension	Gluteal, every 2 or 4 weeks Observe patient carefully for symptoms of post-injection syndrome for 3 h after each dose	3	10	2010

Case studies

Case 30.1

Mr LT is a 20-year-old man. His childhood was disrupted by constant changes to family membership. From an early age his behaviour was difficult, but despite such changes at school he coped and performed academically well. At age 15 he started using cannabis and increasingly lost interest in his studies at school. His parents became concerned as he appeared to undergo a change of personality, communicating with them very little. He eventually dropped out of school and briefly took various short-term jobs. He was unable to sustain any long-term employment. When he was 17 he moved into a flat and seemed to live a twilight existence involving illicit drugs and all-night

raves. Police were called to his flat after a violent disturbance. They found Mr LT living in squalor. He was surrounded by pieces of paper containing incomprehensible messages and was incoherent. He sat with a fixed stare, appearing quite inaccessible. He kept laughing and responding to imaginary people. He was very resistant to hospital admission, and had to be admitted under a section of the Mental Health Act 1983. On the ward he has remained quiet but appears to be in conversation with people who are not there.

Questions

1. Outline the medicine(s) of choice for Mr LT and the rationale for your selection.
2. What factors in his presentation are likely to influence his prognosis?

3. Outline the medicine(s) of choice if there is a short-term, immediate need to control aggressive behaviour.

Answers

1. The choice of medicine used (or not) will be influenced by the working diagnosis. So the first need is to ascertain whether Mr LT's behaviour results from abuse of cannabis and other illicit substances, or whether it is the onset of a psychotic illness such as schizophrenia. If the former, he would be expected to recover within a few days with little or no medication. If, however, this is the first presentation of a schizophrenic illness, the symptoms are likely to persist and it would be appropriate to prescribe an antipsychotic. For first episode psychosis an oral antipsychotic should be offered. The exact choice will partly depend on which is tolerable to the patient, the likelihood of certain side effects, the patient's age (there are additional considerations if the patient is aged <18 years) and the balance and risk of side effects. It would usually be a second generation antipsychotic such as aripiprazole or risperidone. Olanzapine may not be such a suitable choice because of the high likelihood of significant weight gain and metabolic symptoms. If there are concerns that he may not swallow the medications, then an orodispersible formulation may be useful. These formulations are available for aripiprazole and risperidone and some other medicines.
2. A number of factors in Mr LT's history indicate a poor prognosis:
 - there has been a deterioration in his overall functioning;
 - his age (quite young), which is typical for a first breakdown;
 - his poor work record;
 - his substance misuse history;
 - his grossly disorganised behaviour;
 - a number of positive symptoms such as hallucinations.
3. If whilst in hospital Mr LT becomes acutely aggressive because of the psychosis, other medicines may be needed in addition to the prescribed regular antipsychotic, to control his aggression to protect both him and other people. A decision would have to be made about whether to use antipsychotics or benzodiazepines in the short-term. This decision is separate from the longer-term treatment plan. Each hospital should have their own protocol for the management of such emergencies. The NICE guidelines on the management of violence (NICE, 2015) recommend that if a person will not take oral medicines, then use lorazepam injection or haloperidol plus promethazine injections (at the same time).

Case 30.2

Mr GL, aged 32 years, has relapsed for the third time this year. The pattern for the last two psychotic relapses is the same as this presentation, and both required brief admissions. On both previous occasions his positive symptoms responded rapidly to antipsychotics. The first antipsychotic, risperidone, was titrated up to 8 mg/day and he suffered distressing EPSE. This was subsequently changed to olanzapine, and he was stabilised and discharged on a dosage of 15 mg daily. However, he stopped taking this within a couple of weeks of discharge, claiming not to be ill and having gained notable weight. During his second relapse and admission he was successfully treated with amisulpride 400 mg twice daily but again stopped taking it soon after discharge.

Questions

1. Was Mr GL's medication treatment appropriate?
2. What strategies could be adopted to maintain Mr GL's treatment?

3. What would you recommend if Mr GL relapsed and was admitted again?

Answers

1. Mr GL has been treated with three oral second generation antipsychotics all with good effect. The initial treatment was with a fairly large dose of risperidone (8 mg). If this was his first episode and if he was antipsychotic naive, the dose was titrated straight up to this dose quite quickly, and it may well be considered excessive. The usual treatment dosage is 4–6 mg/day. EPSE are dose related and could be expected at a dosage of 8 mg/day. The second choice of olanzapine, another second generation antipsychotic was appropriate, because this rarely causes EPSE. The third choice of amisulpride was unlikely to cause weight gain (unlike olanzapine) but is quite likely to cause EPSE. Choosing a third oral antipsychotic was not addressing the potential issue of adherence.
2. Mr GL has no insight into his illness or the need for continuing treatment. Repeatedly stopping antipsychotics and having relapses leads to a worse prognosis. Therefore, it is really important to properly address Mr GL's repeated discontinuation of antipsychotic medication, which could be for a number of reasons including:
 - His lack of insight into the nature of his illness, and its need for treatment, is part of the illness itself, and his failure to gain insight is a sign of his incomplete recovery, which in turn drives poor adherence to medicines, and so a poorer response.
 - He needs a more supportive home environment with help to remind, encourage and prompt him to take his antipsychotic medication daily.
 - He is suffering from side effects that deter him from taking the antipsychotic regularly.
 Mr GL's opinion and preferences about medication should be sought, and the next antipsychotic should be selected accordingly. He should also be educated (again) about the need for ongoing treatment, as per any chronic illness.
3. If Mr GL were to relapse again it would be important to establish the reason. Repeated relapses will adversely affect his longer-term prognosis. Therefore, a depot formulation of antipsychotic should be considered. In most cases, the use of a depot antipsychotic injection would be the easiest way to ensure adherence in the short-term although if Mr GL is determined to avoid treatment, then this strategy is unlikely to be successful, because he simply would not attend the appointments for the depot injection. In his case, the response to each antipsychotic bodes well, and he is therefore fairly likely to respond to the next antipsychotic if given as a depot. However, because he has had EPSE with high doses of risperidone this may influence the choice of depot. He should be involved in the decision as to which depot. It could be worth trying a risperidone depot but at a moderate dose (not as high as the oral dosage of 8 mg daily). Alternatively, paliperidone, the active metabolite of risperidone, may be appropriate, although this too can induce EPSE in a dose-related manner. However, the patient may prefer this option because it is a monthly, rather than fortnightly, injection. Alternatively, it may be appropriate to try a first generation antipsychotic with a lower propensity to cause EPSE such as flupenthixol decanoate or zuclopenthixol decanoate. These also have great dose flexibility. Therefore, they could be started very gently at low doses to establish whether they are tolerated, before increasing the dose.

Case 30.3

Ms SW, aged 28 years, has a 5-year history of schizophrenia with many admissions to hospital. Throughout the period of her illness she has received a range of different oral antipsychotics including risperidone, olanzapine, quetiapine, amisulpride, as well as the depot formulations of flupenthixol and zuclopenthixol decanoate. For most of this time she has had fixed beliefs that she is being watched and spied on by gangs of men who want to sexually assault her when she is asleep and tarnish her name and reputation to everyone she knows. When she is ill these beliefs torment her and she rarely goes out of her flat, preferring to stay hidden at home. Until recently she has been treated with zuclopenthixol decanoate 500 mg by intramuscular injection every week at her home, plus olanzapine 10 mg at night, fluoxetine 20 mg daily, and procyclidine 5 mg three times daily. She was admitted to hospital 3 months ago. There is no sign of improvement in her mental state; however, she has greatly increased in weight, now approaching 127 kg.

Questions

1. Comment on Ms SW's current treatment plan.
2. What would you recommend next?
3. The team wishes to consider clozapine for Ms SW. What should be done before Ms SW can receive clozapine?

Answers

1. Although sometimes polypharmacy (the use of more than one antipsychotic) is used for patients when there has been poor or inadequate response, the practice is not evidence based and is potentially risky. Additional medicines are often added in a crisis or in the hope of achieving a greater degree of response. As in this case, the strategy is often unsuccessful. The particular issues of note with this patient's treatment regimen are:
 - The combination of two antipsychotics exceeds the BNF maximum dose. The maximum dose of zuclopenthixol decanoate depot is 600 mg/week; therefore, 500 mg weekly is 83% of the maximum dose. The maximum dose of olanzapine is 20 mg; therefore, 10 mg is 50% of the maximum dose. $83\% + 50\% = 133\%$. Doses greater than 100% confer greater risks for side effects, and the Royal College of Psychiatrists monitoring guidance should be followed. This includes a regular review of the dosage and regular blood tests and ECGs.
 - There is a combination of a first generation (zuclopenthixol decanoate) and a second generation (olanzapine) antipsychotic; this reduces the potential benefit of using a second generation antipsychotic with a very low incidence of EPSE because the patient is still suffering with EPSE to the extent that she requires the anticholinergic, procyclidine.
 - The use of a depot formulation suggests that there has been an issue with poor/incomplete/erratic adherence; however, the concurrent use of oral olanzapine means that she is expected to be adherent with this oral formulation. Therefore, the logic for this combination of formulations needs to be reviewed and her adherence assessed.
 - She is at risk of development of TD by being on an antipsychotic long term that is causing EPSE.
 - This regular dose of the anticholinergic procyclidine is likely to cause its own side effects.
 - The need for such frequent dosing of the intramuscular depot might not be necessary; administration at 2-weekly intervals would normally be appropriate.

- She is suffering severe weight gain. This is more likely to be caused by olanzapine by increasing her appetite, rather than by the zuclopenthixol decanoate.
2. Because Ms SW has not fully responded to (more than) two antipsychotics taken at proper therapeutic doses for reasonable periods of time, she meets the definition of treatment-resistant schizophrenia. Trying yet further alternative antipsychotics is not likely to be any more successful than the current treatment regimen, and clozapine is therefore indicated.
 3. The preparation for starting treatment with clozapine involves a number of steps. These include:
 - First, discussing the potential treatment plan with Ms SW. This includes explaining that it is indicated for treatment-resistant schizophrenia and is more likely to be effective than any other antipsychotic. The need to have regular mandatory blood tests, initially weekly, to assess the full blood counts to monitor for any signs of neutropenia must be clearly explained.
 - We would need to consider that until now the use of a depot formulation has been considered necessary. Presumably she has had a history of problems with adherence to oral antipsychotics (this would be the indication for choosing a depot). Therefore, because clozapine is available only as an oral formulation, the team would need to review whether anything would now need to be put in place to support her long-term adherence with oral clozapine, as regular adherence is particularly important with this option; erratic compliance is particularly risky, increasing the likelihood of hypotension (potentially causing syncope), severe sedation and seizures. This may mean planning for additional services and support for Ms SW when she is discharged from hospital and reviewing her living accommodation arrangement (i.e. whether she has staff living with her or visiting who can support her adherence).
 - Ideally the team would want to get Ms SW's consent to having regular blood tests and starting an oral medicine. However, if she is very unwell she may not currently have capacity to agree to these things. If she does not agree and is detained in hospital under the Mental Health Act 1983, although it is legal to enforce blood tests this can be very traumatic and not favourable for the patient's therapeutic relationship with the care team. In addition it is not practically possible to force a patient to take oral tablets.
 - All patients prescribed clozapine and their consultant psychiatrist and the dispensing pharmacy service must be registered with a clozapine monitoring scheme (i.e. ZTAS [Zaponex Treatment Access System], CPMS [Clozaril Patient Monitoring Service] or DMS [Denzapine Monitoring System]). Only then may the clozapine be legally dispensed.
 - Once registered with a clozapine monitoring scheme and before starting clozapine a baseline full blood count and background checks are required to ensure that the patient is not already suffering from neutropenia or another blood disorder. Once these have been checked, clozapine can be prescribed.
 - The Summary of Product Characteristics for clozapine says that depot antipsychotics are contraindicated with it because of the small risk of neutropenia. This is compounded by the nature of the formulation, meaning that the depot antipsychotic remains present in the patient for some time (weeks). Therefore, further doses of this should be stopped before clozapine is started.
 - The prescriber should be aware of the interaction between fluoxetine and clozapine, noting that this causes an increase in clozapine's levels. It may be appropriate to continue the fluoxetine, but the patient may need lower doses of clozapine. Serum levels of clozapine can be checked to optimise the dose and avoid unnecessarily high levels, which are associated with toxicity.

- Once the depot is stopped, which was the cause of the EPSE, then the associated prescription for the anticholinergic procyclidine can also be gradually stopped. This should not be done immediately or abruptly, because the EPSE may continue for some time, and the depot antipsychotic may take weeks to no longer have effects. Furthermore stopping procyclidine abruptly can lead to symptoms of cholinergic rebound. However, the prescribing team should also be aware that

clozapine has notable anticholinergic effects, which would be compounded by concurrent procyclidine.

- Ideally all other treatments would be stopped and clozapine prescribed alone. However, sometimes this is simply not practicable, because the patient would then be left untreated whilst the clozapine is titrated, which routinely takes 2–3 weeks. Therefore, the final steps of gradually withdrawing other medicines may occur alongside the gradual initial titration phase with clozapine.

31 Epilepsy

Gonçalo Cação and Josemir W. Sander

Key points

- An epileptic seizure is a transient paroxysm of uncontrolled neuronal discharges causing an event which is discernible by the person experiencing the seizure and/or an observer.
- Epilepsy is a brain disorder characterised by an enduring predisposition to generate epileptic seizures.
- The annual incidence of epileptic seizures is around 50 cases per 100,000 of the population.
- About 60–70% of those who develop epilepsy will become seizure free on treatment, and about 50% will eventually withdraw their medication successfully.
- Generalised seizures present immediate involvement of both hemispheres and include different types of seizures: tonic-clonic, absence, myoclonic, clonic, tonic and atonic.
- Focal seizures arise from an area limited to one hemisphere and may evolve into a bilateral convulsive seizure.
- Treatment of epilepsy is usually for at least 3 years and, depending on circumstances, sometimes for life.
- Treatment aims to control seizures using one drug without causing side effects and minimising the use of polypharmacy.
- Management of epilepsy requires empowering the person to understand his or her condition and medication, and helping the person to develop effective partnerships with health professionals.

An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain, causing an event that is discernible by the person experiencing the seizure and/or by an observer. Epilepsy is a disorder of the brain characterised by an enduring predisposition to generate epileptic seizures and by the associated neurobiologic, cognitive, psychological, and social consequences. According to the International League Against Epilepsy (ILAE) (Fisher et al., 2014), epilepsy is defined by any of the following conditions:

1. at least two unprovoked (or reflex) seizures occurring more than 24 hours apart;
2. one unprovoked seizure (or reflex) and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years;
3. diagnosis of an epilepsy syndrome.

A person with epilepsy will show recurrent epileptic seizures that occur unexpectedly and stop spontaneously.

Epidemiology

There are problems in establishing precise epidemiological information for a heterogeneous condition such as epilepsy. Unlike most ailments, epilepsy is episodic; between seizures, individuals may be perfectly normal and have normal investigations. Thus, the diagnosis is essentially clinical, relying heavily on eyewitness descriptions of the events. There are also a number of other conditions in which consciousness may be transiently impaired and which may be confused with epilepsy. Another problem is that of case identification, because sometimes the person may be unaware of the nature of the attacks and so may not seek medical help. People with milder epilepsy may also not be receiving ongoing medical care and so may be missed in epidemiological surveys. Because there is some degree of stigma attached to epilepsy, people may sometimes be reluctant to admit their condition. In today's society, in high- and low-income countries, fear, misunderstanding, discrimination and social stigma still exist. These affect the quality of life for people with the disorder and their families.

Epilepsy does impact on an individual's human rights; for example, access to health and life insurance is often affected. A person who suffers from epilepsy may not be able to obtain a driving license, and it has an impact on the choice of career. A global campaign has been established to raise awareness about epilepsy, provide information and highlight the need to improve care and reduce the disorder's impact through public and private collaboration. This is supported through a partnership established between World Health Organization (WHO), ILAE and the International Bureau for Epilepsy.

Epilepsy is recognised as a priority in effective healthcare delivery, and there are still a number of issues that health professionals should consider (WHO, 2015):

- Epilepsy is a chronic neurological disorder that affects people of all ages.
- More than 50 million people worldwide have epilepsy.
- Nearly 80% of people with epilepsy are found in resource-poor settings.
- Epilepsy responds to treatment 70% of the time. Despite this, approximately more than two-thirds of people affected in poor countries are not treated.
- People with epilepsy and their families suffer from stigma and discrimination in many parts of the world.

Incidence and prevalence

Epileptic seizures are common. The incidence (number of new cases per given population per year) in high-income countries is estimated between 40 and 70 cases per 100,000 persons, and the cumulative incidence rate (the risk of having the condition at some point in life) is 2–5%. The incidence is higher in the first two decades of life but falls over the next few decades, only to increase again in late life, mainly because of cerebrovascular diseases. Currently, the elderly are the group in the population with the highest incidence of epilepsy. Most studies of the prevalence of active epilepsy (the number of cases in the population at any given time) in high-income countries provide figures in the range of 4–10 per 1000, with a rate of 5 per 1000 population most commonly quoted. In England, epilepsy has been estimated to affect between 362,000 and 415,000 people (National Institute for Health and Care Excellence [NICE], 2012).

In low-income countries, the prevalence is higher with rates of 10 per 1000 population cited and reported annual new cases twice those seen in high-income countries, presumably because of the higher risk of experiencing conditions that can lead to permanent brain damage. Overall, nearly 80% of epilepsy cases worldwide are found in resource-poor settings.

Prognosis

Up to 5% of all people will suffer at least one seizure in their lifetime. The prevalence of active epilepsy is, however, much lower, and most people who experience seizures have a very good prognosis as about 60–70% of all will eventually become seizure free. About half will successfully withdraw their medication. Once a substantial period of remission has been achieved, the risk of further seizures is greatly reduced. The probability of seizure freedom is particularly high in those with generalised epilepsy and a normal neurological examination. A minority of people (up to a third) will experience chronic epilepsy and in such cases, treatment is more difficult. People with symptomatic epilepsy, more than one seizure type, associated learning disabilities, or neurological or psychiatric disorders are more likely to have a poor outcome. For those who continue to have seizures, in appropriate candidates epilepsy surgery may render seizure freedom more than continued antiepileptic drugs (AEDs) alone. Of people with chronic epilepsy, fewer than 5% will be unable to live in the community or will depend on others for their day-to-day needs. Most people with epilepsy are entirely normal between seizures, but a small minority of people with severe epilepsy may suffer physical and intellectual deterioration.

Mortality

People with epilepsy, especially the young and those with severe epilepsy, are at an increased risk of premature death. Most studies have given overall standardised mortality ratios between two and three times that of the general population (Thurman et al., 2017). Common causes of death include accidents (drowning, head injury, road traffic accidents), status epilepticus, tumours,

cerebrovascular disease, pneumonia, iatrogenic accidents and suicide. Sudden unexpected death in epilepsy (SUDEP) is defined as a sudden unexpected, witnessed or unwitnessed, non-traumatic and non-drowning death in people with epilepsy, with or without evidence for a seizure, and excluding documented status epilepticus, in which postmortem examination does not reveal a toxicological or anatomic cause for death. This entity remains unexplained, but identified risk factors are younger age at onset, frequent convulsions, long duration of epilepsy and refractory epilepsy. Its incidence is about 0.35 cases per 1000 person-years in a population-based incidence cohort of epilepsy (Tomson et al., 2005).

Aetiology

Epileptic seizures are produced by abnormal discharges of neurones that may be caused by any pathological process which affects the cortical layer of the brain. The idiopathic or genetic epilepsies are those in which there is a clear genetic component, and they probably account for a third of all new cases of epilepsy. In a significant proportion of cases, however, no cause can be determined, and these are termed as unknown or cryptogenic epilepsies. Possible explanations for unknown epilepsy include as yet unexplained metabolic or biochemical abnormalities and microscopic lesions in the brain resulting from brain malformation or trauma during birth or other injury. The term ‘symptomatic’ or structural/metabolic epilepsy indicates that a probable cause has been identified.

The likely aetiology depends upon age of onset and seizure type. The commonest causes in young infants are hypoxia or birth asphyxia, intracranial trauma during birth, metabolic disturbances, congenital malformations of the brain and infection. In young children and adolescents, genetic epilepsies account for the majority, although trauma and infection also play a role. In this age group, particularly in children aged between 6 months and 5 years, seizures may occur in association with febrile illness. These are usually short convulsions that occur during the early phase of a febrile disease. They must be distinguished from seizures that are triggered by central nervous system infections which produce fever, for example, meningitis or encephalitis. Unless febrile seizures are prolonged, focal and recurrent, or there is a background of neurological handicap, the prognosis is excellent and it is unlikely that the child will develop epilepsy.

The range of causes of adult-onset epilepsy is very wide. Both genetic epilepsies and those due to perinatal causes may also begin in early adulthood. Other important causes are trauma, developmental disorders (e.g. cortical dysplasias), brain tumours, cerebrovascular diseases, immunological disorders and degenerative conditions. Brain tumours are responsible for the development of epilepsy in up to a third of those between the ages of 30 and 50 years. Over the age of 50 years, cerebrovascular disease is the commonest risk factor for epilepsy and may be present in up to half of people developing the condition in this age group.

Pathophysiology

Epilepsy differs from other neurological conditions because it has no pathognomonic lesion. A variety of different electrical or chemical stimuli can easily give rise to a seizure in any normal brain. The hallmark of epilepsy is a rather rhythmic and repetitive hyper-synchronous discharge of neurones, either localised in an area of the cerebral cortex or generalised throughout the cortex, which can be observed on an electroencephalogram (EEG).

Neurones are interconnected in a complex network in which each individual neurone is linked through synapses with hundreds of others. A small electrical current is discharged by neurones to release neurotransmitters at synaptic levels to permit communication with each other. Neurotransmitters fall into two basic categories: inhibitory or excitatory. Therefore, a neurone discharging can either excite or inhibit neurones connected to it. An excited neurone will activate the next neurone, whereas an inhibited neurone will not. In this manner, information is conveyed, transmitted and processed throughout the central nervous system.

A normal neurone discharges repetitively at a low baseline frequency, and it is the integrated electrical activity generated by the neurones of the superficial layers of the cortex that is recorded in a normal EEG. If neurones are damaged, injured or suffer a chemical or metabolic insult, a change in the discharge pattern may develop. In the case of epilepsy, regular low-frequency discharges are replaced by bursts of high-frequency discharges usually followed by periods of inactivity. A single neurone discharging in an abnormal manner usually has no clinical significance. It is only when a whole population of neurones discharge synchronously in an abnormal way that an epileptic seizure may be triggered. This abnormal discharge may remain localised or it may spread to adjacent areas, recruiting more neurones as it expands. It may also generalise throughout the brain via cortical and subcortical routes, including callosal and thalamocortical pathways. The area from which the abnormal discharge originates is known as the epileptic focus. An EEG recording carried out during one of these abnormal discharges may show a variety of atypical signs, depending on which area of the brain is involved, its progression and how the discharging areas project to the superficial cortex.

Clinical manifestations

The clinical manifestation of a seizure will depend on the location of the focus and the pathways involved in its spread. ILAE has recently published a revised classification of seizure types (Fisher et al., 2017). It divides seizures into three main groups according to its onset (Box 31.1). If it involves initial activation of both hemispheres of the brain simultaneously, the seizures are termed 'generalised'. If a discharge starts in a localised area of the brain, the seizure is termed 'focal'. Lastly seizures are classified as 'unknown onset' if it is not possible to classify as focal or generalised.

Box 31.1 Classification of seizures (Fisher et al., 2017)

Focal onset

Aware/Impaired awareness

Motor onset: automatisms, atonic, clonic, epileptic spasms, hyperkinetic, myoclonic, tonic

Non-motor onset: autonomic, behaviour arrest, cognitive, emotional, sensory

Generalised onset

Motor: tonic-clonic, clonic, tonic, myoclonic, myoclonic-tonic-clonic, myoclonic-atonic, atonic, epileptic spasms

Non-motor (absence): typical, atypical, myoclonic, eyelid myoclonia

Unknown onset

Motor: tonic-clonic, epileptic spasms

Non-motor: behaviour arrest

Generalised seizures

Generalised seizures are subdivided in motor and non-motor (absence) types. The motor includes tonic-clonic, clonic, tonic, myoclonic, myoclonic-tonic-clonic, myoclonic-atonic, atonic and epileptic spasms. The non-motor includes typical absence, atypical absence and absence with special features (myoclonic, eyelid myoclonia).

Tonic-clonic seizures

Tonic-clonic seizures often begin with bilateral myoclonic jerks, followed by a tonic contraction of the extremities and trunk sustained by a short period. Then contractions become progressively longer and interrupted, resulting in clonic jerking. Cyanosis, incontinence and tongue biting may occur. The seizure ceases after a few minutes and may often be followed by a period of drowsiness, confusion, headache and sleep.

Typical absence seizures

Typical absence seizures happen almost exclusively in childhood and early adolescence, and are characterised by behavioural arrest for a few seconds. The child goes blank and stares; fluttering of the eyelids and flopping of the head may occur. The attacks last only a few seconds and afterwards normal activity is resumed as if nothing had happened. They are seen in developmentally normal people and are associated with a typical rhythmic 3-Hz spike and wave complexes on the EEG.

Atypical absence seizures

Atypical absence seizures differ from the previous types because they are mostly seen in people with developmental delay, the behavioural arrest may be longer, the EEG shows background abnormalities (diffuse slowing), and the spike and wave complexes are less than 3 Hz in frequency.

Absence seizures with special features

Absence seizures with special features are absence seizures associated with other characteristics such as eyes myoclonic (Jeavons syndrome) or myoclonic movements.

Myoclonic seizures

Myoclonic seizures are abrupt, very brief, involuntary, shocklike jerks, which may involve the extremities and/or axial trunk muscles. They usually happen in the morning, shortly after waking. They may sometimes cause the person to fall, but recovery is immediate. There are non-epileptic myoclonic jerks that occur in a variety of other neurological diseases and may also occur in healthy people, particularly when they are just going off to sleep (hypnic jerks).

Tonic seizures

Tonic seizures occur during sleep with a duration of approximately 20 seconds. They usually involve all or most of the brain, affecting both sides of the body. If the person is standing when the seizure starts, they may fall.

Clonic seizures

Clonic seizures are rare alone, but most often are part of a tonic-clonic seizure. They are characterised by a rapidly alternating contraction and relaxation of a muscle – clonus. Brief and infrequent clonic seizures in infants usually disappear on their own within a short time.

Atonic seizures

Atonic seizures comprise a sudden loss of muscle tone, causing the person to collapse to the ground. Recovery afterwards is quick. They are rare, accounting for less than 1% of the epileptic seizures seen in the general population, but more common in people with severe epilepsy starting in infancy.

Focal seizures

In focal seizures, discharges are localised, and manifestations often reflect activation of the underlying cortical areas. They are primarily divided according to awareness in focal aware and focal with impaired awareness. Then subdivided according to motor or non-motor onset. The motor onset includes automatism (e.g. chewing, lip smacking, fumbling), atonic, clonic, epileptic spasms, hyperkinetic, myoclonic and tonic seizures. The non-motor onset includes autonomic (e.g. pallor, tachycardia), behaviour arrest, cognitive, emotional and sensory seizures. Symptoms may vary widely from person to person but will normally be stereotyped in one person.

This seizure may progress into a bilateral tonic-clonic seizure, which is termed as focal to bilateral tonic-clonic.

Epileptic spasms

Previously considered a type of generalised epilepsy, it is now placed under both focal and generalised seizures because they are

also seen in children with structural lesions confined to one hemisphere and where surgical treatment can often be curative. They occur in early infancy and are characterised by tonic flexion of the head, neck and trunk, with circumflexion of the upper extremities.

Diagnosis

Diagnosing epilepsy can be difficult because it is first necessary to demonstrate a tendency to recurrent epileptic seizures. The one feature that distinguishes epilepsy from other conditions is its unpredictability and transient nature. The diagnosis is clinical and depends on a reliable account of what happens during the events, if possible, from the individual and from an eyewitness. Investigations may help and the EEG is usually one of them. These investigations, however, cannot conclusively confirm or refute the diagnosis.

Other conditions may cause impairment or loss of consciousness which can be misdiagnosed as epilepsy; these include syncope, breath-holding attacks, transient ischaemic attacks and psychogenic attacks. People may also present with acute symptomatic seizures or provoked seizures as a result of other problems such as drugs, metabolic dysfunction, infection, head trauma or flashing lights (photosensitive seizures). These conditions have to be clearly ruled out before a diagnosis of epilepsy is made. Epilepsy must only be diagnosed when at least one of the three defining ILAE conditions given at the beginning of this chapter is present. The diagnosis must be accurate because the label ‘suffering with epilepsy’ carries a social stigma that has great implications.

An EEG recording is often the only examination required in typical generalised epilepsies, and it aims to record abnormal neuronal discharges. EEGs have, however, limitations that should be clearly understood. Up to 5% of people without epilepsy may have non-specific abnormalities in their EEG recording, while up to 40% of people with epilepsy may have a normal recording between seizures. The diagnosis of epilepsy needs to be strongly supported by a bona fide history of unprovoked seizures. The EEG is, however, invaluable in classifying epilepsy.

The chance of recording the discharges of an actual seizure during a routine EEG, which usually takes 20–30 minutes, is slight and because of this, ambulatory EEG monitoring and EEG video-telemetry are sometimes required. Ambulatory EEG allows recording in day-to-day circumstances using a small recorder. EEG video-telemetry is useful in the assessment of difficult cases, particularly if surgery is considered. The individual is usually admitted and remains under continuous monitoring. This is only helpful in a very few cases and best suited for people who have frequent seizures.

Neuroimaging with magnetic resonance imaging (MRI) is the most valuable investigation when structural abnormalities (e.g. stroke, tumour, developmental abnormalities, hydrocephalus) are suspected. MRI does not need to be done routinely in generalised epilepsy, but is particularly important in people who develop epilepsy before the age of 2 years or in adulthood, in those with any suggestion of focal onset and in those who continue with seizures despite first-line medication.

Other diagnostic investigations, such as functional MRI, magnetic resonance spectroscopy, single-photon emission computerised tomography and positron emission tomography studies, are normally performed only in specific cases, particularly when evaluating for surgical treatment.

Treatment

In 2004 the NICE issued guidance on the diagnosis and treatment of epilepsy in adults and children in primary and secondary care, which was updated in 2014 (NICE, 2014). This guidance covers issues such as when a person with epilepsy should be referred to a specialist centre, the special considerations concerning the care and treatment of women, and the management of people with learning disabilities. The key points of the guidance are summarised in Box 31.2.

Treatment during seizures

Convulsive seizures may look frightening, but the person is not in pain, will usually have no recollection of the event afterwards and is usually not seriously injured. Emergency treatment is

seldom necessary, but the person should, however, be made as comfortable as possible, preferably lying down (ease to the floor if sitting), cushioning the head and loosening any tight clothing or neckwear. During seizures, the individual should not be moved unless he or she is in a dangerous place, for example, in a road, by a fire or hot radiator, at the top of stairs or by the edge of water. No attempt should be made to open the person's mouth or force anything between the teeth. This usually results in damage and broken teeth or other objects may be inhaled, causing secondary lung damage. When the seizure stops, the person should be turned over into the recovery position and the airway checked for any blockage.

Focal seizures are usually less dramatic. During automatisms, people may behave in a confused manner and should generally be left undisturbed. Gentle restraint may be necessary if the automatism leads to dangerous wandering. Attempts at firm restraint, however, may increase agitation and confusion. No drinks should be given after the seizure, nor should extra AEDs be given. It is commonly felt that seizures may be life-threatening, but this is seldom the case. After a seizure, it is important to stay with the person and offer reassurance until the confused period has completely subsided and the person has fully recovered.

Status epilepticus

Status epilepticus is traditionally defined as ongoing seizure activity for ≥ 30 minutes, but from a pragmatic point of view, a seizure that lasts longer than 5 minutes warrants pharmacological intervention. Initial management of status epilepticus is supportive and may include:

- secure airway and resuscitate,
- administer oxygen,
- assess cardiorespiratory function,
- establish intravenous access.

Buccal midazolam (10 mg) is first-line treatment in the community. Rectal diazepam is an alternative if preferred or if buccal midazolam is not available. If intravenous access is already established and resuscitation facilities are available, intravenous lorazepam is administered.

First-line AED for hospital management of status epilepticus is intravenous lorazepam. If unavailable, then intravenous diazepam should be administered or buccal midazolam if immediate intravenous access cannot be secured. If seizures continue, intravenous phenytoin or valproate or phenobarbital should be administered as second-line treatment. In the refractory status, general anaesthesia with propofol, midazolam or thiopentone may be necessary.

Febrile convulsions

Febrile convulsions may occur in the young without epilepsy. Brief events are managed conservatively with the primary aim of reducing the child's temperature. Tepid sponging and use of paracetamol is usual. Prolonged febrile convulsions lasting ≥ 10 –15 minutes or in a child with risk factors, active management is required to avoid brain damage. The drug of choice is diazepam

Box 31.2 Key points on the diagnosis and management of epilepsy (NICE, 2012, 2014)

Diagnosis

- Diagnosis is to be made urgently by a specialist with an interest in epilepsy.

Management

- The individual with epilepsy, and their family and/or carers, should participate in all decisions, taking into account any specific need.
- All should have a comprehensive agreed-upon care plan.
- Treatment should be individualised according to seizure type, epilepsy syndrome, co-medication and comorbidity, the individual's lifestyle and personal preferences.

Prolonged or repeated seizures and convulsive status epilepticus

- Prescribe buccal midazolam or rectal diazepam for use in the community.
- Buccal midazolam is first-line treatment. Rectal diazepam is prescribed if the previous is not available or if it is preferred. Intravenous lorazepam is prescribed if intravenous access is established and resuscitation facilities are available.

Women and girls of childbearing potential

- They must be given accurate information and counselling about contraception, conception, pregnancy, caring for children, breastfeeding and menopause.

Review and referral

- Regular structured review should occur at least once a year.
- Individuals should be given all required information and referral if necessary.
- Individuals should be referred back to tertiary care if seizures are not controlled, uncertainty of diagnostic or treatment failure.

by intravenous or rectal administration. Prophylactic management of febrile convulsions may be required in some children, such as those with pre-existing risk factors or a history of previous prolonged seizures.

Long-term treatment

In most cases, epilepsy can only be treated by regular, long-term drug treatment aiming at suppressing seizures. Full seizure control can be obtained in most cases, and in others drugs may reduce seizure frequency or severity.

Initiating treatment with an AED is a major event in a person's life, and the diagnosis should be unequivocal. Treatment options must be considered with careful evaluation of all relevant factors, including the number and frequency of seizures, the presence of precipitants such as alcohol, drugs or flashing lights, and the presence of other medical conditions. Single seizures do not require treatment unless they are associated with a structural abnormality in the brain, a progressive brain disorder or there is a clearly abnormal EEG recording. If there are long intervals between seizures (>2 years), there is a case for not starting treatment. If there are more than two attacks that are clearly associated with a precipitating factor, fever or alcohol, for instance, then treatment may not be necessary.

Therapy is long-term, usually for at least 3 years and, depending on circumstances, sometimes for life. A full explanation of all of the implications must be given to the person, and the individual must be involved in all stages of the treatment plan. It is vital that the person fully understands the implications and agrees with the treatment goals. Empowerment of the person with epilepsy to be actively involved in the decision-making process will encourage adherence and is essential for effective clinical management. Support for people so that they understand the implications of the condition and why drug therapy is important is crucial to ensure effective clinical management.

Health professionals have a key role in supporting people with epilepsy to ensure they are able to manage their medicines appropriately. AED treatment will fail unless the person fully understands the importance of regular therapy. Poor adherence is still a major factor which results in hospital admissions and poor seizure control, and leads to the clinical use of multiple AEDs.

General principles of treatment

The primary aim of epilepsy treatment is to control seizures using one drug, with the lowest effective dose causing the fewest side effects possible. The established AEDs, those licensed before 2000, are still an important part of the antiepileptic armamentarium, and include carbamazepine, clobazam, clonazepam, ethosuximide, gabapentin, lamotrigine, phenobarbital, phenytoin, piracetam, primidone, sodium valproate, tiagabine, topiramate and vigabatrin. Since 2000, new AEDs such as eslicarbazepine acetate, brivaracetam, felbamate, lacosamide, levetiracetam, oxcarbazepine, perampanel, pregabalin, stiripentol, rufinamide and zonisamide have been introduced. The choice of drugs depends largely on the seizure type, and so correct diagnosis and

classification are essential. Table 31.1 lists the main indications for the more commonly used AEDs, and Table 31.2 summarises the clinical use of the newer AEDs.

Initiation of therapy in newly diagnosed epilepsy

A first-line AED suitable for the person's seizure type should be introduced slowly, starting with a small dose. A hasty introduction may induce side effects that may challenge the person's confidence. For most drugs, a gradual introduction will produce a therapeutic effect just as fast as a rapid introduction, and the person should be reassured about this.

Maintenance dosage

There is no single optimum dose of any AED that will suit all because the required dose varies from person to person

Table 31.1 Antiepileptic drugs for different seizure types

Seizure type	First-line treatment	Adjunctive anti-epileptic drugs
Focal seizures		
	Carbamazepine	Brivaracetam
	Lamotrigine	Clobazam
	Levetiracetam	Eslicarbazepine
	Oxcarbazepine	Gabapentin
	Sodium valproate	Lacosamide
		Perampanel
		Phenytoin
		Pregabalin
		Topiramate
		Zonisamide
Generalised seizures		
Tonic-clonic	Carbamazepine	Clobazam
	Lamotrigine	Levetiracetam
	Oxcarbazepine	Topiramate
	Sodium valproate	
Tonic or atonic	Sodium valproate	Lamotrigine
		Rufinamide
		Topiramate
Absence	Ethosuximide	Clobazam
	Lamotrigine	Clonazepam
	Sodium valproate	Levetiracetam
		Topiramate
		Zonisamide
Myoclonic	Levetiracetam	Clobazam
Sodium valproate	Clonazepam	
Topiramate	Piracetam	
Zonisamide		

Table 31.2 Summary of newer antiepileptic agents

Antiepileptic drugs	Clinical use	Available formulation
Brivaracetam	Adjunctive for focal seizures	Tablets: 10, 25, 50, 75, 100 mg Oral solution: 10 mg/mL Injection solution: 10 mg/mL
Eslicarbazepine acetate	Adjunctive for focal seizures	Tablets: 800 mg
Lacosamide	Adjunctive for focal seizures	Tablets: 50, 100, 150, 200 mg Syrup: 10 mg/mL Infusion: 200 mg/20 mL
Levetiracetam	Monotherapy and adjunctive therapy for focal and generalised seizures	Tablets: 250, 500, 750, 1000 mg Syrup: 100 mg/mL Injection: 500 mg/5 mL Granules: 250 mg, 500 mg, 1 g
Oxcarbazepine	Monotherapy and adjunctive therapy for focal and generalised tonic-clonic seizures	Tablets: 150, 300, 600 mg Syrup: 60 mg/mL
Perampanel	Adjunctive for focal seizures	Tablets: 2, 4, 6, 8, 10, 12 mg
Pregabalin	Adjunctive for focal seizures	Tablets: 25, 50, 75, 100, 150, 200, 225, 300 mg Syrup: 20 mg/mL
Zonisamide	Monotherapy and adjunctive for focal seizures	Capsule: 25, 50, 100 mg

and from drug to drug. Drugs are introduced slowly and then increased incrementally to an initial target dose. Seizure control should then be assessed, and the dose of drug changed if necessary. For most AEDs, dosage increments are constant over a wide range. More care is, however, needed with phenytoin because the serum level–dose relationship is not linear and small dose changes may result in considerable serum level changes. Phenytoin is, however, currently rarely used. Generic prescribing for epilepsy remains controversial. Most specialists would prefer people to remain on the same brand because it provides consistency. This is also preferred by the majority of people with epilepsy and is recommended by [NICE \(2014\)](#). Different preparations of some AEDs may vary in bioavailability or pharmacokinetic profiles. This is obviously important in those people in whom the dosage has been carefully titrated to

achieve optimal control. The Medicines and Healthcare products Regulatory Agency (MHRA) has classified AEDs into three categories ([MHRA, 2013](#)):

- Category 1: phenytoin, carbamazepine, phenobarbital and primidone. People receiving these drugs should be maintained on a specific manufacturer's product.
- Category 2: valproate, lamotrigine, perampanel, rufinamide, clobazam, clonazepam, oxcarbazepine, eslicarbazepine, zonisamide and topiramate. The need for continued supply of a particular manufacturer's product is based on clinical judgement and consultation with the patient/carer, taking into account factors such as seizure frequency and treatment history.
- Category 3: levetiracetam, lacosamide, tiagabine, gabapentin, pregabalin, ethosuximide and vigabatrin. It is usually unnecessary to maintain the patient on a specific manufacturer's product.

Altering drug regimens

If the maximal tolerated dose of a drug does not control seizures or if it is not tolerated, the first drug should be replaced with another first-line AED. To do this, the second drug should be added gradually to the first. Once a good dose of the new drug is established, the first drug should then slowly be withdrawn.

Withdrawal of drugs

AEDs should not be withdrawn abruptly. Withdrawal of individual AEDs should be carried out in a slow, stepwise fashion to avoid the precipitation of rebound seizures (e.g. over 2–3 months). This risk is particularly great with barbiturates (phenobarbital and primidone) and benzodiazepines (clobazam and clonazepam). If a drug needs to be withdrawn rapidly, for example, if there are life-threatening side effects, a benzodiazepine can be used to cover the withdrawal phase.

Examples of withdrawal regimens are given below.

- Carbamazepine
100–200 mg every 2 weeks (as part of a drug change)
100–200 mg every 4 weeks (total withdrawal)
- Phenobarbital
15–30 mg every 2 weeks (as part of a drug change)
15–30 mg every 4 weeks (total withdrawal)
- Phenytoin
50 mg every 2 weeks (as part of a drug change)
50 mg every 4 weeks (total withdrawal)
- Sodium valproate
200–400 mg every 2 weeks (as part of a drug change)
200–400 mg every 4 weeks (total withdrawal)
- Ethosuximide
125–250 mg every 2 weeks (as part of a drug change)
125–250 mg every 4 weeks (total withdrawal)

Variations in the earlier regimens may be used in different settings. People must be monitored closely for any change in seizure frequency. The pace of withdrawal may be slower if the person is within the higher end of the quoted dose range and faster if the person is an in-patient.

When to make dose changes

Some AEDs have long half-lives and it may take time, normally five half-lives, before a change in dose results in a stable blood level. For example, phenobarbital has a half-life of up to 6 days and will take more than 4 weeks to produce a stable blood level. For this reason an assessment of the effectiveness of any dose change should be undertaken several weeks after the dose change has been made and be informed by knowledge of the half-life of the drug.

Newer antiepileptic drugs

The newer AEDs are generally used as second-line drugs when treatment with established first-line drugs has failed. Exceptions to this are levetiracetam and oxcarbazepine. Overall, newer AEDs are not more effective than the established drugs but seem to be better tolerated. Notwithstanding, the chronic side effect profile of the new AEDs has not yet been fully established.

Follow-up and monitoring of treatment

It is essential to follow up people in whom AED treatment has been started. The reason for this is essentially to monitor the efficacy and side effects of treatment, upon which drug dosage will depend, but also to encourage good adherence. This follow-up is particularly important in the early stages of treatment, when an effective maintenance dose may not have been fully established, when the importance of adherence may not have been recognised by the person and when the psychological adjustment to regular treatment may not be resolved.

Chronic epilepsy

The drug treatment of people with uncontrolled epilepsy despite initial attempts is much more difficult than that of those newly diagnosed. Prognosis is worse, drug resistance may have developed, and there may be additional neurological, psychological or social problems.

Assessment. The diagnosis of epilepsy should be reassessed before assuming seizures are intractable because misdiagnosis is common. Progressive neurological conditions should also be ruled out. A treatment history should be obtained and note made of previous drugs used which were helpful, unhelpful or of uncertain benefit. Serum level measurements should be obtained where appropriate, and drugs not previously tried should be identified.

Choice of drug and dosage. Treatment should always be started with one AED appropriate for seizure type and suitable for the individual. Only when attempts at monotherapy fail should a combination of two AEDs be tried. In the majority of people, there is no place for therapy with more than two drugs. The choice of drugs should be made according to seizure type and previous treatment history. Drugs that were helpful in the past or found to be of uncertain benefit, or which have not been used before, should be tried if appropriate to seizure type. The use of sedative AEDs should be minimised where possible.

Intractable epilepsy. It is important to realise that there are limits to AED treatment and that in some people, albeit a small group, seizure control is not possible with the drugs currently available. In such cases the goal of drug treatment changes, and the objectives are to reduce medication to minimise toxicity while providing partial control. The sedative drugs, for example, barbiturates or benzodiazepines, should be used only where absolutely necessary. In these persons, surgical treatment or the use of experimental antiepileptic agents may be considered. However, only a relatively small number of people with focal epilepsy are suitable for curative surgical treatment.

Stopping treatment

Withdrawing therapy should be considered in people who have been seizure free for a considerable period. In no individual case, however, can the safety of drug withdrawal be guaranteed, and the risk of relapse on withdrawal of medication in a person who has been seizure free for more than 2 years is about 40%. The longer the person has been free of seizures, the lower the risk of seizure recurrence when drugs are withdrawn. If a person has a learning disability, focal seizures or symptomatic epilepsy, neurological signs or other evidence of cerebral damage, this risk is much higher, and in such cases it may be best to continue drug treatment indefinitely. Drug withdrawal should be carried out only very slowly in staged decrements, and only one drug at a time should be withdrawn.

The risks of drug withdrawal should be clearly explained to the person, and the possible medical and social implications taken into account. There may be serious social or domestic consequences if seizures recur, and the attacks may be subsequently difficult to control, even if the original AED regimen is re-established. In the final analysis, the decision to withdraw therapy is an individual one, and the person should be made aware of the risks and benefits of withdrawal.

Monitoring antiepileptic therapy

Therapeutic drug monitoring (TDM) involves the measurement of serum drug levels and their pharmacokinetic interpretation. It is an integral component in the management of people who are taking phenytoin and carbamazepine but is less useful in people receiving other AEDs. Indeed, TDM has a very limited use for new AEDs, except in people who are acutely unwell, pregnant or in the elderly. It is also very useful to document AED side effects and in managing drug interactions. Adherence may also be a problem in these people, and hence TDM may be useful to establish treatment adherence.

TDM is indicated:

- at the onset of therapy,
- if seizure control is poor or sudden changes in seizure control occur,
- if toxicity is suspected,
- if poor or non-adherence is suspected,
- to monitor the timescale of drug interactions,
- when changing AED therapy or making changes to other aspects of a person's drug regimen that may interact with the AED.

The frequency of undertaking TDM varies. Those with stabilised epilepsy may require their serum levels to be checked only once a year. TDM may be used more often in some people, for one or more of the above indications. A number of the newer AEDs do not require routine TDM. However, because most are used as adjuvant therapy, it is useful to establish baseline levels of existing drugs before the new agent is introduced. Clinical effects should be monitored and TDM, where appropriate, carried out at 6- to 12-month intervals.

Drug development and action

Some of the established AEDs were developed in animal models in which the potential drugs were assessed in terms of their ability to raise seizure threshold or prevent spread of seizure discharge. The animals involved in these tests would not have epilepsy but would have seizures induced by, for instance, maximal electroshock or subcutaneous pentylenetetrazole. As a consequence the relevance of these models to epilepsy can be questioned.

Established AEDs such as phenytoin, phenobarbital, sodium valproate, carbamazepine, ethosuximide, clonazepam and diazepam are effective but have poor side-effect profiles, are involved in many interactions and have complex pharmacokinetics. Over the past 15 years, there has been renewed interest in the development of new AEDs, based on a better understanding of excitatory and inhibitory pathways in the brain. The main mechanisms of the available drugs are thought to involve:

- voltage-gated sodium channels: most common mechanism of action, shared by carbamazepine, eslicarbazepine, felbamate, lacosamide, lamotrigine, oxcarbazepine, phenytoin, rufinamide, topiramate, valproate and zonisamide;
- voltage-gated calcium channels: ethosuximide, lamotrigine, gabapentin, pregabalin, valproate and zonisamide;
- enhancement of the inhibitory γ -aminobutyric-acid (GABA)-ergic system (Fig. 31.1): benzodiazepines, barbiturates, stiripentol, tiagabine and vigabatrin;
- attenuation of glutamate-mediated excitatory neurotransmission: perampanel;
- synaptic vesicle protein 2A: levetiracetam and brivaracetam.

Unlike most of the older agents, levetiracetam, lacosamide, pregabalin and zonisamide are devoid of clinically significant enzyme-inhibiting or enzyme-inducing properties. Oral contraceptives may increase the metabolism of lamotrigine and topiramate, and oxcarbazepine may induce cytochrome P450 CYP3A4 which is responsible for the metabolism of oral contraceptives (Sabers and Gram, 2000).

Antiepileptic drug profiles

The maintenance doses for the used AEDs are given in Table 31.3, whereas pharmacokinetic profiles of some AEDs are presented in Table 31.4. Drug interactions are summarised in Table 31.5, and common side effects in Table 31.6.

Acetazolamide

Acetazolamide is occasionally used as an AED. It can be prescribed as a second-line drug for most types of seizures, but particularly for focal seizures, absence seizures and myoclonic seizures. Its intermittent use in catamenial seizures has also been suggested. Acetazolamide has only limited use as long-term therapy because of the development of tolerance in the majority of people. Side effects include skin rash, weight loss, paraesthesia, drowsiness and depression. Routine TDM is not available for this drug.

Brivaracetam

Brivaracetam is a new AED, recently approved by the European Medicines Agency and launched in the UK in 2016. It is indicated as adjunctive therapy in the treatment of focal epilepsy in adult and adolescents from 16 years of age. The initial dosage is 25–50 mg twice daily, with a usual maintenance dose of 25–100 mg twice daily. The most common side effects are somnolence, dizziness and fatigue. The clinical experience with this AED in the “real world” is still small, but initial experience suggests that it is effective for some people who had not benefitted from other AEDs.

Fig. 31.1 Action of antiepileptic drugs. GABA, γ -Aminobutyric acid. (From Duncan et al., 2006.)

Carbamazepine

Carbamazepine is a first-line drug for generalised tonic-clonic seizures and focal seizures. It is not effective in absence seizures and myoclonic seizures, where it may even be deleterious. Carbamazepine acts through blockage of voltage-gated sodium channel. Tolerance to its beneficial effect does not usually develop. Adverse events may occur in up to a third of people treated with carbamazepine, but only about 5% of these events will require drug withdrawal, usually because of skin rash, gastro-intestinal disturbances or hyponatraemia. Dose-related

Table 31.3 Commonly used starting and maintenance doses of antiepileptic drugs for adults

Antiepileptic drug	Starting dose (mg)	Average maintenance (total mg/day)	Doses/day
Acetazolamide	250	500–1500	2
Carbamazepine	200	800–2000	2–4 (retard 2)
Clobazam	10	10–40	1–2
Clonazepam	1	2–8	1–2
Eslicarbazepine	400	800–1200	1
Ethosuximide	250	500–2000	2
Gabapentin	300	1800–3600	3
Lacosamide	50	200–400	2
Lamotrigine	25	200–400 ^a	1–2
Levetiracetam	250	1500–3000	2
Oxcarbazepine	300	600–2400	2–3
Perampanel	2	4–12	1–2
Phenobarbital	60	60–240	1–2
Phenytoin	200	200–500	1–2
Pregabalin	25	150–600	2–3
Primidone	250	250–1500	1–2
Rufinamide	200	400–1200	2
Sodium valproate	500	1000–2500	2–4
Tiagabine	5 ^b	30–45	2–3
Topiramate	25	100–500	2
Vigabatrin	500	1000–3000	2
Zonisamide	50	200–500	2

^aReduce by 50% if receiving sodium valproate.
^bIf taking enzyme inducer.

adverse reactions including ataxia, dizziness, blurred vision and diplopia are common. Idiosyncratic reactions, such as skin rash, occur in up to 10%, but rarely cause severe skin eruptions as erythema multiform and Stevens–Johnson syndrome. Others serious adverse events including hepatic failure and bone marrow depression are extremely uncommon.

Carbamazepine exhibits auto-induction, that is, induces its own metabolism as well as inducing the metabolism of other drugs (see Table 31.7). It should, therefore, be introduced at low dosage, and this should be steadily increased over a period of a month. The target serum concentration therapeutic range is 4–12 micrograms/mL. In addition, a number of clinically important pharmacokinetic interactions may occur, and caution should be exercised when co-medication is instituted (see Table 31.5). The slow-release preparation of carbamazepine has distinct advantages, allowing twice-daily ingestion and avoiding high peak serum concentrations. A ‘chewtab’ formulation is also available, and pharmacokinetic studies have shown that it performs well even if inadvertently swallowed whole. Carbamazepine retard reduces fluctuations of serum levels and allows a twice-daily regimen, which can assist adherence.

Clobazam

Clobazam is a 1,5-benzodiazepine that is said to be less sedative than 1,4-benzodiazepine drugs such as clonazepam and diazepam. As with other benzodiazepines, it acts through activation of the ionotropic γ -aminobutyric acid (GABA_A) receptor. The development of tolerance is common, but clobazam is used as an adjunctive therapy for focal and generalised seizures that have proved unresponsive to other medication. Its intermittent use in catamenial epilepsy has also been suggested; it is also used in people with seizure clusters as a single dose of 20–30 mg because it can have a prophylactic action. Clobazam may produce less sedation than other benzodiazepines, but otherwise its adverse effects are similar, including dizziness, behavioural disturbances and dry mouth. Withdrawal may be difficult.

Clonazepam

Clonazepam, a 1,4-benzodiazepine, is a second-line drug for generalised tonic-clonic seizures, absences, myoclonic seizures and as adjunctive therapy for focal seizures, but as with clobazam, effectiveness often wears off with time as tolerance develops. It has limited use in epilepsy management and is almost restricted to refractory myoclonic seizures. It has an adverse effect profile similar to that of clobazam, but may be more sedating.

Diazepam

Diazepam is used mainly in the treatment of status epilepticus, intravenously or in the acute management of febrile convulsions as a rectal solution. Absorption from suppositories or following intramuscular injection is slow and erratic. The rectal solution may also be useful in status epilepticus if it is not possible to give the drug intravenously.

Table 31.4 Pharmacokinetic data of antiepileptic drugs

Drug	Absorption			Protein binding (% bound)	Elimination		
	F (%)	T _{peak} (h)	V _d (L/kg)		T _½ (h)	Renal excretion (%)	Active metabolite
Carbamazepine	75–85	1–5 (chronic dose)	0.8–1.6	70–78	24–45 (single), 8–24 (chronic)	<1	Yes
Diazepam	90	1–2	1–2	96	20–95	2	Yes
Clonazepam	80–90	1–2	2.1–4.3	80–90	19–40	2	–
Gabapentin	51–59	2–3	57.7	0	5–7	100	No
Lamotrigine	100	2–3	0.92–1.22	55	24–35 (induces its own metabolism)	<10	No
Ethosuximide	90–95	3–7	0.6–0.9	0	20–60	10–20	No
Phenobarbital	95–100	1–3	0.6	40–50	50–144	20–40	No
Phenytoin	85–95	4–7	0.5–0.7	90–95	9–40 (non- linear kinetics)	<5	No
Primidone	90–100	1–3	0.4–1.1	20–30	3–19	40	Yes
Sodium valpro- ate	100	0.5–1.0	0.1–0.5	88–92	7–17	<5	No
Vigabatrin	60–80	2	0.6–1.0	0	5–7	100	No
Zonisamide	100	2–4	1.1–1.7	40	52–69	30	Yes

F, Bioavailability; T_{peak}, time to peak; V_d, volume of distribution.

Eslicarbazepine acetate

Eslicarbazepine acetate is a drug which is similar to oxcarbazepine and which is licensed as a second-line treatment for focal seizures. As with oxcarbazepine, its mode of action is thought to be by interacting with voltage-gated sodium channels. Currently, it is available only as a 800 mg tablet. It has a long half-life and can be used once per day. The recommended starting dosage is 400 mg once daily for 1–2 weeks, then increased to 800 mg once daily. The maximum dosage is 1200 mg daily. Its pharmacokinetic profile and side effects are also similar to those of oxcarbazepine.

Ethosuximide

Ethosuximide is a drug of first choice for generalised absence seizures, and it has no useful effect against any other seizure type. Its mechanism of action is through blockage of low-voltage activated calcium channel. Tolerance does not seem to be a problem. The most commonly encountered adverse effects are gastrointestinal symptoms, which occur frequently at the beginning of therapy. Behaviour disorders, anorexia, fatigue, sleep disturbances and headaches may also occur. Idiosyncratic side effects include rash, Stevens–Johnson syndrome and aplastic anaemia.

The therapeutic range commonly quoted is 1–1.5 g daily in two divided doses, increased if necessary up to 2 g daily. The initial dosage is 500 mg daily in two divided doses and increased in steps of 250 mg every 5–7 days. The absorption of ethosuximide is complete, and the bioavailability of the syrup and capsule formulations is equivalent. An increase in daily dose may lead to disproportionately higher increases in average serum concentrations; therefore, careful monitoring is indicated at high doses.

Felbamate

Felbamate may be used as a drug of last resort in people with intractable epilepsy, particularly in those within the Lennox–Gastaut spectrum. It is licensed in the USA and most countries of the European Union, but not in the UK. Its mechanism of action is unknown. The usual dosage is between 2400 and 3600 mg/day. Felbamate exhibits significant pharmacokinetic interactions with phenytoin, carbamazepine and valproic acid. Side effects include diplopia, insomnia, dizziness, headache, ataxia, anorexia, nausea and vomiting. A major limiting problem is its potential to cause aplastic anaemia and liver failure. It, therefore, seems prudent to limit use to specialist centres and severe intractable cases.

Table 31.5 Examples of drug interactions involving antiepileptic drugs

Drug affected	Effect on serum level	Drug implicated	Possible mechanism
Carbamazepine	Increase	Valproate sodium Cimetidine Dextropropoxyphene Erythromycin Isoniazid Troleandomycin Danazol	Enzyme inhibition
	Decrease	Phenytoin, phenobarbital	Enzyme induction
Ethosuximide	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Carbamazepine	Enzyme induction
Lamotrigine	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Phenytoin, carbamazepine	Enzyme induction
Phenobarbital	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Rifampicin	Enzyme induction
Phenytoin	Increase	Valproate sodium Chloramphenicol Isoniazid Disulfiram Fluconazole Flu vaccine Amiodarone	Enzyme inhibition Mechanism unclear
	Decrease	Fluoxetine Phenobarbital Rifampicin Carbamazepine Furosemide Acetazolamide	Enzyme induction Decreased responsiveness of renal tubules. Increased osteomalacia
Sodium valproate	Increase	Salicylates	Displacement from protein binding sites and possible enzyme inhibition
Topiramate	Decrease	Phenytoin, carbamazepine	Enzyme induction
	Decrease	Potential enzyme inducers	Enzyme induction
Zonisamide	Decrease	Carbamazepine, phenytoin, phenobarbital and primidone	Enzyme induction

Gabapentin

Gabapentin is occasionally used as a second-line treatment of focal seizures. Although initially developed as an AED, its main use currently is for the treatment of neuropathic pain. It exerts its effect through blockage of high-voltage activated calcium channels. In view of its pharmacokinetic profile, a three times daily dosage must be used; the usual dosage is 0.9–3.6 g daily. It should be started with 300 mg once daily on day 1, then 300 mg twice daily on day 2 and then 300 mg three times a day on day 3. To date, no clinically significant interactions with other AEDs, or other drugs, have been reported. The most frequently reported side effects are drowsiness, dizziness, diplopia, ataxia and headache. Idiosyncratic effects include increasing seizures.

Lacosamide

Lacosamide, a functionalised amino acid, is a second-line drug for focal epilepsy in people older than 16 years. Its putative mode of action is not shared with any other currently available AEDs. It is said to enhance the slow inactivation of sodium channels and to modulate collapsing response mediator protein-2. The maintenance dosage is 100 mg twice daily, and the maximum dosage is 200 mg twice daily. It should be started at 50 mg twice daily and increased by steps of 50 mg twice daily in weekly intervals. No drug interactions are known. Its commonest side effects are dizziness, headaches, nausea and diplopia. No idiosyncratic side effects have yet been associated with this drug. The drug should be used with caution in people with a history of cardiac conduction problems because it is known to increase PR intervals in some people.

Table 31.6 Side-effect profile of antiepileptic drugs

Drug	Dose related (predictable)	Non-dose related (idiosyncratic)
Brivaracetam	Drowsiness, dizziness, fatigue, nausea, ataxia, irritability	Not reported
Carbamazepine	Diplopia, drowsiness, headache, nausea, orofacial dyskinesia, arrhythmias	Photosensitivity, Stevens–Johnson syndrome, agranulocytosis, aplastic anaemia, hepatotoxicity, teratogenicity
Clobazam	Fatigue, drowsiness, dizziness, ataxia, irritability, hypersalivation, weight gain, psychosis	Rash
Clonazepam	Fatigue, sedation, drowsiness, ataxia	Rash, thrombocytopenia
Eslicarbazepine	Fatigue, drowsiness, diplopia, hyponatraemia, ataxia, nystagmus, tremor	Not reported
Ethosuximide	Nausea, vomiting, drowsiness, headache, lethargy	Rash, erythema multiform, Stevens–Johnson syndrome, aplastic anaemia
Gabapentin	Drowsiness, fatigue, diplopia, ataxia, headache	Increased seizures
Lacosamide	Nausea, vomiting, dizziness, headache, drowsiness, depression, diplopia, impaired memory, impaired coordination, tremor, fatigue, asthenia, pruritus	Not reported
Lamotrigine	Headaches, drowsiness, diplopia, ataxia, tremor, insomnia	Rash, liver failure, Stevens–Johnson syndrome, aplastic anaemia, toxic epidermal necrolysis, pancytopenia
Levetiracetam	Dizziness, drowsiness, irritability, behavioural problems, insomnia, ataxia headache, nausea	Not reported
Oxcarbazepine	Diplopia, ataxia, fatigue, hyponatraemia, headache, nausea, confusion, vomiting	Rash
Perampanel	Drowsiness, ataxia, lethargy, blurred vision, weight gain	Not reported
Phenobarbital	Fatigue, listlessness, depression, poor memory, impotence, irritability, hypocalcaemia, osteomalacia, folate deficiency	Maculopapular rash, exfoliation, hepatotoxicity, teratogenicity, Dupuytren's contracture, frozen shoulder
Phenytoin	Ataxia, nystagmus, drowsiness, diplopia, asterixis, orofacial dyskinesia, folate deficiency	Blood dyscrasias, rash, Dupuytren's contracture, hepatotoxicity, gingival hyperplasia, acne, coarse facies, hirsutism
Pregabalin	Dizziness, ataxia, weight gain, diplopia, tremor, abnormal thinking	Not reported
Piracetam	Diarrhoea, weight gain, insomnia, depression, hyperkinesia	Not reported
Primidone	Fatigue, depression, psychosis, impotence, hyperkinesia, nausea, nystagmus, ataxia, folate deficiency	Rash, agranulocytosis, thrombocytopenia, teratogenicity
Retigabine	Drowsiness, slurred speech, ataxia, tremor, diplopia	Urinary tract symptoms, skin and retinal discolouration
Sodium valproate	Tremor, weight gain, dyspepsia, nausea, vomiting, hair loss, drowsiness, peripheral oedema, hyperammonaemia	Acute pancreatitis, thrombocytopenia, hepatotoxicity, teratogenicity, polycystic ovarian syndrome
Tiagabine	Dizziness, nervousness, tremor, concentration difficulties	Increased seizures, non-convulsive status
Topiramate	Anorexia, weight loss, impaired concentration, impaired speech, paraesthesia, kidney stones	Not reported
Vigabatrin	Drowsiness, weight gain, nystagmus, diplopia, ataxia, irritability, depression, psychosis	Visual field defects, increased seizures
Zonisamide	Ataxia, dizziness, somnolence, anorexia, memory and concentration impairment, confusion	Rash, blood dyscrasias

Table 31.7 Practice points

Problem	Comment
Hepatic enzyme induction	Enzyme induction occurs with carbamazepine, phenytoin, phenobarbital, primidone and topiramate. Interactions occur with a large number of drugs including oral contraceptives.
Use of progesterone-only contraceptives with enzyme-inducing AED	Best avoided. If no acceptable alternative, women should take at least double usual dose of progesterone-only pill.
Use of combined oral contraceptive with enzyme-inducing AED	Preparations containing 50 micrograms of oestrogen should be used.
Continuation of AED during pregnancy	Should be reviewed before attempting pregnancy to determine whether reducing or discontinuing treatment is possible. Avoid use of sodium valproate in childbearing women.
Use of phenytoin as monotherapy	Less frequently considered first- or second-line monotherapy because of poor side-effect profile, narrow therapeutic index and saturation pharmacokinetics.
Changing between generic manufacturers	Because bioavailability or pharmacokinetic profiles may vary between different generic drugs, it is now recommended to prescribe a consistent brand of AED.

AED, Antiepileptic drugs.

Lamotrigine

Lamotrigine is a first-line drug for people with focal and generalised seizures. The main action is through blockage of voltage-gated sodium channel. Lamotrigine does not seem to interact with other concomitantly administered AEDs. However, hepatic enzyme inducers increase the metabolism of lamotrigine, reducing its half-life. Therefore, higher doses need to be administered if it is used in conjunction with enzyme inducers such as phenytoin and carbamazepine. Inhibitors of hepatic enzymes such as sodium valproate block the metabolism of lamotrigine, and reduced doses need to be used if both drugs are given in combination. The recommended starting dosage is 25 mg once daily when used as monotherapy and 25 mg on alternate days in people receiving concomitant sodium valproate, with a maximum recommended dosage of 500 mg daily, but no more than 200 mg daily if concomitant to valproate. It should be increased by 25 mg in 14-day intervals, as too rapid titration may be associated with an increased incidence of skin rash.

Headaches, drowsiness, ataxia and diplopia are the most commonly reported acute adverse effects, particularly during dose escalation. A skin rash is the commonest idiosyncratic side effect and affects up to 5% of individuals.

Levetiracetam

Levetiracetam is a broad-spectrum drug, indicated both as a first-line and as an add-on for the treatment of focal and generalised seizures. Mechanism of action is not fully understood, but it binds to the synaptic vesicle protein 2A. The usual dosage is between 1000 and 3000 mg/day, divided in two daily doses. It is usually started at 250 mg once daily for 1–2 weeks, then increased to 250 mg twice daily and then titrated upwards in incremental steps of 250 mg twice daily every 2 weeks. It is well tolerated, and the most frequent central nervous system

adverse events are dizziness, irritability, asthenia, insomnia and ataxia. No idiosyncratic adverse events have yet been reported.

Oxcarbazepine

Oxcarbazepine is an analogue of carbamazepine. It is an inactive pro-drug that is converted in the liver to the active 10-hydroxy metabolite and bypasses the 10,11-epoxide, the primary metabolite of carbamazepine. The usual dosage is between 600 and 2400 mg daily in divided doses. The spectrum of efficacy and side effects is broadly comparable with carbamazepine, apart from hyponatraemia which is more pronounced with oxcarbazepine. The principal advantage over carbamazepine is the lack of induction of hepatic enzymes, with the consequence that there is no auto-induction of the metabolism of the drug and fewer pharmacokinetic interactions. In addition, more than two-thirds of people who are allergic to carbamazepine can tolerate oxcarbazepine.

Perampanel

Perampanel is licensed for the adjunctive treatment of focal-onset seizures with or without secondarily generalised seizures in people with epilepsy aged ≥ 12 years. It is a selective, non-competitive antagonist of the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid glutamate receptor. Effective dosage is between 4 and 12 mg/day, given in a once-a-day regimen. Commonest side effects are drowsiness, ataxia, lethargy, irritability, weight gain and blurred vision.

Phenobarbital

Phenobarbital, a barbiturate, may be used for the treatment of tonic-clonic and focal seizures. It may also be used in other

seizure types. As with other barbiturates, it acts through activation of the ionotropic GABA_A receptor. Its antiepileptic efficacy is similar to that of phenytoin or carbamazepine. Adverse effects on cognitive function, the propensity to produce tolerance and the risk of serious seizure exacerbation on withdrawal make it an unattractive option, and it should be used only as a last resort. In addition to cognitive effects, barbiturates may cause skin rashes, ataxia, folate deficiency, osteomalacia, behavioural disturbances (particularly in children) and an increased risk of connective tissue disorders such as Dupuytren's contracture and frozen shoulder. Phenobarbital is a potent enzyme inducer and is implicated in several clinically important drug interactions (see Table 31.5).

Phenytoin

In current practice, phenytoin is a second-line drug for focal seizures, tonic-clonic seizures, as well as atonic seizures and atypical absences. It is not effective in typical generalised absences and myoclonic seizures, where it may even be deleterious. It acts through blockage of voltage-gated sodium channel. Tolerance to its antiepileptic action does not usually occur. Phenytoin has non-linear kinetics and a low therapeutic index, and in some patients frequent drug serum level measurements may be necessary. Drug interactions (see Table 31.5) are common because phenytoin metabolism is very susceptible to inhibition by some drugs, whereas it may enhance the metabolism of others (see Table 31.7). Caution should be exercised when other medication is introduced or withdrawn. Effective dosages are between 200 and 500 mg/day.

Adverse events may occur in up to a half of those treated with phenytoin, but only about 10% will necessitate drug withdrawal, most commonly because of skin rash. Dose-related adverse reactions including nystagmus, ataxia and lethargy are common. Cosmetic effects such as gum hypertrophy, hirsutism and acne are well-recognised adverse effects and should be taken into account when prescribing for children and young women. Chronic adverse effects include folate deficiency, osteomalacia, Dupuytren's contractures and cerebellar atrophy. Serious idiosyncratic adverse events, including hepatic failure and bone marrow depression, are extremely uncommon.

Piracetam

Piracetam is indicated only for treatment of refractory myoclonus as an add-on drug. Effective dosages are between 12 and 24 mg/day. The most common side effects are diarrhoea, weight gain, insomnia and depression. There are no known idiosyncratic adverse effects or drug interactions.

Pregabalin

Pregabalin has been licensed for the adjunctive treatment of refractory focal epilepsy. It is closely related to gabapentin and a structural analogue of the neurotransmitter GABA but does not seem to affect transmitter response. It modulates calcium channels by binding to a subunit of Ca²⁺, and this action is thought to

be the basis of its antiepileptic mechanism. The recommended doses for pregabalin are between 150 and 600 mg divided into two doses, although some people may respond to doses outside this range. Pregabalin is normally started at 25 mg twice daily and increased in incremental steps of 50 mg daily every week up to 600 mg daily in two to three divided doses according to clinical need.

Overall, pregabalin is well tolerated, and so far no idiosyncratic side effects have been described. Dizziness, drowsiness, ataxia, tremor and diplopia are the most common side effects. Weight gain occurs particularly with higher doses. No pharmacokinetic interactions have yet been identified. In addition to its use in epilepsy, pregabalin has also been indicated for neuropathic pain and generalised anxiety disorders.

Primidone

Primidone is principally metabolised to phenobarbital and has similar effects but a more severe side-effect profile than phenobarbital. There is nothing to recommend primidone as an AED over phenobarbital.

Rufinamide

Rufinamide is licensed as an orphan drug for the adjunctive treatment of seizures in Lennox–Gastaut syndrome. It is a triazole derivative and is structurally unrelated to any other AED. Its mode of action is unknown. A serious hypersensitivity syndrome that may include rash, fever, lymphadenopathy, hepatic dysfunction, haematuria and multi-organ dysfunction has been reported upon initiation of therapy. Individuals should be warned to seek immediate medical assistance if signs or symptoms of hypersensitivity develop.

Sodium valproate

Sodium valproate is a broad-spectrum AED, effective over the complete range of seizures type, but with particular value in the idiopathic generalised epilepsies. This is mainly due to its broad mechanism of action, known to act on voltage-gated sodium and calcium channels, and also in the turnover of GABA. Tolerance to its antiepileptic action does not usually occur. Drug interactions with other AEDs may be problematic (see Table 31.5). Phenobarbital levels increase following co-medication with valproate, and a combination of these two drugs may result in severe sedation. Sodium valproate may also inhibit the metabolism of lamotrigine, phenytoin and carbamazepine. Enzyme-inducing drugs enhance the metabolism of sodium valproate, so caution should be exercised when other AEDs are introduced or withdrawn.

Up to a third of people may experience adverse effects, but fewer than 5% will require the drug to be stopped. Adverse effects include nausea, diarrhoea, weight gain, alopecia, skin rash and thrombocytopenia. Confusion, stupor, tremor and hyperammonaemia are usually dose related. Serious adverse events, including fatal pancreatic and hepatic failure, are extremely uncommon.

The usual therapeutic range quoted is 1–2 g daily with a maximum dosage of 2.5 g/day. Because of the lack of a good correlation between total valproate concentrations and effect, serum level monitoring of the drug has limited use. TDM should only be performed in cases of suspected toxicity, deterioration in seizure control, to check adherence or to monitor drug interactions. Sodium valproate is more teratogenic than other commonly used AEDs and should be avoided in women of childbearing age (see [Table 31.7](#)).

Stiripentol

Stiripentol is licensed as an orphan drug for severe myoclonic epilepsy of infancy (Dravet syndrome) when used in conjunction with sodium valproate and clobazam. It is an aromatic alcohol and is unrelated to any other AED. Its mode of action is unknown.

Tiagabine

Tiagabine is a drug with mild efficacy in seizure control. It is used as a second-line drug in focal seizures with or without secondary generalisation. It prevents the removal of GABA from the synaptic cleft by blockage of GABA transport. The usual dosage is between 30 and 45 mg daily in two to three divided doses, and it is normally started at 5–10 mg daily in one to two divided doses, with incremental steps of 5–10 mg every week. The most common adverse events are on the central nervous system and consist of sedation, tremor, headache, mental slowing, tiredness and dizziness. Confusion, irritability and depression may occur. Increases in seizure frequency and episodes of non-convulsive status have also been reported. Use in pregnancy is not recommended, although no teratogenicity has been reported in humans.

Topiramate

Topiramate is chemically unrelated to other AEDs and is used as a first-line drug for people with focal seizures with or without secondary generalisation and for generalised seizure. It has multiple mechanism of action: voltage-gated sodium and calcium channels, GABA and glutamate receptors. Recommended dosages are between 75 and 300 mg/day. It has to be titrated slowly, starting with a dosage of 25 mg once daily, titrating upwards in 25- to 50 mg increments every 1–2 weeks up to a usual dosage of 100–200 mg daily in two divided doses. The maximum dosage is 500 mg/day in monotherapy or 400 mg/day as adjunctive therapy. It has no clinically significant interactions with other AEDs, although hepatic enzyme inducers accelerate its metabolism and doses need to be adjusted downwards if the patient is coming off carbamazepine or phenytoin.

Side effects include dizziness, drowsiness, irritability, impaired concentration, paraesthesias, nephrolithiasis and fatigue. People starting topiramate should increase their fluid intake to reduce the risk of kidney stones. Weight loss is seen in up to 40% of those who are taking topiramate.

Vigabatrin

Vigabatrin inhibits GABA degradation, but because of a poor safety profile it is a last resort drug for focal seizures. It is still a first-line treatment of infantile spasms, particularly if associated with tuberous sclerosis. Vigabatrin does not interact with other drugs apart from decreasing phenytoin levels, probably by blocking its absorption. The most common adverse events associated with vigabatrin are behavioural disturbances, ranging from agitation to frank psychosis and visual field defects, which had been associated with long-term treatment in up to 40–50% of patients. Other known adverse effects include drowsiness, headaches, ataxia, weight gain, depression and tremor. Careful monitoring for side effects, particularly ophthalmological, on initiation of therapy is essential.

Zonisamide

Zonisamide, a sulfonamide analogue which inhibits carbonic anhydrase, is a potent blocker of the spread of epileptic discharges. This effect is believed to be mediated through action also at voltage-sensitive sodium channels. It is used as a second-line drug for those with focal seizures with or without secondary generalisation. It can be effective in generalised seizures, particularly myoclonic seizures. Recommended dosages are between 200 and 500 mg/day, although some people may derive benefit from dosages outside this range. When used in monotherapy, the recommended starting dose is 100 mg once daily, titrating upwards every 2 weeks in 100 mg increments. The usual maintenance dosage is 300 mg once daily, and the maximum dosage is 500 mg/day. When used as adjunctive therapy, the recommended starting dosage is 50 mg daily in two divided doses for 7 days, then increased to 100 mg daily in two divided doses, and finally increased in steps of 100 mg every week. The usual maintenance dosage is 300–500 mg daily in one to two divided doses. Its long elimination half-life allows once-daily dosing.

It does not affect levels of carbamazepine, barbiturates or valproate, but may increase the serum concentration of phenytoin by about 10–15%. Zonisamide metabolism is, however, induced by carbamazepine, barbiturates and phenytoin, and higher zonisamide doses may be necessary during co-administration with these AEDs.

Side effects include dizziness, drowsiness, headaches, anorexia, weight loss, skin rashes, irritability, impaired concentration and fatigue. These are mostly transient and seem to be related to the dose and rate of titration. Nephrolithiasis has also been reported, particularly in Caucasians. It is not recommended for women of childbearing age because there are issues about its teratogenic potential.

Recent and future evidence for antiepileptic drugs

ILAE has published an updated review of AED efficacy and effectiveness as initial monotherapy for epileptic seizures and syndromes ([Glauser et al., 2013](#)). After a thorough review of published

reports, they summarised the level of evidence for each seizure type and epilepsy syndrome. In adults with focal-onset seizures, carbamazepine, levetiracetam, phenytoin and zonisamide have level A evidence (highest supporting level of clinical trial evidence). Only oxcarbazepine has level A for children with focal-onset seizures, and gabapentin and lamotrigine have that level for the elderly with the same seizure type. There is no drug with level A evidence for generalised-onset tonic-clonic seizures in adults or in children. Ethosuximide and valproic acid have level A evidence in children with childhood absence epilepsy.

The new AEDs are still not capable of achieving the primary goal of epilepsy treatment – complete freedom of seizures – although some may have a more favourable profile, with lesser drug interactions and side effects. As such, this group of drugs will probably continue to expand, with new AEDs appearing in the quest of epilepsy cure.

Case studies

Case 31.1

Ms JB is a 31-year-old woman with a history of early-morning myoclonic jerks from age 14 years. When she was 18 years old she had her first convulsive seizure. A diagnosis of juvenile myoclonic epilepsy was made, and Ms JB was started on phenytoin with no results. She was then switched to topiramate, which also did not help her seizures. As a last resort, at age 18 years, she was switched to sodium valproate 1200 mg/day which fully controlled her seizures.

At the age of 21 years, she delivered a healthy baby and experienced no problems with epilepsy control. At age 22, she had her second pregnancy and delivered a healthy baby. Three weeks after delivery early-morning myoclonic seizures returned. The dose of sodium valproate was increased to 1500 mg/day to control jerks. However, 6 months later she experienced a recurrence of her convulsive attacks with no clear precipitating factor. Sodium valproate was increased to 2000 mg/day. Early-morning myoclonic seizures crept back and she had further convulsive seizures. Lamotrigine was started and she is now taking 100 mg daily. She has been completely seizure-free for the last 2 years and is now driving again.

Ms JB wants to discuss her medication with you and would like to stop treatment. She has no plans to increase her family.

Question

What advice would you give Ms JB?

Answer

Ms JB should be advised to continue on medication. She has juvenile myoclonic epilepsy, which tends to recur when medication is withdrawn. Because Ms JB has no intention of having further children, pregnancy need not be a consideration in the choice of her continued drug therapy with valproate. She is generally well, and hence it would be sensible to advise her to continue with the present regimen, because sodium valproate and lamotrigine have a synergistic effect in juvenile myoclonic epilepsy. If, however, Ms JB wants to reduce medication, then a slow decrease of sodium valproate with optimisation of treatment with lamotrigine should be considered.

Case 31.2

Mr OB is a 44-year-old man who suffers from focal epilepsy. An MRI scan shows a choroid cyst on the right temporal lobe, bilateral hippocampal sclerosis and cerebral atrophy. Seizures take the form of focal with impaired awareness and at night evolved to bilateral tonic-clonic. He has had trials of treatment with every single drug available and almost every combination.

Six months ago, he was taking 225 mg topiramate, 400 mg phenytoin and 10 mg clobazam each day. He could not tolerate a higher dose of topiramate. At this point levetiracetam was added and titrated up to 2000 mg/day. This led to a significant improvement in Mr OB's seizure control. Indeed, seizures have almost completely been abolished and he is only having occasional nocturnal events. He is, however, complaining of drowsiness and periods of unsteadiness.

Question

What treatment is appropriate for Mr OB?

Answer

Mr OB needs his drug regimen optimising. The decision should be made to reduce either the dose of topiramate or that of phenytoin. Usually phenytoin is reduced first, as it is an enzyme inducer. However, because Mr OB has had a bad experience in the past when an attempt was made to discontinue phenytoin, at which time he had a significant increase in seizure frequency, it would, therefore, be more appropriate to discontinue topiramate. This was done and his improvement has been maintained.

Case 31.3

Ms GD is a 28-year-old woman with a history of early-morning myoclonic jerks since age 14 years. At 16 years of age she presented with her first generalised tonic clonic convulsive seizure and was referred to a hospital specialist who diagnosed juvenile myoclonic epilepsy. At that time Ms GD was started on sodium valproate 1200 mg/day and within a few weeks her seizures were totally controlled. Ms GD has since remained on the same medication and has been well controlled. However, she now wishes to start a family and is concerned about the effects of the valproate on her baby.

Question

What advice would you give Ms GD?

Answer

Sodium valproate is teratogenic, with the most common malformation reported being neural tube defects. Ms GD has had no seizures for more than 5 years, and it must, therefore, be determined whether she still needs medication. The risk of recurrence is low because she has been seizure free for well over 5 years. An important consideration is whether she is a driver, because if she is taken off medication and has a seizure, she will be unable to hold a license. The other issue is the effect of pregnancy on her seizures because some women may experience an increase in seizures during pregnancy. The options that need to be considered include change of medication. The following drugs would be alternatives: lamotrigine, zonisamide and levetiracetam.

Case 31.4

Mr TD is a 41-year-old man who has cryptogenic focal epilepsy. Mr TD experienced his first seizure at age 14, and this was diagnosed as a secondary generalised attack, although discussing his history revealed he might have had focal with impaired awareness seizures. Two years ago Mr TD was referred for assessment, but it was determined that he was not a candidate for surgery. Mr TD was taking carbamazepine 1200 mg/day and could not tolerate higher doses. Previous trials of valproate, phenytoin, phenobarbital, vigabatrin, lamotrigine, oxcarbazepine and topiramate had demonstrated little benefit. Levetiracetam was started and increased to 2500 mg. Improvement in Mr TD's seizure control has been noted over the past 2 years, with only two nocturnal focal with impaired awareness seizures recorded. His current medication is levetiracetam 2500 mg/day and carbamazepine 1200 mg/day.

Question

Should TD's therapy be reduced to levetiracetam monotherapy?

Answer

If a person has been seizure free for 3 years, it is good practice to review therapy. There is a need to discuss with Mr TD whether he wishes to continue with his medication. Issues of relevance include a long history of epilepsy, the diagnosis and the range of drugs previously tried which may indicate an increased risk of seizure recurrence on coming off drugs. It also needs to be clear whether he wishes to drive, because a recurrence would lead to him having to surrender his driving license.

Case 31.5

Mr FD is a 23-year-old student who was involved in a road traffic accident and admitted to hospital with a head trauma. He was stabilised, but during his admission he had a seizure and was then discharged on no medication. Three months later Mr FD attended an outpatient hospital follow-up appointment and was identified to have had no further seizures.

Question

Was Mr FD's clinical management appropriate, and is there a role for prophylactic anticonvulsant medication?

Answer

Mr FD requires a full neurological review. The long-term use of anti-epileptics following head injury is not indicated unless the person has a history of seizures, and Mr FD has had no seizures post-discharge.

Case 31.6

Mr RA is a 75-year-old retired teacher who lives alone. He has long-standing epilepsy, and his current medication includes phenytoin 300 mg daily. Mr RA suffered a recent fall and was rushed to hospital with a suspected fractured neck of femur. On admission he was stabilised and found not to have sustained a fracture. His other medication was furosemide 40 mg in the morning and enalapril 5 mg twice daily. Routine blood levels of the anticonvulsants revealed a toxic level of phenytoin of 40 mg/L (normal therapeutic range 10–20 mg/L).

Question

How long will it take for the toxic levels of phenytoin to fall within the therapeutic range?

Answer

Phenytoin exhibits non-linear pharmacokinetics. Usual management will involve withholding phenytoin and monitoring serum levels each day. One assumption that can be made is that if the hepatic enzymes are fully saturated with phenytoin, then at maximum metabolic capacity approximately 10 mg/L of the drug will be eliminated each day. Initially, however, the drug will redistribute into serum, so for the first few days phenytoin levels will fall slowly. It is usual for the levels to take 6–7 days to fall within the therapeutic range. Therapy will then need to be reviewed. On further investigation it was found that Mr RA had a severe chest infection and was prescribed ciprofloxacin. His antibiotic regimen was completed 5 days ago. Mr RA was suffering from phenytoin toxicity which may have resulted in ataxia and contributed to his fall.

32 Parkinson's Disease

Emma Lane and Roger Barker

Key points

- Parkinson's disease is the second most common neurodegenerative disease, affecting 1% of the population older than 65 years.
- Parkinson's disease is characterised by bradykinesia, resting tremor, rigidity and, later in the disease course, postural instability.
- A range of non-motor features including psychiatric, cognitive and autonomic impairments contribute significantly to an impaired quality of life and are present from early in the disease course in many cases.
- Neuronal loss in the brainstem (substantia nigra) leads to a profound dopamine deficiency in the striatum. This provides the rationale for dopaminergic replacement therapies, although the pathology is not restricted to this site.
- Levodopa, coupled with an amino acid decarboxylase inhibitor, remains the most potent oral treatment for Parkinson's disease.
- End-of-dose wearing off and on-off fluctuations are motor complications synonymous with the ongoing use of levodopa. Despite advances in oral pharmacotherapy, the on-off phenomenon can be difficult to treat effectively.
- Other dopaminergic therapies are available for the management of Parkinson's disease. Dopamine agonists are used, sometimes as first-line therapy, in younger patients, although the increasing recognition of the neuropsychiatric problems that can arise with these agents has reduced their use. It is now therefore recommended that information regarding impulse control disorders is explicitly given to patients when such drugs are used.
- Dopamine agonists can also be given as adjunctive therapies to levodopa, when the primary aim is to smooth out motor fluctuations.
- Other interventions including surgical treatments of Parkinson's disease, such as deep brain stimulation of the subthalamic nucleus, are effective in certain patients with marked motor fluctuations.
- Advanced Parkinson's disease is difficult to manage, particularly the emerging dementia and neuropsychiatric problems. Reduction of dopaminergic therapy is the first approach, and rivastigmine and other cholinesterase inhibitors may be useful for the dementia associated with Parkinson's disease.

Parkinson's disease (PD) is the most common cause of Parkinsonism and is the second most common neurodegenerative disease, after Alzheimer's disease. Although descriptions of the condition appeared before the 19th century, it was James Parkinson's eloquent account in 1817 that fully documented the clinical features of the illness and Charcot in the late 19th century who named the condition after him. Identification of the dopamine deficiency and loss of

pigmented neurons in the substantia nigra occurred in the middle part of the 20th century and was soon followed by the introduction of dopamine replacement therapy with levodopa. Although excellent at managing some of the motor features, levodopa is associated with the development of motor complications after some years in the form of on-off problems and dyskinesias. Such complications can now be treated using a range of other therapeutics including more invasive approaches such as deep brain stimulation.

In addition to these motor features, only some of which respond to dopaminergic agents, the identification of a host of non-motor symptoms from disease onset (and in some cases even ahead of them) is now known to contribute in a major way to the quality of life of patients with PD. This similarly presents a complex therapeutic challenge.

Background

PD affects 1% of the population that are more than 65 years of age, increasing to 2% over the age of 80 years. One in 20 patients is, however, diagnosed before their 40th year. It is estimated that PD affects around 127,000 people in the UK, with more than 6 million sufferers worldwide. Demographically the disease is believed to have a small male/female predominance (around 3:2). Prevalence is recorded as slightly higher in European and North and South American populations compared with Arabic, African and Asian countries. The biggest risk factor for the disease is age, which has major implications for public health as the lifespan of the world's population increases.

Parkinsonism describes the main motor features of the disease but can also be a feature of other, less common neurodegenerative conditions (multiple system atrophy [MSA], progressive supranuclear palsy and corticobasal degeneration), as well as a side effect of various medications.

Aetiology

Both genetic and environmental factors are likely to contribute to the risk of development of PD (Fig. 32.1), with environmental factors precipitating the onset of PD in a genetically susceptible individual.

Fig. 32.1 Summary of pathophysiological processes considered to be central to Parkinson's disease. UPS, Ubiquitin proteasome system.

Environment

The relevance of environmental factors came to the fore in the 1980s, when drug addicts attempting to manufacture pethidine accidentally produced a toxin called MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). The severe Parkinsonian state induced by inhalation or injection of the toxin produced a clinical syndrome that was indistinguishable from advanced PD. Similarities in the structure of MPTP to the commonly used herbicide paraquat opened up exploration of the role of chemicals used in the agricultural industry. Pesticide exposure, rural living, agricultural occupation and well water drinking alongside head injury are all associated with an increased risk of development of PD. Conversely, tobacco smoking, coffee drinking, non-steroidal anti-inflammatory drug use, calcium channel blocker use and alcohol consumption have all been linked to a reduced risk of the disease (Bellou et al., 2016).

Genetics

Single monogenic causes for PD account for a very small number of patients. The first gene of this nature to be discovered was that encoding a mutation in the synaptic protein α -synuclein (Polymeropoulos et al., 1997). Shortly after its identification as the causative gene in this familial form of PD, it was found to be the major component of the intracellular protein accumulations, Lewy bodies that characterise sporadic disease (Spillantini et al., 1997). This highlighted that this protein was central to what goes wrong in all cases of PD and was not just the preserve of a rare familial form of

the condition. Since this discovery, duplication and triplication in the α -synuclein gene, as well as further mutations in it along with mutations in many other genes, have been found to contribute to familial forms of the disease. However, the phenotypic nature of these forms of Parkinsonism is often different from idiopathic disease, causing atypical or early-onset forms of the disease, with the exception of the LRRK2 families.

Although these genes form very much the minority of cases, there is nevertheless clear genetic risk of the development of PD, as is evidenced by recent large genome-wide associated studies (Bras et al., 2015; Edwards et al., 2011). This has revealed a large number of genetic loci linked to an increased risk of development of the disorder.

More recently, through careful clinical observation in Gaucher's disease families, it was recognised that one of the strongest genetic risk factors is a heterozygous mutation in the *GBA* gene. This is found in between 5% and 10% of patients with so-called sporadic disease.

Pathophysiology

The two characteristic pathological features of PD are neuronal loss, especially in the pigmented brainstem nuclei, together with the presence of eosinophilic inclusion bodies, called Lewy bodies, in surviving cells. Dopaminergic neurones within the substantia nigra pars compacta, projecting to the striatum, are particularly affected by the disease, leading to a loss of dopamine in the terminal region. There is considerable reserve in this pathway, and a loss of more than 50% of nigral neurones occurs before overt motor features appear. The identification of Lewy bodies in other areas of the central nervous system (CNS) means that dopamine is not the only neurotransmitter system affected, and all of this correlates with the increasing recognition of the range of other clinical features seen in the course of the disease, some of which even precede the development of the motor phenotype.

Indeed, neuropathologically, the Braak hypothesis proposes that α -synuclein may first accumulate in the dorsal vagal nucleus of the lower brainstem and then gradually ascend rostrally to affect critical brain regions including the substantia nigra and ultimately the cerebral cortex (Braak et al., 2003). If true, this would suggest that prior to the loss of dopamine cells, other cell populations should be affected, resulting in changes in bowel control, mood, sleep and locomotion, all of which would fit with the prodromal features that many patients with PD report. In addition there is early pathology in the olfactory bulb which may also account for the loss of sense of smell that many patients experience ahead of them developing overt motor problems.

All of this not only accounts for the features of prodromal PD, but also the deficits that are reported as the disease evolves and which typically do not respond to dopaminergic replacement therapies.

Clinical features

Motor features

A prerequisite feature for a diagnosis of PD is the presence of bradykinesia. This is the slowness of initiation of voluntary movement, with progressive reduction in speed of repetitive actions. The other cardinal features of the disease are tremor when at rest (pill-rolling tremor), postural instability and cogwheel rigidity. Cogwheel rigidity describes the jerky resistance when limbs are moved. These are listed in most diagnostic guidelines for PD. The disease presents asymmetrically and patients continue to report a 'bad side' as the disease progresses, although pure unilateral disease is rare, and usually raises concerns that some other disease process is occurring if this is the case. It is important to note, however, that many patients (15–20%) never really develop a tremor, whereas up to 60% of people with PD may have a dominant postural tremor (tremor-dominant), worse with the arms held outstretched, which can cause diagnostic confusion with essential tremor (ET). Postural instability is an important milestone in PD, and typically more than half of patients will reach this stage within 10 years of diagnosis. This problem comprises an impairment of righting reflexes, which leads to impaired gait and increased risk of falling.

Patients typically display a characteristic stooped posture and loss of arm swing when walking, which is often a very helpful early diagnostic sign when seeing patients for the first time. There is reduced blink frequency and facial expression (hypomimia), which, together with a low-volume (hypophonic), monotonous speech, may lead to significant difficulties in communication. All of this can easily be misdiagnosed as depression. Writing becomes small (micrographia) and barely legible, with the words falling off the line as the patient continues to write.

Non-motor features

A range of non-motor features encompassing autonomic, cognitive and psychiatric problems are seen in nearly all cases of PD and have a pronounced effect on quality of life. They can precede disease onset and tend to become more prominent as the condition evolves. Common autonomic problems include postural hypotension (falling blood pressure on standing) which may contribute to falls and black-outs later in the disease course and is a leading cause of hospitalisation for patients with PD. Constipation can be an ongoing problem that may precede the diagnosis of PD by up to 20 years and relates possibly to pathology in the enteric nervous system. In terms of psychiatric problems, depression affects approximately 40% of patients and is a major determinant of both carer stress and nursing home placement. Paranoia and hallucinations occur in many patients typically as a prelude of the dementia, but often are provoked and worsened by dopaminergic and related drugs used to treat PD. In addition some of the dopaminergic agonists can induce major behavioural problems in some patients, especially young male patients with PD.

Cognitive impairment at a very mild level is now thought to be present in many patients at diagnosis. However, the development of a frank dementia tends to occur later on in the disease course and is especially related to the age of the

patient at disease onset. Younger onset patients may show cognitive impairment but evolve to a dementia at a slower rate compared with older patients. Longitudinal community-based studies indicate that dementia may ultimately develop in 80% of people with PD (Hely et al., 2008). The cognitive impairment that defines the dementia is often associated with the symptoms of hallucinations that are typically visual with delusional misinterpretation, including paranoid ideation, and rapid fluctuations in attention.

Finally many patients complain of sleep problems, with the major one being a REM sleep behavioural disorder that can occur ahead of the diagnosis of PD. This condition is characterised by patients acting out their dreams. In addition many patients complain of a restless leg syndrome and limb pain.

Differential diagnosis

Although PD is a common form of Parkinsonism, there are numerous other diseases that present with Parkinsonism. A detailed description of these different causes is beyond the scope of this chapter, but a few points should be highlighted. ET is a common condition but does not cause bradykinesia. Nevertheless, it may be very difficult to differentiate from tremor-dominant PD. In about 50% of cases of ET there is a positive family history and in a similar number a good response to a low dose of alcohol. If there are doubts, some form of nuclear medicine imaging looking at dopamine in the brain can help distinguish tremulous PD from ET.

Several clinical and clinicopathological series have highlighted the problems in making a correct diagnosis of PD. If clinical criteria, such as those produced by the UK Parkinson's Disease Brain Bank, are not applied, then the error rate (false-negative diagnosis) may be as high as 25–30%. These criteria are listed in [Box 32.1](#). The common conditions misdiagnosed as PD, outside of ET or dystonic tremor, are other neurodegenerative disorders such as progressive supranuclear palsy, MSA and corticobasal degeneration, as well as small vessel disease affecting the brain.

Drug-induced Parkinsonism

An important differential diagnosis to consider when a patient presents with Parkinsonism is whether their symptoms and signs may be drug induced. This is because drug-induced Parkinsonism is potentially reversible upon cessation of the drug. Reports linking drug-induced Parkinsonism with the neuroleptic chlorpromazine were first published in the 1950s. Since then, numerous other agents have been associated with it. Many of these are widely recognised, although others are not ([Table 32.1](#)). Repeat prescription of vestibular sedatives and antiemetics such as prochlorperazine and cinnarizine are the most commonly encountered causes of drug-induced Parkinsonism. The pathogenesis of drug-induced Parkinsonism is likely due to dopamine receptor blockade, but only in part because there is no clear correlation in incidence and severity with the drug dosage and length of exposure. Sodium valproate is also now recognised to cause an encephalopathy dominated by Parkinsonism and cognitive impairment which is reversible upon drug cessation.

Box 32.1 Clinical criteria for diagnosis of Parkinson's disease

Step 1: Diagnosis of Parkinsonian syndrome

The patient has bradykinesia, *plus one or more* of the following:

- classic rest tremor, 4–6 Hz
- muscular rigidity
- postural instability, without other explanation

Step 2: Exclusion criteria for PD suggesting an alternate diagnosis

- history of repeated strokes
- history of repeated head injury
- history of definite encephalitis
- oculogyric crises
- dopamine receptor blocking agent exposure at onset of symptoms
- more than one affected relative (often not applied)
- sustained remission
- strictly unilateral features after 3 years
- supranuclear gaze palsy
- cerebellar signs
- early severe autonomic involvement
- early severe dementia
- extensor plantar
- cerebral tumour or hydrocephalus on CT scan or MRI
- negative response to large doses of levodopa
- MPTP exposure

Step 3 Supportive prospective positive criteria for PD (three or more required for diagnosis of definite PD)

- unilateral onset
- rest tremor present
- progressive disorder
- progressive persistent asymmetry
- an excellent (>70%) response to levodopa
- a sustained (>5 years) response to levodopa
- severe levodopa-induced dyskinesias
- clinical course >10 years

For a diagnosis, step one should be fulfilled with no exclusion criteria and three supportive criteria should also be present.

CT, Computed tomography; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MRI, magnetic resonance imaging; PD, Parkinson's disease.

Drug-induced Parkinsonism is more common in the elderly and in women. The clinical features can be indistinguishable from PD, although the signs in drug-induced Parkinsonism are more likely to be bilateral at onset. Withdrawal of the offending agent will lead to improvement and resolution of symptoms and signs in approximately 80% of patients within 8 weeks of discontinuation. Drug-induced Parkinsonism may, however, take up to 18 months to fully resolve in some cases. Further, in other patients, the Parkinsonism may improve after stopping the drug, only to then deteriorate. In this situation, the drug may have unmasked previously latent PD.

Investigations

The diagnosis of PD is a clinical one and should be based, preferably, upon validated criteria. In young-onset or clinically atypical PD, a number of investigations may be appropriate. These include copper studies and DNA testing to exclude Wilson's disease and

Table 32.1 Examples of non-neuroleptic drugs associated with drug-induced Parkinsonism

Medication	Comment
Cinnarizine, metoclopramide, prochlorperazine	Antiemetics
Antipsychotics	Dose-dependent effects; clozapine least associated with abnormal movements
Tetrabenazine	Used to treat chorea through a catecholamine-depleting action
Sodium valproate, Non-steroidal anti-inflammatory drugs, amiodarone, phenytoin, oral contraceptives	Unclear how they cause Parkinsonism
Lithium	Lithium causes postural tremor; reports of Parkinsonism occurring with lithium have usually been in the context of prior exposure to neuroleptics
Phenelzine 5-Fluorouracil Pethidine Vincristine-Adriamycin	Only single case reports of drug-induced Parkinsonism with these drugs
Amphotericin	One case report of drug-induced Parkinsonism in a child after bone marrow transplantation and a second in association with cytosine arabinoside therapy

Huntington's or mitochondrial disease, respectively. Brain imaging by computed tomography (CT) or magnetic resonance imaging (MRI) may be necessary to exclude hydrocephalus, cerebrovascular disease or basal ganglia abnormalities suggestive of an underlying metabolic cause. When there is difficulty in distinguishing PD from ET, a form of functional imaging called [¹²³I]β-CIT (2β-carbomethoxy-3β-(4-iodophenyl) tropine) single-photon emission computerised tomography (FP-CIT SPECT; also known as DaTSCAN) may be useful, because this technique can sensitively identify loss of nigrostriatal dopaminergic terminals in the striatum (Fig. 32.2). Thus, in ET, the SPECT scan is normal, whereas in PD, reduced tracer uptake is seen (Jennings et al., 2004).

Differentiating PD from MSA and progressive supranuclear palsy is not an uncommon clinical problem and may be very difficult, particularly in the early disease stages and especially in the case of MSA-Parkinsonism. FP-CIT SPECT cannot differentiate PD from these other forms of degenerative Parkinsonism. MRI brain scanning, anal sphincter electromyography, tilt table testing for orthostatic hypotension and eye movement recordings may all be of some help, although they are rarely diagnostic in their own right. Typically the diagnosis in these cases becomes apparent over time, and should always be considered when patients

Fig. 32.2 A normal FP-CIT SPECT scan image, showing symmetric tracer uptake in both striata (mirror image commas). In Parkinson's disease, the tail of the comma is lost at an early stage, with the most severe loss being contralateral to the side most affected clinically.

respond poorly to dopaminergic therapies with early involvement of other systems outside the nigrostriatal system such as autonomic dysfunction.

Treatment

General approach

The treatment of PD at the current time is wholly symptomatic. No drug has proven to have significant disease-modifying or neuroprotective capabilities, although monoamine oxidase type B (MAO-B) inhibitors have been explored for such activity. At the present time there are several ongoing clinical trials looking at possible disease-modifying therapies which include the neurotrophic factor GDNF, as well as the GLP-1 agonists exenatide and liraglutide.

There is no accepted algorithm for the treatment of PD, although guidance has been produced by the [National Institute for Health and Care Excellence \(NICE, 2017\)](#). A number of factors may influence the first choice therapy for management of motor symptoms, including patient preference, quality of life, severity and type of disease (tremor-dominant vs akinetic rigid), comorbidities and potential benefits and harms of the medicines ([Table 32.2](#)).

The principles of treatment with levodopa have changed little in practice since its initial introduction in 1967, when the drug was started in low doses and gradually increased thereafter ([Cotzias et al., 1967](#)). The benefits that levodopa treatment confers make it the gold standard to this day, nearly 50 years on from its first introduction. Until quite recently it was not often the first-line approach in newly diagnosed patients, but this has changed of late with the recognition of the behavioural problems that dopamine agonists can induce. Thus, many clinicians will now start patients on low-dose levodopa in preference to dopamine agonists, even though this is likely to precipitate the well-recognised motor complications of long-term levodopa therapy earlier. These include a premature wearing off of the anti-Parkinsonian effects of levodopa and fluctuations in the response with the

development of involuntary movements known as dyskinesias. These typically occur after a number of years of treatment and relate as much to the duration of disease as to the drug itself.

The first problem that patients typically describe with levodopa is a wearing-off effect, in which the patient finds that the effect of the medicine does not last until their next dose is due. This manifests itself as the patient starting to 'go off' as they approach their next dosing time. With time this evolves into more complex on-off problems, where patients can 'go off' for no obvious reason. This stage of the illness is also often accompanied by levodopa-induced dyskinesias. Dyskinesias are classed depending on their relationship to levodopa dosing occurring at the peak of levodopa response, so-called peak dose dyskinesia (the commonest type), 'diphasic dyskinesia' at the start and end of levodopa therapy, and the end of dose 'wearing off' dyskinesia. These problems emerge at a rate of approximately 10% per year, so that by 10 years into their illness all PD patients can expect to experience some motor fluctuations of this type. Notably, however, levodopa-induced dyskinesias and fluctuations develop earlier in younger patients with PD and relate to the dose of medication they are given ([Rascol et al., 2000](#)). On-off episodes may be extremely disabling and remain a major therapeutic challenge in the management of PD, although the development of deep brain stimulation and enteral delivery systems for dopaminergic agents have proven beneficial in managing this aspect of PD.

There are limited pharmacotherapeutic options for the management of dyskinesia, so management trends have shifted towards keeping the levodopa dose to a minimum or a 'levodopa-sparing approach'. This takes the form of either later administration of levodopa, provided alternative treatments can give adequate symptomatic control, or the use of combination therapies, in an effort to reduce the cumulative dose of levodopa given. However, the benefit of this approach beyond 5 years into the illness remains a matter of debate.

Drug treatment

Levodopa preparations

Immediate-release levodopa. Irrespective of the debate regarding when to start levodopa therapy, there is no doubt that levodopa remains the most effective oral symptomatic treatment for PD. It is administered with the peripheral dopa-decarboxylase inhibitors carbidopa or benserazide, where carbidopa plus levodopa is known as co-careldopa (Sinemet) and benserazide plus levodopa is co-beneldopa (Madopar). The decarboxylase inhibitor blocks the peripheral conversion of levodopa to dopamine and thereby allows a lower dose of levodopa to be administered. Levodopa readily crosses the blood-brain barrier and is converted by endogenous aromatic amino acid decarboxylase to dopamine and then stored in the surviving nigrostriatal nerve terminals.

Immediate-release co-beneldopa is usually commenced in a dosage of 50 mg, typically three times a day. The patient may be

Table 32.2 Potential benefits and harms of dopamine agonists, levodopa and monoamine oxidase type B inhibitors

	Levodopa	Dopamine agonists	Monoamine oxidase B inhibitors
Motor symptoms	More improvement in motor symptoms	Less improvement in motor symptoms	Less improvement in motor symptoms
Activities of daily living	More improvement in activities of daily living	Less improvement in activities of daily living	Less improvement in activities of daily living
Motor complications	More motor complications	Fewer motor complications	Fewer motor complications
Adverse events	Fewer specified adverse events*	More specified adverse events*	Fewer specified adverse events*

*Excessive sleepiness, hallucinations and impulse control disorders (see the summary of product characteristics for full information on individual medicines).
With kind permission from NICE (2017).

instructed in the early stage of the illness to take the drug with food to minimise nausea. Paradoxically, in more advanced PD, it may be beneficial to take levodopa 30 minutes or so before food, as dietary protein can critically interfere with the absorption of the drug. If there is little or no response to 50 mg three times daily, the unit dose may be doubled to 100 mg. Should the patient's levodopa dose escalate to 600 mg/day with no significant response, the diagnosis of PD should be reviewed. Levodopa, commenced in the above way, is usually well tolerated. Nausea, vomiting and orthostatic hypotension are the most commonly encountered side effects. These adverse events may be circumvented by increasing the levodopa dose more slowly, or co-prescribing domperidone 10 or 20 mg three times daily; however, recently there have been some concerns with the cardiac safety of this agent. Later in the illness, and in common with all anti-Parkinsonian drugs, levodopa may cause vivid dreams, nightmares or even precipitate a confusional state, which tends to indicate that the patient is starting to develop a PD dementia.

Clinically relevant drug interactions with levodopa include hypertensive crises with MAO-A inhibitors. Levodopa should, therefore, be avoided for at least 2 weeks after stopping the inhibitor, although the non-selective forms of these drugs are rarely prescribed nowadays. Levodopa can also enhance the hypotensive effects of antihypertensive agents and may antagonise the action of antipsychotics. The absorption of levodopa may be reduced by concomitant administration of oral iron preparations.

Controlled-release levodopa. Both Sinemet and Madopar are available as controlled-release (CR) preparations. The nomenclature for Sinemet CR is confusing, as the drug is marketed as Sinemet CR (carbidopa/levodopa 50/200) and also as Half Sinemet CR (carbidopa/levodopa 25/100). Trying to prescribe Half Sinemet CR unambiguously can be difficult. If the instruction is misinterpreted and a tablet of Sinemet CR is halved, the slow-release mechanism is actually disrupted.

Levodopa in CR preparations has a bioavailability of 60–70%, which is less than the 90–100% obtained from immediate-release formulations. CR preparations have a response duration of 2–4 hours, compared with 1–3 hours for immediate release. Limited benefit has been shown for CR use over immediate-release levodopa in terms of dyskinesia development and response fluctuation frequency. However, CR preparations may be of help in

simplifying drug regimens, in relieving nocturnal akinesia, and in co-prescribing with immediate-release levodopa during the day to relieve end-of-dose deterioration.

Two commonly encountered problems with CR preparations are, first, changing the patient from all immediate-release to all CR levodopa. This is poorly tolerated, because CR levodopa has a longer latency than immediate-release levodopa to turn the patient 'on' (typically 60–90 vs 30–50 minutes), and the patient's perception is that the quality of their 'on' period is poorer. Second, CR preparations should not be prescribed more than four times a day, because the levodopa may accumulate, causing unpredictable motor fluctuations and especially leading to dyskinesias later in the day.

Co-careldopa intestinal gel. An intestinal gel preparation of levodopa and carbidopa (Duodopa) is currently available that is administered directly into the small bowel (specifically, the jejunum) via a percutaneous route, using a portable electronic pump. Through continuous delivery in this way, motor fluctuations may be significantly reduced. Although effective, this treatment modality requires careful patient selection, and because of its cost, it is constantly being reviewed by central agencies authorising drug choice in PD. The endoscopic insertion of a percutaneous jejunostomy carries a definite morbidity and mortality. The treatment is also very expensive while mechanical problems with tube detachment and blockage have been reported. Thus, it is currently used only in advanced fluctuating patients who are deemed not to be suitable for deep brain stimulation or apomorphine infusions.

Other prolonged-release levodopa preparations that are in clinical trials include Rytary (IPX066) which is currently available in the USA. It utilises a mixed population of coated microspheres to vary the rate of release in a controlled fashion to provide the benefit of immediate relief as well as prolonging that benefit through slower release of the active agent. Two gastric retentive formulations are also in development, which slow down the passage of the drug through the pylorus aperture to improve levodopa uptake.

Dopamine agonists

In theory, dopamine agonists, which stimulate dopamine receptors both post- and pre-synaptically, would seem to be a very

attractive therapeutic option in PD, because they may bypass the degenerating nigrostriatal dopaminergic neurones. Unfortunately, experience to date with the current oral agents reveals them to be less potent than levodopa and less well tolerated, with significant risks of side effects, for example, impulse control disorders, that have been more recognised since the beginning of this century.

Of the two main structural classes, the ergot- and non-ergot-derived dopamine agonists differ in their affinity for different members of the dopamine receptor families. Predominant activity is through the D2-like receptor class, whereas some express a preferential binding for D3 subtypes over D2. It is not known whether these differences are clinically significant, but experience to date would suggest not. Plasma half-lives vary considerably; cabergoline is an ergot dopamine agonist with a plasma half-life of 63–68 hours, meaning that once-daily dosing is possible, although it is now rarely used because of its fibrotic side effects. Ropinirole and pramipexole are non-ergot derivatives that originally had to be administered three times daily and have become the dopamine agonists of choice nowadays. Slow-release preparations of ropinirole (XL) and pramipexole (PR) are available for once-daily dosing. A transdermally administered non-ergot dopamine agonist, rotigotine, is also available as a 24-hour adhesive patch.

There have been very few comparative studies performed between the dopamine agonists, so it is not possible to be definitive as to which drug should be recommended. However, currently, ergot-derived dopamine agonists are avoided because of the side effects and the need, therefore, for annual screening of patients receiving these drugs. Thus, ropinirole, pramipexole and rotigotine are the most widely prescribed dopamine agonists, and if a patient does not get on with one of these, it may be worthwhile changing from one agonist to another, because there is variability in a given patient's tolerance to the different drugs.

Dopamine agonist side effects. The principal side effects of the dopamine agonists are nausea and vomiting, postural hypotension, hallucinations, confusion and, in some cases, major behavioural problems linked to impulse control disorders. These latter problems can be very significant and lead to major financial and social problems. Thus, there is a greater emphasis now on informing patients about these side effects when they are prescribed these drugs, with a recommendation that this advice is clearly documented in the hospital notes (NICE, 2017). Ergot derivatives run the risk of causing pleuropulmonary fibrosis and therefore are not routinely used anymore.

Ropinirole and pramipexole were previously implicated in causing 'sleep attacks', with sudden onset of drowsiness, leading to driving accidents in some cases. The term sleep attack is almost certainly a misnomer, however, as patients do have warning of impending sleepiness, although they may subsequently be amnesic for up to several minutes while in this state. Excessive sleepiness attributable to anti-Parkinsonian drugs is actually not a new phenomenon and is almost certainly a 'class effect' of all dopaminergic therapies. It is essential to advise patients who are taking all anti-Parkinsonian agents that they may be prone to excessive drowsiness. This may be compounded by the use of other sedative drugs and alcohol.

Dopamine agonists have also been associated with impulse control disorders. These disorders include pathological gambling, hypersexuality, punding and excessive shopping. The onset may relate to dopamine D2/3 receptor stimulation in predisposed individuals. Patients and their carers should be warned about these potential problems before the drug is prescribed, and patients should be regularly screened for abnormal behaviours while taking the agonist. However, in some cases, patients hide this information from their treating clinician, as well as family, and the problems are identified only when a major crisis emerges as a consequence of this behaviour, for example, house repossession, among others. This latter problem with impulse control disorders, although rare, has meant that these dopamine agonist therapies are now used less as first-line treatments, and this has been reflected in the NICE guidelines (NICE, 2017).

Apomorphine

Apomorphine is a specialised drug in the treatment of advanced PD, but almost certainly continues to be underused. It is the most potent non-selective dopamine agonist available but has a short half-life, a single bolus administration lasting for 45–60 minutes. It is therefore administered as either a bolus or subcutaneous infusion depending on the purpose. A bolus subcutaneous injection of apomorphine is suitable for patients who are optimised on their oral medications but who still suffer from troublesome, typically unpredictable 'off' periods or would benefit from rapid early-morning relief until their oral medication takes effect. Alternatively, continuous infusion is a useful therapeutic option in patients who are no longer well controlled by standard oral therapies and in whom apomorphine injections have proven effective. Frequent use of the injection (four to six times per day) is associated with increasing dyskinesia, so control is improved by the continuous infusional delivery of the drug (Trenkwalder et al., 2015).

Initiation of apomorphine therapy can be as an in-patient or as an outpatient by a nurse specialist, geriatrician or neurologist. Nausea and vomiting at the start of therapy can be treated with domperidone, usually 20 mg three times a day for 2–3 days before initiation. Other antiemetics such as prochlorperazine or metoclopramide cannot be used because they block dopamine receptors and make PD worse. Orthostatic hypotension can be managed with medication or with non-pharmacological interventions. Neuropsychiatric disturbance, probably at a lower frequency than with oral agonists, and skin reactions, including nodule formation, are other potential side effects. Apomorphine, in conjunction with levodopa, may, in rare cases, cause a Coomb's positive haemolytic anaemia, which is reversible. It is recommended that patients are screened before beginning treatment and at 6-monthly intervals thereafter.

Catechol-O-methyl transferase inhibitors

Inhibitors of the enzyme catechol-O-methyl transferase (COMT) represent a useful addition to the range of therapies available for

PD (Schrag, 2005). Use of the first agent in this class, tolcapone, was originally suspended in Europe because of fears over hepatotoxicity, although the drug became available again in 2005, accompanied by strict prescribing and liver function monitoring guidelines. Entacapone is also available, and studies have not shown derangement of liver function with this drug; thus, it is used much more.

COMT itself is a ubiquitous enzyme, found in the gut, liver, kidney and brain, among other sites. In theory COMT inhibition may occur both centrally, where the degradation of dopamine to homovanillic acid is inhibited, and peripherally, where conversion of levodopa to the inert 3-*O*-methyldopa is inhibited. In practice, both tolcapone and entacapone act primarily as peripheral COMT inhibitors and by so doing increase the amount of levodopa that enters the CNS.

Placebo-controlled studies in patients with fluctuating PD have confirmed the efficacy of entacapone in decreasing 'off' time and permitting a concomitant reduction in levodopa dose. A 20% reduction in 'off' time is reported, translating into nearly 1.5 hours less immobility per day. This reduction tends to occur towards the end of the day, a time when many patients with PD are at their worst in terms of motor function. A comparison of entacapone and tolcapone suggested that tolcapone may be the more potent COMT inhibitor, achieving up to an extra 1.5 hours of 'on' time per day (Entacapone to Tolcapone Switch Study Investigators, 2007).

When entacapone is prescribed, a 200 mg dose is usually given with each dose of levodopa administered, up to a frequency of 10 doses/day. The increased dyskinesias means an overall reduction of 10–30% in the daily dose of levodopa may be anticipated. Entacapone can be employed with any other anti-Parkinsonian drug, although caution may be needed with apomorphine. Entacapone is also marketed as a compound tablet containing levodopa and carbidopa (Stalevo). Although each tablet contains 200 mg of the COMT inhibitor, seven different doses of levodopa are available (50, 75, 100, 125, 150, 175 and 200 mg) to provide flexibility. The compound tablet may help adherence by significantly reducing the total daily number of tablets a patient needs to take.

Tolcapone is prescribed as a fixed 100 mg three times a day regimen, increasing if necessary to 200 mg three times a day. It may only be used after the patient has tried and not responded positively to entacapone and where provision for 2-weekly monitoring of liver function tests for the first 12 months, reducing in frequency thereafter, is available. Again, a concomitant reduction in levodopa may be necessary to offset an increase in dyskinesias.

The optimal way to use COMT inhibition is unknown. A patient experiencing end-of-dose deterioration, or generally underdosed, would seem to be the ideal candidate. However, few comparative studies of COMT inhibitors versus dopamine agonists are available to provide guidance as to which class of drug is best to use and when. The STRIDE-PD study (Stocchi et al., 2010) assessed the potential benefit of combined treatment with levodopa and entacapone in *de novo* PD patients to address whether this combined treatment was associated with a lower incidence of dyskinesias. Unfortunately, the opposite was

actually found, with a higher incidence of dyskinesias in patients randomised to levodopa and entacapone compared with levodopa alone. Other than exacerbation of dyskinesias, COMT inhibitors may also cause diarrhoea, abdominal pain and dryness of the mouth. Urine discolouration is reported in approximately 8% of patients who are taking entacapone.

It is best to avoid non-selective MAO inhibitors or a daily dose of selegiline in excess of 10 mg (which in reality never happens in PD) when using entacapone. In addition, the co-prescribing of venlafaxine and other noradrenaline (norepinephrine) reuptake inhibitors is best avoided. Entacapone may potentiate the action of apomorphine. Patients who are taking iron preparations should be advised to separate this medication and entacapone by at least 2 hours.

Monoamine oxidase type B inhibitors

The propargylamines selegiline and rasagiline are inhibitors of MAO-B. Inhibition of this enzyme slows the breakdown of dopamine, effectively having a 'levodopa-sparing' effect in the striatum. The result of this is both a mild therapeutic effect and a possible delay in the onset of or reduction in existing motor complications. Both drugs may also have an antiapoptotic effect. Apoptosis is a form of programmed cell death thought to be important in several neurodegenerative conditions, including PD. Whether the drugs have a neuroprotective effect by this or some other means remains controversial, but the current consensus is that this is not the case. Different protocols and starting doses have made comparing outcomes from different trials impossible (Mínguez-Mínguez et al., 2013). However, their mild symptomatic effect, ease of use, relative absence of side effects and putative neuroprotection, in the absence of any other neuroprotective agents available, makes them still a common choice as first-line therapy for many doctors. A recent meta-analysis found a significant and comparable effect of the two drugs on Unified Parkinson's Disease Rating Scale scores in early PD (Jost et al., 2014).

A single daily dose of 5 or 10 mg of selegiline is prescribed. Higher doses are associated with only minimal additional inhibition of MAO. Selegiline may also be administered as a lyophilised freeze-dried buccal preparation. The dosage of rasagiline is 1 mg daily. Both selegiline and rasagiline may be used as *de novo* or adjunctive treatments in PD, although trial data for the latter indication is strongest for rasagiline and buccal selegiline.

Selegiline can rarely cause hallucinations and confusion, particularly in moderate-to-advanced disease, typically through enhancing the actions of levodopa centrally. The withdrawal of selegiline may then be associated with significant deterioration in motor function. Unlike selegiline, rasagiline is not metabolised to amphetamine-like products, so neuropsychiatric side effects are less frequent. A critical interaction occurs with opioid analgesics; selegiline in particular is associated with hyperpyrexia and CNS toxicity if administered concomitantly with pethidine. Selective serotonin reuptake inhibitors should be used with caution in combination with MAOB inhibitors because there remains a small

theoretical risk of serotonin syndrome, although there has been only a single case report.

Amantadine

Amantadine was introduced as an anti-Parkinsonian treatment in the late 1960s. It has a number of possible modes of action, including facilitation of presynaptic dopamine release, blocking dopamine reuptake, an anticholinergic effect (nicotinic antagonist), and also may act as a weak *N*-methyl-D-aspartate (NMDA) receptor antagonist. Initially employed in the early stages of treatment, where its effects are mild and relatively short-lived, it is more commonly used as an antidyskinetic agent in advanced disease, the only drug licensed for such use.

Daily doses of 100–400 mg amantadine may be used. Some recommend even higher doses for improved antidyskinetic effect, although side effects become much more frequent at higher doses. These side effects include a toxic confusional state and peripheral and corneal oedema. Monitoring is not needed, but attention needs to be paid to patients reporting sudden visual changes. Livedo reticularis, a persistent patchy reddish-blue mottling of the legs, and occasionally the arms, is also a side effect.

Antimuscarinic drugs

The availability of antimuscarinic drugs such as trihexyphenidyl and orphenadrine predated the introduction of levodopa by nearly 90 years. Antimuscarinic drugs can have a moderate effect in reducing tremor but do not have any significant benefit upon bradykinesia. The use of antimuscarinic agents has declined because of troublesome side effects, including constipation, urinary retention, cognitive impairment and toxic confusional states. In selected younger patients, an antimuscarinic drug may still be helpful, but close monitoring is advised.

Surgical treatment

Surgical approaches for the management of PD include both lesioning (-otomies) and deep brain stimulation (a high-frequency signal that functionally turns off the nucleus being stimulated). The functional effects are similar, but deep brain stimulation is preferred clinically and has the advantage of being reversible and controllable to a degree. Various targets in the basal ganglia have been considered, but overwhelmingly deep brain stimulation of either the internal part of the globus pallidus or the subthalamic nucleus is the therapy of choice in most patients. The intervention is costly, but significant benefits can be gained, especially for patients who have previously had a good response to levodopa but are experiencing major motor fluctuations or dyskinesia. Careful case selection is essential for all forms of surgical intervention for PD: older and less biologically fit patients, those with active cognitive and/or neuropsychiatric problems, and patients with a suboptimal levodopa response are generally regarded as poor surgical candidates (Worth, 2013).

New potential surgical approaches also include the delivery of growth factors, dopamine cells and viral vectors (for the delivery of growth factors or enzymes required for dopamine

synthesis). Clinical trials have demonstrated proof of principle for cell transplantation studies using fetal dopamine cells, and the future looks promising for stem cells as a more viable, quality-controlled source of transplantable cells (Barker et al., 2015). Hybridising these novel approaches with the more established deep brain stimulation is also being postulated in a multifaceted approach to managing this condition long-term.

Patient care

Common therapeutic solutions to problems encountered in the management of people with PD are presented in Table 32.3. After diagnosis, the provision of an explanation of the condition, education and support are essential. PD charities produce an excellent range of literature to help the newly diagnosed patient come to terms with the condition. Patients who drive are advised to inform their insurance company and also the UK Driver and Vehicle Licensing Agency.

A doctor will record impairments in the clinic, while the patient is more concerned with their disability and handicap. Thus, a patient can be noted to have seemingly marked impairment and yet may not complain about significant disability. The converse may also be true. Not all patients, therefore, require immediate treatment. Further, concomitant depression may distort the patient's perception of his or her disability, leading to inappropriate prescribing of anti-Parkinsonian therapy. In this situation, the use of an antidepressant may be more helpful. There is no good evidence base for which antidepressant should be used, and both the tricyclic agents and selective serotonin reuptake inhibitors have their advocates.

Accurate adherence with the timing of therapy may be particularly important in patients who are beginning to experience long-term treatment complications. It can be helpful for patients to keep diaries when they begin to experience problems with either bradykinesia or dyskinesia, so that these symptoms can be related to drug and food intake. Careful changes in timing of drug therapy or meals may initially be sufficient to reduce variation in performance. Some patients experience troublesome early-morning bradykinesia. It may then be beneficial to prescribe an initial dose of a rapidly acting agent, such as dispersible oral co-beneldopa, to take on first waking so that the patient can then get up and dress. A combination of levodopa with dopamine agonists, which are more slow acting, may be useful in the patient with motor fluctuations. A combination of levodopa and a COMT inhibitor may be more appropriate in a patient with end-of-dose deterioration.

Other factors that need to be considered in patients with PD are the benefits of adequate sleep and rest at night, which may be made more difficult if they have urinary frequency or problems with nocturnal bradykinesia. Judicious use of hypnotic therapy may be appropriate, whereas a tricyclic antidepressant may offer the dual benefit of sedation with anti-muscarinic effects. Low friction sheets to assist turning in bed and encouragement of mobility through physiotherapy may also be helpful.

The treatment of the patient with severe disease remains one of the greatest challenges in the management of PD. On-off fluctuations may be refractory to oral dopaminergic therapies. Sudden freezing episodes compound failing postural stability, leading to

Table 32.3 Common therapeutic solutions in the management of Parkinson's disease

Problem	Cause	Possible solution
Early-onset dyskinesias in young patient with Parkinson's disease	Exposure to levodopa	Delay introduction of levodopa, use lowest possible dose, use alternative agent (e.g. dopamine agonist, MAOB inhibitor), or start amantadine
One dose of levodopa does not last until the next (wearing off)	Advanced disease (pre- and post-synaptic changes)	More frequent, smaller doses of levodopa, COMT inhibitor, dopamine agonist or MAOB-inhibitor Start slow-release levodopa in addition to immediate-release agents
Pain and immobility during the night	Evening dose of levodopa not lasting long enough	Use slow-release levodopa preparation or slow-release dopamine agonist last thing at night
Freezing episodes and/or unpredictable motor fluctuations	Advanced disease (pre- and post-synaptic changes)	Dopaminergic therapies, apomorphine, Duodopa or surgery Physiotherapy helpful for freezing; sensory cues can help (stripes on the floor, etc.). Some recent evidence to suggest rivastigmine may help some patients with freezing of gait
Mismatch between patient's symptoms and signs	Consider underlying depression	Consider antidepressant (e.g. citalopram)
Confusion and hallucinations with preserved cognition	Toxic (drug-related) psychosis	Exclude intercurrent infection or other medical problem Review and reduce anti-Parkinsonian therapy Consider atypical antipsychotic agent such as quetiapine
Fatigue and tiredness	Underlying brain pathology or dopamine agonists	Reduce or stop dopamine agonists; modafinil may help and should be tried
Poor sleep or RBD	Check no other cause for sleep problem such as going off at night, nocturia, sleep apnoea, etc.	For RBD, use clonazepam 0.25–0.5 mg at night or melatonin If insomnia is the major issue, try low-dose amitriptyline or a Z-drug
Confusion and hallucinations with impaired cognition	Underlying brain pathology and cholinergic deficit	Reduce anti-Parkinsonian therapy Cholinesterase inhibitor may be tried

COMT, Catechol-O-methyl transferase; MAOB, monoamine oxidase type B; RBD, REM sleep behavioural disorder.

increasing falls and injuries. In select patients, the use of apomorphine, either as bolus injection (via a penject device) or as a continuous subcutaneous infusion, may be helpful, as might the use of cholinesterase inhibitors (Worth, 2013).

The presence of reduced dexterity in virtually all people with PD means that thought needs to be given to the way in which medication is dispensed and stored. If the patient is taking a complex regimen of drugs or has early cognitive problems, the use of pre-packaged therapies may improve adherence.

Patients' relatives also need emotional and social support through what can be a very demanding period. It can be very difficult for relatives to cope with the patient's loss of physical mobility, together with a personality change. The involvement of occupational therapists, social workers and specialists in palliative care in this situation is important.

Psychosis and dementia

When cognitive impairment is problematic, the use of conventional antipsychotic medication is inappropriate because the pharmacological actions of such drugs, dopamine receptor antagonism, can precipitate a catastrophic worsening of

Parkinsonism. Behavioural disturbances require discussion with carers and, if possible, with the patient themselves. A graded withdrawal of anti-Parkinsonian drugs is often indicated, aiming to simplify the regimen to levodopa monotherapy and especially removing drugs that are well known to cause neuropsychiatric problems such as amantadine and dopamine agonists. In rare cases, it may be necessary to reduce the dose or even completely withdraw levodopa therapy to control aggressive, sexually demanding or psychotic features. When reduction in dopaminergic therapy is ineffective or not tolerated because of unacceptable immobility, an atypical antipsychotic drug may be considered. In practice, the choice is restricted to quetiapine or clozapine, because risperidone and olanzapine are associated with worsening Parkinsonism, even in low doses (NICE, 2017). Further, both risperidone and olanzapine should not be used in cognitively impaired elderly people because of an increased risk of stroke. Clozapine is difficult to use for PD-associated psychosis because of the need to register the patient with a blood-monitoring programme. When quetiapine is used, it should be commenced at a low dose of 25 or 50 mg at night and increased slowly. The sedative effects may be helpful in promoting sleep.

Table 32.4 Management of autonomic/enteric problems in Parkinson's disease

	Symptom response to dopamine replacement therapy	Treatment options	Cautionary notes
Faecal incontinence	Unresponsive	None available	Check that this is not overflow diarrhoea from faecal impaction.
Urinary incontinence	Responsive	Antimuscarinic drugs; incontinence pads	Antimuscarinics agents could worsen cognitive impairments, constipation and produce a dry mouth.
Erectile dysfunction	Responsive	Consider sildenafil or similar agent	Consider if erectile dysfunction is part of a more general major autonomic problem.
Dysphagia (impaired swallowing) and speech	Responsive	Refer to speech and language therapists	Check no non-Parkinson's disease cause for problems with speech (e.g. dentures) or swallowing.
Nocturia		Consider antimuscarinic	Make sure there are no primary urological problems such as prostatism.
Sialorrhoea (excessive drooling)	Responsive	Glycopyrronium bromide inhaler/oral medication; Botox injections into salivary glands If neither of the above work consider: <ul style="list-style-type: none"> • antimuscarinic such as a hyoscine patch • low-dose clonidine • sublingual atropine eye drops 	
Excessive sweating	Unresponsive	β-Blockers can occasionally help	
Postural hypotension	May be induced by dopamine replacement therapy	Midodrine or fludrocortisone	May worsen with dopamine agonists and lead to falls; falls are a leading cause of hospitalisation in Parkinson's disease
Constipation	Responsive	Bulking agents, osmotic laxative, macrogol	May improve with a switch from oral therapy to rotigotine patch
Weight loss		Refer for nutritional advice	Make sure no other cause for this such as underlying malignancy

Many ongoing trials, see [Schrag et al. \(2015\)](#) for further information.

Cholinesterase inhibitors have shown promise in treating the neuropsychiatric features of PD and may also have modest cognitive-enhancing benefits. Visual hallucinations, delusions, apathy and depression seem to be particularly responsive to these agents. These effects have been demonstrated for rivastigmine, the only cholinesterase inhibitor licensed for use in PD dementia in a large, multicentre, double-blind, placebo-controlled study ([Emre et al., 2004](#)). Although not licensed, memantine has also been shown to be effective in smaller-scale clinical trials and can be used in combination with rivastigmine in some patients.

Autonomic problems

Treating the autonomic problems where possible is critical to improving a patient's quality of life. Understanding the root cause of the non-motor events is important because many are either unresponsive to dopamine replacement therapy or may actually be induced by them. [Table 32.4](#) lists the main treatment options available for the major autonomic effects which commonly occur in patients. These include disorders of gut motility, constipation or difficulty with swallowing,

disturbances of micturition, sometimes presenting as nocturia, and postural hypotension. Constipation can be managed in the usual way with osmotic laxatives and, if necessary, stimulant laxatives and stool-softening agents. The management of postural hypotension includes assessment of the patient's autonomic function to establish whether this is primarily drug-related or associated with an autonomic neuropathy. If the patient is dizzy on standing, simple measures such as advice on rising slowly may be adequate. The use of elastic stockings, to reduce pooling of the blood in the lower limbs, is sometimes helpful, although poorly tolerated. Pharmacological approaches include the use of midodrine (a selective α_1 -adrenergic agonist) or fludrocortisone. It is also important to consider other therapies the patient is receiving that might contribute to such symptoms, for example, diuretics, and to stop these if possible.

Case studies

Case 32.1

Mr ST, a 35-year-old man, develops a worsening tremor of his right hand and has difficulty running on a treadmill at his local gym as his right leg will not keep up. His father developed PD in his early 70s.

On examination he has a bilateral tremor more on the right than the left and does not swing his right arm when walking. He has no other major deficits and no significant medical history.

Questions

1. What is the most likely diagnosis?
2. What other points do you need to consider?
3. What treatment, if any, would you recommend?

Answers

1. PD. The asymmetric onset of tremor, bradykinesia of the right leg and the loss of arm swing would all make one suspect this is the most likely diagnosis despite his young age.
2. In all patients with young-onset PD, it is important to exclude other causes. It is thus essential to take a medication history to ensure that this could not be drug induced, although the asymmetry of presentation would be against this. It is important to exclude a metabolic cause given his age, such as Wilson's disease, so relevant blood tests should be done, as well as an MRI scan of the brain to exclude signal change within the basal ganglia suggestive of a metabolic problem. Finally a genetic cause should be considered (e.g. Parkin mutation). However, even at this age most cases are sporadic and having a single family member with the condition who developed it late in life is not significant. Given the condition is quite common, one is allowed by chance to have another member of the family with PD.
3. Treatment options depend upon whether the motor symptoms impact on his quality of life. NICE (2017) suggests that if they do, levodopa should be offered, whereas if they do not impact on his quality of life, either a dopamine agonist, levodopa or an MAO-B inhibitor could be considered. He should also be told about the support networks that exist for PD and be encouraged to link up to

a research programme if possible, as he would be an ideal patient for emerging experimental therapies such as cell transplants or gene therapies.

Case 32.2

Mr HM, a 47-year-old man, with PD is well controlled with ropinirole XL 16 mg/day and rasagiline 1 mg once daily. He denies any problems when you review him in clinic, but his wife e-mails you to say that he spends a lot of time at night on eBay buying engine parts for a particular type of car that he has always been interested in.

Questions

1. What is being described here?
2. What is the cause of this behaviour?
3. How would you manage it?

Answers

1. Impulse control disorder.
2. This is likely to be driven by his premonitory personality and the use of the dopamine agonist.
3. Mr HM needs to be seen in the PD clinic, although this does not need to be done urgently (unless the level of expenditure on this activity is excessive). In clinic the patient should be given the opportunity to bring this issue up, and if not then it should be raised because often patients deny or do not recognise that this is an issue/problem. Once raised, it should be explained that this is a well-known side effect of the ropinirole, and that this drug should be stopped and replaced with levodopa. The rationale for this and the consequences of doing this need explaining, and the patient may require specialist input, such as cognitive behavioural therapy to help them wean off the dopamine agonist successfully.

Case 32.3

Mrs AB, a 63-year-old woman, has had PD for 5–6 years. She now finds her medication is not working as well as it used to, and that she takes a long time to get going in the morning and is rather fidgety last thing in the day. She is currently taking Madopar CR five times a day and selegiline 10 mg once daily, as well as 8 mg ropinirole XL once daily.

Questions

1. What is Mrs AB describing?
2. What is causing these symptoms?
3. How would you treat them?

Answers

1. Mrs AB has a combination of being 'off' in the morning and 'on' with dyskinesia in the evening.
2. She is on a regimen of drugs that is suboptimal for someone with PD for this length of time. Her dose of ropinirole is low; most patients experience an optimal response when receiving 16–20 mg daily of the drug. In addition, she has no immediate-release Madopar in the morning, so it takes her a while to get going and then during the day the use of only Madopar CR at this frequency means she is slightly overdosed in the evening.

3. She should reduce the Madopar CR to twice a day, increase the ropinirole to 16 mg/day and start an immediate release of Madopar (e.g. Madopar 62.5 or 125) three times a day.

Case 32.4

Mr CD, a 59-year-old man, has had PD for 12 years. He has responded well to levodopa in the past but now finds that he has unpredictable 'off' periods during the day and peak dose dyskinesias that are present for several hours every day. He has a medical history of hypertension and is known to have benign prostatic hypertrophy. His current regimen is Sinemet 110 six times a day; Half Sinemet CR twice a day, amantadine 100 mg three times a day and a rotigotine patch 12 mg once a day.

Question

What treatment would you recommend and why?

Answer

Mr CD has now entered the advanced stages of PD with marked motor fluctuations and as such is heading towards a more invasive therapeutic intervention.

In the first instance one could try fractionating his levodopa load, so, for example, one could put him on Sinemet CR twice a day and then Sinemet 62.5 eight times a day, while also increasing the amantadine up to the maximum dosage of 400 mg/day.

However, even if this is effective, the problems are likely to re-occur because his nigrostriatal pathway has now degenerated to the point that the uptake, release and post-synaptic effects of the levodopa are erratic. He will therefore need to be considered for:

- a subcutaneous apomorphine pump
- deep brain stimulation
- Duodopa infusion therapy (into the small bowel)

Given his age, response to therapy to date and the absence of major non-motor complications or comorbidities, he would be a good candidate for any one of these treatments. However, in the UK it is very difficult for him to have Duodopa treatment because of its expense, unless there are exceptionally good reasons for him not to have already been treated or offered treatment with apomorphine or deep brain stimulation treatment.

Case 32.5

Mrs EF, a 76-year-old woman, has had PD for about 10 years. She is well controlled on Madopar 125 four times a day, Madopar CR

twice a day and amantadine 100 mg twice a day. However, over the last few months she has been seeing animals in her bedroom at night and on occasions thinks there is someone else in the house. She lives on her own, but her friend who comes with her to the clinic says she is becoming more withdrawn and suspicious of others.

Questions

1. What is being described here?
2. What investigations would you suggest?
3. What therapeutic management could be considered for Mrs EF?
4. What is likely to happen to Mrs EF in the next few years?

Answers

1. Mrs EF has developed neuropsychiatric problems with her PD that involves visual hallucinations with delusions and a degree of paranoia.
2. It is important to make sure that nothing else is causing this, such as a low-grade infection or some other comorbid condition or metabolic problem. Thus, an infective screen and a series of routine blood tests should be undertaken. It is unlikely to relate to a new intracranial problem such as encephalitis or a chronic subdural haematoma, but if there are focal neurological signs, then imaging of the brain is recommended with or without cerebrospinal fluid examination. However, the most likely cause is her underlying PD with cortical Lewy body pathology which with her medication is driving her current neuropsychiatric syndrome.
3. If no other cause is found, then the drugs should be reduced. The most likely agent is the amantadine, so this should be withdrawn over the next few weeks. If she does not improve with this change, then levodopa dose could be reduced, although this may make her unacceptably immobile and 'off'. If this occurs, the Madopar needs to be re-introduced and rivastigmine 1.5 mg twice a day needs to be started (after appropriate electrocardiogram screening) or alternatively quetiapine (25 mg at night). Mrs EF also needs to be closely followed up ideally by a specialist community nurse who can visit her at home.
4. Mrs EF is likely to progress to a PD dementia because these symptoms are typically an indication of this complication of PD.

33 Dementia

Denise Taylor

Key points

- Globally, 47.5 million people live with dementia; 850,000 people in the UK have dementia, and this number is projected to rise to more than 1 million by 2025.
- In the UK, 62% of people with dementia are female, probably because life expectancy is higher in females and age is the biggest known risk factor for dementia.
- There is no cure for any form of dementia, except for the pseudo-dementias, which may respond to treatment.
- Risk reduction for dementia includes reducing modifiable cardio- and cerebrovascular risk factors.
- Early interventions include planning for the future in terms of advocacy and end-of-life care options.
- Pharmacological treatment is multifactorial and includes pharmacological support of cognitive function and non-pharmacological support of patients and their carer/family.
- Acetylcholinesterase inhibitors and memantine improve cognitive function, including improvements in social relationships, behaviour, engagement with the individual's environment, language and delay entry to nursing home care.
- Acetylcholinesterase inhibitors delay the neurodegenerative process.
- Future treatments include monoclonal antibodies and small molecule treatment.
- Maintaining physical and mental health by inclusion in socially and mentally stimulating activities is an important part of care.
- Healthcare professionals and carers need to adapt their communication style to best support the individual.

Definition

The word *dementia* is an umbrella term for a host of neurodegenerative diseases which cause progressive cognitive impairment, sufficient to interfere with work, social function and relationships. It is important to recognise that cognitive function is not just about memory but includes language, visuospatial and perceptual ability, thinking and problem solving, and personality. This progressive impairment is the root cause of distress for carers and family of people with dementia, as the person they love seems to change and disappear.

Epidemiology

Incidence and prevalence

Dementia is a global issue, with an estimated 47.5 million people living with dementia worldwide; this estimate is predicted to rise to more than 150 million by 2050 (Public Health England, 2016). In 2015, there were an estimated 856,700 people in the UK with dementia, with 720,251 living in England, 45,321 in Wales, 70,162 in Scotland and 20,966 in Northern Ireland (Alzheimer's Society, 2014). Established prevalence rates link the risk of dementia with increasing age, rising from 1 in 688 people younger than 65 years, to 1 in 14 people older than 65 years, to 1 in 6 older than 80 years and 1 in 3 of older than 90 years. However, in February 2016, the actual number of people in England with a recorded diagnosis in the record of their primary care doctor was 426,000, indicating a prevalence of 0.756% or 1 person in 132 (Health and Social Care Information Centre, 2016). Thus, about 41% of people with signs and symptoms of dementia in England are not yet diagnosed.

Furthermore, recent research suggests the proportion of people living with dementia has decreased by 20% over the last two decades, linked mainly to a reduction in male smoking, leading healthier lives and reduction of cardiovascular risks (Matthews et al., 2016). In the 1990s it was predicted there would be 250,000 new cases of dementia each year, whereas study findings put this at 210,000 per year (Winblad et al., 2016).

Prognosis

There is no cure for any of the dementias, with an average life expectancy post-diagnosis of 5–10 years; however, some people have survived for 20 years.

Annual UK societal costs of dementia are estimated at £26.3 billion: £4.5 billion on state social care, £11.6 billion on unpaid care, £4.3 billion on health care, £5.8 billion on individual social care and £100 million on other costs. These are higher than the cost of cancer, heart disease or stroke.

In the UK, up to one-third of Alzheimer's disease (AD) cases may be attributable to potentially modifiable risk factors, and 21.8% of AD cases could be attributed to physical inactivity. A 20% reduction in risk factors per decade could reduce UK prevalence rates by 16.2% (300,000 cases) by 2050 (Winblad et al., 2016). Table 33.1 describes the risk factors for dementia.

Table 33.1 Risk factors for dementia

Risk factors	Association
Age	Higher blood pressure in midlife Increased incidence of some diseases (encephalitis, delirium) Changes to nerve cells, DNA and cell structure Weakening of body's natural repair systems Changes in the immune system
Lifestyle factors	Smoking – doubles risk of dementia by increasing cardiovascular disease (stroke and diabetes), narrowing cerebro- and cardiovascular blood vessels, causing oxidative stress to the brain Lack of regular physical activity along with sedentary lifestyle Excessive alcohol consumption Diet high in saturated fat, sugar and salt and obesity in midlife
Concomitant disease	Parkinson's disease Stroke Type 2 diabetes High blood pressure
Genetic (small proportion of cases)	Early onset/younger people with dementia (40,000 people in UK with dementia <65 years) People with Down's syndrome are more likely to develop Alzheimer's disease in early 30s due to chromosome 21 missense Frontotemporal dementia (Pick's disease); Huntingdon's chorea

Subsequent public health strategies are aimed at people in their middle years reducing cardiovascular and cerebrovascular risks and maintaining brain function to decrease individual risks for dementia. [Table 33.2](#) outlines these protective factors. A review of combined data for brain reserve and cognitive decline from 22 studies of more than 29,000 participants demonstrated a 46% lower risk of dementia in people with high levels of mental activity than in those with low levels ([Valenzuela and Sachdev, 2006](#)).

Clinical manifestations

It is now well established that a prodromal period exists in the development of dementia, whereas in people with a genetic missense mutation, the process may be established from birth. In those with sporadic disease, the process may be triggered some 20–30 years before the signs and symptoms are displayed. Symptoms, which may be termed mild cognitive impairment (MCI), may or may not progress to a dementia. However, findings suggest that individuals with predominantly memory problems (amnesic MCI) on presentation will progress to dementia.

Table 33.2 Protective factors for dementia

Protective factor	Associated with...
Higher levels of education	Use it, don't lose it (brain function)
More mentally demanding occupations	Examples include teaching, research, mathematics, writers, accountants, lawyers, medicine
Cognitive stimulation	Doing puzzles, crosswords, learning a second language, dancing, singing
Social engagement	Being socially active improves mood, relieves stress, reduces risk of depression and reduces loneliness

Alzheimer's disease

AD is the most common form of dementia, accounting for 62% of people diagnosed with a dementia in the UK. AD was first described by Dr Lois Alzheimer in 1917 and includes early- and late-onset variants. It has been proposed that the prodromal period of AD is typically a 9-year decline in cognitive function, and part of that decline may possibly include a diagnosis of amnesic MCI. It is increasingly understood that taking active steps to reduce personal risk factors for dementia could affect this progression. There is no licensed treatment for MCI.

Causes of Alzheimer's disease

The majority of AD is of idiopathic or sporadic origin. Identified risk factors for developing AD are both modifiable and nonmodifiable and are described in [Table 33.3](#).

Genetic research in families indicates that almost 50% of individuals with AD have at least one first-degree relative with a dementia. This statement has resulted in controversy, but researchers suggest that if the patient has late-onset AD, similarly affected relatives may have died of other causes before developing AD ([Bateman et al., 2012](#)). This has led other researchers to postulate that perhaps the formation of plaque and neurofibrillary tangles is not a process of normal aging at all but in fact the early stages of AD.

Pathophysiology of Alzheimer's disease

The pathophysiology of AD is associated with an excess of intracellular neurofibrillary tangles and extracellular amyloid- β . Amyloid precursor protein is a chain of 771 amino acids found widely throughout the body, including high concentrations in platelets, where it plays an as yet unknown function.

The cholinergic system is critical to normal memory and other cognitive functions. In AD there is a selective loss of cells in the basal forebrain, and the depletion of neurons in this area correlates with memory and cognitive decline in AD. When the first mild symptoms of AD occur, there is already a significant deficit in acetylcholine. Levels eventually reduce by 40–90% in

Table 33.3 Nonmodifiable and modifiable risk factors for Alzheimer's disease

Non-modifiable	Modifiable
<p>Gender – females have greater incidence than men, but this is related to the longevity of females as compared with men</p> <p>Increasing age</p> <p>Genetic risk</p> <ul style="list-style-type: none"> • Early onset (40–55 years) linked to mutation of the amyloid precursor protein gene located on chromosome 21 (also referred to as AD1 genetic indicator) • Early onset (30–55 years) linked to mutation of the Presenilin 1 (PS1) gene located on chromosome 14; follows autosomal-dominant inheritance (also referred to as AD3 genetic indicator) • Onset (40–90 years) linked to mutation of the Presenilin 2 (PS2) gene located on chromosome 1; follows autosomal-dominant inheritance (also referred to as AD4 genetic indicator) • Familial Alzheimer's disease (onset 40–90 years or older) linked to the apolipoprotein E4 allele encoded on chromosome 19 (also referred to as AD2 genetic indicator) 	<p>Physical and cardiovascular health in middle years</p> <p>Head injury – amyloid is deposited in the brain within 24 h of injury</p> <p>Education – a high level of education is a protective factor in familial Alzheimer's disease</p> <p>High intraneuronal calcium levels lead to cell damage and ultimately cell death, which triggers amyloid deposition and formation of neurofibrillary tangles</p> <p>Ongoing intellectual activity – the 'use it or lose it' hypothesis suggests that continued learning is a protective factor in reducing the risk of developing Alzheimer's disease</p> <p>Environmental toxin as a neurotoxin rather than a causative factor (e.g. excessive alcohol intake, pesticides, aluminum levels in water or diet)</p>
Adapted from Bateman et al., (2012).	

moderate to severe AD. Other affected neurotransmitter systems are noradrenaline, dopamine, serotonin, glutamate and gamma-aminobutyric acid (GABA).

There are a number of hypotheses on the potential cause of the neuropathological processes that result in AD, and the most accepted are outlined in the following sections.

The neurofibrillary tangles hypothesis. It has been suggested that neurofibrillary tangles (NFTs) form due to the hyperphosphorylation of tau protein within the cell to form oligomers and then tangles. The tangles then impair the axonal flow of nutrients in and waste products out of the cell, resulting in cell death and dramatic loss in cholinergic neurons (Ballard et al., 2011). These cells produce acetylcholine and project diffusely into the hippocampus, basal nucleus of Meynert and entorhinal cortex.

NFTs have been found in brains of people with dementia pugilistica, in those with parkinsonism, in older people with Down's syndrome and in older people without dementia. It has been postulated that NFTs may be a pathological substrate for memory loss in AD, normal aging and MCI. Current research is focussed on the development and testing of a vaccine against NFTs which would, if successful, be aimed at preventing the AD process (Davtyan et al., 2016).

The amyloid hypothesis. The amyloid hypothesis suggests that the aberrant cleavage of amyloid precursor protein by β - and/or gamma-secretase enzymes results in amyloid- β , a peptide of 36–43 amino acids, toxic to nerve cells. AB40 is a soluble form of amyloid- β and associated with cerebrovascular plaques. A combination of the AB40 and the insoluble AB42, if not cleared, builds up to form early plaques via oligomerisation in the limbic and associated cortices. This blocks cell-to-cell transmission at synapses (Ballard et al., 2011). This affects synaptic efficacy, resulting in greater deposition of AB42, microglial and astrocyte activation and inflammatory response. This in turn leads to altered neuronal homeostasis, oxidative injury and tangle formation and ultimately in AD. Amyloid- β circulates in plasma, cerebrospinal fluid and brain interstitial fluid, mainly as soluble AB40. The extent of its

presence is now used to improve the accuracy of AD diagnosis for clinical research studies (Albert et al., 2011).

The three dominantly inherited forms of early-onset AD (defined as occurring before 60 years of age) are associated with amyloid- β , presenilin 1 (PS1) and presenilin 2 (PS2) genetic missense mutations, which alter the role of gamma-secretase, leading to an increased production of AB42. In affected people this process remains unchecked throughout life, leading to early-onset dementia. For those with sporadic AD, there is a trigger which starts this process at a later stage in the individual's life, which ultimately leads to dementia (Bateman et al., 2012).

Genetic risk factors. The apolipoprotein E (APOE) gene enables the production of a protein, apolipoprotein E, which is responsible for linking lipids and proteins together to enable the removal of cholesterol and other fats from the bloodstream. If this process is blocked, then the risk of dementia increases. There are three well-known alleles of the APOE gene: e2, e3 and e4. Greater than 50% of the population carry e3, which has a neutral role in AD development. e2, however, is rare and thought to be protective, whereas e4 increases the risk of AD, and this risk increases with the number of alleles carried. These alleles are autosomal dominant and are inherited from both maternal and paternal parents, meaning people may carry any combination of e2 with e3 or e4 or both of each allele (Ballard et al., 2011; Bateman et al., 2012).

The presence of the e4 allele increases the risk of deposition of β -amyloid in the brain from birth and subsequent development of AD, although it must be stressed that this is not a 100% risk factor – environmental, dietary and physical properties may decrease this risk. In people without the e4 allele, there is a 10–15% risk of developing AD; this rises to greater than 75% if both alleles are e4. The genetic forms of AD are described in Table 33.3. Evidence suggests that AD is the sum of inherent host factors (a genetic predisposition) and external (environmental) factor(s) which act as a neurotoxin or catalyst for the neuropathological processes. Genetic testing is not recommended at this time, although it is often included as part of clinical trials.

Table 33.4 Progression and staging of Alzheimer's disease

Progression	Clinical presentation	Associated physical problems
Early stages (1–3 years)	Recent memory impairment, forgetting names, losing direction when out, depression, impaired activities of daily living, language difficulties	Visuospatial problems (e.g. walking into things)
Middle stages (2–10 years)	Amnesia, aphasia, inability to calculate solutions, inability to problem solve, personality change, behavioural changes (e.g. wandering); psychiatric changes such as delusions; inability to bathe, eat, toilet or dress without assistance	Falls, accidents involving cooking or other activities, impaired motor skills, may forget to eat and therefore have nutritional problems, may be unable to use the toilet correctly and develop chafing due to poor hygiene and soiling.
Late stages (8–12 years)	Short- and long-term memory loss, mutism or nonsensical speech, posture becomes rigid and inflexion, complete dependence on others, seizures	Inability to communicate needs (hunger, toileting); difficulty in swallowing or chewing food; decreased immune response, susceptibility to infections increased; double incontinence; bedridden patients are at risk of pressure sores and pneumonia

The progression and staging of AD are shown in [Table 33.4](#). It is important to note that as cognitive impairment increases over time, there is matching physical deterioration, resulting in increasing frailty and vulnerability. Ultimately individuals move from relatively independent states of mobility to being bed-bound, mute and withdrawn.

Vascular dementia

Vascular dementia (VaD) is the result of ischaemic changes within the brain, associated with smoking, transient ischaemic attacks, strokes, long-term or poorly managed hypertension, atrial fibrillation and/or type II diabetes. Improved management of cardiovascular risks reduces the risk of vascular dementia.

Dementia with Lewy bodies

The cause of dementia with Lewy bodies (DLB) is not well understood, although there are proposed genetic links to the PARK11 gene, also associated with Parkinson's disease. Cases are sporadic, with no strong hereditary link, but the risk is heightened with the inheritance of the e4 allele of apolipoprotein E (APOE) as in AD.

Neuropathology

Neuropathology demonstrates the presence of abnormal collections of α -synuclein protein within the cytoplasm of Lewy bodies, which are similar in structure to those seen in Parkinson's disease. Lewy bodies are also found in Pick's disease and Huntington's chorea. Similarly, there are losses of dopamine-producing neurones in the substantia nigra and a loss of acetylcholine-producing neurones in the basal nucleus of Meynert as in AD.

There is increasing evidence to suggest that there may be a range of Lewy body disorders, with older patients more likely to develop cortical disease. Historically DLB had been viewed as a variant of AD, but it is a disorder in its own right and includes Lewy body dementia, Lewy body variant of AD, diffuse Lewy body disease, cortical Lewy body disease and senile dementia of Lewy body type.

People with DLB demonstrate an extreme sensitivity to the extrapyramidal side effects of antipsychotic medication, with a two- to threefold increase in mortality even with atypical antipsychotics. This may be explained by deficits in nigrostriatal dopaminergic neurones and may be mediated via acute blockade of postsynaptic dopamine D₂ receptors in the striatum ([McKeith et al., 2005](#)).

The rarer dementias

There are more than 100 diseases that can cause dementia; however, many are rare, and the most common of these are presented in the following sections.

Parkinson's disease dementia

Long-term follow-up of people with Parkinson's disease (PD) suggests that up to 78% will eventually develop a dementia, with symptoms such as fluctuating cognition and visual hallucinations similar to DLB. Consensus guidelines suggest that DLB and Parkinson's disease dementia are overlapping clinical syndromes and lie on different points on the spectrum of Lewy body disease, sharing common underlying neuropathological processes ([McKeith, 2006](#)). Furthermore, distinguishing DLB and Parkinson's disease dementia as separate entities may be useful in clinical practice but is of limited value in terms of investigating and treating the underlying pathology.

Frontotemporal dementia

Frontotemporal dementia (FTD), previously known as Pick's disease, is the largest cause of dementia for younger people in the UK, usually affecting people between the ages of 45 and 64. However, 3 out of 10 people with FTD develop the condition at an older age. Autopsy studies show that neurodegeneration in the frontal and temporal lobes is linked to deposition of abnormal tau proteins inside neurones, which clump together in spherical arrangements known as 'Pick bodies'.

The frontal lobes regulate personality, emotions and behaviour, as well as reasoning, planning and decision-making. The temporal lobes are involved in the understanding and production of language.

Progression rates of FTD range from less than 2 years to greater than 10 years, with people living 8 years on average after symptom onset. About 10–15% of people with FTD have a strong family history, with several close relatives in different generations affected. Typically, in these cases, FTD is inherited from a parent as a genetic missense mutation in one of three genes: MAPT, GRN or C9ORF72. The children or siblings of a parent with genetic missense mutation have a 50% chance of inheriting it. These families should be offered referral to specialist genetics service for counselling with appropriate support. In comparison, inherited early-onset AD affects less than 1 in 1000 people with AD (Warren et al., 2013).

Corticobasal degeneration

Corticobasal degeneration is a rare disease, with neurodegeneration affecting the cortex and basal ganglia, and has some overlap with FTD. The cause is unknown, but neuropathology indicates high levels of tau protein. Onset is usually between the ages of 60 and 80, with a life expectancy of 8 years post-diagnosis.

Progressive supranuclear palsy

Progressive supranuclear palsy is a rare progressive movement disorder, also known as Steele–Richardson–Olszewski syndrome. It affects many brain areas, resulting in symptoms similar to those of Parkinson’s disease. Onset is usually in the 60s, but it can affect younger people.

The cause of progressive supranuclear palsy is unknown but is associated with high levels of tau deposition in affected brain areas.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is a rare prion disease, with the most common sporadic variant normally affecting people older than 40 years. Estimates suggest the disease affects about 1 in every 1 million people each year. The trigger for sporadic CJD is unknown and could be inherited or transmitted from person to person.

More recently, the new variant CJD, typically affecting younger adults, was caused by eating meat from cattle infected with bovine spongiform encephalopathy. In new variant CJD, there may be many years between a person being infected and the development of symptoms.

HIV-associated neurocognitive disorder

HIV has adverse effects on the immune system. These include the development of neurocognitive disorders in up to half of people with HIV, called HIV-associated neurocognitive disorder (HAND). This may be a direct result of the virus’s effects on a weakened immune system, enabling infections and cancers.

Huntington’s disease

Huntington’s disease is an inherited fatal genetic brain disease. Children of a parent with Huntington’s disease have a 50%

chance of inheriting it; however, in 1–3% of cases there is no history of the disease in family members. Genetic testing is available, but the family members need appropriate support. Huntington’s disease is caused by mutations in the gene encoding the protein called huntingtin, resulting in misshaped huntingtin proteins which form aggregates with inclusion in neurons, resulting in cell death.

Multiple sclerosis

If multiple sclerosis occurs in the brain, those affected may experience varying degrees of cognitive impairment. However, the decline is not usually sufficiently severe or progressive to be termed ‘dementia’ but is referred to as ‘cognitive difficulties’.

Niemann–Pick disease type C

Niemann–Pick disease type C is a rare inherited genetic disorder. Importantly, it is not related to FTD, which is also referred to as Pick’s disease. It is caused by an inability to deal with cholesterol and other lipids. Lipid accumulates in all cells, including those in the brain.

Normal pressure hydrocephalus

Normal pressure hydrocephalus occurs when excess fluid accumulates in the brain. This does not cause pressure to build up within brain tissue.

Posterior cortical atrophy

Posterior cortical atrophy, also known as Benson’s syndrome, is a rare neurodegenerative condition where damage occurs in the posterior brain region.

Alcohol-related brain damage

Binge drinking, or drinking excessive amounts of alcohol to become drunk, over a prolonged period of time can lead to a range of conditions known as alcohol-related brain damage (ARBD), the most common of which is alcoholic dementia, previously referred to as alcohol-related dementia. This includes Korsakoff’s syndrome, also known as Korsakoff’s psychosis (Zahr et al., 2011). Recent research suggests that APoE-e4 may be associated with a higher risk of Wernicke–Korsakoff in individuals who drink heavily (Harwood et al., 2010).

The exact number of people with ARBD is not known. It is likely to be under-diagnosed due to the stigma associated with alcohol misuse and people not seeking help, together with health-care professionals’ lack of awareness of the process of ARBD. UK postmortem studies suggest ARBD affects about 1 in 200 of the general adult population. Among those with alcoholic addiction, this figure rises to one in three. It is not clear why some people develop ARBD whereas others do not.

People with ARBD tend to be middle-aged, typically in their 40s or 50s, although they can be younger or older. ARBD is thought to cause more than 10% of dementia in younger people, defined as those aged under 65. ARBD is more prevalent in

Table 33.5 Differential diagnostic features of the main dementias

Feature	Onset and progression	Early symptoms	Late symptoms
Alzheimer's disease	Insidious onset with progressive decline of cognitive and physical function	Predominantly memory loss	Emergence of aphasia and agnosia
Vascular dementia	Sudden onset with stepwise progression Periods of stability followed by an episode of sharp decline	Person has insight Emotional lability and depression Focal neurological signs	Shuffling gait with a wide base, differentiated from Parkinson's disease as has preserved arm swing, presence of seizures and continued cerebral ischaemia
Dementia with Lewy bodies	Fluctuating periods of alertness and confusion Fluctuating cognitive function	Less severely impaired recent memory Early gait disturbance and parkinsonism with falls	Hallucinations, periods of confusion and psychotic symptoms
Fronto-temporal dementia	Gradual but progressive changes in behaviour, mood and personality	Apathy, poor judgement and insight, speech/language problems	Apathy, disinhibition – including sexual, depression, euphoria

people with poor socioeconomic backgrounds and affects men more frequently than women. However, affected women develop ARBD at a younger age than men and after fewer years of alcohol misuse.

Consequences of the dementia process

Behavioural changes in dementia

As the disease progresses, the resultant neuropathological damage is associated with changes in behaviour, mood, personality and the ability to communicate effectively. As a result of this, 95% of people with a dementia develop behavioural changes, and these can be found challenging to those that care for them (informal and formal carers). These challenging behaviours are also referred to as behavioural and psychological symptoms of dementia (BPSD). Symptoms include delusions, hallucinations, agitation or aggression, depression, anxiety, elation or euphoria, apathy or indifference, disinhibition, irritation or lability, a change in eating patterns and aberrant motor behaviour (wandering). As dementia progresses, people lose the sense of whether it is day or night and subsequently disrupt carers' sleep as they get up and dressed in the middle of the night. This is called sundowning. Formal and informal carers worry about people walking away from their chair/bed and 'wandering' around, going for walks on their own (because they can get lost). However, it is important to note that all people like to move around and enjoy a walk outside. Exercise should be built into the daily routine, and dementia care environments should include areas where people can walk safely on their own. A wide variety of behaviours can be displayed which in general are not harmful. However, they can be difficult to control and are a major reason for caregiver stress and admission to long-term care.

These symptoms may be caused by the disease affecting a particular area of the brain – for example, the sexual disinhibition observed in FTD, or the inability to convey a need for fluid, food, pain relief or other symptom. It is important to note that people

with dementia may express an emotion such as sadness or happiness but not be able to remember the reason. This is because factual memory for events and learning is stored in the hippocampus which is one of the first structures affected. However, emotional memory is stored in the amygdala which generally is only affected in the late stages.

Agitation. Agitation has been defined as behaviour which is seen as disruptive but nonaggressive (e.g. moaning, pacing, crying, arguing). It ranges to aggression in its severe forms, where the person may be aggressive or endanger others or him- or herself (e.g. kicking, screaming, throwing objects, self-injury, scratching). These behaviours can be very distressing to the caregiver and are the behaviours most likely to lead to institutionalisation. Therefore, support of the carer is key. Educational programmes for carers using behavioural techniques are more effective than most pharmacological treatments (Marriott et al., 2000).

Diagnosis of the dementias

There is considerable overlap of disease states, with dementias of mixed aetiology in combination of AD and VaD, or DLB and PDD being relatively common. Currently, computed tomography (CT) and/or magnetic resonance imaging (MRI) is used to exclude treatable forms of the symptoms (e.g. space-occupying lesions, hydrocephalus or ischaemic changes). These can also be used to give a 'probable' diagnosis of dementia with reference to consensus guidelines, clinical examination and test results. Information for differential clinical and disease features which may aid a probable diagnosis is described in Table 33.5.

At present, a definitive diagnosis can only be made at autopsy or if the individual takes part in a clinical trial where lumbar punctures (to check levels of *tau*), genetic testing and positron emission test (PET) scanning or high-volumetric MRI scanning is available.

Table 33.6 Possible signs of dementia

Sign	Change displayed
Day-to-day memory	Difficulty recalling events that happened recently Although long-term memory may remain relatively unaffected, short-term memory may become badly impaired and may be identified as repeating the same questions, forgetting names and routes, and losing/misplacing items. People with dementia forget not only the specifics of an item or event but also the context.
Concentrating, planning or organising	Difficulties making decisions, solving problems or carrying out a sequence of tasks – e.g. cooking a meal, not knowing how to make a cup of tea or forgetting what order to put clothes on when getting dressed May begin to lose interest in people, objects and hobbies (e.g. sitting passively in front of the TV for hours, sleeping for long periods and neglect of personal care) Problems with tasks (e.g. working out change when paying in a shop, remembering appointments or paying bills)
Judgement	Inability to judge situations or people (e.g. putting on too many clothes on a hot day or too few on a cold day)
Language	Difficulties following a conversation or finding the right word for something. Conversations tend to be badly affected, with frequent pauses, forgetting very commonplace words, losing the thread of what is being said midsentence, and substituting unusual words (e.g. <i>hand clock</i> for <i>watch</i>).
Visuospatial skills	Problems judging distances (e.g. on stairs) and seeing objects in three dimensions. If distinct visual impairments such as inability to read or recognise signs, consider referral for occipital lobe scanning variant Alzheimer's disease.
Orientation	Losing track of the day or date, becoming confused about where they are or forgetting the way home from shopping or work
Changes in mood	Becoming frustrated or irritable, withdrawn, apathetic or anxious, easily upset or unusually sad, suspicious, depressed, or agitated. Dramatic mood swings which show noticeably more or less emotion than previously can indicate possible cause for concern. Patients may become angry if friends/family comment on such behaviour changes.
Visual hallucinations, delusions or paranoia ^a	Seeing things that are not really there and/or believing things that are not true and/or paranoid beliefs that people are stealing from them or trying to harm them in some way

^aHallucinations and paranoia are specific to certain forms of dementia, where it is the parts of the brain responsible for behaviour and emotional responses that are most affected.

General signs and symptoms of dementia

Dementia is neurodegenerative, so there is gradual onset, often noticed at times of stress or change (e.g. when admitted to hospital with an infection or when there is a change in environment such as going on holiday). The presentation of symptoms is influenced by pre-morbid personality, and those with good social skills can hide decline from relatives and carers.

Early symptoms include:

- memory loss, especially for recent events;
- difficulties with learning and/or retaining new information;
- being more repetitive;
- misplacing objects (e.g. car keys or spectacles);
- difficulty with complex tasks such as cooking, driving or dealing with finances;
- reduced ability to reason and problem-solve;
- impairment of spatial and visuospatial awareness (e.g. bumping into objects, driving accidents, getting lost in a familiar place);

- language problems, including inability to find the right word or difficulty following conversations;
- behavioural changes, including being more irritable, passive, withdrawn or suspicious.

All healthcare professionals are in a position to recognise early signs and symptoms of neurodegeneration and signpost or refer people appropriately (Table 33.6). It is also important to remember that at each stage of dementia, there is an associated decline in physical functioning, which may affect caring and require support from social services.

Classification of dementias

There is no definitive test for any dementia which is routinely available in primary care. It is a process of careful history taking; observation of the person's behaviour, cognition, mood, and

Table 33.7 Proportion of different forms of dementia in UK (Alzheimer's Society, 2014)

Different forms of dementia	%
Alzheimer's disease – includes posterior cortical atrophy	62
Vascular dementia	17
Mixed dementia – Alzheimer's disease and vascular dementia together	10
Dementia with Lewy bodies	4
Other rarer causes of dementia – includes corticobasal degeneration, Down's syndrome, HIV dementia, prion disease, Huntington's disease, alcohol-related brain disease	3
Parkinson's disease dementia	2
Frontotemporal dementia – common in people <65 years, associated with Pick's disease	2

intellectual functioning; and then the systematic exclusion of all other possible causes (i.e. a diagnosis of exclusion). It is important to note that in each country there may be a different proportion of the dementias. AD is most prevalent in the UK, whereas in Japan it is vascular dementia. This is thought to be a product of cultural, genetic and environmental confounders. [Table 33.7](#) provides details of the proportion of dementia types in the UK.

The screening process

Routine laboratory tests such as urea and electrolytes, full blood counts, thyroid function, folate, vitamin D, blood glucose or HbA1c are all undertaken to exclude possible treatable causes of cognitive decline (sometimes termed 'pseudo-dementias'), such as anaemia, thyroid disease, hyponatraemia, hypercalcaemia, hypo- or hyperglycaemia, renal impairment, serology (for venereal disease, including syphilis) and substance or alcohol misuse. Other exclusions include investigating confusion associated with the start or withdrawal of a medication or substance (legal or illegal). A midstream urine (MSU) test excludes delirium associated with urinary tract infections, and a chest and skull X-ray can exclude a chest infection or a space-occupying lesion (SOL). If available, head MRI for quantification of brain changes and the presence of space-occupying lesions, ischaemic lesions or other trauma should be undertaken. An MRI can also be used to identify the extent of neurodegeneration in a particular region of the brain, which can aid determination of the final diagnosis.

There is increasing sophistication in the use of positron emission tomography (PET) scanning, which allows greater accuracy of diagnosis by the distribution of neurodegeneration in brain regions and the deposition of β -amyloid and intracellular neurofibrillary tangles (NFTs) throughout the brain. Lumbar puncture samples are also often used to measure levels of various proteins, including tau and β -amyloid. However, these are not routinely used in practice due to cost, lack of expertise and possible adverse

Box 33.1 Differential diagnosis of dementia mnemonic

S	Systemic disease

effects on the individual from invasive procedures. Consensus guidelines outline definitive ranges for such measurements and are used to establish diagnosis in people entered into clinical trials and define outcome measures of efficacy and appropriateness ([Albert et al., 2011](#); [Sperling et al., 2011](#)).

The most important part of the diagnostic procedure is taking an accurate and detailed history, paying particular attention to intellectual functioning and neurological symptoms. Details of social and occupational history are important to discover. Athletes with a history of head injury or concussion (e.g. boxers) have a high risk of developing pugilistic dementia. Heavy alcohol drinkers may have ARBD. Interviewing carers or relatives is especially important because individuals may be unaware they have a memory or cognitive problem, and the process may also highlight a family history of dementia.

A useful mnemonic to remember the differential diagnosis of dementia is shown in [Box 33.1](#).

Assessing cognitive function

Psychological tests, including a mini-mental state examination (MMSE), usually the Folstein ([Folstein et al., 1975](#)), assessment of perception (visuospatial deficits, mood, executive function, memory) and assessments for depression are also part of the differential diagnostic process. They are also used to monitor severity, progression of the disease and response to pharmacological and non-pharmacological treatments interventions. Examples are shown in [Table 33.8](#) and also in the joint guidance on assessing cognition from the [Alzheimer's Society and Royal College of General Practitioners \(2015\)](#).

Diagnostic features of Alzheimer's disease

Key features include an insidious onset of symptoms, predominantly memory loss in the early stages. Progressive cognitive and physical decline is observed, with the emergence of aphasia and agnosia (failure of recognition) in later stages, where good principles of palliative care are needed. The 10 warning signs of AD are described in [Table 33.9](#).

Ascertaining severity of Alzheimer's disease

The previously noted investigations can be supplemented by clinically based assessments such as biographical review, examples of which include the Clinician Interview Based Impression of

Table 33.8 Validated scales to test cognition

Scale	Overview of scale	Time to complete	Cutoff point for dementia
Abbreviated Mental Test Score (AMTS)	A 10-item scale, validated in hospital but used in UK primary care	<5 min	6–8/10
6-Item Cognitive Impairment Test (6CIT)	Three orientation items: count backwards from 20, months of the year in reverse, learn an address Validated in primary care	<5 min	8/24
Mini-Cog	Three-item word memory and clock drawing Validated in primary care Low sensitivity	2–4 min	5/8
General Practitioner Assessment of Cognition (GPCOG)	Developed for primary care and includes a carers' interview	5 min	Part 1: 5–8/9 complete part 2, 0–/9 cognitive impairment Part 2: 0–3/6 cognitive impairment
Montreal Cognitive Assessment Scale (MoCA)	Tasks are executive function and attention, with some language, memory and visuospatial skills Validated in many conditions, including mild cognitive impairment, Alzheimer's disease and Parkinson's disease dementia	10 min	26/30
Addenbrookes Cognitive Examination–III (ACE)	Validated in 5 domains: attention, memory, fluency, language, visuospatial	10–20 min	82–88/100
Folstein Mini-Mental State Examination (MMSE)	Eleven-item measure of cognitive functioning and its change that has been extensively studied and has good validity Less effective for dementia with Lewy bodies and frontotemporal dementia due to its focus on memory	10 min	≤24/30 Cut-point not valid in different cultures and in particularly highly educated or uneducated participants

Table 33.9 Ten warning signs for Alzheimer's disease

Warning sign	Signs of normal aging
Memory loss that disrupts daily life Forgetting recently learned or inability to learn new information; repeatedly asking for the same information	Sometimes forgetting names or appointments but remembering them later
Challenges in planning or problem solving Changes in managing finances or following a plan, taking longer to do things	Making occasional errors when balancing a cheque-book or household accounts
Difficulty completing familiar tasks at home, work or leisure Getting lost driving to familiar places; difficulty with project management at work; difficulty remembering rules of a favourite game	Occasionally needing help with settings on microwave or television
Confusion with time or place Losing track of dates, seasons or passage of time; may forget where they are or how they got there	Getting confused about the day of the week but working it out later
Trouble understanding visual images and spatial relationships An early sign and includes trouble reading, judging distance and determining colour or contrast; may also present as hallucinations; distorted perceptions (e.g. passing a mirror and thinking someone else is in the room)	Vision changes related to cataracts
New problems with communication Difficulty following or maintaining conversation; problems finding or using the correct word	Sometimes having trouble finding the right word

Continued

Table 33.9 Ten warning signs for Alzheimer's disease—cont'd

Warning sign	Signs of normal aging
Misplacing items May put items in unusual places (spectacles in the fridge); may accuse people of stealing; cannot retrace steps to find the item	Misplacing things like spectacles or TV remote occasionally
Impaired or reduced judgement Make poor decisions, often involving money or large donations to telemarketers; less attention to personal grooming	Making a bad decision occasionally
Withdrawal from work or social activities May have trouble keeping up with favourite activities or remembering how to do them; may withdraw socially because of these changes	Sometimes feeling weary of work, family and social obligations
Changes in mood or personality May become confused, suspicious, depressed, fearful, anxious or even delusional; may be easily upset doing routine tasks when out of their comfort zone	Developing a specific way of doing things and being irritable when a routine is disrupted

Adapted from [Alzheimer's Association \(2009\)](#).

Severity (CIBIS) and the Clinician Interview Based Impression of Change (CIBC). The latter can be adapted to include input from the carer (CIBIC-plus).

Severity in AD has historically been defined by the Folstein Mini-Mental State Examination (MMSE) score:

- normal cognitive function: MMSE 27–30;
- mild AD: MMSE 21–26;
- moderate AD: MMSE 10–20;
- moderately severe AD: MMSE 10–14;
- severe AD: MMSE <10 ([National Institute for Health and Care Excellence \[NICE\], 2016](#)).

There is continued controversy about the use of the Folstein MMSE because it was originally designed to measure cognitive function in people with mental illness, including schizophrenia, but not dementia ([Folstein et al., 1975](#)). In March 2009 a judicial review highlighted the potential discriminatory effects of the MMSE as a rating scale for the start and withdrawal of treatment because of its limitations in people with previously poor intellect, non-white Caucasian ethnicity and low socioeconomic groups. This is due to the tendency for the MMSE to suggest false negatives in these groups. It has also been found to not be sensitive in people with previously high intellect because it gives false negatives. However, the Folstein MMSE is still used, but it is now copyrighted and incurs a charge for use ([Folstein et al., 1975](#)).

Diagnostic features of vascular dementia

VaD generally presents with sudden onset, and the dementia follows a stepwise progression. This means that there are periods of cognitive stability followed by periods of rapid decline. The neuropathology of VaD is distinctive, with either localised or generalised areas of brain atrophy and ventricular dilatation and associated areas of cerebral ischaemia and evidence of arteriosclerosis in major vessels. This cerebral damage results in focal neurological signs (absent in AD), and commonly associated clinical features include emotional lability, depression, early memory problems, apraxia, agnosia, dysarthria and dizziness.

The types of symptoms exhibited after damage to a particular area of the brain in VaD or any other dementia, which also influences behaviour, can be seen in [Table 33.10](#).

Generally, insight is more preserved than in AD, but this often leads to increasing distress for patients because they are more aware of the prognosis of the disease. In late-stage VaD, there is a shuffling gait, which can be distinguished from Parkinson's disease by its broad base and preserved arm swing. Fitting and continued episodes of cerebral ischaemia are also late features of this disorder.

Diagnostic features of dementia with Lewy bodies

People with DLB exhibit typically delirium-like cognitive states with periods of fluctuating confusion, which vary in duration and severity from person to person and from time to time within an individual.

Visuospatial, visuo-perceptive and frontal deficits are common. Memory impairment is often less than in the other dementias in the early stages.

Compared with people with AD, people with DLB are more likely to have clouding of consciousness, significant Parkinsonism features, less severely impaired recent memory and a large number of different psychotic features. DLB is diagnosed on the presence of central features and core features; two of the latter are needed for a diagnosis of probable DLB and one for possible DLB ([McKeith et al., 2005](#)).

The central feature is progressive cognitive decline of sufficient magnitude to interfere with normal social and occupational function and including one or more of the following core features:

- fluctuating cognition,
- recurrent visual hallucinations (usually people or animals),
- spontaneous features of parkinsonism.

Other features which may support a diagnosis of DLB include repeated falls, syncope, transient loss of consciousness, systemised delusions, hallucinations in other modalities, rapid eye movement (REM) sleep behaviour disorder and depression. However, less likely to be present are a history of stroke or any

Table 33.10 Area of brain degeneration and associated behaviour change in the dementias

Site of brain degeneration/lesion	Change in behaviour exhibited
Frontal lobe Involving motor cortex Bilateral	Behaviour – disinhibited, over-familiar, tactless, over-talkative, jokes, pranks, errors of judgement, sexual indiscretions, disregard for the feelings of others Mood – fatuous and euphoric Concentration and attention – reduced Insight – impaired Contralateral spastic paresis or dysphasia, optic atrophy same side, anosmia, grasp reflex reduced Urinary incontinence
Parietal lobe Nondominant lobe affected Dominant lobe affected	Psychiatric changes less likely, neuropsychological disturbances often resembling hysteria Visuospatial difficulties Dysphasia, motor and dressing apraxias, right–left side disorientation, finger agnosia, agraphia, body image disorder
Temporal lobe Unilateral lesion/degeneration Bilateral If dominant lobe affected	Sometimes asymptomatic Personality change resembling frontal lobe symptoms but often accompanied by intellectual deficits and neurological signs Emotional instability and aggressive behaviour Associated with epilepsy and increasing schizophrenic-like disorder Specific learning impairment – in right-handed people, verbal skills affected; in left-handed people, nonverbal skills affected Amnesic syndrome and visual field defects Language and intellectual impairment
Occipital lobe	Disturbance in visual recognition, often misdiagnosed as hysteria Complex visual hallucinations, often mistaken for non-organic mental illness
Corpus callosum	Severe and rapid intellectual deterioration
Diencephalon and brainstem	Amnesic, hypersomnia, akinetic mutism Progressive intellectual deterioration, emotional lability with euphoria Abrupt outburst of temper, excessive eating, endocrine/pituitary disorder

other physical illness or brain disorder sufficient enough to interfere with cognitive performance.

The fluctuation in cognition pattern is associated with:

- hallucinations, usually visual but also auditory;
- periods of confusion and attention deficit;
- other psychotic symptoms;
- early gait disturbances;
- extrapyramidal features, such as rigidity, bradykinesia, tremor and fixed posture (i.e. signs of parkinsonism and Parkinson's disease) (McKeith et al., 2005).

Diagnostic features of the rarer dementias

Diagnostic features of Parkinson's disease dementia

A differential diagnosis is made on the following criteria:

- Those people with Parkinson's disease who develop a dementia more than 12 months after the initial motor symptoms should be diagnosed with Parkinson's disease dementia.
- If the dementia precedes the motor symptoms or the duration of the motor symptoms is less than 12 months, then the diagnosis is DLB (McKeith, 2006).

Diagnostic features of frontotemporal dementia

Age is a diagnostic factor, with 7 out of 10 people with FTD aged between 45 and 64 years, as well as the presence of four main variants:

- behavioural variant;
- semantic dementia deficits in verbal and nonverbal understanding of memory;
- progressive non-fluent aphasia, a language disorder in which people have problems speaking;
- FTD associated with motor disorder, including motor neurone disease, corticobasal degeneration and progressive supranuclear palsy.

Diagnostic features of corticobasal degeneration

Early presenting symptoms affect movement and include stiffness, jerky movements and a unilateral inability to control hand movement. Eventually this affects other limbs, leading to loss of balance and coordination, and is also associated with cognitive deficits, including memory loss, perceptual difficulties and difficulties in swallowing and speaking.

Diagnostic features of progressive supranuclear palsy

The tau pathology results in paralysis of eye movements (causing double vision), affecting balance control and resulting in frequent falls. Other symptoms include stiff or slow movements, difficulties walking and speaking, swallowing problems and personality changes. A parkinsonian-like tremor may be present, but it is much less prominent than in Parkinson's disease.

A small proportion of people with progressive supranuclear palsy develop an overlapping condition with FTD, but the majority experience cognitive difficulties rather than a dementia syndrome. This cognitive impairment may affect the speed of thought processes and memory, but affected individuals will remain aware of what is going on around them.

Diagnostic features of Creutzfeldt–Jakob disease

In sporadic CJD, the disease progression is rapid over a few months, with early symptoms including minor lapses of memory, mood changes and loss of interest. Within weeks, the person may experience clumsiness, feel muddled, become unsteady when walking, and have slow or slurred speech. Symptoms progress to jerky movements, shakiness, stiffness of limbs, incontinence and loss of the ability to move or speak. By this stage, the person is unlikely to be aware of his or her surroundings or disabilities. The majority of people affected by CJD usually die within 6 months of their early symptom development.

Diagnostic features of HIV-associated neurocognitive disorder

Cognitive difficulties include mild deficits in short-term memory, learning, thinking, concentration and reasoning.

Diagnostic features of Huntington's disease

This neurodegeneration starts in the striatum, which is why first symptoms depict abnormal movements, including twitches and muscle spasms and problems with balance and coordination. Other symptoms include depression, mood swings, irritability and cognitive impairment, including difficulties with concentration, planning and organisational skills. The age of onset and disease course vary for each person, and dementia can occur at any stage of the illness. Some may experience short-term memory loss or develop obsessive behaviours. Unlike in AD, people with Huntington's disease dementia continue to recognise people and places until the very late stages of the disease.

Diagnostic features of multiple sclerosis cognitive difficulties

Symptoms include memory, concentration and problem solving. Emotional problems include mood swings and personality changes.

Diagnostic features of Niemann–Pick disease type C

Niemann–Pick disease type C mainly affects school-age children but can occur at any time, from early infancy to adulthood, and symptoms start with progressive loss of movement and difficulties with walking and swallowing.

Dementia occurs most commonly in those people who develop symptoms in late adolescence or early adulthood, with the main symptoms including confusion, memory problems and difficulties in concentrating and learning.

Diagnostic features of normal pressure hydrocephalus

Symptoms include difficulties with walking, dementia syndrome and urinary incontinence. Generally, there is no cause, but it may develop after recovery from a head injury, brain haemorrhage or severe meningitis.

Diagnostic features of posterior cortical atrophy

Initially, people with posterior cortical atrophy tend to have a relatively well-preserved memory but experience visual problems, such as difficulty recognising faces and objects in pictures, which then affect literacy and numeracy. Symptoms of posterior cortical atrophy occur in the mid-50s or early 60s, but diagnosis may take longer because of the subtle onset.

Diagnostic features of alcohol-related brain damage

ARBD is defined as long-term decline in memory or thinking caused by excessive alcohol use resulting in thiamine deficiency and neurodegeneration associated with the toxicity of alcohol itself on neurons. Associated alcohol misuse factors include repeated head injuries sustained from falls or fights and associated damage to the cardiovascular system, including raised blood pressure and cholesterol. However, these are all also risk factors for other dementias.

Treatment of dementia

Alzheimer's disease

Currently there are two pharmacological groups licensed for the treatment of the symptoms of AD: the acetylcholinesterase inhibitors (AChEIs) donepezil, rivastigmine and galantamine, and the *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine. The [NICE \(2016\)](#) technology appraisal guidance for prescribing donepezil, galantamine, rivastigmine and memantine states that treatment aims are to promote independence, maintain function and treat symptoms, including cognitive, non-cognitive (hallucinations, delusions, anxiety, marked agitation and associated aggressive behaviour), behavioural and psychological symptoms. Donepezil, galantamine and rivastigmine are all recommended as treatment options for managing mild and moderate AD. Memantine is recommended as an option for managing moderate AD for

people who cannot take AChEIs and as an option for managing severe AD. Information to guide the prescribing of medicines for dementia is shown in [Table 33.11](#).

Acetylcholinesterase inhibitors

Acetylcholinesterase inhibitors exert their pharmacological activity by inhibiting the enzyme acetylcholinesterase to increase the concentration of acetylcholine at sites of neurotransmission.

Galantamine also enhances the action of acetylcholine on nicotinic receptors. Although these agents belong to the same group, they all produce their pharmacological effect in a slightly different way. Therefore, if a response to one agent is not seen, it is justifiable to try another. This also applies to the individual experience of adverse effects.

AD is progressive, which means that there will be less acetylcholine produced throughout the course of the disease. At the start of treatment with an AChEI, patients usually improve from

Table 33.11 Prescribing and monitoring medicines for dementia

	Donepezil	Rivastigmine	Galantamine	Memantine
Activity	Reversible acetylcholinesterase inhibitor activity, dose-dependent activity Greater selectivity acetylcholinesterase	Pseudo-irreversible with greater selectivity acetylcholinesterase Dose-dependent activity	Reversible competitive AChEI with enhanced action of acetylcholine on muscarinic receptors Dose-dependent activity	Uncompetitive NMDA-receptor antagonist which modulates pathological levels of glutamate
Dosing	Start at 5 mg once daily and increase to 10 mg once daily after 4 weeks Evening dosing, just before retiring; if insomnia and vivid dreaming, change to morning.	Start 1.5 mg twice daily with morning and evening meals If well tolerated at 2 weeks, increase to 3 mg twice daily Subsequent increases to 4.5 mg and then 6 mg twice daily based on good tolerability and minimum 2 weeks of treatment before dose increase	Initially 4 mg twice daily for 4 weeks increasing to 8 mg twice daily for 4 weeks to maintenance dose of 12 mg twice daily	5 mg once daily, increasing by 5 mg/week to a maximum of 20 mg once daily If sedation occurs, change to an evening dose to aid sleep
Forms available (UK)	5 mg and 10 mg tablets Oral solution 1 mg/1 mL Orodispersible tablets 5 mg, 10 mg	Capsules 1.5 mg, 3 mg, 4.5 mg, 6 mg Oral solution 2 mg/1 mL Patches 4.6 mg/24 h, 9.5 mg/24 h, 13.3 mg/24 h	Immediate-release tablets 8 mg or 12 mg twice-daily dosing Oral solution 4 mg/1 mL Modified release capsules; 8 mg, 16 mg, 24 mg once daily	Tablets 5 mg, 10 mg, 15 mg, 20 mg film Oral solution 10 mg/1 mL sugar-free
General	Low side-effect profile (nausea 14%, vomiting 8% and diarrhoea 12%)	Low side-effect profile but may cause severe anorexia in some and weight loss (nausea 47%, vomiting 31% and diarrhoea 19%) Licensed for use in Parkinson's disease dementia	Low side-effect profile (nausea 24%, vomiting 13% and diarrhoea 9%)	Low side-effect profile: constipation, dizziness, diarrhoea. Uncommon side effects include abnormal gait, confusion, fatigue, hallucinations
Pharmacokinetics	Peak concentration 3–4 h post-dose $t_{1/2} = 70$ h (steady state in 3 weeks) Linear pharmacokinetics Metabolised in liver CYP450 system, modify dose in mild to severe hepatic impairment Renally excreted Food does not affect absorption 95% protein bound	$t_{1/2}$ approximately 2 h Inhibition lasts 10 h Renal excretion of rivastigmine and inactive metabolites involving cytochrome isoenzymes: CYP1A2, CYP2D6, CYP3A4/5, CYP2E1, CYP2C9, CYP2C8, CYP2C19 or CYP2B6 CYP450 minimally involved in metabolism Dose adjustment in moderate hepatic and renal impairment may be necessary Food delays absorption and affects AUC Protein binding 40%	Serum max 0.5 to 1 h $t_{1/2}$ 7–8 h Reduce dose in moderate hepatic impairment and avoid in severe impairment Avoid if eGFR <9 mL/min/1.73 m ² Food affects absorption but does not affect extent of absorption Protein binding 18% Linear pharmacokinetics in dose range of 4–16 mg twice daily	t_{max} between 3 and 8 h Linear pharmacokinetics No CYP450 catalysed-metabolism 90% renally excreted If moderate renal impairment, titrate to 10 mg, and if tolerated, increase with monitoring to 20 mg In severe renal impairment, maximum dose 10 mg daily Food does not affect absorption 45% protein bound

Table 33.11 Prescribing and monitoring medicines for dementia—cont'd

	Donepezil	Rivastigmine	Galantamine	Memantine
Cautions	Asthma, COPD, sick sinus syndrome, supraventricular conduction disorders, susceptibility to peptic ulcers Common adverse effects mainly cholinergic, especially GI, also excessive mucous production and leg cramps	Asthma, COPD, sick sinus syndrome, supraventricular conduction disorders, susceptibility to peptic ulcers Common adverse effects mainly cholinergic, especially GI, also excessive mucous production and leg cramps If treatment is interrupted >3 days, re-initiate at 1.5 mg twice daily to reduce adverse effects (vomiting) Skin application-site reactions may occur with patch, mild or moderate in intensity Not an indication of sensitisation but may lead to allergic contact dermatitis	Asthma, COPD, sick sinus syndrome, supraventricular conduction disorders, susceptibility to peptic ulcers Common adverse effects mainly cholinergic, especially GI, also excessive mucous production and leg cramps Stevens–Johnson syndrome and acute generalised exanthematous pustulosis have been reported – informed patients to discontinue at the first sign of a rash	Avoid in severe hepatic impairment Avoid concomitant NMDA antagonists (e.g. amantadine, ketamine, dextromethorphan) Caution if history or diagnosis of epilepsy or seizures
Pharmacodynamic cautions	Cholinesterase inhibitors (cholinomimetics) should not be given concomitantly with other cholinomimetics, and they have the potential to antagonise the effect of anticholinergic medication. If anticholinergic medications such as atropine are abruptly stopped, there is a potential risk of exacerbation of cholinesterase inhibitors effects. Pharmacodynamic interactions with medicinal products that significantly reduce the heart rate, such as digoxin, β -blockers, certain calcium-channel blocking agents and amiodarone are possible, and caution should be taken with medicinal products that have potential to cause torsades de pointes. In such cases, an ECG should be considered. An exaggerated response to succinylcholine-type muscle relaxation during anaesthesia could occur.			
Always check in the latest Summary of Product Characteristics because this is more explicit than in the BNF for interactions with other medication. AChEI, Acetylcholinesterase inhibitor; AUC, area under the curve; BNF, British National Formulary; COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; eGFR, estimate of glomerular filtration rate; GI, gastro-intestinal; NMDA, N-methyl-D-aspartate; t_{max} , time to maximal response; $t_{1/2}$, half-life of a drug.				

pretreatment function and assessment scores. As the disease progresses, the amount of acetylcholine produced will be less than at pretreatment, so individual patient performance will decline, eventually to a stage where the agent will seem to have little clinical effect. One of the difficulties with measuring improvement or response to a treatment is that because the disease is progressing, signs and symptoms may seem to worsen rather than improve. However, AChEIs ensure that any acetylcholine that is produced (at any stage of the disease) will be available for neuronal transmission for longer. This means that the symptoms of AD, such as functions in activities of daily living, cognitive function and behaviour, will be alleviated to some extent for the time that the patient remains on treatment. Each of these agents has different formulations which may help people with swallowing difficulties or problems with dose titration.

Cautions for use. AChEIs should be prescribed with caution in patients with ‘sick sinus syndrome’ or other supraventricular cardiac conduction conditions, patients with concomitant asthma or obstructive pulmonary disease and those with, or at risk of, peptic ulcer disease. Rivastigmine should be prescribed with caution in patients with renal impairment or mild to moderate hepatic impairment.

All AChEIs cause gastro-intestinal effects such as diarrhoea, muscle cramps, fatigue, nausea, vomiting, insomnia and

dizziness. These are generally mild and transient, and they often disappear within a few days of continued treatment. However, in some patients, these effects may be severe and result in significant weight loss. To reduce these effects, the medication can be taken after food, and/or an anti-emetic may be co-prescribed. Another approach is extending the time period required to reach the maximum therapeutic dose for such patients. If there is no history of Parkinson’s disease or DLB, then long-acting metoclopramide may be given during the dose titration period. The alternative for those patients with Parkinson’s disease or DLB is domperidone at 10–20 mg three or four times daily.

Selection of any concomitant medication for a person with dementia should include an analysis of its propensity to cause antimuscarinic effects because this interferes with memory and may exacerbate or cause confusion. Examples include hyoscine, oxybutynin, procyclidine, antipsychotics (including some atypicals), tricyclic antidepressants, furosemide, digoxin and cimetidine.

Controversies associated with treatment. Numbers needed to treat for AChEIs range from 3 to 7 at low dose and delay disease progression by at least 6 months, with increasing evidence from clinical practice that some patients benefit for periods of greater than 7 years (Livingston and Katona, 2000). There is robust evidence demonstrating that these agents delay the need

for institutionalisation of the person with dementia by making it easier for the carer to provide care in the home environment (Geldmacher et al., 2003).

The heterogeneous nature of AD itself and the fact that many people have a mixed dementia syndrome imply that each patient may have a unique set of symptoms which one medication is not able to address.

Stopping and changing treatment. If a patient seems to have no improvement in objective scores but also no deterioration, it could be argued that the neurodegenerative process is being held at steady state. Therefore, the agent should be continued. If a patient has failed to tolerate the maximum effective dose of a particular agent over a 3-month assessment period, an alternative should be considered.

If withdrawing an AChEI, evidence suggests that patients should be carefully reviewed for the next 48–72 hours and for 2 weeks after discontinuation. This is because when an AChEI is withdrawn, the person with dementia can rapidly decline, and it then becomes apparent that the medication was producing effects in areas that had not been previously acknowledged. Dementia is a syndrome affecting many parts of a person's cognitive function, including personality, communication and behaviours, as well as memory. Just because a poor response in memory is seen, this does not mean the medicines are not being effective in other aspects. If the medicines are restarted within 2 weeks, patients often return to their level of function before withdrawal. If the period before restarting is longer than this, the deterioration appears to remain, although further progression may be halted for a further period of time if medication is restarted.

N-Methyl-D-aspartate receptor antagonist – memantine

Memantine is a voltage-dependent, moderate-affinity uncompetitive NMDA-receptor antagonist. It blocks excessive calcium ion influx into the neuron to prevent associated neuronal death but allows normal physiological functioning. It is licensed for the treatment of people with moderate through to severe AD. Studies demonstrate significant improvement in cognition and functioning (activities of daily living) global outcomes and also that fewer people taking memantine develop agitation (Hermann et al., 2011).

Memantine is licensed for use in patients with moderate and severe AD and may be co-prescribed with AChEIs dependent on specialist advice. It should also be considered at mild stages of AD if AChEIs cannot be tolerated or are contraindicated (NICE, 2016).

Emerging treatments for Alzheimer's disease

Since a Global Summit on Dementia in 2013, in response to the World Health Organization report (WHO, 2012), there has been wider international collaboration on potential treatments and sharing of information. Currently, there are several compounds in 3- to 4-year phase III clinical trials looking at the prevention of amyloid and tau deposition using monoclonal antibodies.

Monoclonal antibodies. Monoclonal antibodies clear toxic amyloid- β directly or by microglia and astrocyte activation. There

are currently five fully human monoclonal antibodies in clinical trials (olanzumab, ducanumab, gantenerumab, crenezumab and Biogen/Eisai's BAN2401), all with slightly different modes of action. Some of the difficulties of treatment with monoclonal antibodies are that they possess limited brain bioavailability and can cause immunogenicity and serious adverse effects such as cerebral oedema.

Small molecules. Small molecules aid in prevention and treatment by reducing amyloid- β production, tau aggregation or neuroinflammation. Examples include gamma-secretase and β -secretase modulators to reduce aberrant cleavage of amyloid precursor protein (APP); inhibitors of tau aggregation; and tau vaccines and azeliragon, an antagonist of the receptor of advanced glycation end products (RAGE), which leads to inflammation and oxidative damage when occupied. RAGE also mediates transport of amyloid- β from the blood into the brain (Connelly, 2015).

Other targets. Other targets include the repositioning of agents currently used to treat hypertension (calcium channel blockers) and diabetes (pioglitazone), as well as exploring the effect of insulin resistance on brain function (Kim, 2015).

Treatment of rarer dementias

For all rarer dementias, there is currently no cure and generally no licensed treatment; consequently, management is symptomatic, combining medication, physiotherapy, occupational therapy and speech and language support. The exceptions are as follows:

- Rivastigmine is licensed for use in Parkinson's disease dementia.
- The current triad of antiretroviral medication regimen has resulted in a reduction in HIV-related dementia to approximately 2%, from 20% to 30% (Alzheimer's Society, 2015a).
- If normal pressure hydrocephalus is diagnosed and treated early with cranial surgery to drain excess fluid, symptoms generally improve after surgery, with some people making an almost complete recovery. In the majority of these cases, AD is the cause of posterior cortical atrophy; therefore, AChEIs and/or memantine may be of benefit.
- In ARBD, treatment is based on the person staying alcohol-free and rehabilitation from either dementia services, acquired brain injury services or the community mental health team. Any improvement in the person's abilities is usually greatest in the first 3 months of abstinence but can continue for 2–3 years. About 25% of people affected by ARBD make a very good recovery, with about 50% achieving partial recovery and needing support to manage their lives but possibly still being able to live in their own homes or in sheltered housing. The final 25% make no recovery and generally require long-term residential care (Alzheimer's Society, 2015b).

Treatment strategy for behavioural and psychological symptoms of dementia

First-line treatment for any challenging behaviour is either a psychological or alternative therapy intervention (NICE and Social Care Institute for Excellence [SCIE], 2011). These interventions should be given sufficient chance to exert an effect before trying

Box 33.2 Potential causes of behavioural change

- Depression
- Pain (remember that patients walk into objects)
- A superimposed acute confusional state (delirium) caused by infection (chest and urinary tract infections are most common)
- New medication being started or one stopped (including purchased and recreational, e.g. alcohol)
- Side effect or withdrawal effect of a medicine
- Communication problems (check glasses for correct prescription/clean; hearing aids [battery/turned on], denture use)
- Aggression might indicate the person wants to communicate but cannot and becomes frustrated
- Recent change in environment/staff/routine
- Review to determine if this is a common trigger (antecedent); linked to a behaviour
- Identify what changes this behaviour (e.g. distraction)

an alternative. If they are effective, then the person should just be monitored. It is important to remember that the disease is always progressing, and therefore challenging behaviours will stop or change. **Box 33.2** details the possible causes of behavioural change.

Psychological and alternative therapies. Psychological and alternative therapies are first-line non-pharmacological treatment options and include adapting the environment (e.g. lighting, space to walk, colour schemes, access to outdoors). Behavioural interventions include distraction, reality orientation, occupational activities, reminiscence, cognitive stimulation and singing. Any possible underlying causes should be explored (e.g. pain, anxiety, depression, a recent change or upsetting event). Lavender oil (aromatherapy and massage) and melissa oil (aromatherapy) have both demonstrated significant improvement in agitation versus placebo (Fu et al., 2013).

Improving the staff knowledge of behavioural and psychological symptoms of dementia (BPSD) and how to manage them using non-pharmacological methods has been shown to result in a sustained 50% reduction in the use of antipsychotics over a year. In addition, improving social interaction also resulted in reduced rates of prescribing for patients with severe dementia (Fossey et al., 2006).

More importantly, treating unrecognised pain was found to reduce agitation significantly, as well as other neuropsychiatric symptoms (Husebo et al., 2011).

Behavioural treatment and carer support are priorities in managing sundowning. These are in addition to minimising napping during the day, regular exercise and establishing a day and night routine. Use of bright light (Lux) in the morning can reduce the incidence of agitation in the evening. Small studies have shown that people with dementia who receive light therapy in winter months display reduced behavioural problems such as agitation (NICE and SCIE, 2011).

Increasingly, forms of psychotherapy and modified cognitive-based therapy are being used with some success in people with dementia in the mild to moderate stages (Junaid and Hegde, 2006). Other psychosocial interventions include reminiscence and/or validation therapy; interactions with animals, music and children; and cognitive stimulation therapy (Toh et al., 2016).

Short-term pharmacological management of behavioural and psychological symptoms of dementia. If the behaviours are anxiety or mood related, then second-line treatment is low doses of selective serotonin reuptake inhibitors (SSRIs). These have reduced antimuscarinic effects compared with tricyclic antidepressants, and sertraline is the safest in terms of cardiovascular risks.

Occasionally an antipsychotic may be appropriate if all other avenues have been tried and the individual is a danger to him- or herself or others and/or is extremely distressed. Risperidone is the only licensed antipsychotic in the UK for the treatment of severe aggression in AD which has not responded to other treatments, but it can only be prescribed for a maximum period of 6 weeks. The [Royal College of Psychiatrists \(2016\)](#) recommend that the treatment decision is made by a specialist in dementia after discussion with the person's carer and/or family and the multidisciplinary team, and the reason recorded in the patient's medical record. The lowest dose producing the desired effect should be used, and the continued need should be reviewed regularly and the treatment discontinued when appropriate.

Longer-term prescribing of antipsychotics. If a challenging behaviour continues and requires longer-term management, then an alternative to an antipsychotic must be considered because rates of mortality are increased over those who do not take long-term antipsychotics. The long-term negative outcomes of being prescribed an antipsychotic in dementia were shown in the DAART-AD trial (Ballard et al., 2009). This study identified that at 24 months, the survival rate for those receiving an antipsychotic was 46% compared with 71% in the placebo arm; 36 months' survival was 30% compared with 50%; and at 42 months, it was 26% compared with 53%.

Potential alternatives include acetylcholinesterase inhibitors, memantine, citalopram, gabapentin and pregabalin. If highly antimuscarinic agents are initiated, monitoring is required because they reduce cognitive functioning by reducing cholinergic load and are linked with increased mortality and morbidity (Fox et al., 2011). People with dementia tend to be very sensitive to any centrally acting medication, and the prolonged action of sedatives increases the risk of falls. Therefore, if necessary, the smallest possible dose should be prescribed for the shortest time.

Patient care

Safer medicines use

Two-thirds of prescribing of antipsychotics in people with dementia is inappropriate and associated with increased morbidity and mortality for as long as it is prescribed. Both typical and atypical antipsychotics are associated with large side-effect profiles, with numbers needed to harm ranging from 4 to 13. Deaths related to antipsychotic prescribing are associated with cerebrovascular and cardiovascular events, as well as pneumonia (Wang et al., 2005).

If highly antimuscarinic agents are initiated, monitoring their effect is important because they reduce cognitive functioning by

reducing cholinergic load and are linked with increased mortality and morbidity (Fox et al., 2011).

Medication should be reviewed regularly to reduce the presence of iatrogenic disease and to gain maximum benefit from medicines for dementia and cognitive functioning by lessening the use of highly antimuscarinic medication. It is important to ensure that the carer (with the permission of the person with dementia) is also involved in all aspects of medicines use because the carer is the person ensuring adherence with any medication regimen. For advice on medicines optimisation, please see Table 33.12. When the disease becomes end stage, then there should be a judicial review of all medication, and the principles of good palliative care should be put into place.

Preventing dementia

Reducing cardiovascular risk

If 1000 people with hypertension were treated with adequate treatment for 5 years, then 19 cases of dementia would be prevented (Kelly et al., 2009).

Aspirin does not improve cognitive functioning, but it will prevent further ischaemic events and should be prescribed if indicated.

Before and at all stages of dementia, people need advice on lifestyle changes to keep healthy and improve cerebrovascular and cardiovascular perfusion. There is robust evidence to

Table 33.12 Suggestions to enhance medicines optimisation and prescribing

Problem	Suggestions
Labelling issues	Carers appreciate complete directions such as 'at night' or 'after breakfast' so that they can plan dosing schedules according to mealtimes. If a medication is being taken for sleep, e.g. then directions such as 'take 1 h before bedtime' can help so that the medication is starting to take effect before the recipient actually goes to bed.
Disease progression	Disease progression effects physical functions as well and includes swallowing and chewing difficulties. Always ask if there is a problem because many carers just try to get the medication into the person any way they can, often mixing it with yoghurt, jam or mashed potato. Where possible, ensure liquid formulations are used if this is a problem. Carers value any support in this area because they have been told how important it is for the medicines to be taken but do not realise the potential effects of opening a long-acting capsule into yoghurt. Poor memory, a reduced sense of smell and the effects of medication may result in a reduced food and fluid intake, resulting in weight loss, dehydration and electrolyte disturbance. The provision of sip feeds may be useful in people at this stage of the disease. Control of bowels and bladder may reduce over time; in moderate to moderately severe stages, people may forget where the toilet is or not recognise the physical signs associated with bowel and bladder control. Regular toileting (on waking and after meals and before bed) may help, but also the provision of incontinence aids may be needed. Also think about the need for skin care to ensure that skin breakdown and possible pressure sores do not occur.
Simplifying medication regimens	Consider the use of long-acting preparations (e.g. galantamine XL) as an alternative to twice-daily dosing or patches if a long-acting form is needed. Long-acting preparations will take longer to reach steady state, but this often reduces the incidence of side effects and improves adherence to complex medication regimens.
Repeat dispensing issues	Concomitant medicines that run out at different times and may have different prescribers – try to rationalise prescribing and ordering to ensure a common quantity of medication is available. Prescriptions for the cognitive enhancer are often collected from a different place, increasing strain on the carer, especially if it means ringing a consultant's secretary to ensure a prescription is sent and sufficient quantities are ordered to last until the next appointment. You may be able to help ensure that the prescriber understands exactly what is needed and by when. Changing brands of concomitant medication can be confusing for any person, let alone someone with a memory problem who may just remember shape and/or colour. Great care is needed when making these changes to ensure that it is fully understood that it is the same medication and not another new one. Parallel imports may also be confusing.
Remembering medication	Memory and/or compliance aids may be a welcome addition to help make sense of the medication, as would a medication reminder card which also includes brief details of what to take and when. If you are helping individuals with a memory problem who live on their own, it is recommended to find out how they currently try to remember to take their tablets (many write notes for themselves and then tick things off the calendar or have a note on the fridge or a telephone call from a family member) and see if you can help improve the system. Try not to introduce anything too complex because they may not remember new information or routines. Suggestions that fit with their current daily activities may be most successful. It may also help to telephone them for a few days to see how they are getting on.

Continued

Table 33.12 Suggestions to enhance medicines optimisation and prescribing—cont'd

Problem	Suggestions
Medicines review	<p>Discuss with the carer and person with dementia what they feel is most important; they will generally have one pressing issue which they would like to resolve.</p> <p>There is often at least one medication that people are not using either at all or as prescribed. Try to establish why. It may be that the behaviour has changed and the item is no longer needed or that an adverse event occurred which has put them off using the medication. If the latter, then a smaller dose or alternative medication may be more appropriate. Asking key questions can help identify what actually happened. Always communicate this with the prescriber (with the individual's permission) because this reduces waste and unnecessary prescribing and helps keep accurate records of medication regimens.</p> <p>Check that the time of day a dose is to be taken is appropriate if a side effect occurs (e.g. if insomnia and/or nightmares occur in people on donepezil, ensure the dose is taken in the morning because this will improve sleep patterns).</p>
Managing side effects	<p>Diarrhoea, nausea, vomiting, anorexia and headache are common side effects on initiation and on dose titration of AChEIs. Carers need support to understand this is normal and that tolerance will generally develop. These may be transient (5–7 days), but if continuous, then a shared decision should be made on the balance of benefits and adverse reactions. Due to the different modes of action, another agent may be tried.</p> <p>Antiemetics</p> <p>For nausea/vomiting on initiation or dose titration of AChEIs, domperidone is preferred because it does not cross the blood–brain barrier or have anticholinergic side effects. Domperidone should be taken regularly three or four times daily for 3 or 4 days and then reduced to zero as symptoms subside. Long-acting metoclopramide is an option for those without movement disorders.</p> <p>Diarrhoea</p> <p>If diarrhoea is a problem, loperamide may be co-prescribed. The dose and frequency are generally titrated to the side effect and then taken regularly. Ensure that the dose is not so high or continued too long as to cause constipation.</p> <p>Donepezil is prescribed at night; however, it may cause vivid dreams interfering with sleep, in which case, this may be best administered in the morning.</p> <p>Memantine</p> <p>Side effects include dizziness, headache, confusion, hallucinations (which can also be part of the dementia process) and tiredness. Keeping a diary of tiredness is recommended because a short nap in the mid-afternoon may reduce the problem, as would administering the dose at night to aid sleep.</p>
Referral of side effects	<p>If side effects of AChEIs are severe and/or debilitating, then refer back to the prescriber. Referral should also be made if there are signs of urinary flow difficulties or worsening of asthma, COPD or cardiovascular symptoms, especially blackouts.</p> <p>With memantine, if hallucinations are distressing the individual, refer to specialist. NICE guidelines set out strict conditions to be met before the use of an antipsychotic.</p>
Starting new medicines	<p>If new medicines are started (including purchase of OTC products for coughs and colds), check whether they cause anticholinergic side effects because this will increase confusion, impair memory function and possibly antagonise the effect of the cholinesterase inhibitor. Dextromethorphan and memantine are contraindicated.</p>
Concomitant prescribed medicines (for other medical conditions)	<p>Ensure understanding of what each medication is for and common side effects associated with each, highlighting those that need to be reported immediately. It is often helpful to provide a medicine reminder chart which indicates what each is for, including common side effects and when to take them. Always check for interactions.</p> <p>Remember that any agent which has anticholinergic side effects will increase confusion and reduce cognitive functioning (as well as the other adverse effects, such as constipation, dry mouth, cardiovascular effects). Therefore, where possible, check for anticholinergic load (e.g. oxybutynin, antidepressants or antipsychotics) and recommend alternatives if possible.</p> <p>Remember that any medication with CNS effects (e.g. benzodiazepines, opiates or dopaminergic agents) may negatively affect cognitive functioning. Benzodiazepines are also amnesic.</p> <p>Any agent which has the potential to cause confusion, e.g. long-acting hypoglycaemic agents, non-steroidal anti-inflammatory agents and H₂ antagonists such as cimetidine, should be carefully monitored and/or withdrawn if possible.</p> <p>Side effects of aspirin are well known. Ask about gastro-intestinal problems, and check for excessive bruising after falls or knocks.</p>
Stopping cognitive enhancers	<p>Stopping cholinesterase inhibitors can produce a dramatic decline in cognitive and physical functioning which may require the agent to be restarted.</p>

AChEIs, Acetylcholinesterase inhibitors; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; NICE, National Institute of Health and Care Excellence; OTC, over-the-counter.

demonstrate that an active lifestyle and using the brain to learn a new language, dance or take part in gym activities alongside a healthy diet reduce the risk of dementia (Public Health England, 2016).

Herbal supplements, aromatherapy and social and behavioural interventions

People with dementia and family members may use various herbal supplements to try to prevent and/or delay the onset of dementia.

Claims of cognitive enhancement have been made for a number of supplements; the key ones are listed here. Cochrane Reviews on Dementia and Cognitive Improvement (<http://dementia.cochrane.org/>) hosts a number of systematic reviews on herbal supplements, aromatherapy and social and behavioural interventions for people with dementia. Another useful resource is the NICE-SCIE guideline on supporting people with dementia (NICE and SCIE, 2011).

Ginkgo biloba

The proposed mechanism of action of ginkgo biloba is to increase blood supply by dilating cerebral blood vessels and decreasing blood viscosity. There are some isolated reports of bleeding with ginkgo biloba with a theoretical interaction with aspirin or warfarin, possibly resulting in increased bleeding (Bent et al., 2005). The prescriber should be consulted before use in these circumstances. It is also proposed that the compound modifies neurotransmitter systems and decreases the density of oxygen free radicals. The evidence for improvement in cognitive functioning is inconsistent with three studies showing equivalence to placebo and one showing a substantial positive effect. However, it is known that ginkgo appears to be safe to use and is well tolerated; it is unknown whether long-term use has any effect on the onset of dementia (Birks and Grimley Evans, 2009).

Vitamin E

Vitamin E has an antioxidant effect, and it was thought this might reduce the onset of the neurodegenerative process. However, a review in 2012 stated there was no evidence of the efficacy of vitamin E in the prevention or treatment of people with AD or mild cognitive impairment and that the risks to individuals outweighed any benefits (Farina et al., 2012).

Folic acid, vitamin B₁₂ and iron

The dietary supplement folic acid, vitamin B₁₂ and iron are linked with cognitive dysfunction, confusion and/or memory problems, when there is a deficit. Older people may not eat sufficient fresh green vegetables or dietary protein to sustain normal levels. In addition, active transport mechanisms for vitamin B₁₂ absorption are often impaired. However, if a deficiency has not been identified, supplementation with folic acid, vitamin B₁₂ or iron will generally not have any clinical effect.

Supporting people with concerns about possible dementia

People often worry about the possibility of dementia if their memory seems to be less effective as they get older. With aging, our mental speed tends to decline, with thinking, problem solving and recall all becoming slower. Being very busy, depressed or anxious can impair the way in which short-term memories are laid down. If short-term memories are not laid down, then long-term memories will not be formed. For example, if you are not paying complete attention to a person when he or she is speaking, the information will not be retained completely, which results in reduced recall of the conversation, disruption of the short-term memory process and consequent inability to recall the conversation or interaction. Forgetting the occasional word or making a poor decision once in a while is nothing to be worried about. The time to seek help or refer to memory services is when changes in cognitive functioning impair an individual's ability to care for him- or herself or participate in work or social interactions. Healthcare professionals are often reluctant to discuss cognitive changes with people, but further information and signposting is welcomed so that they can address their own concerns.

Communicating with people with dementia and their carers

The most important thing to remember when talking to people with dementia is that they are still able to communicate and will probably enjoy the opportunity. The following points will aid effective communication, but supporting information may be necessary from relatives or caregiver(s) when accurate and reliable information is needed (e.g. an accurate medication history). People with dementia may make up answers if they think they should know but are unable to remember an answer.

Adapting communication skills

The fundamental principle of communication with people with dementia is to try to capitalise on the preserved memory systems. Therefore, the following strategies are advisable:

- Simplify sentences.
- Simplify vocabulary.
- Use yes-or-no, not multiple choice, questions.
- Talk about the here and now, not the abstract.
- Use direct language wherever possible.
- Avoid teasing and sarcasm.
- Check that what you say is understood.
- Summarise information.
- Provide written information.
- Use a slow speech rate.
- Speak clearly and audibly.
- Use a pleasant, accepting tone.
- Vary the pitch and tone of the voice.
- Limit the number of participants in the conversation.

Skilled communicators can establish a conversation with the person in a time and place that they remember and thus allow

them to participate. It is also increasingly important to read the person's body language as the disease progresses. This is because often the person cannot communicate effectively with words, and physical exhibitions of agitation, depression, pain or frustration may be conveyed via pacing, withdrawal or shouting/hitting, for example.

Information provision for carers

The physical and psychological support of carers is very important; it is well evidenced that if they are not given the support they need, then the caring process breaks down, and early institutionalisation occurs (Eska et al., 2013). People need and want different advice at different stages of the illness, so always offer information even if it is not always accepted. Wide-ranging guidance for carers and healthcare professionals can be found in the NICE-SCIE (2011) guideline. As the disease progresses, carers may seek advice on how to manage behavioural changes and the reasons for their development. Useful information is provided by the Alzheimer's Society (2015c).

People with dementia and/or their carers may seek information on a number of issues to address before insight into care is lost. Awareness of any local dementia services and signposting people for information is therefore important. Topics may include:

- access to financial, social and healthcare advice and services;
- legal issues, such as continuing to drive or end-of-life care;
- occupational therapy for living aids, such as stair lift, stair gates, shower and bathing aids, walking and dressing aids;
- memory aids, including tools and prompts, as well as activities for improving cognitive and memory function;
- carer support and education on caring for a person with dementia.

Case studies

Case 33.1

Mrs LB is well known at your pharmacy because she organises the repeat prescriptions for her husband and collects these every 2 months. Mr TB, her husband, has hypertension and is prescribed losartan and simvastatin. Mr TB has recently retired; he was a banker, and you have only met him occasionally. Mrs LB has asked if she can speak with you. She seems quite upset and emotional. She says that over the last few months, her husband has been acting increasingly out of character. She has found him taking his tablets again because he was adamant he had not taken them earlier, although Mrs LB had watched him take them. In addition, he has been getting dressed as if he was going to work, in his suit with a packed briefcase. Mrs LB has had to remind him that he has retired and no longer needs to go to work. Of more concern is that Mr TB has started to have small accidents in the car – minor incidents such as hitting the garage door when reversing or the curb when driving. Mrs LB would like to know if these could be side effects of one his medicines. This is because on a few occasions recently he has taken double the dose of his medications.

Questions

1. What do you think could have potentially caused these behaviours?
Three months later, Mr TB and Mrs LB arrive at the pharmacy looking shocked and a little upset. You take them to the counselling room. Mr TB gives you a prescription for donepezil 5 mg each evening and says that they have just been told that he probably has AD. Mr TB says he has had 'every test possible and that's what they've come up with'. It is a shock to both of them because no one in Mr TB's family has ever had a dementia. They both want to know more about this medicine.
2. What information should you provide Mr TB and Mrs LB about the benefits of treatment while also ensuring they understand this medicine is not a cure?
The next weekend, Mr TB's daughter, their only child, visits the pharmacy and asks to speak to you. She is 32 years old, recently married and planning to start a family. She wants to know what her chances are of developing AD and whether she should consider not having a baby.
3. How do you respond to Mr TB's daughter?

Answers

1. Mr TB is neither delusional nor obsessive; these incidents are signs of short-term forgetfulness and changes in visuospatial co-ordination. Although simvastatin can cause depression and amnesia in some people, this is generally seen early in the treatment. Early recognition allows early diagnosis and the ability to rule out treatable pseudo-dementias. Depending on your local organisations and memory clinics available, you could suggest that Mrs LB makes an appointment for her husband to see his primary care doctor (with Mrs LB co-attending) to discuss possible referral for a memory clinic assessment. In some areas/countries, you may be able to refer Mr TB, or they could self-refer.
2. Mr TB and Mrs LB should be informed that acetylcholinesterase inhibitors (AChEIs), like donepezil, are not a cure for AD, or any dementia, but they can improve the symptoms associated with dementia. Importantly, these medicines work very well for one-third of people and somewhat well for another third; for the remaining third, they seem not to have an effect. AChEIs have linear kinetics; subsequently, effects are dose dependent, and it may take up to 3 weeks or longer to attain steady state. Therefore, if response appears to be negative, a dose increase should be tried and/or a change to another AChEI because they each have a slightly different mode of action. It should be explained to Mr TB and Mrs LB that the medicine needs to be taken at the same time of day. However, because donepezil can cause nightmares and affect sleeping, this would require a change to morning dosing. All AChEIs can cause nausea, vomiting and diarrhoea, so Mr TB and Mrs LB should be informed that because of this, doses are started low and titrated up over 2-week intervals to ensure that tolerance occurs. This titration will also affect the time taken for maximum efficacy to be reached. These effects can be managed with antispasmodics that do not act on the central nervous system, such as long-acting metoclopramide, domperidone or loperamide, as appropriate. It is always important to remember that any sedative medication, such as phenothiazines and sedative antihistamines, will impair cognitive functioning, especially if it is also highly antimuscarinic.
3. Because Mr TB's AD is not familial, you should explain to his daughter that there is unlikely to be a genetic risk (although this could be confirmed if needed). You could say that evidence shows that good public health interventions can reduce the risk of dementia. This includes reducing cardiovascular risks, appropriate treatment of ischaemic heart and vascular disease, keeping

fit and exercising three to four times weekly for 30–40 minutes to maintain an ideal body weight and engaging in social and mental activities to maintain good brain function. These can all reduce the risk of experiencing dementia. Environmental changes, such as avoiding centrally acting toxins and brain injury (sports such as boxing, rugby and football with repeated head trauma), can also reduce this risk. Although there are compounds being investigated in phase III studies for prevention of dementia, these are with populations with genetic risk factors. Currently, there are no pharmacological or herbal remedies which reduce the risk of idiosyncratic dementia.

Case 33.2

Mr SJ is a slim 65-year-old gentleman who has atrial fibrillation and is prescribed digoxin, enalapril, warfarin and simvastatin. He had been going to his primary care doctor for his warfarin tests – sometimes twice in the same day – and then forgetting about them a week later. His wife said he was also quite withdrawn and had lost interest in his garden and radio shows. It was the nurse in his local surgery who referred him to his primary care doctor for a dementia screen because she was concerned about his behaviour. Mr SJ was subsequently prescribed rivastigmine 1.5 mg capsules twice daily, and 2 weeks ago this was increased to 3 mg capsules twice daily. Today, he and his wife are at the pharmacy. They would like to know what Mr SJ can take for his nausea because it is putting him off his food, and he has already lost 2 kg in weight over the last 2 weeks.

Questions

1. What advice do you give Mr and Mrs SJ on managing the nausea and weight loss?
Nine months later, Mr SJ is admitted to hospital for investigation into two recent falls at home, both of which resulted in extensive bruising because of the warfarin. Mr SJ did not fall or trip; Mrs SJ described the fall as though his legs just gave way. Mr SJ said he felt a little dizzy, and the next thing he could recall was that he was on the floor. The primary care doctor recently started atenolol 25 mg once daily because Mr SJ's blood pressure had increased to 150/95 mmHg. The rivastigmine he was prescribed has been successful because he is now socially engaged, able to complete activities of daily living and is very happy within himself. The consultant asks your opinion on whether the rivastigmine should be stopped because they consider it likely that Mr SJ's fall was due to bradycardia caused by rivastigmine.
2. What information could you provide to the consultant, and what treatment options would you recommend?

Answers

1. Nausea and vomiting are associated with dose increases of AChEIs and can be managed either by slowing down the rate of titration and/or co-prescription of an antiemetic such as metoclopramide. Because weight loss can impair physical strength, and resultant electrolyte imbalances may affect cognitive function in older people, it is important to address this issue. An alternative would be to consider rivastigmine patches to see if a more controlled dose release over 24 hours would have a reduced incidence of nausea. Mr SJ should be encouraged to eat small amounts more frequently until his body has time to develop tolerance to the dose increase, which usually takes about 2 weeks.
2. Rivastigmine is positively enhancing Mr SJ's life and therefore that of his wife and family. This is important because carer stress is

the key reason for people with dementia being admitted to care facilities.

Rivastigmine may cause bradycardia, which may contribute to the occurrence of torsade de pointes in patients with uncompensated heart failure, recent myocardial infarction, bradyarrhythmias, hypokalaemia or hypomagnesaemia or concomitant medicines which induce QT prolongation and/or torsade de pointes (e.g. antipsychotics, citalopram, antiarrhythmics). Rivastigmine therapy has been associated with hypertension. Atenolol is well known to cause bradycardia leading to syncope, which leads to falls.

Therefore, it would be appropriate to suggest withdrawing the atenolol used for blood pressure control, as it has led to bradycardia. An alternative would be to suggest increasing the dose of enalapril to control the rise in blood pressure, rather than adding a new medication. If the bradycardia still continued and the rivastigmine was still considered beneficial, then a pacemaker could be used to control heart rate and reduce falls.

Case 33.3

Mrs AS is a 76-year-old woman, and before her AD was diagnosed 5 years ago, she was fiercely independent and an active member of the community. Mrs AS now attends the local church service once a week and a coffee morning with her friends. However, she has resigned her previous secretarial position on a local women's group. She was started on galantamine XL 8 mg and subsequently increased to galantamine XL 24 mg once daily about 9 months ago. Her husband has been pleased with the effect because she is more sociable and plays with the grandchildren again. However, Mrs AS has started to get very agitated in the evening and refusing to sit down. She has been insisting that she wants to walk to post a letter and then gets very angry when her husband locks the door to prevent her from leaving the house. Last night, Mrs AS was so angry that she slapped her husband. He has asked your advice on what course of action he should take. He wants to know if he should encourage her to take an over-the-counter sleeping aid or if he should just persevere in trying to explain that she does not need to go out.

Questions

1. How do you respond to Mrs AS's husband's concerns?
Eight months later, the primary care doctor for the local care home contacts you about Mrs AS. Mrs AS was admitted 2 months ago when her husband was unable to look after her following a small stroke. The staff have explained that Mrs AS has settled in well and enjoys her daily walk in the garden and her singing group sessions. She has always been friendly and polite and never gets angry. However, over the last 2 days, Mrs AS has lashed out at the same member of staff while he was helping her wash and dress. This morning, this staff member received a black eye, and the staff member wants Mrs AS's behaviour addressed. The primary care doctor asks if you think risperidone 500 micrograms at night would be an appropriate choice for Mrs AS.
2. How do you respond to the primary care doctor's question?

Answers

1. This behaviour sounds like 'sundowning', where people experience night-day reversal and associated agitation. This might be caused by too much napping during the day or inadequate exposure to bright light (dimmed lights, closed curtains or blinds or not being out of the house during the daytime) to suggest daytime,

leading to a loss of time orientation. As night approaches, there should be clear signals of closing curtains, turning down lights, calming the environment and establishing a routine which is suggestive of night time. Lavender and *Melissa officinalis* oils can be used as a massage (even only to the hands or feet) or used via a diffuser for inhalational effects to help decrease incidences of agitated behaviour. It is best if these are used before the expected behaviour, as part of a routine before bedtime and sleeping.

Short courses of small doses of z-hypnotics may also help if the oils are ineffective. However, tolerance quickly develops, and so does the potential for adverse effects such as postural hypotension, falls and decline in cognitive function, including memory impairment, as well as additional medication and possible interactions.

- When behaviour changes occur, there should always be an ABC assessment. A = antecedent (what causes the behaviour), B = behaviour, and C = change (what changes the behaviour). This assessment needs to be undertaken to review Mrs AS's recent change in behaviour.

On further inquiry, the care home revealed that there has been a new male member of staff involved in helping Mrs AS to wash and dress. When Mrs AS's husband was contacted, he was very upset. He explained that his wife was a very private person with

respect to nudity, would not undress in front of him and had always insisted on washing and bathing herself. He said it was understandable that Mrs AS had become upset and angry when a male assistant was helping her, as this had never happened before, and she would have felt threatened. The recommendation is to ensure a female staff member helps Mrs AS when washing and dressing. Therefore, it is important to always question the reason behind a behavioural change and ensure that the family members are also informed. They may highlight possible reasons for the change. An antipsychotic should only be prescribed when the individual is a risk to him- or herself or others and after trialling non-pharmacological interventions. An antipsychotic should not be prescribed for sedation and in this situation would be unlikely to reduce Mrs AS's fear and distress. Good practice indicates that an antipsychotic should only be prescribed after a team discussion and further discussion with the patient and family outlining the associated increased risks for morbidity and mortality. The decision to prescribe should be documented in the patient's medical record and reviewed frequently to ensure it is still appropriate. The lowest possible dose to achieve the required effect should be prescribed. However, in this case, the cause of Mrs AS's changed behaviour was identified, and therefore no new medication was prescribed.

34 Pain

Roger David Knaggs and Gregory J. Hobbs

Key points

- Pain is multifactorial in its aetiology.
- Treatment often requires use of a combination of drugs with different mechanisms of action.
- Opioids are generally effective for acute pain and pain at the end of life. However, they are less effective for other types of pain, particularly low back pain and fibromyalgia. Adjuvant analgesics, such as tricyclic antidepressants or antiepileptic drugs, should be considered before opioids for persistent non-cancer pain.
- For cancer pain, the World Health Organization (WHO) analgesic ladder forms the basis for the use of analgesic drugs. Some clinicians prefer to omit weak opioids and start strong opioid therapy earlier.
- Breakthrough pain is treated with doses of immediate-release opioids, usually prescribed in addition to modified release formulations.
- Antiemetics and laxatives should be prescribed for patients taking opioids.
- Cancer pain may vary as the disease progresses. Drug therapy should be reviewed regularly to ensure that the most appropriate agent is being used for the type, site and intensity of pain.
- Most drugs are available in a range of different formulations, but whenever possible, the oral route should be used.
- When managing patients with chronic pain, analgesic drugs are used together with other non-pharmacological therapies as part of a biopsychosocial treatment framework.

Pain is defined as:

An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.

(International Association for the Study of Pain, 2012)

Acute pain may be thought of as a physiological process having a biological function, allowing the patient to avoid or minimise injury. Persistent or long-term pain, on the other hand, may be considered more as a disease in its own right than a symptom (Woolf, 2004).

Aetiology and neurophysiology

Neuroanatomy of pain transmission

The majority of tissues and organs are innervated by special sensory receptors (nociceptors) connected to primary afferent nerve fibres of differing diameters. Small myelinated A δ fibres

and unmyelinated C fibres are responsible for the transmission of painful stimuli to the spinal cord, where these afferent primary fibres terminate in the dorsal horn.

Pain transmission further within the central nervous system (CNS) is far more complex and understood less well. The most important parts of this process are the wide dynamic range cells in the spinothalamic tract that project to the thalamus and on to the somatosensory cortex. Modulation or inhibition of these neurones within the spinal cord result in less activity in the pain pathway. This modulatory action can be activated by stress or certain analgesic drugs, such as morphine, and is an important component of the gate theory of pain (Fig. 34.1).

The gate control theory recognises the pivotal role the spinal cord plays in the continual modulation of neuronal activity by the relative activity of large-diameter myelinated (A β) and smaller-diameter (myelinated A δ and unmyelinated C) peripheral fibres and by descending inhibitory messages from the brain. Conversely, other influences can lead to an increased sensitivity to noxious stimuli. The most important of these is pain itself, and further painful stimuli can lead to increased pain sensitivity. This occurs through neurochemical and anatomical changes within the CNS. This enhancement of neuronal function is known as central sensitisation (Woolf, 2011) and manifests clinically as hyperalgesia (increased pain from a stimulus that usually provokes pain) and allodynia (pain from a stimulus that does not usually provoke pain).

Neurotransmitters and pain

Various neurotransmitters in the dorsal horn of the spinal cord are involved in pain modulation. These include amino acids such as glutamate and γ -aminobutyric acid (GABA), monoamines such as noradrenaline and 5-hydroxytryptamine (5-HT, serotonin) and peptide molecules, of which the opioid peptides are the most important. Opioid receptors are found in both the CNS and the periphery; in the CNS they are found in high concentrations in the limbic system, the brainstem and the spinal cord. The natural ligands (molecules that bind to the receptor) at opioid receptors are a group of neuropeptides including the endorphins.

Assessment of pain

Evaluation and diagnosis of pain requires a description of the pain and an assessment of its consequences. This should include a full

Fig. 34.1 Gate control theory of pain.

medical history, medication history and assessment of previous pain problems, paying attention to factors that influence the pain, for example, movement. An appropriate physical examination is usually performed. Additional diagnostic laboratory tests, imaging, including plain radiography, computed tomography (CT) and magnetic resonance imaging (MRI), and diagnostic nerve blocks may be used to confirm the diagnosis. Further, to develop an individualised management plan for people with chronic pain, a more detailed assessment of pain-related disability is usually required, including psychological and social assessment.

Pain is, however, a subjective phenomenon, and quantitative assessment is difficult (Breivik et al., 2008). The most commonly used instruments for acute pain are visual analogue and verbal rating scales. Visual analogue scales are 10-cm-long lines labelled with an extreme at each end, usually 'no pain at all' and 'worst pain imaginable'. The patient is required to mark the severity of the pain between the two extremes of the scale. Verbal rating scales use descriptors such as 'none', 'mild', 'moderate' and 'severe'. More elaborate questionnaires such as the Brief Pain Inventory (Cleland and Ryan, 1994) and the McGill Pain Questionnaire (Melzack and Torgerson, 1971) help describe other aspects of the pain experience, and pain diaries may be used to record the influence of activity and medication on pain.

Management

Acute pain usually results from noxious stimulation as a result of tissue damage or injury. It can be managed effectively using analgesic drugs and is often self-limiting.

Long-term pain may be considered as pain which continues beyond the usual time required for tissue healing. Treatment may require involvement from specialist pain management services, hospices and a multidisciplinary approach that assesses and manages patients using a biopsychosocial approach. Initial treatment is usually directed at the underlying disease process where possible, for example, medicines, surgery or anti-tumour therapy. However, non-pharmacological treatments such as physical therapy and various psychological techniques including cognitive behavioural therapy may also form part of a multimodal treatment programme. In addition, pain can be modulated using techniques such as stimulation-based analgesia such as

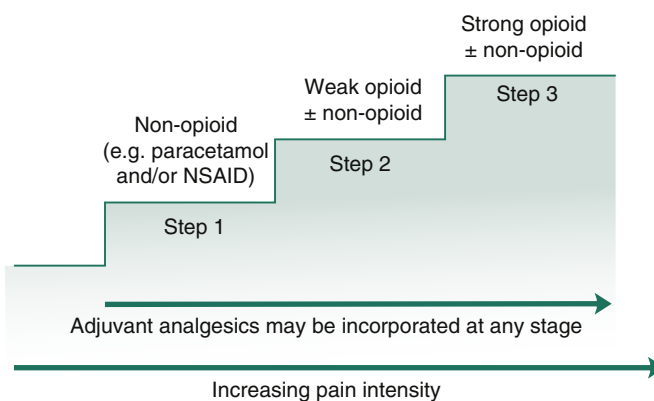

Fig. 34.2 World Health Organization three-step analgesic ladder. NSAID, Non-steroidal anti-inflammatory drug.

transcutaneous electrical nerve stimulation (TENS), acupuncture and massage, or invasive procedures such as injections, neurolytic nerve blocks and spinal cord stimulation.

Research is progressing such that pain management is moving from symptom control towards mechanism-based pharmacological therapy (Baron et al., 2012; Woolf, 2004), although it can be difficult to apply in routine clinical practice.

Analgesic ladder

The World Health Organization (WHO) analgesic ladder (Fig. 34.2) forms the basis of many approaches to the use of analgesic drugs, particularly in pain at the end of life. There are essentially three steps: non-opioid analgesics, weak opioids and strong opioids. The analgesic efficacy of non-opioids, such as paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) (e.g. aspirin, ibuprofen and diclofenac), is limited by side effects and ceiling effects; that is, beyond a certain dose, no further pharmacological effect is seen. If pain remains uncontrolled, then a weak opioid, such as codeine or dihydrocodeine, may be helpful. There may be additional benefit in combining a weak opioid with a non-opioid drug, although many commercial preparations contain inadequate quantities of both components and are no more effective than a non-opioid alone. Strong opioids, of which morphine is considered the gold standard, have no ceiling effect, and therefore increased dosage continues to give increased analgesia, but side effects often limit the effectiveness. Adjuvant drugs, such as corticosteroids, antidepressants or antiepileptics, may be utilised at any step of the ladder.

Analgesic drugs

Paracetamol

Despite being used in clinical practice for more than 50 years and much investigation, the mechanism by which paracetamol exerts its analgesic effect remains uncertain. Inhibition of prostaglandin synthesis within the CNS has been proposed, although this is probably not the only mechanism. Interaction with the serotonin (Tjolsen et al., 1991) and endocannabinoid (Högstätt et al., 2005) neurotransmitter systems have been demonstrated in animal models.

Fig. 34.3 Paracetamol metabolism in humans.

The bioavailability of paracetamol is around 60% after oral administration, but if given by the rectal route, it is much lower and much more variable. A formulation for intravenous infusion has been promoted more recently, and this has largely replaced the rectal route of administration. Therapeutic plasma levels are reached within 30 minutes of oral administration. The elimination half-life of paracetamol is relatively short ($t_{1/2} = 2-4$ hours); hence, frequent dosing is required to maintain its analgesic effect.

With normal doses, the majority of a dose of paracetamol is metabolised and inactivated in the liver, undergoing a phase II conjugation reaction with glucuronic acid (Fig. 34.3). A small proportion of a dose is metabolised using a cytochrome P450 mediated reaction that forms a reactive intermediate, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). Usually, NAPQI can be deactivated by conjugation with glutathione in the liver. However, after ingestion of a large amount of paracetamol, the hepatic stores of both glucuronic acid and glutathione become depleted, leaving free NAPQI, which causes liver damage.

The usual therapeutic dose for adults is paracetamol 1 g taken four times daily. It is very important that this dose is not exceeded; otherwise, hepatotoxicity is more common. This may be particularly problematic for malnourished adults with low body weight (Claridge et al., 2010). A reduced maximum daily dose (3 g/24 h) by intravenous infusion is recommended for patients with hepatocellular insufficiency, chronic alcoholism or dehydration. Paracetamol is also available as an over-the-counter (OTC) medicine and is a component of many cold and influenza remedies. Compared with other analgesics, paracetamol is not as potent; however, when taken in combination with an NSAID or opioid, there is an additive analgesic effect.

Non-steroidal anti-inflammatory drugs

Mechanism of action

NSAIDs exert their analgesic and anti-inflammatory effects through inhibition of the enzyme cyclo-oxygenase, responsible for the synthesis of prostaglandins. NSAIDs are used widely to relieve

Box 34.1 'GRAB' mnemonic for serious, potentially fatal side effects of non-steroidal anti-inflammatory drugs

G – gastro-intestinal	Gastro-intestinal side effects are the most common unwanted effects of NSAIDs. These may be non-specific and less serious (e.g. dyspepsia, diarrhoea, nausea and vomiting) or more serious (e.g. ulceration, bleeding, intestinal obstruction).
R – renal	In susceptible individuals, especially the elderly, NSAIDs may cause acute renal failure. NSAIDs alter salt and water homeostasis, which may worsen heart failure and produce a small increase in blood pressure.
A – asthma	NSAIDs, particularly aspirin, may worsen asthma and cause bronchospasm in some patients.
B – blood disorders	All NSAIDs reduce platelet aggregation and increase the risk of bleeding, not just from the gastro-intestinal tract.

NSAID, Non-steroidal anti-inflammatory drug.

pain, with or without inflammation, in people with acute and persistent musculoskeletal disorders. In single doses, NSAIDs have superior analgesic activity compared with paracetamol (Hyllsted et al., 2002). In regular higher doses, they have both analgesic and anti-inflammatory effects, which makes them particularly useful for the treatment of continuous or regular pain associated with inflammation. NSAIDs have been shown to be suitable for the relief of pain in dysmenorrhoea, toothache and some headaches and to treat pain caused by secondary bone tumours, which result from lysis of bone and prostaglandin release.

Side effects and tolerability

The side effects of NSAIDs are produced as a result of decreasing prostaglandin production required for normal body function, particularly in the gastro-intestinal and respiratory tracts, kidneys and platelets. Although effective in conditions in which there is an inflammatory contribution to pain, NSAIDs have serious, potentially fatal side effects that may be remembered by the acronym 'GRAB' (Box 34.1).

It has been estimated that there are 2000 deaths each year in the UK directly related to NSAID use, but the assumptions used in this estimate are hard to determine (Rainsford and Bjarnason, 2015). More widespread prescribing of proton pump inhibitors may have reduced this figure. Over recent years there have been increasing concerns regarding the cardiovascular side effects of nonselective NSAIDs, and there is increasing realisation that thromboembolic and ischaemic vascular events are not solely associated with COX-2 selective drugs (Coxib and Traditional NSAID Trialists' [CNT] Collaboration, 2013).

COX-2 selective drugs

Cyclo-oxygenase exists in two forms: cyclo-oxygenase-1 (COX-1) and cyclo-oxygenase-2 (COX-2). COX-1 is a constitutive enzyme that is expressed under normal conditions in a variety of tissues, including the gastro-intestinal tract and kidney, where it

catalyses the production of prostaglandins required for homeostatic functions. It does not have a role in nociception or inflammation. COX-2 is an inducible enzyme that appears in damaged tissues shortly after injury and leads to the formation of inflammatory prostaglandins within these tissues. COX-2 selective NSAIDs should, theoretically, inhibit the formation of inflammatory prostaglandins without affecting the activity of COX-1 in areas such as the gut. In practice, use of COX-2-specific drugs is associated with reduced risk of gastro-intestinal side effects when compared with non-selective drugs. However, their use has also been linked with adverse effects, particularly cardiovascular side effects, and this now limits their use.

Clinical considerations

The potential benefits of treatment with an NSAID or COX-2 selective drug must be weighed against the risks. Differences in anti-inflammatory activity between NSAIDs are small, but there is considerable variation in individual patient response as well as the incidence and type of side effects. In acute pain between 40% and 70% of patients will respond to any NSAID (Moore et al., 2013). Of the remaining patients, those who do not respond to one NSAID may well respond to another. An analgesic effect should normally be seen within a week, whereas an anti-inflammatory effect may not be achieved or assessable clinically for up to 3 weeks.

Guidance on NSAID use

The lowest effective dose of NSAID or COX-2 selective inhibitor should be prescribed for the shortest time necessary. The need for long-term treatment should be reviewed periodically. Prescribing should be based on the safety profiles of individual NSAIDs or COX-2 selective inhibitors, on individual patient risk profiles, for example, gastro-intestinal and cardiovascular. Prescribers should not switch between NSAIDs without careful consideration of the overall safety profile of the products and the patient's individual risk factors, as well as the patient's preference (Medicines and Healthcare Products Regulatory Agency [MHRA], 2005).

Concomitant aspirin, and possibly other antiplatelet drugs, greatly increases the gastro-intestinal risks of using NSAIDs and severely reduces any gastro-intestinal safety advantages of COX-2 selective inhibitors. Aspirin should only be co-prescribed if absolutely necessary.

Other non-opioid analgesics

Nefopam is a drug which is chemically related to orphenadrine and diphenhydramine; however, it is not an opioid, anti-inflammatory drug or antihistamine. The mechanism of analgesic action remains unclear. As a non-opioid, it is not associated with the problems of dependence and respiratory depression. The drug has a very high number of dose-related side effects in clinical use that may be linked to its antimuscarinic actions. Nefopam may be useful in asthmatic patients and in those who are intolerant of NSAIDs; however, it has become much more costly over recent years.

Opioid analgesics

Opioid analgesics mimic the actions of these natural ligands and exert their effect through the MOR (μ), DOR (δ) and, to a lesser extent, the KOR (κ) receptors.

Opioids for mild to moderate pain

Opioids for mild to moderate pain ('weak opioids') are prescribed frequently, either alone or in combination with other analgesics, for a wide variety of painful disorders. There are three major drugs in this group, codeine, dihydrocodeine and dextropropoxyphene, which are recommended as step 2 of the WHO analgesic ladder for pain that has not responded to non-opioid analgesics. Despite this recommendation, there is little data demonstrating that weak opioids are of any benefit in the relief of long-term pain, and it may be more beneficial to use a smaller dose of a more potent opioid.

Codeine. Codeine is the prototypical opioid for moderate pain. It is structurally similar to morphine, and about 10% of the dose is demethylated to form morphine, and the analgesic effects are likely to be due to this active metabolite. It is a powerful cough suppressant as well as being constipating. In combination with NSAIDs, the analgesic effects are usually additive, but the variability in response is considerable. A genetic polymorphism occurs within the population such that the hepatic microsomal enzyme CYP2D6 that is responsible for the conversion of codeine to morphine does not catalyse this conversion in approximately 8% of the Caucasian population. The duration of analgesic action is about 3 hours.

Dihydrocodeine. Dihydrocodeine is only available in a few countries and is chemically similar to codeine. It has similar properties to codeine when used at the same dosage and may be slightly more potent.

Dextropropoxyphene. Historically, dextropropoxyphene was prescribed in combination with other analgesics such as paracetamol (co-proxamol). There are few data on its therapeutic value, and at least one review concluded that analgesic efficacy is less than aspirin and barely more than placebo. At best, dextropropoxyphene failed to show any superiority over paracetamol (Li Wan Po and Zhang, 1997). At worst, it is a dangerous drug which has the potential for steadily developing toxicity. Patients with hepatic dysfunction and poor renal function are particularly at risk. It is associated with problems in overdose, notably a non-naloxone-reversible depression of the cardiac conducting system. Dextropropoxyphene interacts unpredictably with a number of drugs, including carbamazepine and warfarin. In 2005, the MHRA announced concerns about the safety and effectiveness of co-proxamol and directed that it should be withdrawn from clinical use in the UK; however, it still remains available as an unlicensed medicine for the small number of patients who do not obtain analgesia with other analgesic medicines.

Opioids for severe pain

Morphine. Morphine is the gold-standard opioid analgesic for severe pain ('strong opioid'). It is available for administration by a range of administration routes, including oral, rectal and injectable formulations, and has a duration of action of about

4 hours after oral administration. Morphine is metabolised in the liver, and one metabolite, morphine 6-glucuronide, is pharmacologically active; this should be taken into consideration in patients who have renal failure.

A general protocol for morphine use to obtain rapid relief from acute pain is to use intravenous bolus doses of 2–5 mg titrated until pain relief is achieved. In the initial management of long-term pain, an oral regimen is more appropriate using an immediate-release formulation. A usual starting dose is 5–10 mg every 4 hours, and the patient should be advised to take the same dose as often as is necessary for breakthrough pain. It may be necessary to double the dose every 24 hours until pain relief is achieved, although a slower dose escalation will often suffice. After control is achieved, it is usual to change to an oral modified-release formulation, which allows less frequent dosing, either daily or twice daily.

Theoretically, there is no ceiling effect when the dose is increased. However, side effects usually prevent dose escalation; daily doses of up to oral morphine 1 or 2 g/day may be required for some cancer patients, but relatively few require more than about 200 mg daily.

Other strong opioids. Opioids such as pethidine and dextromoramide offer little advantage over morphine in that they are generally weaker in action with a relatively short duration of action (2 hours). Dipipanone is only available in a preparation which contains an antiemetic (cyclizine), and increasing doses lead to sedation and the risk of developing a tardive dyskinesia with long-term use. Methadone has a long elimination half-life of 15–25 hours, and accumulation occurs in the early stages of use. It has minimal side effects with long-term use, and some patients who experience serious adverse effects with morphine may tolerate methadone.

Oxycodone and hydromorphone are synthetic opioids that have been used for many years in North America and more recently in Europe. They are available in both immediate- and modified-release preparations. Some patients appear to tolerate these semi-synthetic opioids better than morphine, but there is no evidence to suggest which patients achieve better effect with either of these drugs.

Fentanyl is available as a transdermal formulation for long-term use. The patch is designed to release the drug continuously over 3 days. When starting the drug, alternative analgesic therapy should be continued for at least the first 12 hours until therapeutic levels are achieved, and an immediate-acting opioid should be available for breakthrough pain. Patches are replaced every 72 hours.

The relative potencies of the commonly used opioids are summarised in Table 34.1.

Clinical considerations. Use of opioids is almost universally accepted in cancer pain and acute pain after injury, trauma or surgery. There has been a marked and progressive rise in the prescribing of opioid drugs in the UK over the past decade. The trend of increased prescribing continues (Zin et al., 2014), with most prescriptions now for patients with non-cancer pain. However, most trials in this patient group have been for a limited duration, and for most patients, opioids only provide modest benefits for short periods. In other healthcare systems, there have been similar trends in increased opioid prescribing. The United States is considered currently to have a ‘prescription opioid crisis’; in 2015, there were nearly as many deaths from unintentional overdose as deaths from road traffic accidents (Laderman and Martin, 2017).

Table 34.1 Relative potencies of opioid drugs

Drug	Potency (morphine = 1)
Codeine	0.1
Dihydrocodeine	0.1
Tramadol	0.2
Pethidine	0.1
Morphine	1
Diamorphine	2.5
Hydromorphone	7
Methadone	2–10 (with repeat dosing)
Fentanyl (transdermal)	150

The best outcomes are obtained in the long-term if the opioid dose can be kept low and particularly if use is intermittent. However, it is difficult to identify those people likely to experience good outcomes at the point of opioid initiation. As a general rule, strong opioid use is more likely to become problematic when patients have mental health problems (such as depression and anxiety) and/or a history of misuse of alcohol or other drugs, including opioids.

Agonist–antagonist and partial agonists

Most of the drugs in the agonist–antagonist category are either competitive antagonists at the μ opioid receptor, where they can bind to the site but exert no action, or they exert only limited actions; that is, they are partial agonists. Those that are antagonists at the μ opioid receptor can provoke a withdrawal syndrome in patients receiving concomitant opioid agonists such as morphine. These properties make it difficult to use these agents in the control of long-term pain, and the process of conversion from one group of drugs to another can be complex.

Buprenorphine

Buprenorphine is a semi-synthetic, highly lipophilic opioid that is a partial agonist at the μ opioid receptor and an antagonist at both the δ and κ receptors. It undergoes extensive metabolism when administered orally and to avoid this effect, it is given sublingually. It has high receptor affinity and, through this property, a duration of action of 6 hours.

A long duration of action and high bioavailability would suggest a role for buprenorphine in the management of long-term pain. Buprenorphine is also available as a transdermal formulation and may be an effective alternative to other strong opioids for long-term non-cancer pain. There is limited evidence of efficacy in osteoarthritis and low back pain. After sublingual or intravenous administration, the incidence of nausea and vomiting appears to be substantially higher than

with morphine; however, respiratory depression and constipation are less frequent.

Pentazocine

Pentazocine, a benzomorphan derivative, is an agonist and at the same time a very weak antagonist at the μ opioid receptor. This drug became popular in the 1960s, when it was thought it would have little or no abuse potential. This is now known to be untrue, although its abuse potential is less than that of the conventional agonists such as morphine. It produces analgesia that is clearly different from morphine and is probably due to agonist actions at the κ receptor. There are no detailed studies of its use in long-term pain, but its short duration of action (about 3 hours) and the high incidence of psychomimetic side effects make it a totally unsuitable drug for such use.

Tramadol

Tramadol is a centrally acting analgesic that has opioid agonist activity and also has monoamine reuptake properties similar to many antidepressants. It is not as potent as morphine, and efficacy is limited by side effects, including an unfavourably high risk of drowsiness, nausea and vomiting. Its monoaminergic activity appears to be valuable in the management of neuropathic pain and hence may be an acceptable alternative to an opioid.

Tapentadol

Tapentadol is another centrally acting analgesic that combines opioid agonist activity and noradrenaline reuptake inhibition (NRI). In animal models, the NRI component is a key mechanism and may even predominate over opioid actions in chronic (and especially neuropathic) pain states. In humans there is a reduced incidence of some of the typical opioid-induced side effects compared with equianalgesic doses of classical opioids. This supports the hypothesis that tapentadol analgesia is only partially mediated by opioid agonist mechanisms.

Side effects of opioids

The adverse effects of opioids are nearly all dose related, and tolerance develops to the majority with long-term use.

Respiratory depression

Respiratory depression is potentially dangerous in patients with impaired respiratory function, but tolerance develops rapidly with regular dosing. It can be reversed by the MOR opioid antagonist, naloxone.

Sedation

Sedation is usually mild and self-limiting. Smaller doses, given more frequently, may counteract the problem. Rarely, dexamphetamine or methylphenidate has been used to counteract this effect.

Nausea and vomiting

Antiemetics should be co-prescribed routinely with opioids for the first 10 days. Choice of antiemetic will depend upon the cause, and a single drug will be sufficient in two-thirds of patients. Where nausea is persistent, additional causes should be sought and prescribing reviewed. If another antiemetic is used, it should have a different mechanism of action.

Constipation

Opioids reduce intestinal secretions and peristalsis, causing a dry stool and constipation. Unlike other adverse effects, constipation tends not to improve with long-term use, and when opioids are used on a long-term basis, most patients need a stool softener (e.g. docusate sodium) and a stimulant laxative (e.g. senna) regularly. Dosage should be titrated to give a comfortable stool. High-fibre diets and bulking agents do not work very well in preventing constipation in patients on opioids. Co-danthrusate (dantron + docusate sodium) and co-danthramer (dantron + poloxamer 188) are alternatives; however, because of the potential carcinogenicity and genotoxicity of dantron, they are only indicated for use in terminal care. More recent alternatives include methylnaltrexone, naloxegol, oral prolonged-release naloxone and peripherally restricted opioid antagonists. Each of these has greater affinity for MOR opioid receptors in the gastro-intestinal tract and prevents binding of the opioid agonist, allowing the agonist to reach the central nervous system.

Smooth muscle spasm

Opioids cause spasm of the sphincter of Oddi in the biliary tract and may cause biliary colic, as well as urinary sphincter spasm and urinary retention. Thus, in biliary or renal colic, it may be preferable to use another drug without these effects. Historically, pethidine was believed to be the most effective, but there is no evidence for this practice (Thompson, 2001).

Other side effects

There is increasing evidence that long-term opioid use may cause clinically significant adverse effects on the endocrine system. For example, opioid-induced pituitary dysfunction can lead to testosterone deficiency in men. Effects on the immune system are evident in animal studies and are also under scrutiny in humans.

Tolerance, dependence and addiction

Treatment with opioids in the long-term may cause tolerance to the analgesic effect, although the mechanisms by which this happens remain unclear (Holden et al., 2005). When this occurs, the dosage may be increased or, alternatively, another opioid can be substituted. When switching to an alternative opioid, equivalence tables should be consulted but should only be considered a guide because there is significant variation for individuals. It is usual to reduce the equivalent dose by between 25% and 50% to ensure safety. Addiction is relatively uncommon when opioids are prescribed for pain relief.

Opioids and driving

In 2015 the law on driving whilst taking certain controlled drugs was strengthened. The new offence refers to driving with specified controlled drugs in the body, in excess of a specified limit. The new offence has a statutory 'medical defence' to protect patients who may test positive for certain specified drugs taken in accordance with the advice of a healthcare professional or the patient information leaflet that accompanies the medicine.

Special techniques for opioid administration

Patient-controlled analgesia

Patient-controlled analgesia (PCA) is a system which allows patients to titrate the dose of opioid to suit their individual analgesic requirements. The drug is delivered using a syringe attached to an electronic or elastomeric pump, which delivers a preset dose when activated by the patient depressing a button. A lockout period, during which the machine is programmed not to respond, ensures that a second dose is not delivered before the previous one has had an effect. Some devices allow an additional background infusion of drug to be delivered continuously. A maximum-dose facility ensures that the machine does not deliver more than a preset dose over a given time. PCA is a useful technique for the management of pain after surgery. The system is convenient and enjoys a high degree of patient acceptability.

The traditional intermittent intramuscular injection of opioids can be effective but is less versatile than titrated intravenous administration. The subcutaneous route is subject to most of the problems associated with intramuscular administration but tends to be less painful.

Opioid use via any route is associated with nausea, and antiemetics should be prescribed routinely. Administration of compound preparations containing both opioids and antiemetics is not recommended as few preparations contain drugs with similar pharmacokinetic profiles and accumulation, usually of the antiemetic, may occur.

Epidural analgesia

Epidural injections and infusions may be effective in relieving pain arising from both malignant causes and non-cancer diseases and are very effective in postoperative and labour pain. Various combinations of local anaesthetics, opioids or steroids can be administered into the epidural space near to the spinal level of the pain.

Epidural opioids

Effective analgesia can be obtained by administering small doses of opioids to the epidural space. Because there are opioid receptors in the spinal cord, smaller doses than administered by other parenteral routes are required and may be given with and without long-acting local anaesthetic drugs. However, severe respiratory depression, nausea and vomiting, urinary retention and pruritus can occur after their use. Life-threatening respiratory depression can occur when additional opioids are given by other routes

to patients already receiving epidural opioids, and this practice should be actively discouraged. Respiratory depression which occurs soon after administration, due to intravascular absorption, is relatively common and simple to detect and treat. However, respiratory depression can also occur many hours after opioid administration. This is most common with morphine, probably because of its lower lipophilicity compared with fentanyl and diamorphine. Fentanyl has much greater stability than diamorphine, and it can be prepared with bupivacaine in a terminally sterilised formulation which minimises the risk of adding the incorrect dose to an infusion fluid in a clinical environment and maintains sterility.

Local anaesthetics

Local anaesthetic drugs, such as lidocaine and bupivacaine, produce reversible blockade of neural transmission in autonomic, sensory and motor nerve fibres by binding to sodium channels in the axon membrane from within, preventing sodium ion entry during depolarisation. The threshold potential is not reached, and consequently, the action potential is not propagated. The concentration of local anaesthetic and dose used determine the onset, density and duration of the block. There are marked differences in the recommended maximum safe doses of different local anaesthetic agents. If the maximum dose is exceeded, serious cardiovascular (arrhythmias) and CNS side effects (convulsions) may be observed.

Local anaesthetic drugs injected close to a sensory nerve or plexus will block the conduction of nerve impulses, including pain from sensory fibres, and provide excellent analgesia. Some local anaesthetics are given with adrenaline (epinephrine) to reduce systemic toxicity and increase the duration of action.

Local anaesthetics can be administered directly to wounds or by local infiltration to produce postoperative analgesia; however, these approaches will not normally block pain arising from deep internal organs. Local anaesthetic techniques are particularly useful in day-case surgery and children. Continuous infusions via a catheter will allow prolonged analgesia. More permanent neural blockade for the control of cancer pain may be achieved by using a neurolytic agent such as absolute alcohol or phenol.

A topical formulation of lidocaine has been marketed for the management of neuropathic pain caused by post-herpetic neuralgia. Up to three plasters may be worn for a 12-hour period each day.

Epidural local anaesthetics

Long-acting local anaesthetic drugs such as bupivacaine are most effective in relieving pain after major surgery. They work by blocking nerves in the spinal canal serving both superficial and deep tissues, and thus analgesia can be obtained in deep internal organs. Sensory and sympathetic nerves that maintain smooth muscle tone in blood vessels are blocked. As a result, vasodilation can occur, which may result in significant hypotension. Epidural catheters allow continuous infusions and long-term therapy by this route. Adverse effects may include muscle weakness in the area supplied by the nerve and, rarely, infection and haematomas.

Adjuvant medicines

To be an analgesic, a drug must relieve pain in animal models and give demonstrable and reliable pain relief in patients. Drugs such as the opioids and the NSAIDs clearly are analgesics. In some types of pain, such as cancer pain or neuropathic pain, the addition of non-analgesic drugs to analgesic therapy can enhance pain relief. A list of some adjuvant drugs is given in Table 34.2. It should be remembered that some drugs, such as tricyclic antidepressants (TCAs), have intrinsic analgesic activity, perhaps related to their ability to affect 5-HT and noradrenergic neurotransmission.

Antidepressants

Long-term pain is accompanied frequently by anxiety and depression. Thus, it is not surprising that the use of antidepressants and other psychoactive drugs is a routine component of pain management. There is evidence that some of these drugs have analgesic properties independent of their psychotropic effects.

The TCAs are frequently used for the treatment of long-term pain conditions with and without antiepileptic drugs, and there is a substantial body of literature about their analgesic action (McQuay et al., 1996).

The biochemical activity of the TCAs suggests that their main effect is on serotonergic and noradrenergic neurones. The TCAs inhibit the reuptake of the monoamines, 5-HT and/or noradrenaline in neurones found within in the brain and spinal cord. Through a rather complex mechanism, this causes an initial fall in the release of these transmitters followed by a sustained rise in the concentration of neurotransmitter at synapses in the pain neural pathways. This rise usually takes 2–3 weeks to develop. Tricyclic antidepressants are effective analgesics in headache, facial pain, low back pain, arthritis and, to a lesser degree, cancer pain.

Clinical use of antidepressants in long-term pain

When used in pain management, it is usual to start with a low TCA dose, for example, amitriptyline 10–25 mg at night and to titrate upwards according to response and adverse effects. Within clinical trials TCA doses have varied considerably, but most are lower than the doses used in psychiatry, in the order of amitriptyline 50–75 mg/day. Under specialist supervision, higher doses, for example, amitriptyline 150–200 mg/day, may be appropriate.

Tricyclic antidepressants have a wide range of adverse effects due to interaction with histamine and muscarinic acetylcholine receptors, and these may cause a marked reduction in patient adherence. Newer antidepressant drugs have generally been disappointing from the analgesic perspective. Outcomes with selective serotonin reuptake inhibitors (SSRIs) have been disappointing. Scientific (Sindrup and Jensen, 1999) and clinical evidence suggest that both noradrenergic and serotonergic transmission need to be enhanced for an analgesic effect to be seen (Sindrup et al., 2005). The serotonin/noradrenaline reuptake inhibitors (SNRIs) venlafaxine and duloxetine have effects on both monoamines and appear to possess analgesic activity in neuropathic pain conditions (e.g. diabetic neuropathy and

Table 34.2 Adjuvant drugs used in the treatment of pain

Drug class	Type of pain	Example
Antiepileptics	Neuropathic pain Migraine Cluster headache	Carbamazepine Sodium valproate Gabapentin Pregabalin Lamotrigine
Antidepressants	Neuropathic pain Musculoskeletal pain	Amitriptyline Imipramine Venlafaxine Duloxetine
Intravenous anaesthetic agents	Neuropathic pain Burn pain Cancer pain	Ketamine
Skeletal muscle relaxants	Muscle spasm Spasticity	Baclofen Dantrolene Botulinum toxin (type A)
Steroids	Raised intracranial pressure Nerve compression	Dexamethasone Prednisolone
Antibiotics	Infection	As indicated by culture and sensitivity
Antispasmodics	Colic Smooth muscle spasm	Hyoscine butylbromide Loperamide
Hormones/hormonal analogues	Malignant bone pain Spinal stenosis Intestinal obstruction	Calcitonin Octreotide
Bisphosphonates	Bone pain (caused by cancer or osteoporosis)	Pamidronate (for cancer pain) Alendronate

post-herpetic neuralgia). Some antidepressant compounds, including trazodone and mirtazapine, do not act via monoamine reuptake inhibition and do not appear to possess intrinsic analgesic activity. They are effective antidepressants and may have a place in the treatment of co-existing depression, but analgesia should be managed separately.

Antiepileptic drugs

The usefulness of this group of drugs is well established for the treatment of neuropathic pain (Wiffen et al., 2013). Conditions which may respond to antiepileptics include trigeminal neuralgia, postherpetic neuralgia and multiple sclerosis, glossopharyngeal neuralgia and similar pains that may follow amputation or surgery. Several classes of drugs show antiepileptic activity, and these can be broadly classed as sodium channel blockers (carbamazepine, phenytoin), glutamate inhibitors (lamotrigine), voltage-gated calcium channel ligands (gabapentin, pregabalin), gamma-aminobutyric acid (GABA) potentiators (sodium valproate, tiagabine) or drugs

showing a mixture of these effects (topiramate). Failure to respond to one particular drug does not indicate that antiepileptics as a broad class will be ineffective. A drug with a different mechanism of action or combination therapy could be considered.

Antiepileptics are surprisingly effective in the prophylaxis of migraine and cluster headache. Their mode of action is unclear, but both of these conditions are associated with abnormal excitability of certain groups of neurones, and the neuronal depression caused by antiepileptics is probably important.

Ketamine

Ketamine is an intravenous anaesthetic agent with a variety of actions within the CNS. Many of its effects are related to its activity at central glutamate receptors, although it also has actions at certain voltage-gated ion channels and opioid receptors. Low doses of ketamine (0.1–0.3 mg/kg/h via the intravenous route) can produce profound analgesia, even in situations where opioids have been ineffective, such as neuropathic pain. Despite its variable oral availability, oral administration of ketamine can be surprisingly effective (Annetta et al., 2005; Mercadante, 1996). Its usefulness is limited by troublesome psychotropic side effects, although the simultaneous administration of benzodiazepines or antipsychotics can reduce these problems.

Anxiolytics

Benzodiazepines may be used for short-term pain relief in conditions associated with acute muscle spasm and are sometimes prescribed to reduce the anxiety and muscle tension associated with long-term pain conditions. Many authorities believe that they reduce pain tolerance and there is good evidence that they can reduce the effectiveness of opioid analgesics, although the mechanism by which this occurs is unclear. Clonazepam has been used in the management of neuropathic pain. Diazepam can be used to control painful spasticity, due to acute or spinal cord injury, but sedation may be troublesome, and tizanidine (see following discussion) is probably a more suitable choice.

Antihistamines

These agents were introduced into the management of long-term pain because of their sedative muscle relaxant properties. These actions are non-specific, and it is not clear whether the clinical effect is mediated centrally or peripherally. Most clinical studies have been carried out with hydroxyzine, which has shown benefit in acute pain, tension headache and cancer pain, but is not commonly used in current clinical practice.

Skeletal muscle relaxants

The drugs described in this section are used for the relief of muscle spasm or spasticity. It is essential that the underlying cause of the spasticity and any aggravating factors such as pressure sores or infections are treated. Skeletal muscle relaxants usually help spasticity, but this may be at the cost of decreased muscle tone elsewhere, which may lead to a decrease in patient mobility, which may make matters worse.

Baclofen, which has a peripheral site of action, working directly on skeletal muscle, is probably the most commonly prescribed skeletal muscle relaxant. It is a derivative of the inhibitory neurotransmitter GABA and appears to be an agonist at the GABA_B receptor. Baclofen is used commonly in the treatment of spasticity caused by multiple sclerosis or other diseases of the spinal cord, especially traumatic lesions.

The α_2 -adrenergic agonist tizanidine has potent muscle relaxant activity and is an alternative to baclofen. It may also have some direct analgesic effects.

Dantrolene is an alternative that is effective orally and which may have fewer, but potentially more serious, adverse effects. Its effect is due to a direct action on skeletal muscle and takes several weeks to develop.

Botulinum toxin

The bacterium *Clostridium botulinum* produces a potent toxin that interferes directly with neuromuscular transmission. Purified preparations of the type A toxin produce long-lasting relaxation of skeletal muscle. The effect often lasts in excess of three months and avoids the systemic side effects of agents such as baclofen. Great care must be taken in administering this drug because spread may occur to adjacent muscle groups, producing excessive weakness. Use of botulinum toxin has been approved by National Institute for Health and Care Excellence (NICE) for prophylaxis of migraine (NICE, 2014). Overdosage, with systemic absorption, may lead to generalised muscle weakness and even respiratory failure.

Clonidine

The α -adrenergic agonist clonidine has been shown to produce analgesia, and there is evidence that both morphine and clonidine produce a dose-dependent inhibition of spinal nociceptive transmission that is mediated through different receptors for each drug. This may explain why clonidine has been shown to work synergistically with morphine when given by the intrathecal or epidural routes. Clonidine also appears to be effective when given by other routes or even topically, but it may cause severe hypotension by any route.

Cannabinoids

Cannabis has been used as an analgesic for hundreds of years. Problems concerning the legal status of cannabis in most countries have hindered the scientific investigation of its analgesic properties. The active ingredient in preparations made from the hemp plant, *Cannabis sativa*, is δ -9 tetrahydrocannabinol. This compound has analgesic activity in animal models of experimental pain as well as in the clinical situation (Burns and Ineck, 2006). Overall, analgesic activity appears relatively weak, and it has not been possible to separate the analgesic activity from the potent psychotropic effects characteristic of these drugs, but a commercial preparation, Sativex, is now licensed for the management of spasticity in multiple sclerosis. There may be a clearer analgesic effect in neuropathic pain, but the evidence for this remains limited and must be considered along with the misuse potential when prescribing.

Stimulation-produced analgesia

Stimulation-produced analgesia can be used for trauma, postoperative pain, labour pain and various types of long-term pain.

Transcutaneous electrical nerve stimulation and acupuncture

Transcutaneous electrical nerve stimulation (TENS) machines are portable battery-powered devices that generate a small current to electrodes applied to the skin. The electrodes are placed at the painful site or close to the course of the peripheral nerve innervating the painful area, and the current is increased until paraesthesia is felt at the site of the pain. The current stimulates the large, rapidly conducting (A β) fibres which close the gating mechanism in the dorsal horn cells, and this inhibits the small, slowly conducting (A δ and C) fibres. TENS, in particular, offers the patient a simple, noninvasive, self-controlled method of pain relief with relatively few adverse effects.

Acupuncture also works using a similar manner, although additional mechanisms, including stimulation of endogenous opioid release, may be involved. Acupuncture was recommended by NICE for several years for the treatment of low back pain but has been withdrawn in most recent guidance (NICE, 2016).

Treatment of selected pain syndromes

Postoperative pain

The majority of patients experience pain after surgery. The site and nature of surgery influences the severity of pain, although individual variation between patients does not allow prediction of the severity of pain by the type of operation.

Apart from the obvious humanitarian benefit of relieving suffering, pain relief is desirable for a number of physiological reasons after surgery or any form of major tissue injury. For example, poor-quality analgesia reduces respiratory function, increases heart rate and blood pressure, and amplifies the stress response to surgery. The use of intermittent and patient-controlled intermittent intravenous opioids injections has been described earlier in this chapter. However, opioids themselves may delay recovery and are associated with adverse events in the postoperative period (Kehlet et al., 1996). It is now common to treat postoperative pain using a 'multimodal approach', consisting of paracetamol, an NSAID, opioids and local anaesthetic blocks or wound infiltration. NSAIDs such as diclofenac and ketorolac must be used with caution in the postoperative period where there is a possibility of renal stress, such as blood loss, and the normal protective effect of prostaglandins on the kidney will be lost, culminating in acute renal failure. There is no evidence to support the pre-emptive use of either NSAIDs or local anaesthetic techniques, although there is some theoretical and clinical evidence suggesting that opioids given before surgery may be more effective than when given postoperatively.

Cancer pain

Cancer and pain are not synonymous. One-third of patients with cancer do not experience severe pain. Of the remaining two-thirds that do, about 88% can be controlled using basic principles of pain management (Scottish Intercollegiate Guidelines Network, 2008). Pain associated with cancer may arise from many different sources and may exhibit the characteristics of both acute and long-term pain. The mechanisms and sources of cancer pain may change with time, and regular assessment is required. Cancer occurs more frequently in the elderly, who may have a larger proportion of other painful conditions than the younger population. Pain may be arising from these sources too, and these require treatment at the same time.

Cancer pain can be treated both with drugs and other interventional techniques, such as radiotherapy and nerve blocks. Usually, drug treatment is based on the WHO analgesic ladder together with the use of adjuvant analgesics. Opioids are the mainstay for the treatment of cancer pain, although increasingly, some clinicians progress from non-opioid drugs to a strong opioid such as morphine, omitting the middle step of the analgesic ladder.

Although this chapter is concerned only with the management of pain, care of the patient with a terminal illness requires management of all aspects of the patient. The Liverpool Care Pathway (LCP) in England was promoted for many years as a resource to promote high-quality care in the last days of life (Ellershaw and Wilkinson, 2003). The LCP acknowledged that death was imminent and ensured the patient's comfort by omitting long-term non-essential medication and ensuring anticipatory prescribing in case the patient experienced pain, delirium, vomiting or breathlessness. However, in 2013, after much criticism in the media, it was phased out and replaced with an individual approach to end-of-life care for each patient (NICE, 2015).

Opioid use in cancer pain

Morphine remains the first-line opioid used for the management of cancer pain and may be given in immediate or modified release oral formulations. If not tolerated, alternatives such as oxycodone or hydromorphone, both having relatively long half-lives, may be considered. Optimal dosage is determined on an individual basis for each patient by titration against the pain. Patients requiring long-term modified-release opioids should have additional oral doses of rapidly acting opioid to act as an 'escape' medicine for incident or breakthrough pain. The British National Formulary recommends that the standard dose of a strong opioid for breakthrough pain is one-tenth to one-sixth of the regular 24-hour total daily dose. Methadone should not be used as first-line treatment of cancer pain but may be useful when alternatives have failed or the patient has experienced intolerable adverse effects.

When the oral route is unavailable, other routes of administration such as the buccal, rectal, transdermal or parenteral (subcutaneous, intravenous) or spinal (epidural or intrathecal) routes may be considered. Syringe drivers or implanted pumps may be used to provide analgesia in cases where conventional opioid delivery is ineffective. Morphine and oxycodone are available

for parenteral administration, and in the UK, diamorphine is also suitable and readily available. Diamorphine hydrochloride has the advantage of being very water soluble, so a high dose may be given in a small volume, which reduces the frequency of changes of syringes and refills necessary to provide adequate pain relief. The proportion of patients who need an implanted pump for intrathecal drug delivery is extremely small and is confined largely to those who are persistently troubled with unacceptable adverse effects. Such patients may achieve pain relief with lower equivalent opioid doses and have few problems with side effects. Long-term maintenance of indwelling lines and catheters requires training for the patient and specialist expertise from physicians and nursing teams, but excellent long-term results are possible.

Use of adjuvant drugs and treatments for cancer pain

Neuropathic pain is common in cancer. As many as 40% of cancer patients may have a neuropathic component to their pain. Tricyclic antidepressants and antiepileptic drugs should be introduced early, but where these are ineffective, ketamine can have a beneficial effect.

Levomopromazine, a phenothiazine with analgesic activity, is a useful alternative when opioids cannot be tolerated. It causes neither constipation nor respiratory depression and has antiemetic and anxiolytic activity. It is sedative, which may be either a virtue or a problem in palliative care.

Corticosteroids are useful in managing certain aspects of acute and persistent cancer pain. They are particularly useful for raised intracranial pressure and for relieving pressure caused by tumours on the spinal cord or peripheral nerves. Dexamethasone is the most commonly used steroid to ameliorate raised intracranial pressure in patients with brain tumours. High steroid doses given for 1 or 2 weeks do not require a reducing-dosage regimen. Also, they may produce a feeling of well-being, increased appetite and weight gain, all beneficial for cancer patients, although these effects are usually transient.

It is essential that underlying causes of pain be treated; therefore, it is appropriate to use antibiotics to treat infections, radiotherapy to reduce tumour bulk or control bone pain, or surgery to achieve fracture fixation or to relieve bowel obstruction in conjunction with antispasmodics such as hyoscine N-butylbromide.

Specific cancer pain syndromes

Three types of malignant pain are briefly outlined to indicate various therapeutic approaches.

Cancer of the pancreas. Pain is caused by infiltration of the tumour into the pancreas as well as by obstruction of the bowel and biliary tracts and metastases in the liver. Patients may experience anorexia, nausea, vomiting and diarrhoea, and they also are often depressed. Surgery, radiotherapy and chemotherapy may relieve pain for long periods, as does neurolytic blockade of the coeliac plexus. Opioid analgesics are useful and may be administered by the intravenous or epidural routes by either bolus injection or continuous infusion.

Mesothelioma of the lung. Mesothelioma causes pain when the tumour penetrates surrounding tissues such as the pleura, chest wall and nerve plexuses. The WHO analgesic ladder should be used first, but it should be remembered that a NSAID may be beneficial because inflammation is often a component of the chest wall involvement. Adjuvants such as TCAs or steroids may be helpful. As the tumour progresses, nerve blocks or neurosurgery may be necessary, and invasion of the vertebrae can lead to nerve root or spinal cord compression. In the latter case, high-dose steroids such as dexamethasone may be given intravenously, but radiotherapy is also useful in reducing the size of the tumour.

Metastatic bone pain. Metastatic bone pain is usually treated with courses of chemotherapy and radiotherapy, but analgesics may also be beneficial. A prostaglandin-like substance has been isolated from bone metastases, and therefore an NSAID and, more recently, bisphosphonates are often used in bone pain. Steroids also interfere with prostaglandin formation, and dexamethasone, therefore, has a role, especially where there is nerve root or spinal cord compression.

Neuropathic pain

Neuropathic pain may be defined as ‘pain arising as a direct consequence of a disease or lesion affecting the somatosensory system’ and may occur as a result of pathological damage to nerve fibres in a peripheral nerve or in the CNS (Table 34.3). Neuropathic pain may be spontaneous in nature (continuous or paroxysmal) or evoked by sensory stimuli. Because the underlying aetiology

Table 34.3 Examples of causes of neuropathic pain

Cause of neuropathy	Examples
Trauma	Phantom limb Peripheral nerve injury Spinal cord injury Surgical
Infection/inflammation	Post-herpetic neuralgia HIV
Compression	Trigeminal neuralgia Sciatica
Cancer	Invasion/compression of nerve tissue by tumour
Ischaemia	Post-stroke pain Metabolic neuropathies (e.g. diabetic peripheral neuropathy)
Demyelination	Multiple sclerosis
Drugs	Vinca alkaloids Ethanol Taxols Antibacterials for TB and HIV

HIV, Human immunodeficiency virus; TB, tuberculosis.

is different from inflammatory types of pain, patients typically present with disturbances in sensory function often describing their pain as tingling, shooting or electric shocks. It is possible for patients to present with pain in the context of sensory loss. Unlike inflammatory pain, neuropathic pain serves no biological advantage and can be described as an illness in its own right.

Typically, neuropathic pain does not respond as well to conventional analgesics, such as paracetamol and NSAIDs. Guidelines for the pharmacological management of neuropathic pain in the non-specialist setting have been published (NICE, 2013).

Specific neuropathic pain syndromes

Postherpetic neuralgia. The pain associated with herpes zoster infection is severe, continuous and often described as burning and lancinating. Antiviral therapy, such as aciclovir, initiated at the first sign of the rash can reduce the duration of the pain, particularly post-herpetic pain, which follows the disappearance of the rash. Tricyclic antidepressants such as amitriptyline are the mainstay of treatment, commencing with low doses (e.g. amitriptyline 10–25 mg at night) and gradually increased according to pain relief (usual dose amitriptyline 50–75 mg at night). This may be combined with antiepileptic drugs if the response is poor or incomplete. Carbamazepine is historically important, but newer antiepileptic drugs, such as gabapentin and pregabalin, are considered first-line therapy and are often better tolerated. One study has demonstrated a significant difference in the incidence and, to a lesser extent, the intensity of pain in patients who received a single epidural methylprednisolone and bupivacaine injection compared with those who received antiviral therapy and analgesia as ‘standard care’ (van Wijck et al., 2006). However, given the modest clinical effects on acute pain and no effect on the incidence of postherpetic neuralgia, the routine use of epidural local anaesthetic and steroid injection is not widely supported.

Diabetic peripheral polyneuropathy. Nerve damage and neuropathy are among the long-term complications of diabetes mellitus (see Chapter 45) and are most prevalent in elderly patients with type II diabetes. Patients often describe numbness but also experience a burning sensation in their feet. The sensory loss can result in painless foot ulcers. Tricyclic antidepressants or SNRIs (duloxetine or venlafaxine) and antiepileptics, such as gabapentin and pregabalin, have been beneficial.

Trigeminal neuralgia. Trigeminal neuralgia presents as abrupt, intense bursts of severe, lancinating pain, provoked by touching sensitive trigger areas on one side of the face. The disorder may spontaneously remit for periods of several weeks or months. Antiepileptic drugs, particularly carbamazepine, have been used successfully. If drug therapy is ineffective, neurosurgical techniques such as decompression of the trigeminal nerve may be considered. If surgery is successful, antiepileptics should be withdrawn gradually afterwards.

Peripheral nerve injury and neuropathy. Damage to or entrapment of nerves can cause pain, unpleasant sensations and paraesthesiae. Tricyclic antidepressants and antiepileptic drugs,

such as gabapentin, have been used with some success to treat neuropathic pain (Moore et al., 2014). A neuroma occurs when damaged or severed nerve fibres sprout new small fibres in an attempt to regenerate. Pain develops several weeks after the nerve injury and is often due to the neuroma growing into scar tissue, causing pain as it is stretched or mobilised. Treatment of neuroma is very difficult, and few treatments are successful. Options include surgery and injections of steroid and local anaesthetic agents.

Complex regional pain syndromes. Complex regional pain syndromes are an important group of painful conditions that may follow trauma or damage to nerves and are characterised by neuropathic pain, trophic changes and motor dysfunction. The key elements of successful treatment are effective multimodal analgesia, including drugs with efficacy for neuropathic pain, and aggressive physiotherapy to facilitate a return to normal function. Sympathetic blockade using local anaesthetics may have a therapeutic role.

Back and neck pain

Back pain is one of the commonest reasons for seeing a medical practitioner. Despite this, the problem is poorly understood. The most practical classification is based on the duration of symptoms (BenDebba et al., 1997). Acute low pain is generally defined as pain that lasts for a few days or weeks. The majority of these problems tend to be self-limiting and resolve spontaneously. Typical treatments include rest, adequate analgesia with a NSAID and/or a weak opioid and maintaining physical activity.

Long-term back pain lasts for much longer and progressively leads to a chronic state associated with pain, depression, anxiety and disability. Early intervention is necessary to ensure good functional and vocational outcomes. If a patient is off work for as much as 6 months, then there is a less than 50% chance of the individual ever returning to work. The likelihood of returning to work falls to less than 25% after 1 year and is almost zero after 2 years. Although pharmacological therapies may aid rehabilitation, other treatment strategies have a greater role to play in the management of long-term back pain. Guidelines for the management of non-specific long-term low back pain and sciatica have been developed (NICE, 2016). It is essential for the patient to develop good self-management skills, and current recommendations emphasise the importance of using a biopsychosocial approach. Other treatment options include psychological therapies using a cognitive behavioural approach and manual therapy (spinal manipulation, mobilisation or soft tissue techniques such as massage) but only in combination with graded exercise programmes. Acupuncture is no longer recommended.

Osteoarthritis and rheumatoid arthritis

Pain often is a presenting symptom in osteoarthritis or the inflammatory arthritides, which include rheumatoid arthritis. The pathophysiology and management of osteoarthritis and rheumatoid arthritis is covered in Chapter 54.

Myofascial pain

Myofascial pain is pain arising from muscles and is associated with stiffness and neuropathic symptoms, such as tingling and paraesthesiae. It may occur spontaneously or after trauma, such as whiplash injury. Myofascial pain syndrome is sometimes also termed myositis, fibrositis, myalgia and myofasciitis. Acute muscle injury can be treated using first aid techniques with the application of a cooling spray or ice to reduce inflammation and spasm, followed by passive stretching of the muscle to restore its full range of motion. Injection therapy with local anaesthetic or saline may be used to disrupt sensitive muscle trigger points. Local injections of botulinum toxin have also been shown to be effective where muscle spasm is prolonged and severe. TENS and acupuncture have an important role to play in reducing pain and muscle spasm. Treatment of long-term myofascial syndromes should always include a programme of physical therapy.

Postamputation and phantom limb pain

The majority of amputees suffer significant stump or phantom limb pain for at least a few weeks each year. Pain will be present in the immediate postoperative period in the stump, and this may be caused by muscle spasm, nerve injury and sensitivity of the wound and surrounding skin. As the wound heals, the pain generally subsides. If it does not, the reason may be vascular insufficiency or infection. Pain occurring a number of years after amputation may be caused by changes in the structure of the bones or skin in the stump. Reduction in the thickness of overlying tissue with age may expose nerve endings to increased stimuli or ischaemia. Usually, conventional analgesics are beneficial for stump pain, although sometimes relatively high doses may be required. Tricyclic antidepressants may also be helpful for stump pain, and surgery may be necessary to restore the vascular supply or reduce trauma to nerve endings.

Phantom pain is a referred pain which produces a burning or throbbing sensation, felt in the absent limb. Cramping sensations are caused by muscular spasm in the stump. The patient with phantom limb pain is often anxious, depressed and frightened, all of which exacerbate the pain. Conventional analgesic drugs alone are generally not adequate for phantom pain, but TCAs and antiepileptic drugs are useful adjuvants. Other therapy which can be effective includes TENS and sympathetic blockade. These patients frequently require management at specialist pain centres.

Headache

Everybody experiences the occasional tension headaches. They are caused by muscle contraction over the neck and scalp. Often they respond to simple analgesics available OTC, such as paracetamol and NSAIDs. They may also respond to TCA drugs given as a single dose at night as well as non-pharmacological treatments, such as TENS. NSAIDs may be

indicated if the headache is associated with cervical spondylosis or neck injury.

Migraine

Most migraine attacks respond to simple analgesics such as aspirin or paracetamol. Soluble preparations are best because gut motility is reduced during a migraine attack, and absorption of oral medication may be delayed. Migraine treatment has improved markedly with the development of the triptan drugs, such as almotriptan, eletriptan, rizatriptan, sumatriptan, naratriptan and zolmitriptan (Goadsby, 2005). These are 5HT_{1B/1D}-agonists that will often abort an attack, especially when given by the subcutaneous route. Their vasoconstrictor activity precludes their use in patients with angina or cerebrovascular disease, but the side effects are less serious than with the ergot derivatives they have replaced.

Prophylactic drug treatment of migraine includes α -adrenergic blockers, antiepileptics and TCAs. Long-term treatment is undesirable.

Cluster headache

Cluster headache is a disabling condition characterised by severe unilateral head pain occurring in clusters of attacks varying from minutes to hours. It shares some pathological features with migraine and treatment is similar, although high-resolution MRI studies have shown specific anatomical differences in the brains of people with cluster headache. Triptans are effective in acute attacks, as is inhalation of 100% oxygen. Prophylaxis is similar to that of migraine.

Dysmenorrhoea

Dysmenorrhoea is a common cause of pelvic pain in women. NSAIDs are effective as first-line therapy due to their effect on cyclo-oxygenase inhibition, but it can also be helped by the prescription of oral contraceptives because pain is absent in anovulatory cycles. Dysmenorrhoea due to endometriosis may require therapy with androgenic drugs such as danazol or regulators of the gonadotrophins such as norethisterone.

Burn pain

Patients with burns may require a series of painful procedures such as physiotherapy, debridement or skin grafting. Premedication with a strong opioid before the procedure and the use of Entonox (premixed 50% nitrous oxide and 50% oxygen) may be necessary to control the pain. Regular opioid administration may be useful to prevent the pain induced by movement or touch in the affected area. The anaesthetic drug ketamine has potent analgesic activity when used in subhypnotic doses. Its short duration of action may be beneficial to reduce the pain of dressing changes or other forms of incident pain. Even with low doses, a significant proportion of patients will experience side effects of dysphoria or hallucinations. These can be treated with benzodiazepines or antipsychotic compounds, such as haloperidol.

A summary of medicine indications and common therapeutic problems associated with analgesic use are presented in Table 34.4.

Problem	Solution	Example
Neuropathic pain	Antiepileptics	Carbamazepine Sodium valproate Gabapentin Lamotrigine
	Antidepressants	Amitriptyline Imipramine
	Intravenous anaesthetic agents	Ketamine
Malignant bone pain	Bisphosphonates	Pamidronate Calcitonin
Muscle spasm/spasticity	Skeletal muscle relaxants	Baclofen Dantrolene Botulinum toxin (type A)
Raised intracranial pressure	Corticosteroids	Dexamethasone Prednisolone
Nausea with morphine	Antiemetic	Cyclizine Droperidol Ondansetron
	Use an alternative route of administration	Topical or subcutaneous
Constipation	Determine if drug induced, e.g. opioids or tricyclic antidepressant	Co-prescribe laxatives (e.g. docusate sodium and senna)
Antidepressants in patients with ischaemic heart disease	Use a less cardiotoxic antidepressant	Duloxetine Venlafaxine
Drug interactions with carbamazepine	Use an antiepileptic which does not affect hepatic enzymes	Gabapentin
Renal failure	Morphine accumulates	Consider lower dose
	Use a drug which is not eliminated by kidney	Fentanyl Buprenorphine
Sedation/impaired cognition	Identify any drug-related causes and adjust dose or stop drug	

Case studies

Case 34.1

Mrs NP is a 55-year-old care home assistant who has type 2 diabetes. Her current prescription is for metformin 500 mg three times a day and amitriptyline 50 mg at night. When collecting her repeat prescription, she mentions that she 'Can't get on with the new tablets' because they make her very drowsy in the mornings. You invite Mrs NP for a review of her medication. During the consultation, Mrs NP explains that for some time she has suffered from constant tingling and occasional shooting pain in her legs and feet, and 3 months ago amitriptyline 10 mg daily was prescribed. About one month ago, the dose of amitriptyline was increased to 50 mg daily. She takes the dose at night, as advised by her primary care doctor. When she works an early shift (about three times a week), she usually omits the dose of amitriptyline to be sure that she wakes up in time to get to work. Mrs NP says that she takes the metformin regularly and has no associated problems. She is keen to be fit enough to work because she is supporting her youngest son, who is studying to be a doctor.

Question

What advice should you give to this patient?

Answer

Mrs NP has developed diabetic peripheral neuropathy, a type of neuropathic pain. She is experiencing intolerable side effects from the increased dose of amitriptyline and therefore does not take it regularly. There are several options to improve tolerability. Firstly, Mrs NP should consider increasing the dose of amitriptyline more slowly. She may also benefit from taking her amitriptyline dose earlier in the evening, approximately 60–90 minutes before retiring to bed, so that it results in less hangover effect the following day. If neither of these strategies is beneficial, she should consult her primary care doctor about switching to an alternative drug to manage her neuropathic symptoms. Most recent guidance (NICE, 2013) recommends either gabapentin, pregabalin or duloxetine as alternatives to a tricyclic antidepressant as first-line therapy for neuropathic pain in the non-specialist setting.

Case 34.2

A 55-year-old lady, Mrs LT, with metastatic abdominal cancer from a probable primary in the pelvis, presents with an abdominal mass. Mrs LT's pain is uncontrolled despite regular prescription of oral opioids, and she has been sick for a week. Subacute bowel obstruction is present.

Question

How should Mrs LT be managed?

Answer

Management should begin with admission and rehydration. Mrs LT may be dehydrated and have marked electrolyte abnormalities which would need to be corrected. The oral route is unavailable for the

delivery of adequate analgesia, and thus consideration should be given to the use of parenteral administration, either by the subcutaneous route or using patient-controlled analgesia. The sickness should be treated, and an underlying cause sought. This may be subacute obstruction which, in turn, may be due to constipation caused by the opioids or by the disease process. Abdominal masses that indent on palpation are faeces (not tumour). Abdominal radiographs would show fluid levels if there was obstruction rather than constipation. Other possible causes of vomiting are recent anticancer therapy, anxiety, dyspepsia from NSAIDs, raised intracranial pressure and vertigo. Surgery may be needed to relieve the obstruction, but the need may be avoided by use of hyoscine *N*-butylbromide, which may control colic with little additional sedation. If the problem is one of constipation, rectal measures may be necessary to re-establish function. These may include suppositories, enemas or digital disimpaction. Once control of pain has been achieved and bowel function has returned to normal, she must receive regular combination laxative therapy, ideally, a stimulant laxative, such as senna, and a faecal softener, such as docusate sodium. A high fluid intake and increased dietary fibre should be encouraged because this will help prevent stool from becoming hard. There has been interest in the use of peripheral opioid receptor antagonists to reduce opioid-induced constipation. Because they have higher affinity for the opioid receptor than the agonist, they bind preferentially to opioid receptors in the gastro-intestinal tract, allowing the agonist to continue to have its desired effect in the CNS. A combination of prolonged-release oxycodone and prolonged-release naloxone (Targinact) or naloxegol may be an alternative if maximal laxative therapy does not help this patient. Attention should be paid to Mrs LT's emotional and spiritual needs at all times.

Case 34.3

A 28-year-old man, Mr FR, had a crush fracture of his ankle after falling from a roof. Fixation 9 months ago was described as satisfactory, but his leg is now very painful to even small stimuli, and he cannot use it or bear weight. Mr FR's lower leg has muscle wasting and is much colder than the opposite limb. The skin is very sensitive to touch, shiny and has a poor circulation.

Question

What is this condition, and how should this pain be treated?

Answer

Mr FR has presented with a complex regional pain syndrome. Management should be aggressive and directed towards functional restoration. Use of effective multimodal analgesia using pharmacological and non-pharmacological treatments is required. The aim is to facilitate aggressive physiotherapy and occupational therapy. There may be a burning component to the pain, which may respond to low doses of TCAs such as amitriptyline (10–25 mg at night initially, increased in small increments to 50–75 mg at night). Aggressive treatment early in the course of the disease can reduce the length of time patients, such as Mr FR, have this problem, and early referral to seek specialised help is recommended. A small percentage of patients will continue to have problems whatever treatment is given.

Case 34.4

An 85-year-old man, Mr PL, is admitted to hospital after falling down a flight of stairs and landing heavily on his right side. On admission, Mr PL is in severe pain and finds breathing, and

especially coughing, unbearably painful. A chest X-ray reveals that he has fractures of the 5th to 8th ribs on the right side.

Question

How should Mr PL's pain be managed, and what are the risks of under-treatment?

Answer

Multiple rib fractures are potentially very serious, and good analgesia can prevent potentially dangerous complications. Initial analgesia should include both potent opioids and NSAIDs (unless contraindicated). Opioids should be administered parenterally in the first instance, and subsequent use of patient-controlled analgesia would allow the patient to titrate his own analgesic requirements. The chest injury may well result in damage to the underlying lung, and it is essential to administer unrestricted high-flow oxygen to the patient because the combination of lung injury and ventilatory suppression secondary to either pain or the effects of opioids could lead to dangerous hypoxia. TENS may also prove helpful. Arterial oxygen saturation (and preferably arterial blood gases) should be monitored. If pain remains poorly controlled or if Mr PL's oxygenation deteriorates, thoracic epidural analgesia using a mixture of local anaesthetic and opioid may be considered. Failure to treat pain adequately in this situation may lead to a reduction in Mr PL's ability to cough and clear secretions from the chest. This can lead to respiratory failure and even death. Analgesia should be sufficient to allow regular physiotherapy to minimise the risk of such complications.

Case 34.5

A 45-year-old woman, Mrs SG, presents to her primary care doctor with a 2-day history of back pain after a lifting injury at work. The pain is constant and aching in character with radiation into the posterior aspect of both thighs as far as the knee. Physical examination shows Mrs SG to be maintaining a very rigid posture with some spasm of the large muscles of the back. Her range of movement is very poor, but there are no neurological signs in the legs.

Question

Which drugs may help Mrs SG's pain? What other advice should Mrs SG be given?

Answer

Acute back pain is very common and is rarely associated with serious spinal pathology. The absence of neurological signs is reassuring and indicates that early activity, possibly aided by a short course of analgesics, is the best way forward. A short course of regular NSAID (e.g. ibuprofen 400 mg three times a day) is recommended first-line treatment if not contraindicated. Paracetamol alone is not now recommended. If unable to take a NSAID, paracetamol in combination with a weak opioid is suggested. A muscle relaxant such as baclofen 20–40 mg/day in divided doses may be beneficial for short-term use only. The role of opioids is less clear. Short-term use (7–14 days) of a weak opioid such as codeine or tramadol is probably safe. Longer-term use is less satisfactory because there is no clear evidence of efficacy, and sedative side effects may reduce the patient's capacity and motivation to remain active. Mrs SG should be advised to remain active and accept that some pain is likely during the recovery phase. Failure to remain active and, in particular, excessive bed rest are both associated with worse outcomes.

Case 34.6

A 50-year-old man, Mr TW, is admitted to hospital with an acute onset of severe mid-thoracic spinal pain. He is found to be anaemic, and investigations show that Mr TW has multiple myeloma with widespread bony lesions, including fresh spinal fractures.

Question

Which drugs may help Mr TW's pain? What particular hazards may occur in this condition?

Answer

Mr TW is extremely ill, and even with aggressive chemotherapy, he is unlikely to survive more than a few months. Most of his pain will be related to the destruction of bone, and the aim should be to provide pain relief via a 'central' mechanism through the use of opioids and to reduce the rate of bone destruction and associated inflammatory responses. A potent opioid will be required, and oral morphine would

usually be the drug of first choice. In this situation, a combination of a modified-release preparation together with liberal 'as-required' dosing would be appropriate. The correct dose is the dose required to produce adequate pain relief without producing excessive sedation. Inflammatory pain may be improved by the use of NSAIDs and these should be given regularly, although they may be contraindicated in this condition (see following discussion). High-dose corticosteroids may achieve a similar effect and may also reduce the hypercalcaemia that is often seen in myeloma. Bone destruction and its associated pain may be reduced by the use of bisphosphonate compounds. In this case, intravenous pamidronate should be given.

Renal failure is common in myeloma. This may be due to obstruction of renal tubules by myeloma proteins or the effects of some chemotherapeutic agents. If renal impairment occurs, opioids should be used with caution so as to avoid problems with accumulation. Transdermal fentanyl may be a more appropriate drug. NSAIDs can precipitate acute renal failure in the presence of reduced renal blood flow. Finally, platelet function is often poor in patients with myeloma. This can be due to direct effects of myeloma proteins on platelets, bone marrow replacement by myeloma or the effects of chemotherapy. Use of NSAIDs may be associated with increased risk of gastrointestinal haemorrhage.

35 Nausea and Vomiting

Emma Mason and Philip A. Routledge

Key points

- Patients must be assessed carefully and, when necessary, reassessed frequently to identify the underlying cause of their nausea and/or vomiting.
- Antiemetics are symptomatic treatments only and do not treat the underlying cause.
- Choice of agent is based on an understanding of the likely pathophysiology, the receptors involved, the available route of administration and side effects.
- In certain situations, prophylactic regimens are beneficial, for example, motion sickness, postoperative nausea and vomiting, and chemotherapy-induced nausea and vomiting.
- Simple regimens are used when possible to prevent postoperative nausea and vomiting, such as parenteral cyclizine or prochlorperazine administered at induction. These and other antiemetics can be used for rescue therapy if vomiting occurs postoperatively.
- The choice of antiemetic to use in conjunction with cytotoxic chemotherapy depends on the 'emetogenicity' of the cytotoxic drugs used.
- Anticipatory emesis associated with chemotherapy can be treated with benzodiazepines, and dexamethasone may be useful in alleviating delayed emesis.

Nausea and vomiting are commonly (but not universally) associated symptoms. The word *nausea* is derived from the Greek *nausia*, meaning 'seasickness', and *vomiting* is derived from the Latin *vomere*, meaning 'to discharge'. Nausea is a subjective sensation, whereas vomiting is the reflex physical act of expulsion of gastric contents. Retching is defined as 'spasmodic respiratory movements' against a closed glottis with contractions of the abdominal musculature without expulsion of any gastric contents, that is, 'dry heaves' ([American Gastroenterological Association, 2001](#)). It is important to differentiate vomiting from regurgitation, rumination and bulimia. Regurgitation is the return of oesophageal or gastric contents into the hypopharynx with little effort. Rumination is the passive regurgitation of recently ingested food into the mouth followed by re-chewing, re-swallowing or spitting out. It is not preceded by nausea and does not include the various physical phenomena associated with vomiting. Bulimia involves overeating followed by self-induced vomiting.

Epidemiology

Nausea and vomiting from all causes have significant associated social and economic costs in terms of effects on quality of life and the need for extra medical care. In the community, nausea (with or without vomiting) is most likely to be associated with infection, particularly gastro-intestinal infection. Vestibular disorders may cause vomiting, as can motion sickness. Nausea and vomiting may be associated with pain, caused, for example, by migraine and severe cardiac pain. Many medicines cause nausea and occasionally also vomiting as a common dose-related (type A) adverse effect. This is particularly common with opioid use in palliative care. Nausea and vomiting also occur postoperatively or in association with cytotoxic chemotherapy or radiotherapy. These and other causes of nausea and vomiting are listed in [Table 35.1](#).

Pathophysiology

Complex interactions between central and peripheral pathways occur in the production of the clinical features of nausea and vomiting. The most important areas involved peripherally are the gastric mucosa and smooth muscle (the enteric brain) and the afferent pathways of the vagus and sympathetic nerves. Centrally, the significant areas involved are the area postrema, the chemoreceptor trigger zone (CTZ), the nucleus tractus solitarius (NTS) and the vomiting centre.

From a pharmacotherapeutic point of view, the most important aspect of this complex pathophysiology is the variety of receptors involved, including histaminergic (H_1), cholinergic (muscarinic M_1), dopaminergic (D_2), serotonergic ($5HT_3$) and neurokinin-1 (NK_1) receptors. In the clinical situation, these become targets for various drugs directed at controlling the symptoms.

There are 10^8 neurons in the intestine, and a complex interaction occurs among these, the mucosa, the smooth muscle in the intestine, the parasympathetic (vagus nerve) and sympathetic nerves and the higher centres in the spinal cord and brain to result in normal gastro-intestinal peristaltic activity. The enteric brain and the vagus nerve monitor stimuli from mucosal irritation while smooth muscle monitors stretch, which may result in nausea and/or vomiting.

Table 35.1 Selected causes of nausea and vomiting

Central	
1. Intracranial	Migraine Raised intracranial pressure (tumour, infection, haemorrhage, hydrocephalus, etc.)
2. Labyrinthine	Iatrogenic Labyrinthitis, motion sickness, Ménière's disease, otitis media Cancer chemotherapy Many other medicines (e.g. opioids) Radiotherapy Postoperative
Endocrine/metabolic	Pregnancy, uraemia, diabetic ketoacidosis, hyperthyroidism, hyperparathyroidism, hypoparathyroidism, Addison's disease, acute intermittent porphyria
Infectious	Gastroenteritis (viral or bacterial) Other infections elsewhere
Gastro-intestinal disorders	Mechanical obstruction (gastric outlet or small bowel) Organic gastro-intestinal disorders (e.g. cholecystitis, pancreatitis, hepatitis) Functional gastro-intestinal disorders (e.g. non-ulcer dyspepsia, irritable bowel syndrome)
Psychogenic disorders	Psychogenic vomiting, anxiety, depression
Pain related	Myocardial infarction

Adapted from Quigley et al. (2001).

The area postrema in the floor of the fourth ventricle contains the CTZ and is a special sensory organ rich in dopaminergic, serotonergic, histaminergic and muscarinic receptors. It is located outside the blood–brain barrier, and it is likely that chemicals, toxins, peptides, drugs and neurotransmitters in the cerebrospinal fluid (CSF) and bloodstream interact with this area to cause nausea and vomiting. However, the precise mechanism is not known.

The vomiting centre is situated in the dorsolateral reticular formation close to the respiratory centre and receives impulses from higher centres, visceral efferents, the eighth (auditory) nerve (the latter two through the nucleus tractus solitarius) and from the CTZ (Fig. 35.1). It includes a number of brainstem nuclei required to integrate the responses of the gastro-intestinal tract, pharyngeal muscles, respiratory muscles and somatic muscles to result in a vomiting episode. The vomiting centre may be stimulated in association with, or in isolation from, the nausea process.

The vomiting reflex can be elicited either directly via afferent neuronal connections, especially from the gastro-intestinal tract, and is probably dependent on the integrity of the nucleus tractus solitarius, or from humoral factors dependent on the integrity of the area postrema. The sequence of muscle excitation and inhibition necessary for the act of vomiting is probably controlled by a central

pattern generator located in the nucleus tractus solitarius, and information from the CTZ and vagus nerve converges at this point.

The central causes of nausea and vomiting include increased intracranial pressure, dilation of cerebral arteries during migraine and stimulation of the labyrinthine mechanism or of the senses of sight, smell and taste.

The peripheral causes of nausea and vomiting include motion sickness, delayed gastric emptying and gastric mucosal irritation (e.g. ulceration, non-steroidal anti-inflammatory drugs [NSAIDs]). These mechanisms are all mediated through the vagal afferent neurons. The vomiting associated with distension or obstruction of the gastro-intestinal tract is mediated through both the sympathetic and vagal afferent neurons.

Patient management

Management of the patient with nausea and vomiting is approached in three steps:

1. Recognise and correct any complications. This includes correction of dehydration, hypokalaemia and metabolic alkalosis in the acute situation with symptoms of less than 4 weeks in duration. Weight loss and malnutrition are features of chronic nausea/vomiting, that is, when symptoms have been present for 4 weeks or longer.
2. Where possible, identify the underlying cause (see Table 35.1) and institute appropriate treatment. Here it is important to be aware that metabolic or endocrine conditions such as hypercalcaemia, hyponatraemia and hyperthyroidism can result in vomiting.
3. Implement therapeutic strategies to suppress or eliminate symptoms which are dependent on the severity and clinical context. Ideally, antiemetic drugs are prescribed only when the cause of the nausea and/or vomiting is known, because by suppressing symptoms, they may otherwise delay diagnosis. This is especially true in children. However, they may sometimes be necessary temporarily in situations when directly addressing the underlying cause will not bring symptom relief sufficiently rapidly.

Some scenarios illustrating common therapeutic problems in the management of nausea and vomiting are outlined in Table 35.2.

Antiemetic drugs

Several classes of antiemetic drugs are available that antagonise the neurotransmitter receptors involved in the pathophysiology of nausea and vomiting. These classes of drugs are generally distinguished from each other by the identity of their main target receptor, although some act at more than one receptor.

Antihistamines

Antihistamine medicines include cinnarizine, cyclizine, diphenhydramine and promethazine. They have some efficacy in nausea and vomiting caused by a wide range of conditions, including

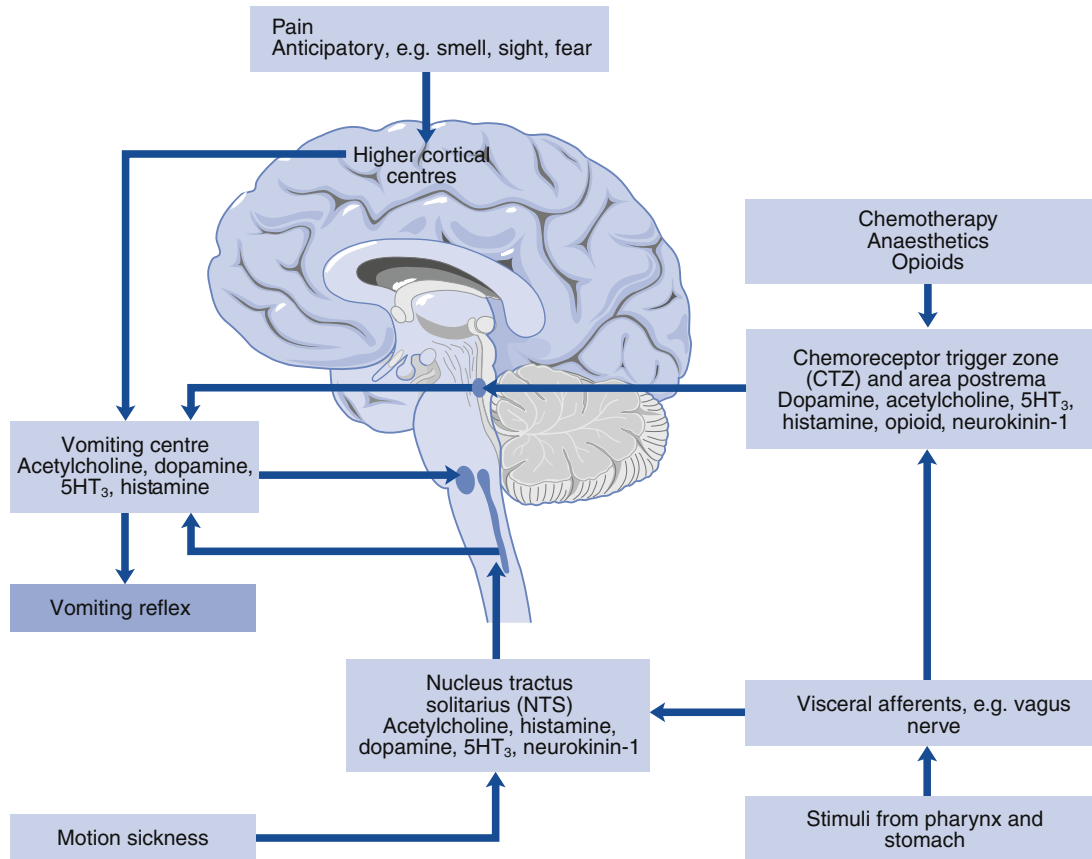

Fig. 35.1 Schematic representation of pathways involved in nausea and vomiting.

Table 35.2 Common therapeutic problems in managing patients with nausea and vomiting	
Problem	Possible cause/solution
Persistent nausea and vomiting despite treatment	Is the cause correctly diagnosed? Review the antiemetic agent and the dose: if both correct, change to or add a second agent.
Patient with PONV is vomiting despite suitable antiemetic regimen	Check analgesia: pain may be causing nausea and vomiting, or patient-controlled analgesia may require adjustment downward to reduce analgesic dose.
Patient with bowel obstruction is passing flatus	Prokinetic drug is first-choice antiemetic. 5HT ₃ antagonists may also be effective.
Patient with bowel obstruction is not passing flatus	Spasmolytic drug is first choice. Prokinetic drugs are contraindicated. Similarly, bulk-forming, osmotic and stimulant laxatives are inappropriate; phosphate enemas and faecal softeners are better.
A terminally ill patient receiving diamorphine is vomiting, despite use of haloperidol	Levomopromazine given as a 24-h subcutaneous infusion can be very effective.
A patient with renal failure (uraemia) is vomiting	Consider a 5HT ₃ antagonist.
A patient develops an acute dystonic reaction to metoclopramide	Give an intramuscular injection of an antimuscarinic (e.g. procyclidine). Such extrapyramidal reactions to metoclopramide are more common in young adults (especially females), and this agent is best avoided in this group.
PONV, Postoperative nausea and vomiting.	

motion sickness and postoperative nausea and vomiting (PONV). They are thought to block H₁ receptors in the CTZ and possibly elsewhere. However, several of these agents also have potent anticholinergic (M₁) receptor antagonist activity, which may contribute significantly to their efficacy and their adverse effect profile (see the section ‘Antimuscarinics’). The sedative effects of some antihistamines may also contribute to antiemetic activity, although this property appears not to be essential, and it can be a particular problem when skilled tasks, such as driving, need to be performed. Nevertheless, the non-sedating antihistamines, for example, fexofenadine, are of limited value in nausea and vomiting.

Antimuscarinics

This is one of the oldest classes of antiemetics, of which many members are potent inhibitors of muscarinic receptor (M₁) activity, both peripherally and centrally. Antimuscarinic drugs such as atropine, hyoscine and glycopyrronium have been used preoperatively to inhibit salivation and excessive respiratory secretions during anaesthesia. Antimuscarinics act by inhibiting cholinergic transmission from the vestibular nuclei to higher centres within the cerebral cortex, thereby explaining their predominant use in the treatment of motion sickness. Hyoscine hydrobromide (scopolamine hydrobromide) is the most widely used agent, and it can be given orally, by subcutaneous or intramuscular injection, or transdermally for motion sickness. Inhibition of peripheral muscarinic receptors can cause drowsiness, dry mouth, dilated pupils and blurred vision, decreased sweating, gastro-intestinal motility and gastro-intestinal secretions and difficulty with micturition. Antimuscarinics agents may also precipitate closed-angle glaucoma in susceptible individuals.

Antidopaminergics

Phenothiazines and butyrophenones

Phenothiazines (e.g. prochlorperazine, perphenazine and trifluoperazine) and butyrophenones (e.g. haloperidol and droperidol) act as antagonists at dopamine (D₂) receptors in the CTZ but may also have cholinergic receptor, muscarinic M₁ and histaminergic (H₁) receptor antagonist activity. As a consequence, they share several adverse effects with antihistamines and antimuscarinics, including drowsiness. In addition, the dopamine-blocking effects may be associated with acute dystonia (especially in children) and tardive dyskinesias or parkinsonism when used for prolonged periods. Prochlorperazine is less sedating and available as a buccal tablet and suppository for use when vomiting precludes oral administration. Phenothiazines are sometimes used for drug-associated emesis, including chemotherapy-induced nausea and vomiting (CINV), but like the butyrophenones, they have in many situations been superseded by more specific agents such as metoclopramide and the selective 5HT₃ antagonists. Levomepromazine is sometimes used to relieve nausea and vomiting in terminal care.

Metoclopramide

At lower doses, metoclopramide acts as a selective D₂ antagonist at the CTZ, and its effects mirror those of the phenothiazines and

butyrophenones. However, it also exerts peripheral D₂ antagonism at these doses and stimulates cholinergic receptors in gastric smooth muscle, thus stimulating gastric emptying. It may, therefore, be more effective than phenothiazines and butyrophenones when nausea is related to gastro-intestinal or biliary disease. At higher doses, it may exert some 5HT₃-receptor antagonism, but at these doses, the incidence of acute dystonic reactions, particularly in young women and the elderly, may limit its usefulness in CINV.

Domperidone

Although domperidone does not readily cross the blood–brain barrier, it is a selective antagonist of D₂ receptors at the CTZ, which lies outside the blood–brain barrier in the area postrema. It may also have peripheral effects that result in increased gastro-intestinal motility and faster gastric emptying. It is used in drug-associated vomiting, including CINV, and is relatively non-sedating. It can be given orally or by suppository. Acute dystonic reactions occur less frequently than with metoclopramide. It prevents nausea and vomiting during treatment with apomorphine and other dopamine agonists in Parkinson’s disease and is also used to treat vomiting associated with emergency hormonal contraception.

Olanzapine

Olanzapine is an atypical antipsychotic that antagonises multiple neuroreceptors, including dopaminergic (D₂), serotonergic (5HT₃), histaminergic (H₁), muscarinic and adrenergic receptors. Clinical studies suggest that olanzapine is effective in the prevention of CINV when used in combination with other antiemetics (Navari, 2014; Navari et al., 2011). The exact mechanism of olanzapine acting as an antiemetic is unclear, but its effects on the neuronal pathways involved in nausea and vomiting may partially explain its property. However, adverse effects such as akathisia and drowsiness may limit its use, and it is not licensed in Europe for this indication.

Selective 5HT₃-receptor antagonists

Serotonin (5-hydroxytryptamine [5HT]) plays an important role in nausea and vomiting. The subtype 5HT₃-receptors, which mediate the vomiting pathway, are located peripherally on vagal nerve endings in the gastro-intestinal tract and centrally in the brain, with high concentrations found in the area postrema and nucleus tractus solitarius. Highly emetogenic agents such as cisplatin are thought to disrupt gastric mucosa and initiate the release of 5HT from enterochromaffin cells, which stimulate the 5HT₃-receptors on afferent vagal nerve endings and thus trigger the emetic reflex. Selective 5HT₃-receptor antagonists that act centrally and peripherally are now commonly used to treat or prevent CINV (with drugs of moderate to high emetogenic potential) and PONV. They are also effective in radiotherapy-induced nausea and vomiting. Selective 5HT₃ antagonists are generally well tolerated, with the most common adverse effects being constipation, headache, dizziness and sensation of warmth or flushing. Some available agents include granisetron, ondansetron and

palonosetron. They are all more expensive than antihistamines, phenothiazines, antimuscarinics or dopamine antagonists.

Neurokinin-1 receptor antagonists

Substance P is a bioactive peptide that shares a common amino acid sequence with other bioactive peptides known as tachykinins. It appears to play an important role as a neurotransmitter in emesis, as well as in pain and a number of other inflammatory processes. Substance P binds to the subtype neurokinin-1 (NK₁) receptors, which are found in the area postrema and nucleus tractus solitarius. Selective NK₁ receptor antagonists, aprepitant and fosaprepitant (a prodrug of aprepitant), are now available for use as an adjunct to dexamethasone and a 5HT₃ antagonist in preventing nausea and vomiting associated with moderately and highly emetogenic chemotherapy. A newer NK₁ receptor antagonist netupitant is now available as a fixed-dose combination with palonosetron (a 5HT₃ antagonist) known as NEPA for the prevention of acute and delayed nausea and vomiting associated with moderately emetogenic chemotherapy and highly emetogenic cisplatin-based chemotherapy. They appear to be well tolerated, but NK₁ receptor antagonists are inhibitors, and sometimes inducers, of cytochrome P450 (CYP3A4) and inducers of CYP2C9 and glucuronidation. Therefore, potential drug interactions with chemotherapeutic agents and other concomitantly administered agents, for example, warfarin, may occur.

Cannabinoids

It is likely that the antiemetic activity of cannabinoids is related to stimulation of central and peripheral cannabinoid (CB1) receptors. Cannabinoids have modest antiemetic activity that is of similar magnitude to prochlorperazine in CINV, but they can cause a range of adverse CNS effects, including drowsiness and sometimes behavioural disturbances, which may at times be severe and which can persist for up to 72 hours after discontinuation. Thus, although the synthetic cannabinoid nabilone is indicated for nausea and vomiting caused by cytotoxic chemotherapy unresponsive to conventional antiemetics, it is recommended that patients are made aware of possible changes in their mood and other unwanted effects on their behaviour. In addition, nabilone should be used under close supervision, preferably in a hospital setting. A systematic review suggests that cannabinoids may have a role in refractory CINV (Smith et al., 2015).

Corticosteroids

Corticosteroids are known to have antiemetic effects. Their mechanism of action is unclear, but corticosteroid receptors are thought to exist in the area postrema. As single agents, they appear to be at least as effective as prochlorperazine in preventing nausea and vomiting associated with mild to moderately emetogenic cytotoxic chemotherapy. Dexamethasone, the most widely used corticosteroid in this context, improves the antiemetic activity of prochlorperazine and metoclopramide and may reduce some of the side effects associated with the latter. When combined with 5HT₃ antagonists, corticosteroids are particularly effective in CINV associated with moderately emetogenic

chemotherapy or when used in delayed emesis. The same combination of dexamethasone and a 5HT₃ antagonist, and sometimes with aprepitant, may also be effective in CINV associated with highly emetogenic chemotherapy regimens.

Complementary and alternative medicines

Systematic reviews support the use of stimulating wrist acupuncture point PC6 for preventing PONV as an alternative to conventional antiemetics (Lee et al., 2015), but the evidence for its use in combination with antiemetics for prevention of PONV is inconclusive. A systematic review of randomised trials has also demonstrated the efficacy of ginger (at least 1 g preoperatively) in PONV after certain types of surgery (Chaiyakunapruk et al., 2006). Ginger has also been claimed to be beneficial in motion sickness and pregnancy-associated nausea, but the evidence for each is limited (Ernst and Pittler, 2000).

Drug treatment in selected circumstances

Postoperative nausea and vomiting

PONV are common symptoms, with an incidence of 30% for vomiting and 50% for nausea. In high-risk groups the incidence can be as high as 80% (Gan et al., 2014). The aetiology is complex and multifactorial and includes patient-, medical-, surgical- and anaesthetic-related factors. Management is multimodal and involves strategies to reduce baseline risk, such as using less emetogenic induction agents, avoidance of volatile anaesthetic agents and use of opioids and consideration of the use of regional rather than general anaesthesia and adequate hydration.

Not all patients will experience PONV, but some are at higher risk. A simple scoring system is commonly used to risk stratify those who are likely to develop PONV so that prophylactic antiemetics can be given. The scoring system is based on the presence or absence of four factors:

- female gender,
- history of motion sickness or PONV,
- non-smoker,
- use of postoperative opioids.

The incidence of PONV with the presence of none, one, two, three or all four of these risk factors has been shown to be 10%, 20%, 40%, 60% and 80%, respectively (Apfel et al., 1999). Use of risk scores based on these criteria helps appropriately tailor antiemetic use and can significantly reduce the incidence of nausea and vomiting in clinical practice (Kovac, 2013).

Most antiemetic agents have some efficacy in PONV, but combination therapy with drugs from different classes may be needed in patients at medium to high risk of PONV (Gan et al., 2014). Prophylactic treatment with dexamethasone and/or 5HT₃ antagonists (e.g. ondansetron, granisetron) are commonly used, as well as butyrophenones (e.g. haloperidol, droperidol) and antihistamines (e.g. cyclizine). NK₁ receptor antagonists (e.g. aprepitant) are also effective in the treatment and prophylaxis of PONV, but the cost may prohibit their routine use. The stimulation of acupuncture point PC6 appears to be safe but is rarely used, despite

Table 35.3 Classification of chemotherapy-induced nausea and vomiting

Classification	Definition
Acute	Occurring within the first 24 h after initiation of chemotherapy; generally peaks after 5–6 h
Delayed	Occurring from 24 h to several days (days 2–5) after chemotherapy
Breakthrough	Occurring despite appropriate prophylactic treatment
Anticipatory	Occurring before a treatment as a conditioned response to the occurrence of chemotherapy-induced nausea and vomiting in previous cycles
Refractory	Recurring in subsequent cycles of therapy, excluding anticipatory chemotherapy-induced nausea and vomiting

Reproduced by kind permission from [Navari and Aapro \(2016\)](#).

some supporting evidence for its efficacy ([Lee et al., 2015](#)). Metoclopramide and cannabinoids appear to be of limited value in the management of PONV.

If PONV occurs despite prophylaxis therapy, then a further rescue antiemetic should be given, preferably from an alternative class to those given as prophylaxis.

Premedication with opioids increases the incidence of PONV, and this may be reduced by concurrent administration of either atropine or hyoscine, which are primarily used as anti-secretory drugs at premedication.

Chemotherapy-induced nausea and vomiting

There are different types of CINV identified depending on their onset and the possible underlying aetiology (see [Table 35.3](#)). Acute CINV is often associated with an increase in plasma serotonin concentrations for the most emetogenic agents, whereas delayed and anticipatory vomiting seem to be mediated by serotonin-independent pathways.

Management of CINV depends on the emetogenicity of the chemotherapy regimen and the use of combinations of antiemetic drugs based on their varying target receptors. Chemotherapy agents are divided into four emetogenic levels ([Table 35.4](#)) defined by the expected frequency of emesis ([Kris et al., 2006](#)).

5HT₃ and NK₁ receptor antagonists given as a combination with (or without) dexamethasone are the mainstay treatment for acute and delayed CINV in highly and moderate emetogenic chemotherapy regimens ([Roila et al., 2016](#)). Newer-generation 5HT₃ receptor antagonists, such as palonosetron, appear to be more effective than older 5HT₃ receptors, such as ondansetron and granisetron; this could be partly explained by their prolonged half-life and high affinity for 5HT₃ receptors ([Rojas et al., 2008](#)).

Evidence also points to synergism between 5HT₃ inhibition (e.g. by palonosetron) and NK₁ receptor inhibition (e.g. by

Table 35.4 Relative emetogenicity of chemotherapy drugs

Emetic risk (incidence of emesis without antiemetics)	Agent
High (>90%)	Cisplatin Methotrexate Streptozotocin Cyclophosphamide ≥ 1500 mg/m ² Carmustine Dacarbazine Dactinomycin
Moderate (30–90%)	Oxaliplatin Cytarabine >1000 mg/m ² Carboplatin Ifosfamide Cyclophosphamide <1500 mg/m ² Doxorubicin Daunorubicin Epirubicin Idarubicin Irinotecan
Low (10–30%)	Paclitaxel Docetaxel Mitoxantrone Topotecan Etoposide Pemetrexed Methotrexate Mitomycin Gemcitabine Cytarabine ≤ 1000 mg/m ² Fluorouracil Bortezomib Cetuximab Trastuzumab
Minimal (<10%)	Bevacizumab Bleomycin Busulfan 2-Chlorodeoxyadenosine Fludarabine Rituximab Vinblastine Vincristine Vinorelbine

From [Kris et al. \(2006\)](#).

netupitant) ([Thomas et al., 2014](#)), hence their therapeutic use in combination. A combined preparation such as netupitant and palonosetron (NEPA) is available for use.

Studies have also shown the use of olanzapine is effective in prevention of CINV when added to NK₁ receptor antagonists ([Chiu et al., 2016](#)).

In lower-level acute emesis, metoclopramide or prochlorperazine are commonly used and are often sufficiently effective. Dexamethasone can also be prescribed as a single agent for this indication, but its use in these circumstances appears to be uncommon in the UK.

Box 35.1 Factors that cause nausea and vomiting in their own right and may contribute to the failure of apparently appropriate prophylactic regimens for chemotherapy-induced nausea and vomiting

- Hypercalcaemia or other metabolic or endocrine disturbance
- Central nervous system metastases
- Antibiotics such as erythromycin/clarithromycin
- Gastro-intestinal obstruction
- Radiotherapy enteropathy

Dexamethasone is the most extensively evaluated steroid in the management of CINV. Used alone, it is not sufficiently effective for prevention of CINV in moderately or highly emetogenic chemotherapy. However, it enhances the effect of other agents such as 5HT₃ and NK₁ antagonists in high-risk situations and, together with metoclopramide, it also appears to be useful in treating delayed emesis (Ioannidis et al., 2000).

The best management for anticipatory emesis is the avoidance of acute and delayed emesis during previous cycles. However, when anticipatory nausea and vomiting are a problem, a low dose of a benzodiazepine such as lorazepam is often effective.

When apparently appropriate antiemesis regimens fail, consideration should be given to the possibility of other underlying disease-related and medication-related issues (Box 35.1). Patients often derive benefit from antiemetics given as prophylaxis, and a further course at the same or a higher dose can be given. An alternative class of drug with a different pharmacological action (e.g. olanzapine or a cannabinoid) should also be considered if symptoms are not controlled.

Pregnancy-associated nausea and vomiting

Pregnancy-associated nausea and/or vomiting is defined as nausea and/or vomiting during early pregnancy where there are no other causes. It can affect up to 80% of pregnancies and typically starts around 4th to 7th week of gestation and peaks at around 9 weeks. Some women may continue to have nausea and/or vomiting into the second trimester, but in the majority of cases, symptoms are usually resolved by the 20th week of gestation (Shehmar et al., 2016). Risk factors for vomiting include a personal history of previous pregnancy-associated nausea/vomiting or motion sickness or migraine-associated nausea/vomiting and a family history of hyperemesis gravidarum or a large placental mass, for example, due to multiple pregnancy. First-trimester nausea and vomiting are not usually harmful to either the fetus or the mother and are not generally associated with a poor pregnancy outcome.

In contrast, hyperemesis gravidarum is a condition of intractable vomiting complicating between 0.3% and 3.6% of pregnancies (Shehmar et al., 2016). This is a serious condition characterised by dehydration, electrolyte imbalance and nutritional deficits with a body weight loss of more than 5% of pre-pregnancy weight. Patients will require hospital admission to correct the biochemical abnormalities.

In first-trimester nausea and vomiting, simple measures such as small, frequent, carbohydrate-rich meals and reassurance are sufficient to control symptoms. Ginger and PC6 acupressure have also

been advocated, although the evidence base is equivocal in early pregnancy (Jewell and Young, 2003). Other studies on the use of acupuncture in pregnancy-associated nausea and vomiting remain unclear (King and Murphy, 2009). A recent Cochrane review was unable to recommend any intervention for nausea and vomiting in early pregnancy due to lack of robust evidence (Matthews et al., 2015). It is important to avoid antiemetic drugs when possible, and the measures outlined previously (carbohydrate-rich meal and reassurance) should be considered as first-line treatment.

Prescribing an antiemetic in the first trimester of pregnancy should only be done when the benefit outweighs the risks. Antihistamines (e.g. promethazine or cyclizine) or prochlorperazine should be given as first-line therapy and for a limited time period. If symptoms persist, then a limited course (no longer than 5 days) of metoclopramide or ondansetron could be considered.

In the serious condition of hyperemesis gravidarum, drug therapy may be used in addition to fluid and vitamin replacements (e.g. thiamine). In extreme cases, postpyloric feeding or enteral feeding is required. Corticosteroids have been found to be effective when all other treatment options have failed. There are few safety or efficacy data on which to select the most appropriate treatments, so the agents recommended for vomiting in pregnancy mentioned previously are generally those used in the UK.

Pyridoxine is no longer recommended for use in pregnancy-associated nausea and/or vomiting.

Migraine

Migraine is a paroxysmal disorder with attacks of headaches, nausea, vomiting, photophobia and malaise. Treatment is directed at:

- prophylaxis: trigger avoidance; β -blockers, pizotifen and, in severe cases, a 5HT_{1B/D}-receptor agonist such as sumatriptan;
- analgesia, including aspirin, paracetamol, opioids and NSAIDs;
- antiemetics.

Nausea and vomiting in migraine are associated with headache intensity, and the concomitant gastric stasis aggravates the nausea and vomiting and may also delay absorption of oral analgesics. Metoclopramide and domperidone attenuate the autonomic dysfunction and promote gastric emptying, but the risk of acute dystonic crisis, especially with metoclopramide therapy, should be borne in mind, especially in young women and children but also in the elderly.

Labyrinthitis

Labyrinthine dysfunction results in vertigo, nausea and vomiting. Episodes may last a few hours or days. Causes include labyrinth viral infections, tumours and Ménière's disease. The onset of episodes is often unpredictable and disabling. Betahistine sometimes has some benefit. The antimuscarinics, antihistamines, phenothiazines or benzodiazepines can be used to suppress the vestibular system. Usually, hyoscine is sufficient, but if there is severe vomiting, prochlorperazine or metoclopramide may be of value.

Motion sickness

Motion sickness is a syndrome, a collection of symptoms without an identifiable cause. It is brought on by chronic

repetitive movements which stimulate afferent pathways to the vestibular nuclei and lead to activation of the brainstem nuclei. Histaminergic and muscarinic pathways are involved. The symptoms include vague epigastric discomfort, headache, cold sweating and nausea which may culminate in vomiting. This is often followed by marked fatigue which can last hours or days. The onset of symptoms may be abrupt or gradual.

The antimuscarinics agent hyoscine is the prophylactic drug of choice, although there is no evidence of its benefit once motion sickness is established (Spinks and Wasiaik, 2011). Antihistamine drugs may also be effective. The less sedating antihistamines cinnarizine or cyclizine are used. Promethazine, an antihistamine with sedative effects, is also effective, but phenothiazines, domperidone, metoclopramide and 5HT₃-receptor antagonists appear to be ineffective in this situation. Treatment should be started before travel; for long journeys, promethazine or transdermal hyoscine may be preferred for their longer duration (24 hours and 3 days, respectively). Otherwise, repeated doses will be needed.

The most important adverse effect of many drugs used is sedation, whilst for antimuscarinic drugs, it is blurred vision, urinary retention and constipation. In laboratory studies, the degree to which these effects impair performance, for example, driving a car, is highly variable, but subjects who take anti-motion sickness drugs should normally be deemed unfit for such tasks. These drugs also potentiate the effects of alcohol.

Many non-drug treatments have been advocated for the alleviation of motion sickness, including wristbands, which act on acupuncture points, variously positioned pieces of coloured paper or card, as well as plant extracts such as ginger. The evidence base for these interventions remains very limited.

Drug-associated nausea and vomiting

As well as chemotherapeutic agents, many commonly used medications for other disorders can cause nausea and vomiting (Quigley et al., 2001). Opioids are perhaps the most important group clinically, but dopamine agonists (used in Parkinson's disease), theophylline, digoxin and macrolide antibiotics such as erythromycin can all cause nausea and/or vomiting, often in a dose-related manner (type A toxicity). High-dose oestrogen, used in postcoital contraception, can produce these symptoms. Consideration should be given to altering the dose of the offending agent when possible and to administering the medication with food. With some agents, tolerance may develop. Thus, tolerance to the emetic effects of opioids often develops within 5–10 days, and therefore, antiemetic therapy is not generally needed for long-term opioid use.

Palliative care-associated nausea and vomiting

Nausea and vomiting are common and distressing symptoms in cancer patients. In most cases, the causes of nausea and vomiting are multifactorial, including concurrent infection, drugs and metabolic disturbances such as renal failure.

It is important to determine the predominant underlying cause for patients' symptoms by obtaining a careful history,

conducting an examination and requesting appropriate investigations so that potentially reversible causes of nausea and vomiting can be treated (Box 35.2) and the most suitable antiemetic prescribed.

Oral antiemetic therapy is effective for treatment of nausea in patients with advanced cancer, but the subcutaneous route is preferred for those with severe persistent vomiting, either as a single-dose injection or a continuous infusion via a syringe driver. When patients' symptoms improve, switching from subcutaneous injection to the oral route may be preferable. Non-pharmacological interventions such as avoidance of certain food smells or unpleasant odours, relaxation techniques and use of acupuncture should be considered.

CINV is described in detail elsewhere in the chapter. Strong opioids such as morphine, diamorphine, oxycodone and fentanyl cause nausea and/or vomiting in up to one-third of patients after initiation of treatment, but the incidence is lower for weaker opioids such as codeine. Metoclopramide, cyclizine or haloperidol are often given for the relief of the nausea and vomiting induced by opioids.

Gastrointestinal or intestinal obstructions in advanced malignancy are usually caused by occlusion of the lumen (intrinsically and/or extrinsically) or by the absence of normal peristaltic propulsion. Surgery remains the definitive treatment for luminal occlusion due to cancer, but this is often inappropriate for patients who are frail or have advanced malignancy. The main aim of pharmacological interventions is symptom control. A prokinetic dopamine (D₂) antagonist such as metoclopramide or domperidone should be used for patients with nausea and vomiting associated with functional gastric or intestinal stasis. Prokinetics are also used in patients with partial gastric outlet obstruction but can worsen patients' symptoms of abdominal pain in complete gastric outlet obstruction. Because prokinetics can exacerbate abdominal colicky pain associated with intestinal obstruction, their use should be avoided in that situation, and antiemetics such as cyclizine or haloperidol should be used for symptom control.

Dexamethasone has also been used for control of symptoms in malignant intestinal obstruction, not only for antiemetic effect but also to reduce inflammatory tumour oedema around the obstructive lesion. Antimuscarinics such as hyoscine butylbromide and somatostatin analogues such as octreotide have been used for symptom relief in intestinal obstruction by reducing gastro-intestinal secretion and motility and thus reducing the

Box 35.2 Potentially treatable causes of nausea and vomiting in palliative care

- Anxiety

frequency and volume of vomitus. Olanzapine may also have a role in refractory nausea and vomiting caused by underlying malignancy, although this is an unlicensed (off-label) indication (Fonte et al., 2015).

Biochemical disturbances such as hypercalcaemia and renal failure can cause nausea and vomiting in patients with advanced malignancy, and correction of these may alleviate symptoms. However, aggressive treatment with bisphosphonates or insertion of nephrostomy tubes, respectively, would not often be appropriate for those who are in the terminal stages of their illness. Haloperidol and cyclizine appear to be effective for biochemical causes of nausea and vomiting. Levomepromazine has antidopaminergic, antihistaminergic, antimuscarinic and antiserotonergic activity. It is effective for most causes of nausea and vomiting and may help alleviate restlessness. It can also be given intramuscularly, intravenously or subcutaneously, including by continuous subcutaneous infusion. It may be considered if first-line antiemetics are insufficiently effective. Unfortunately, sedation and postural hypotension can be a problem in association with this agent.

Conclusion

Nausea and vomiting are symptoms caused by a variety of underlying causes. Thorough clinical assessment and appropriate investigations should be undertaken when prescribing a therapeutic trial of an antiemetic. The choice of agent(s) should be based on the likely cause and severity of the symptoms, the possible underlying pathophysiology, and the recommendations of evidence-based guidelines which take into account clinical effectiveness and cost-effectiveness.

Case studies

Case 35.1

Mr AN, a 30-year-old man, presents seeking a remedy for vomiting which had an acute onset, 12 hours previously.

Question

What questions should Mr AN be asked to determine the nature, cause and seriousness of these symptoms?

Answer

The cause of vomiting needs to be determined where possible to allow appropriate treatment to be initiated. The following questions should be asked:

- Are there symptoms or signs of infection, such as diarrhoea, sore throat, dysuria, photophobia, fever? Infection, often of the gastro-intestinal tract, is one of the commonest causes of vomiting.
- Is there headache? Raised intracranial pressure and meningitis can present with vomiting as an early symptom, usually without any nausea.

- Is there abdominal pain? Abdominal pain before vomiting usually means an organic gastro-intestinal cause. Pain after vomiting may be due to muscle tenderness.
- Has the patient started any new drugs (opioids, chemotherapeutic agents, digoxin, nicotine, NSAIDs, oral hypoglycaemics and some antibiotics are common causes) or drunk excess alcohol?
- Is there vertigo? If present, this is suggestive of a labyrinthine cause.

Case 35.2

Ms VW, a 19-year-old woman who is 12 weeks pregnant, presents to hospital with intractable nausea and vomiting which has not responded to home therapy and which has resulted in hypotension and dehydration.

Question

List, in order of importance, the therapeutic strategies for this problem.

Answer

Treatment would normally involve:

- intravenous rehydration and electrolyte replacement, vitamin replacement (e.g. thiamine),
- bed rest,
- antiemetics (e.g. cyclizine, promethazine or prochlorperazine) and review response after 24 hours,
- postpyloric feeding,
- corticosteroids,
- parenteral nutrition.

Case 35.3

Mrs MC, a 45-year-old woman, presents with ovarian carcinoma for which she is due to receive a course of cancer chemotherapy.

Question

What drugs might be appropriate, when should they be given, and what advice should be given to Mrs MC regarding monitoring of symptoms after treatment with the chemotherapy?

Answer

Mrs MC is likely to receive repeated cycles of emetogenic chemotherapy with carboplatin (moderate emetogenic risk) or cisplatin (high emetogenic risk) and, therefore, should be given prophylactic antiemetics before the start of chemotherapy. The choice of drugs includes 5HT₃-receptor antagonists (ondansetron, granisetron or palonosetron) combined with dexamethasone for some moderate-emetic-risk situations and one of the 5HT₃-receptor antagonists with an NK₁-receptor antagonist (aprepitant or fosaprepitant) for high-risk situations, with or without dexamethasone to provide additional benefit. The monitoring of emesis and nausea both within and outside hospital for up to 5 days after treatment is useful in deciding which patients may need other therapies. It is also important to remember that patients should be given appropriate doses of antiemetics as rescue therapy to cover delayed-onset nausea.

Case 35.4

A hospital with a large number of surgical specialties, including major in-patient thoraco-abdominal and day-care procedures, wishes to update its PONV programme.

Question

What principles should be taken into account for a PONV programme?

Answer

The programme should contain a PONV risk score which can be used in preoperation assessment. A simplified score has been devised

(Apfel et al., 1999), adding one point for each of the following: female gender, non-smoking status, history of PONV and opioid use. In low-risk individuals scoring 0 or 1 (less than 10% risk), prophylactic antiemetic therapy is unnecessary. Moderate-risk subjects (score 1, risk 20%) may require single-agent antiemetic prophylaxis, whereas in high-risk subjects (score 3, risk 60%) two agents (one of them often dexamethasone) may be needed if intravenous anaesthesia is not possible. In very high-risk subjects (score 4, risk greater than 80%), intravenous anaesthesia should be considered when possible, and dexamethasone and another antiemetic agent should be administered. PONV rescue therapy should be chosen depending on the postoperative clinical situation.

36 Respiratory Infections

Catherine Molyneux and Ali Robb

Key points

- Viral respiratory tract infections are usually mild and self-limiting, but influenza, severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) can have severe consequences for individuals, for public health and for economic activity.
- Exacerbations of chronic bronchitis are not always infective in origin; antibiotics are used when the sputum is purulent, but other therapeutic modalities are also valuable.
- *Streptococcus pneumoniae* remains the single most common cause of community-acquired pneumonia (CAP). Reduced susceptibility to penicillin can complicate the management of serious pneumococcal infections, but more significant degrees of resistance are currently not widespread among UK strains.
- CAP can be caused by a variety of pathogens, and this is reflected in the antimicrobial regimens recommended for initial treatment.
- There are many potential causes of hospital-acquired (nosocomial) pneumonia, and each unit with patients at risk will have its own resident bacterial flora. This will strongly influence the choice of antibiotics for empiric therapy.
- Patients with cystic fibrosis form a particularly high-risk population. Their respiratory tract flora becomes increasingly abnormal with age. Colonisation with *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Burkholderia cepacia* complex is associated with reductions in lung function.
- Antibiotic stewardship interventions, including close adherence to local guidelines, are important to maintain the effectiveness of antibiotic agents.

Respiratory tract infections are the most common group of infections seen in the UK and the commonest acute problem dealt with in primary care ([National Institute for Health and Care Excellence \[NICE\], 2008a](#)). Most are viral, for which (with some exceptions) only symptomatic therapy is available, and many are self-limiting. However, the term includes some serious bacterial infections for which prompt treatment is important.

The respiratory tract is divided into upper and lower parts: the upper respiratory tract consists of the sinuses, middle ear, pharynx, epiglottis and larynx, whereas the lower respiratory tract consists of the structures below the larynx, the bronchi, bronchioles and alveoli. Although there are anatomical and functional divisions both within and between these regions, infections do not always respect such boundaries. Nevertheless, it is clinically

and bacteriologically convenient to retain a distinction between upper respiratory tract infections (URTIs) and lower respiratory tract infections (LRTIs).

Upper respiratory tract infections

Colds and flu

URTIs with coryzal symptoms, rhinitis, pharyngitis and laryngitis, associated with varying degrees of systemic upset, are extremely common; adults average 2–4 infections per year and children, 6–8, although up to 12 have been reported in some groups of children ([NICE, 2015a](#)).

These infections are usually caused by viruses. Rhinoviruses cause up to 50% of colds and up to 70% in the autumn. Various other viruses, including coronaviruses and the parainfluenza viruses, account for the rest.

Most viral URTIs are mild and self-limiting. However, new respiratory viruses continue to be identified, some of which produce more serious illness, for example, Middle East respiratory syndrome (MERS) coronavirus, first described in 2012, which can cause a spectrum of disease from asymptomatic infection to respiratory failure.

In general, the management of URTIs is symptomatic and consists of rest, adequate hydration, simple analgesics and antipyretics. Apart from one or two exceptional situations, antiviral drugs are not indicated and in most cases are not effective.

Antibacterial drugs have no activity against viral infections, although in the past they were widely prescribed, sometimes with spurious rationale, such as prophylaxis against bacterial superinfection, or simply because patients demanded them. In recent years, there has been heightened awareness of the adverse consequences of antibiotic overuse, the most serious of these being the promotion of antibiotic resistance.

Issuing antibiotic prescriptions for uncomplicated URTIs also reinforces the idea that these infections require medical intervention and is likely to lead to requests for an antibiotic in subsequent illnesses. This increased awareness of the harms of excessive antibiotic prescribing has led to national campaigns aimed at discouraging the public from seeking antibiotic treatment for viral infections, such as the National Health Service (NHS) antibiotic awareness campaign ([Public Health England, 2015a](#)).

Unfortunately, antibiotic prescription rates in the UK have plateaued after falling through the 1990s, and most people who request an antibiotic for an acute uncomplicated respiratory

tract infection receive one (NICE, 2008a). Therefore, further work to educate and change the behaviour of both patients and prescribers is required.

Influenza

True influenza is caused by one of the influenza viruses (influenza A, B or, rarely, C). Influenza commonly causes a syndrome of fever (greater than 38 °C), myalgia, headache, sore throat and cough. It is usually self-limiting in healthy adults but can cause a severe pneumonitis and can be complicated by secondary bacterial infection. Serological studies in healthcare workers have suggested that 30–50% of infections in this group are asymptomatic, but this may vary with strain (Public Health England, 2015b).

Influenza tends to occur during the winter months, usually in an 8- to 10-week period; the timing, length and severity of this season can vary. The seasonality provides an opportunity to offer preventive vaccination in the autumn. In the UK the influenza vaccination strategy has changed in recent years. In 2012 the Joint Committee on Vaccination and Immunisation (JCVI) recommended extension of the programme to children aged between 2 and 17. A phased extension to the programme therefore began in 2013. The eligible cohorts are published each year. Children are vaccinated with a quadrivalent intranasal live attenuated vaccine; alternative authorised vaccines may be used for children in clinical risk groups for whom the intranasal vaccine is unsuitable (Public Health England, 2015b).

Vaccination with an inactivated quadrivalent vaccine is used in patients at higher risk of severe disease and healthcare workers. Patients at risk of severe influenza who are eligible for influenza vaccination in England are:

- people older than 65 years,
- people with chronic respiratory disease,
- people with chronic kidney disease,
- people with chronic liver disease,
- people who are immunosuppressed,
- people with chronic neurological disease,
- asplenic patients,
- pregnant women,
- people with a body mass index greater than 40.

Unfortunately, the virus mutates so rapidly that the circulating strains tend to change from season to season, necessitating annual revaccination against the prevailing virus (Public Health England, 2015b).

Influenza A and B infections are amenable to both prevention and treatment with neuraminidase inhibitors (NAIs) such as zanamivir and oseltamivir, although there is controversy about whether the benefits justify the cost. Zanamivir is administered by dry powder inhalation, whereas oseltamivir is given orally. There is an intravenous preparation of zanamivir which is unlicensed but available on a named patient basis. Oseltamivir is the first-line agent in most situations, but zanamivir is preferred where oseltamivir resistance is suspected or for severely immunocompromised patients when H1N1 is the predominant strain of influenza A in circulation (Public Health England, 2015c). H1N1 is a strain of influenza, where the *H* and *N* refer to antigens on the virus particle, the variants of which have been determined and identified by a number.

National guidelines for England recommend that NAIs can be used in secondary care for influenza at any time, but primary care doctors can only give NHS prescriptions for NAIs when the chief medical officer has confirmed that influenza is circulating and if the patient falls into a defined risk group (Public Health England, 2016a).

The group eligible for prophylaxis or treatment consists of those eligible for vaccination with inactivated vaccine as listed previously and women who are less than 2 weeks post-partum. The patient must be able to commence treatment within a defined time after the onset of symptoms or exposure to a patient with influenza.

Prophylaxis with NAIs is only offered to patients who are not protected by vaccination. This usually means those who have not been vaccinated, but in some years, the vaccine is poorly matched to the circulating strain and is therefore unlikely to be effective. In these years, vaccinated patients are eligible for prophylaxis (NICE, 2008b, 2009).

Whether oseltamivir treatment of people with symptoms of influenza can prevent the development of complications such as pneumonia is still a matter of vigorous debate, with two recent meta-analyses coming to different conclusions (Dobson et al., 2015; Jefferson et al., 2014).

The anti-Parkinsonian drug amantadine, which has activity against the influenza A virus, is not recommended for the treatment or prophylaxis of influenza because resistance emerges rapidly, and there is a high incidence of adverse effects.

Pandemics, or global epidemics, of influenza A occur around every 25 years and affect huge numbers of people. The 1918 ‘Spanish flu’ pandemic is estimated to have killed 20 million people. Further pandemics took place in 1957–1958 (Asian flu), 1968–1970 (Hong Kong flu) and 1977 (Russian flu).

The World Health Organization (WHO) declared a worldwide influenza pandemic in June 2009 after the emergence of a novel H1N1 strain of swine lineage. In the UK, NICE guidance was superseded during the pandemic, and NAIs were given to all individuals with flu-like illness. A vaccine was also developed. Pandemic planning had been in operation for many years with plans for rapid vaccine development and stockpiling of antivirals. However, in retrospect, infections caused by the pandemic strain were generally associated with much milder disease than seen in previous pandemics, and some authorities have been accused of over-reaction.

There were also adverse outcomes of the widespread use of NAIs during the 2009 pandemic. Resistance to oseltamivir emerged in some units (Gulland, 2009). Some critics argued that the side effects of NAIs and uncertainty of benefit meant that the cure was worse than the disease (Strong et al., 2009). However, the relatively benign course of the 2009 pandemic should not provide false reassurance regarding the potential risks associated with future pandemics.

Avian influenza

An avian strain of influenza A, H5N1, emerged in South East Asia in 2003. It is now considered endemic in many parts of South East Asia and remains a concern for public health. A second

avian strain, H7N9, was first detected in humans in 2013. To date, human cases have only been detected in China (WHO, 2014). Person-to-person spread of these strains remains limited, but they can cause severe disease, and there are concerns that they may mutate to become more easily transmissible between humans.

Sore throat (pharyngitis)

Causative organisms

Pharyngitis is a common condition. In most cases, it never comes to medical attention and is treated with simple therapy directed at symptom relief. Many cases are not due to infection at all but are caused by other factors, such as smoking. Where infection is the cause, most cases are viral and form part of the cold-and-flu spectrum. Epstein–Barr virus (EBV), which causes glandular fever (infectious mononucleosis), is a less common but important cause of sore throat because it may be confused with streptococcal infection.

The only common bacterial cause of sore throat is *Streptococcus pyogenes*, also known as the Lancefield group A β -haemolytic streptococcus. Other, less frequent bacterial causes include *Streptococcus dysgalactiae* (also known as Lancefield group C/G streptococci), *Arcanobacterium haemolyticum*, *Neisseria gonorrhoeae* and *Mycoplasma* sp.

In the past, prompt treatment of possible group A streptococcal infections was considered useful to prevent suppurative and non-suppurative complications. The suppurative complications include quinsy and mastoiditis, among many others. The most common non-suppurative (immune mediated) complications are rheumatic fever and glomerulonephritis, but there are others, including neurological complications such as Sydenham's chorea.

In the UK, complication rates are now low and the benefit of antibiotic treatment even in patients whose sore throat is caused by group A streptococci is therefore thought to be small (NICE, 2008a). A cohort study in UK general practice found more than 4000 people needed to be treated for URTI, otitis media or pharyngitis to prevent one serious complication (Petersen et al., 2007).

Although *C. diphtheriae* is rare in the UK, it should be considered when investigating travellers returning from parts of the world where diphtheria is common. *C. ulcerans* is as common a cause of clinical diphtheria in the UK as *C. diphtheriae* but usually runs a more benign course.

Clinical features

The presenting complaint is sore throat, often associated with fever and the usual symptoms of the common cold. The Centor score is a clinical scoring system used to identify those at higher risk of bacterial infection (Centor et al., 1981). The criteria are the presence of tonsillar exudate, history of fever, tender anterior surgical lymphadenopathy or adenitis and absence of cough. Each feature scores one point. Those with a Centor score of 3 or 4 have a 40–60% risk of group A streptococcal infection. Those with a Centor score of zero or one are unlikely to have group A streptococcal infection (Aalbers et al., 2011)

Scarlet fever, a toxin-mediated manifestation of streptococcal infection, is associated with a macular rash and sometimes considerable systemic illness. There has been an increased incidence of scarlet fever recently, with 14,387 cases in England between week 37 of 2014 and week 25 of 2015. Most of these cases were in children, with the peak incidence in those aged 1–4 (Public Health England, 2015d).

In the UK, there has been a recent increase in rates of group A streptococcal infection. This includes invasive group A streptococcal infection (iGAS), associated with infection in normally sterile sites such as blood or tissue. The UK experienced an upsurge in invasive group A streptococcal infection in 2008, and an enhanced surveillance protocol was put into place in 2009. These infections are extremely serious, and prompt antibiotic treatment is vital. The serotypes involved vary from year to year, with emm ST1, emm ST12 and emm ST89 most common in the 2015–16 season (Public Health England, 2016b).

Diagnosis

Microbiological diagnosis of the cause of pharyngitis is not usually required in a primary care setting. If a specific bacterial diagnosis is needed, a swab is sent for microbiological culture. Group A β -haemolytic streptococci are usually the organism sought, but if there is a history of treatment failure or recurrent infection, the plates are incubated for 48 hours to look for *Arcanobacterium haemolyticum* (Public Health England, 2015e). The main drawback to culture methods is that the results are not available for at least 24 hours. They also do not distinguish between infection and carriage.

Rapid antigen tests (RATs) for the detection of group A streptococcal antigens are available. Their performance depends on the skill of the user. The use of rapid antigen tests is one of the major points of disagreement in international guidelines. In the UK and the Netherlands, decisions on whether antibiotic treatment is appropriate depend on clinical severity, whereas in the USA, France and Finland, RATs are used (Pelucchi et al., 2012).

Treatment

Most people will recover from sore throat after 7 days. Analgesics such as paracetamol and ibuprofen are useful for reducing pain and fever. Under current guidance, most patients should not be prescribed an antibiotic. Delayed antibiotic prescriptions may be useful. In this scenario, the prescription is post-dated, or patients are advised only to use it if symptoms worsen or do not improve (NICE, 2008a).

NICE (2008a) guidelines suggest that patients with a Centor score of 3 or 4 are considered for an immediate or delayed antibiotic prescription. People who have marked systemic upset, those who are at increased risk of complications and those with valvular heart disease should be given an antibiotic. A low threshold for antibiotic prescribing is also recommended for those who are at risk of immunosuppression, those with previous rheumatic fever and those at risk of severe disease.

Penicillins such as penicillin V are recommended as first-line treatment for group A streptococcal pharyngitis. There is evidence that cephalosporins may be more effective clinically and in eradicating group A streptococci from the pharynx; however, given the higher cost and wider spectrum of activity, international guidelines (Pelucchi et al., 2012; Shulman et al., 2012) still favour penicillin V for 10 days. Aminopenicillins such as amoxicillin should be avoided if primary EBV infection is likely because, for reasons that are not understood, these drugs often cause skin rashes if used in this condition.

Five days of erythromycin or clarithromycin is recommended for patients with penicillin allergy. This is because a review of antibiotics for streptococcal pharyngitis in children found that this treatment was as effective as 10 days of penicillin V (Altamimi et al., 2012).

Acute epiglottitis

Causative organisms

Acute epiglottitis is a rapidly progressive cellulitis of the epiglottis and adjacent structures. Previously, almost all childhood cases and a high proportion of adult cases were caused by *Haemophilus influenzae* type b (Hib), with the rest being caused by other organisms such as pneumococci, streptococci and staphylococci. With the advent of routine vaccination against *H. influenzae* type b in October 1992, this disease has become uncommon.

Clinical features

The typical patient is a child between 2 and 4 years old with fever and difficulty speaking and breathing. The patient may drool because of impaired swallowing. Local swelling has the potential to cause rapid-onset airway obstruction, so the condition is a medical emergency.

Diagnosis

The diagnosis is made clinically, and initial management is concentrated on establishing or maintaining an airway. This takes priority over all other diagnostic and therapeutic manoeuvres. Thereafter, the diagnosis may be confirmed by visualisation of the epiglottis, typically described as 'cherry-red'. Microbiological confirmation may be obtained by culturing the epiglottis and the blood, but not until the airway is secure.

Treatment

In view of the high prevalence of amoxicillin resistance among encapsulated *H. influenzae*, the treatment of choice is a cephalosporin. It is customary to use a third-generation cephalosporin such as cefotaxime or ceftriaxone, but most infections should respond to a second-generation agent such as cefuroxime. If a sensitive organism is recovered, high-dose parenteral amoxicillin may be substituted.

Otitis media

Causative organisms

Inflammation of the middle ear (otitis media) is seen most frequently in children younger than 3 years. Most cases are due to bacteria, although viruses such as influenza virus and rhinoviruses have been implicated in a sizeable minority. *Streptococcus pneumoniae* and *H. influenzae* are the two most commonly encountered bacterial pathogens. *Moraxella catarrhalis* and *S. pyogenes* account for a smaller proportion of cases, perhaps 10%, and other bacteria are rarely seen.

Clinical features

Classically, otitis media presents with ear pain, which may be severe. If the drum perforates, the pain is relieved, and a purulent discharge may follow. There may be a degree of hearing impairment plus non-specific symptoms such as fever or vomiting. Complications include mastoiditis (which is now rare), meningitis and, particularly in the case of *H. influenzae* infection, septicæmia and disseminated infection. With the advent of routine vaccination against *H. influenzae* type b, these complications are uncommon.

Diagnosis

The diagnosis of otitis media is essentially made clinically, and laboratory investigations have little role to play. Unless the drum is perforated, sending a swab of the external auditory canal for microbiological culture is not required, and in fact, the results are likely to be unhelpful or misleading. For this reason, a causative organism is rarely isolated, and empirical treatment is provided.

Treatment

There has been much debate about whether or not antibiotics should be used for the initial treatment of acute otitis media (AOM). A Cochrane systematic review identified 12 trials covering 3854 episodes (Venekamp et al., 2015). Antibiotic treatment led to a statistically significant reduction in the number of children with pain in the first 7 days; however, symptoms spontaneously settled in 82% of children. Twenty children had to be treated for one to benefit; however, one child developed diarrhoea for every 14 treated, leaving the risk and benefit finely balanced. Antibiotics were most useful in patients under 2 with bilateral acute otitis media and patients with perforation and discharge. Therefore, antibiotics are currently only recommended for people who are systemically unwell, those who are at risk of serious complications and those whose symptoms have lasted more than 4 days and are not improving. They should also be considered for children under 2 with bilateral acute otitis media and for children with ear discharge (NICE, 2008a).

If antibiotic treatment is to be given, it should be effective against the three main bacterial pathogens: *S. pneumoniae*, *H. influenzae* and *S. pyogenes*. The streptococci are usually

sensitive to penicillins, but these are much less active against *H. influenzae*, so the broader-spectrum agents amoxicillin and ampicillin are preferred. These drugs have identical antibacterial activity, but amoxicillin is recommended for oral treatment because it is better absorbed from the gastro-intestinal tract. About 20% of *H. influenzae* strains are resistant to amoxicillin due to production of β -lactamase, so if there is no response to amoxicillin, an alternative agent should be chosen.

Current national guidance suggests erythromycin or clarithromycin for patients with penicillin allergy; however, these drugs are much less active against *H. influenzae*, so alternatives to amoxicillin should only be used if the history of penicillin allergy is convincing (NICE, 2015b).

Pneumococcal conjugate vaccines, which are currently given routinely in the childhood vaccination schedule, may reduce the incidence of acute otitis media, although a review found only modest benefit when the 7-valent conjugate vaccine was used in healthy infants and no additional benefit in high-risk children (Fortanier et al., 2014). A small benefit was also found for influenza vaccination (Norhayati et al., 2015). Long-term antibiotic prophylaxis might have a role in some children, but any benefit has to be balanced against the risks, such as the development of antibiotic resistance and adverse effects of the antibiotics used (Leach and Morris, 2006).

Acute sinusitis

Causative organisms

Normally, the paranasal sinuses are sterile, but they can become infected after damage to the mucous membrane which lines them. This usually occurs after a viral URTI but is sometimes associated with the presence of dental disease. Sinusitis is caused by a virus in 98% of cases. Bacterial acute sinusitis is usually caused by the same organisms which cause otitis media (*S. pneumoniae* and *H. influenzae*), but occasionally other organisms such as *Staphylococcus aureus*, viridans streptococci (a term used to describe α -haemolytic streptococci other than *S. pneumoniae*) and anaerobes may be found.

Clinical features

The main feature of acute sinusitis is facial pain and tenderness, often accompanied by headache and a purulent nasal discharge. Complications include orbital involvement leading to periorbital cellulitis and intracranial involvement, including frontal bone osteomyelitis, meningitis and brain abscess. The average duration of the illness is 2.5 weeks, although most patients will be improving after 7–15 days (NICE, 2013a).

Bacterial infection should be suspected when three or more of the following criteria are present: discoloured or purulent discharge greater on one side, severe local pain greater on one side, a fever above 38 °C, deterioration after an initial milder illness and a raised erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) (NICE, 2013a). The condition may become chronic with persistent low-grade pain and nasal discharge, sometimes with acute exacerbations.

Diagnosis

This is usually clinical. However, in chronic cases, samples from sinus washouts may be sent for bacterial culture in an attempt to isolate the causative organism.

Treatment

Paracetamol or ibuprofen is used to alleviate pain. An intranasal decongestant may be useful if nasal congestion is problematic. Irrigating the nose with saline and applying warm face packs may also alleviate symptoms. If patients have severe or prolonged symptoms, intranasal corticosteroids may be considered.

If the patient is at high risk of complications or bacterial infection is thought likely, antibiotics should be prescribed. First-line agents are amoxicillin, phenoxymethyl penicillin and doxycycline. If there is no response after 48 hours or if the agent is poorly tolerated, second-line options include co-amoxiclav and azithromycin (NICE, 2008a).

Lower respiratory tract infections

Acute bronchitis

Acute bronchitis is acute inflammation of the bronchial tree leading to cough which lasts up to 3 weeks.

Causative organisms

Most cases are thought to be viral, but this is uncertain because no cause is identified in a large number of patients in clinical studies.

Clinical features

Patients may have sputum production, wheeze, dyspnoea and systemic upset. There are usually no focal signs on examination of the chest, although wheeze may be present.

Diagnosis

Diagnosis is usually clinical; microbiological investigation is not necessary in most cases. If symptoms persist for longer than 3 weeks, further investigation is indicated to rule out diagnoses such as chronic obstructive pulmonary disease (COPD) or tuberculosis. In smokers with persistent cough, malignancy must be considered.

Treatment

Treatment of acute bronchitis usually consists of analgesia, hydration and comfort measures. Antibiotics should be given if the patient has an impaired ability to fight infection or if the acute bronchitis is likely to worsen a pre-existing condition. If antibiotics are required, the first-line agent is amoxicillin, with doxycycline as an alternative (NICE, 2015c).

Pertussis

Pertussis is a highly infectious disease caused by *Bordetella pertussis*. *Bordetella parapertussis* causes a similar although usually milder infection. The illness classically begins with a coryza followed by a cough that becomes paroxysmal, usually within 1–2 weeks. The paroxysms of coughing may be followed by an inspiratory whoop or by vomiting. Infants may not develop the whoop. The disease usually lasts 2–3 months. Severe complications are most common in infants under 6 months of age and include bronchopneumonia, weight loss and cerebral hypoxia with resulting brain damage. Deaths are also most common in infants under 6 months.

Adults and older children who usually have received vaccination or have been infected previously often lack the classical picture of the disease. The inspiratory whoop and post-tussive vomiting are often absent, and they may simply present with prolonged cough. Cases in adults and older children are therefore often missed, increasing the risk of onward transmission.

In the 1950s there were more than 120,000 notifications of pertussis in England and Wales. Although there were periods of reduced vaccine uptake in the 1970s and 1980s, by 1992, 92% or more of children had been vaccinated by their second birthday, and notifications were down to fewer than 5000 a year. Although vaccine coverage remained above 95%, increased rates of pertussis were seen in 2011. This continued into 2012 when a national outbreak was declared. The reasons are unclear but may include the change to acellular vaccine, better case ascertainment and genetic changes in *B. pertussis* (Public Health England, 2016c).

During the 2012 outbreak, the highest rates of illness were in infants aged less than 3 months, and most became ill before they were old enough to receive their first vaccine. A maternal vaccination programme was therefore introduced. Pregnant women were immunised, ideally at between 28 and 32 weeks of gestation to allow time for maternal antibody to be produced and transferred to the baby (Public Health England, 2016c).

Diagnosis

There is a statutory duty in England to notify the local health protection team of suspected cases of pertussis to facilitate further public health action (Health Protection Agency, 2012).

Culture of a pernasal swab has traditionally been the method of diagnosis in the first 2 weeks of the illness; however, this is increasingly being replaced with polymerase chain reaction (PCR) techniques, which have increased sensitivity. Oral fluid testing for antitoxin immunoglobulin G (IgG) can be performed for patients between 5 and 16 years of age who have had a cough for more than 2 weeks and have not been vaccinated in the last year (Public Health England, 2013a). Serology testing for antitoxin IgG in serum samples is used to confirm the diagnosis in adults, if the date of symptom onset is more than 2 weeks before the date of the test and they have not been vaccinated recently. Serological testing is unable to distinguish between antibodies formed in response to disease and those formed in response to vaccination and so is unreliable in patients who have been recently vaccinated.

Treatment

Macrolides are the mainstay of treatment. A 3-day course of azithromycin or a 7-day course of erythromycin or clarithromycin is recommended. Erythromycin is not used in infants under 1 month old due to an association with pyloric stenosis. If the patient cannot take a macrolide, then co-trimoxazole is an alternative in patients older than 1 month. Cotrimoxazole cannot be used in pregnancy (Public Health England, 2013a).

Children are excluded from schools and nurseries until they have completed a course of treatment. If the diagnosis was made late and they have not been treated, they are excluded until 21 days have passed from the onset of symptoms (Public Health England, 2013a).

Because the paroxysmal cough is due to toxin-mediated damage, treatment does not eliminate the symptoms. The role of treatment is to reduce infectivity and onward transmission.

Bronchiolitis

Bronchiolitis is characterised by inflammatory changes in the small bronchi and bronchioles, but not by consolidation. It is particularly recognised as a disease of infants in the first year of life, in whom a small degree of airway narrowing can have a dramatic effect on airflow. However, the causal organisms are equally capable of infecting adults, who may then act as reservoirs of infection. Approximately one in three infants will develop bronchiolitis in their first year of life (NICE, 2015d).

Causative organisms

Most cases of bronchiolitis are caused by respiratory syncytial virus (RSV), which occurs in annual winter epidemics, but human metapneumovirus (hMPV), parainfluenza viruses, rhinoviruses, adenoviruses and occasionally *M. pneumoniae* have also been implicated.

Diagnosis

Bronchiolitis is characterised by a prodrome of fever and coryzal symptoms which progresses to wheezing, respiratory distress and hypoxia of varying degrees. Aetiological confirmation may be made by immunofluorescence and/or viral culture of respiratory secretions, although increasingly the diagnosis of respiratory syncytial virus is made using rapid antigen detection tests or by PCR.

Treatment

The treatment of bronchiolitis is mainly supportive and consists of oxygen, adequate hydration and ventilatory assistance if required. Nebulised ribavirin for the treatment of bronchiolitis is not mentioned in the NICE (2015d) guidelines.

Babies born earlier than 35 weeks of gestation or those less than 6 months of age at the onset of the RSV season are at high risk of the disease. Likewise, infants under 2 years old with congenital heart disease, chronic lung disease or with severe immunodeficiency are similarly at high risk. All such patients are candidates for prophylactic treatment with palivizumab. This is

a humanised monoclonal antibody used for passive immunisation against respiratory syncytial virus (Public Health England, 2015f). There is currently no vaccine against RSV.

Exacerbations of chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) renders patients more vulnerable to respiratory infection, and infectious exacerbations cause significant morbidity and mortality. These acute exacerbations of COPD are a frequent cause of morbidity and admission to hospital. An exacerbation is defined as 'a sustained worsening of the patient's symptoms from his or her usual stable state that is beyond normal day-to-day variations, and is acute in onset' (NICE, 2010).

Diagnosis

Common symptoms include worsening breathlessness, cough, increased sputum production and change in sputum colour. It is important to remember that not all acute exacerbations of COPD have an infective aetiology and that many infective exacerbations will be triggered by viruses. Bacterial causes include *M. catarrhalis*, *H. influenzae* and *S. pneumoniae*.

Severe exacerbations can cause marked breathlessness, confusion, marked reduction in performance of activities of daily living and use of accessory muscles at rest. These patients require hospital admission. Milder exacerbations can be managed in the community. Sending sputum samples for culture as routine practice in primary care is not recommended.

Treatment

NICE recommends antibiotic therapy for exacerbations of COPD associated with purulent sputum or where there are clinical signs of pneumonia or consolidation on chest X-ray (NICE, 2010). Recommended treatment is with an aminopenicillin (e.g. amoxicillin), a macrolide or a tetracycline, according to local guidance with modification according to sputum culture results if sputum has been sent. However, routine sputum cultures are not recommended for patients managed in primary care.

Co-amoxiclav has the advantage of covering β -lactamase-producing strains of *H. influenzae* and *M. catarrhalis* that are therefore resistant to amoxicillin. However, this agent has a greater incidence of side effects, such as a higher risk of *Clostridium* (now named *Clostridioides*) *difficile* infection (CDI) and a much higher incidence of cholestatic jaundice.

Numerous other drugs are promoted for the treatment of COPD exacerbations. The activity of ciprofloxacin against *S. pneumoniae* is insufficient to justify its use as monotherapy against pneumococcal infections. However, it has useful activity against *H. influenzae* and *M. catarrhalis*. Levofloxacin, the active isomer of ofloxacin, does not seem to offer any great microbiological advantage. Moxifloxacin is a quinolone that retains activity against Gram-negative organisms such as *Haemophilus* and *Moraxella* but has greater activity against Gram-positives such as *S. pneumoniae*. It has been favourably compared with standard treatment in exacerbations of COPD (Wilson et al., 2004). However, its use has been limited by the high incidence of CDI

associated with quinolone use and, rarely, the development of life-threatening hepatic toxicity and prolonged QT syndrome.

Community acquired pneumonia

Pneumonia is infection of the lung parenchyma. The alveoli fill with bacteria, inflammatory cells and fluid in a process called consolidation. Mild pneumonia can be treated in the community, but patients with moderate to severe disease will require hospital admission. In hospitalised patients, the diagnosis is confirmed by the presence of consolidation on the chest X-ray. Diagnosing pneumonia in primary care is more complicated. Clinical studies have defined community-acquired pneumonia (CAP) differently, but fever greater than 38 °C, pleural pain, dyspnoea, tachypnoea and new signs on examination of the chest seem to be useful for separating CAP from bronchitis in the absence of a chest X-ray. The British Thoracic Society (BTS) guidelines (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009) define CAP as symptoms of a lower respiratory tract infection (cough and at least one other), new focal signs on chest examination, at least one systemic feature and no other explanation for the illness. The NICE (2014) guidelines on community-acquired pneumonia suggested using a point-of-care CRP test to decide on antibiotic treatment in adult patients with LRTI if a clinical diagnosis of community-acquired pneumonia has not been made. Under these guidelines, antibiotics would not be given if CRP is less than 20, a delayed antibiotic prescription should be considered if CRP is greater than 20 but less than 100 and antibiotics should be offered if CRP is greater than 100 (NICE, 2014).

When community-acquired pneumonia is diagnosed clinically in an adult in the community, the 'CRB 65' mnemonic score is used to determine clinical risk. Table 36.1 describes the factors considered within the CRB score, where one point is scored for each of the following: confusion, respiratory rate, blood pressure and age. Patients with a CRB 65 score of 0 can be safely managed at home. Hospital assessment should be considered for patients with a score of 1 or more and especially if the score is 2 or more (NICE, 2014).

Severity scoring of community-acquired pneumonia in hospital patients uses the 'CURB 65' mnemonic score, which adds blood urea nitrogen of greater than 7 to the CRB 65 score. Patients with a CURB 65 of 0 or 1 are low risk and suitable for treatment at home. Patients with a CURB 65 score of 2 are at intermediate risk and should be considered for a short in-patient admission or outpatient treatment under hospital supervision. Patients with a CURB 65 score of 3 or more are at high risk and will require in-patient management (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009; NICE, 2014).

In children, bacterial pneumonia should be considered where there is persistent or repetitive fever of greater than 38.5 °C with chest recession and a raised respiratory rate (BTS Community Acquired Pneumonia in Children Guideline Group, 2011).

Causative organisms

The most common cause of community-acquired pneumonia is *S. pneumoniae*. *H. influenzae* (usually noncapsulate strains) are another common cause. *S. aureus* can cause a severe necrotising pneumonia, classically occurring after an influenza infection.

Table 36.1 CRB score for assessing the severity of community-acquired pneumonia presenting in primary care

Marker	Explanation of marker
C	Confusion defined as AMTS <8 or new disorientation in person, place or time
R	Respiratory rate ≥ 30 breaths/min
B	Systolic blood pressure <90 mmHg or diastolic <60 mmHg
65	Age >65
Score	Each severity marker present scores 1 point
0	Low risk of mortality, <1%
1–2	Intermediate risk of mortality, 1–10%
3–4	High risk of mortality, >10%

AMTS, Abbreviated Mental Test Score developed and validated by Hodkinson (1972).

Organisms causing atypical pneumonia include *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Coxiella burnetii* and viruses. It is not possible to determine the microbiological cause of pneumonia clinically or radiologically.

L. pneumophila is the cause of Legionnaire's disease, which occurs sporadically and in outbreaks often associated with contaminated air-conditioning or water systems. From 2002 to 2008, there were 300–600 new cases a year reported in England and Wales. Legionnaire's disease may be rapidly progressive, with very extensive consolidation and consequent respiratory failure.

Viral infections should not be forgotten as causes of pneumonia, although in practice it is unusual to make a definitive early diagnosis, so most cases are treated with antibacterials. Influenza can cause a primary viral pneumonia and can be complicated by secondary bacterial (particularly staphylococcal) pneumonia. Chickenpox can be complicated by primary varicella pneumonia, particularly in adults, and cytomegalovirus is capable of causing a variety of infections, including pneumonia, in patients with compromised cell-mediated immunity.

Diagnosis

Microbiological testing is not recommended as routine practice for adults or children with low-risk disease treated in the community. However, sputum culture may be useful in those who do not respond to first-line antibiotic treatment.

Adults with moderate- or high-severity CAP should have blood cultures and sputum cultures performed. The 2009 BTS guidelines also recommend pneumococcal antigen testing for all

Table 36.2 Empirical treatment of community-acquired pneumonia in patients with no history of penicillin allergy

CAP severity	Antibiotic of choice
Mild	Amoxicillin oral
Moderate	Amoxicillin and clarithromycin i.v. or oral
Severe	Co-amoxiclav (i.v. until clinical improvement) and clarithromycin i.v. or oral

CAP, Community-acquired pneumonia; i.v., intravenous.

patients with moderate- or high-severity CAP (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009). The success of sputum culture depends on the quality of the sample because samples from the upper respiratory tract will be contaminated with the normal regional flora. In patients who are severely ill and especially those requiring admission to an intensive care unit (ICU), more invasive sampling such as bronchoalveolar lavage may be required to tailor treatment.

The UK national guidelines for HIV testing in the UK recommend offering an HIV test to patients with bacterial pneumonia (British HIV Association et al., 2008). The BTS guidelines recommend that patients with high-severity CAP should have *Legionella* urinary antigen testing (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009). The NICE (2014) guideline extends this to patients with moderate-severity pneumonia. However, because urine antigen testing only detects serogroup 1 *L. pneumophila*, a negative test does not exclude *Legionella* infection.

The other atypical pathogens may require serological diagnosis with complement fixation tests being performed in parallel on acute and convalescent serum. The convalescent sample should be taken 2 weeks after the onset of symptoms; however, these results are obviously too late to tailor treatment. Respiratory multiplex PCRs which detect agents such as *Mycoplasma*, *C. pneumoniae* and *C. psittaci* are increasingly commonly available and allow diagnosis of atypical infection during the acute illness.

Empirical treatment

Both the BTS and NICE have produced guidelines for the treatment of community-acquired pneumonia in adults. The BTS (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009) and NICE (2014) guidelines make similar treatment recommendations (Table 36.2). Local guidelines may vary depending on local resistance rates and the demographics of the local population.

For mild disease, the recommended treatment is with amoxicillin, which provides activity against pneumococci and most strains of *H. influenzae*. Doxycycline or clarithromycin are the preferred alternatives in penicillin-allergic patients. However, for moderate or severe disease requiring admission to hospital, guidelines recommend that, until the aetiology is known, treatment should

cover both 'typical' causes (e.g. *S. pneumoniae* and *H. influenzae*) and atypical causes (e.g. *M. pneumoniae*, *Chlamydophila* species and *Legionella*). For patients with moderate or severe CAP, the current national guidelines (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009; NICE, 2014) therefore recommend a combination of a β -lactam drug plus a macrolide. For moderate disease, oral amoxicillin plus a macrolide is suggested, whereas for severe disease, a broad-spectrum β -lactamase stable penicillin (co-amoxiclav) and a macrolide should be given intravenously. In patients allergic to penicillin, a second-generation (e.g. cefuroxime) or third-generation (e.g. cefotaxime or ceftriaxone) cephalosporin can be used instead of co-amoxiclav, together with clarithromycin. For mild disease, the BTS guidelines (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009) suggest a 7-day course, although the NICE (2014) guidance shortens this duration to 5 days. For more severe disease, a 7- to 10-day course is suggested, but this may need to be extended, for example, if the infection was caused by *S. aureus* or Gram-negative bacilli.

In children, a different approach is recommended. In the BTS guidance (BTS Community Acquired Pneumonia in Children Guideline Group, 2011), amoxicillin is recommended for all children, and oral administration is preferred unless the child cannot tolerate oral fluids, has problematic oral absorption or is showing signs of septicaemia. The agents recommended include amoxicillin, co-amoxiclav, cefuroxime, cefotaxime or ceftriaxone. Macrolides may then be added if the child does not respond to first-line treatment.

Targeted therapy

The treatment of choice for pneumococcal pneumonia is benzylpenicillin or amoxicillin. Erythromycin monotherapy may be used in penicillin-allergic patients, but resistance rates are rising. Macrolides are bacteriostatic rather than bactericidal, and the comparative efficacy of this approach is not known. There is retrospective evidence that combination therapy using both a β -lactam and a macrolide can reduce mortality in patients whose pneumonia is complicated by pneumococcal bacteraemia (Martinez et al., 2003). However, a Dutch study found that narrowing the spectrum of antibiotic cover in patients with a pneumococcal bacteraemia was associated with a lower mortality rate regardless of severity (Cremers et al., 2014).

Pneumococci with reduced susceptibility to penicillin are becoming increasingly common, particularly in continental Europe and the USA. In the UK, about 5–10% of strains express 'intermediate susceptibility' (minimum inhibitory concentration [MIC] 0.06–2 mg/L), but high-level resistance (MIC > 2 mg/L) remains uncommon. Intermediate susceptibility may result in treatment failure in conditions such as meningitis at sites where antibiotic penetration is reduced, but antibiotic penetration into the lungs is sufficiently good that penicillin and amoxicillin remain effective for pneumonia. Strains expressing high-level resistance are unlikely to respond to penicillins. However, such strains are often co-resistant to macrolides and other first-line agents and may require treatment with glycopeptides or linezolid. The European Respiratory Society and European Society

for Clinical Microbiology and Infectious Diseases (ESCMID) guidance on the treatment of LRTI reported no documented cases of treatment failure with adequate doses of penicillins in extrameningeal infection (Woodhead et al., 2011). A new formulation of amoxicillin/clavulanic acid (2 g/125 mg given 12 hourly) is reported to have successfully treated strains, with an amoxicillin MIC of 4–8 mg/L (Woodhead et al., 2011).

M. pneumoniae does not possess a cell wall and is therefore not susceptible to β -lactam agents. A tetracycline or a macrolide is a suitable alternative. Tetracyclines are also effective against *C. pneumoniae*, *C. psittaci* and *C. burnetii*, but erythromycin is probably less effective. Quinolones are highly active against these organisms.

Staphylococcal pneumonia is usually treated with flucloxacillin. Meticillin-resistant *S. aureus* (MRSA) pneumonia is being seen more commonly in the community and in hospital. Strains of *S. aureus* expressing Panton-Valentine Leukocidin, an exotoxin, are capable of causing a severe necrotising pneumonia and if clinically suspected should warrant urgent critical care and specialist microbiological input.

Treatment recommendations for Legionnaire's disease are based on a retrospective review of the famous Philadelphia outbreak of 1976 (Fraser et al., 1977), in which two deaths occurred among the 18 patients who were given erythromycin, compared with 16 deaths in 71 patients treated with penicillin or amoxicillin. This observation accords with the facts that *Legionella* is an intracellular pathogen and that macrolides penetrate more efficiently than β -lactams into cells. Azithromycin is probably the most effective of the macrolide/azalide derivatives, but clinical evidence to confirm this is lacking. Other agents with proven clinical efficacy and good intracellular activity against *Legionella* include rifampicin and quinolones. There have been no randomised controlled clinical trials comparing the new quinolones and the newer macrolides for the treatment of *L. pneumophila*. Guidance, based on observational studies, suggests non-severe cases should be treated with an oral fluoroquinolone (with a macrolide as an alternative). Severe cases are treated with a combination of a fluoroquinolone plus either a macrolide or rifampicin, de-escalating to a fluoroquinolone as the sole agent after the first few days (BTS Community Acquired Pneumonia in Adults Guideline Group, 2009). Treatment is not recommended for the non-pneumonic form of legionellosis (Pontiac fever), which presents as a self-limiting flu-like illness.

Prevention

Pneumococcal 23-valent polysaccharide vaccine and influenza vaccine should be offered to all those at risk of infection. For pneumococcal infection, this includes patients who fulfil the following criteria:

- asplenia or dysfunction of the spleen,
- chronic respiratory disease,
- chronic heart disease,
- chronic renal disease,
- chronic liver disease,
- diabetes,

- immunosuppressed,
- aged 65 years or older,
- cochlear implants,
- cerebrospinal fluid leaks.

In the UK, children are immunised with the 13-serotype conjugate vaccine as part of the normal childhood vaccination schedule. This should both protect them and reduce the circulation of these serotypes in the community; however, there is concern that vaccination may lead to serotype replacement, with serotypes not included in the vaccine filling the empty ecological niche ([Public Health England, 2013b](#)).

Hospital-acquired pneumonia

Hospital-acquired pneumonia (HAP) is defined as pneumonia developing more than 48 hours after admission and not incubating at the time of admission. It is a major cause of morbidity and mortality in hospital patients in the developed world. An important subset of HAP is ventilator-associated pneumonia (VAP), which is defined as pneumonia occurring more than 48 hours after endotracheal intubation.

The range of pathogens associated with HAP is wide. Traditionally, it has been divided into early infection, occurring after less than 5 days in hospital when more sensitive organisms are likely to be involved, and late infection, which carried a higher risk of multidrug-resistant organisms. However, these distinctions are not absolute.

Common pathogens include Gram-negative organisms such as *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae* and *Acinetobacter* spp. *S. aureus*, including MRSA is the main Gram-positive organism implicated. *S. pneumoniae* and *Haemophilus influenzae* are sometimes found in early-onset HAP, and the patient may have been incubating the infection at the time of admission; they are rare in late-onset HAP. HAP may be polymicrobial. It is rarely due to viruses or fungi unless the host is immunosuppressed. Hospital water supplies have been implicated in sporadic cases, and occasionally there have been outbreaks of *L. pneumophila*. Therefore, this possibility should be considered.

Clinical features

Nosocomial pneumonia accounts for 10–15% of all hospital-acquired infections, usually presenting with sepsis and/or respiratory failure. Up to 50% of cases are acquired on intensive care units. Predisposing features include stroke, mechanical ventilation, chronic lung disease, recent surgery and previous antibiotic exposure.

Diagnosis

Sputum is commonly sent for culture, but this is sometimes unhelpful because it may be contaminated by mouth flora. If the patient has received antibiotics, the normal mouth flora is often replaced by resistant organisms such as staphylococci or Gram-negative bacilli, making the interpretation of culture results difficult. Bronchoalveolar lavage is often more helpful. Blood cultures may be positive.

Treatment

The range of organisms causing nosocomial pneumonia is very large, so broad-spectrum empiric therapy is indicated. The choice of antibiotics will be influenced by preceding antibiotic therapy, the duration of hospital admission and, above all, by the individual unit's experience with hospital-acquired bacteria. It is important that units maintain surveillance systems and monitor their resistance rates so that guidelines can be modified over time. Both the British Society for Antimicrobial Chemotherapy ([Masterton et al., 2008](#)) guidelines and the [NICE \(2014\)](#) guidelines recommend following local policies based on local pathogen and susceptibility data.

Co-amoxiclav is sometimes used for early HAP but lacks pseudomonal cover. Agents such as piperacillin/tazobactam and meropenem have broad-spectrum activity including *Pseudomonas* sp. but do not cover MRSA, so an additional agent such as vancomycin or linezolid would be required in MRSA-colonised patients or in units with high rates of MRSA infection. With concerns about the spread of carbapenem-resistant *Enterobacteriaceae*, there has been a national attempt to control carbapenem use, with acute hospital trusts required to reduce their carbapenem prescribing below the 2014–15 baseline. The aim is to relieve the evolutionary selective pressure driving the development and spread of carbapenem resistance and therefore to reduce the spread of carbapenemase-producing organisms. There have also been attempts to use narrower-spectrum agents to reduce *C. difficile* risk. A study using amoxicillin and temocillin has been published; however, this combination lacks *P. aeruginosa* and *S. aureus* cover, and additional agents are therefore required in some circumstances ([Habayeb et al., 2015](#)).

Options in patients with type one hypersensitivity to penicillin include aztreonam or ciprofloxacin and an antibiotic with activity against Gram-positive bacteria (e.g. a glycopeptide or linezolid).

Prevention

General strategies for minimising the incidence of HAP include early postoperative mobilisation, analgesia, physiotherapy and promotion of rational antibiotic prescribing.

One of the Department of Health's (DH's) high-impact interventions ([DH, 2011](#)) is a care bundle for ventilated patients, aimed at reducing the prevalence of VAP. The high-impact interventions are a set of practice interventions introduced to provide NHS trusts with the tools to reduce serious healthcare-associated infections. Since 2008, the Health and Social Care Act controlling healthcare-associated infection has been a legal requirement for NHS trusts; it forms part of the code of practice all NHS trusts operate under. Implementation of care bundles such as this provides evidence that NHS trusts are complying with this obligation.

The recommendations in the ventilator care bundle include head-of-bed elevation, sedation holding to reduce the duration of mechanical ventilation, aspiration of secretions every 1–2 hours via a subglottic port in patients who have been intubated more than 72 hours, limiting stress ulcer prophylaxis to high-risk patients and good general hygiene of tubing management and suction.

Another strategy proposed for the prevention of VAP is selective decontamination of the digestive tract (SDD), based on the premise that the infecting organisms initially colonise the patient's oropharynx or intestinal tract. By administering non-absorbable antibiotics such as an aminoglycoside or colistin to the gut and applying a paste containing these agents to the oropharynx, it is proposed that the potential causative organisms will be eradicated and the incidence of pneumonia thereby reduced. In some centres, an antifungal agent such as amphotericin B is added; others also advocate addition of a systemic broad-spectrum agent such as cefotaxime.

The role of selective decontamination of the digestive tract remains controversial. A Cochrane review suggested that it did reduce respiratory tract infections, although mortality was only reduced if systemic antibiotics were also given (Di'Amico et al., 2009). However, questions remain about longer-term benefits and the potential effects on antibiotic resistance. The use of aerosolised antibiotics in this context has been considered; agents which would be suitable for administration by this route and with the appropriate antimicrobial spectrum include aminoglycosides (particularly tobramycin) and the polymyxin drug colistin. There are no published data available at present, and therefore this approach cannot be universally recommended.

Aspiration pneumonia

One further condition which may be seen either in hospital or in the community is aspiration pneumonia, initiated by inhalation of stomach contents contaminated by bacteria from the mouth. Risk factors include alcohol, hypnotic drugs and general anaesthesia; all of these may induce a patient to vomit while unconscious. Gastric acid is very destructive to lung tissue and leads to severe tissue necrosis. Damaged tissue is then prone to secondary infection, often with abscess formation. Anaerobic bacteria are particularly implicated, but these are often accompanied by aerobic organisms such as viridans streptococci.

Treatment

Treatment with amoxicillin and metronidazole is usually adequate. However, broader-spectrum drugs may be used if there are reasons to suspect Gram-negative involvement, for example, if the patient has been in hospital or has previously been exposed to antibiotics. Options for treatment in such patients include co-amoxiclav, piperacillin/tazobactam and carbapenems.

Novel coronaviruses

Most coronaviruses cause mild URTIs, but two have emerged in recent years which are more serious.

Severe acute respiratory syndrome

Clinically, the severe acute respiratory syndrome (SARS) coronavirus causes pneumonitis, presenting with a flu-like prodrome and progressing to dyspnoea, dry cough and often adult respiratory distress syndrome, requiring ventilatory support. Treatment of SARS is largely supportive. It was first described in 2003 after a large outbreak originating in China spread throughout

Box 36.1 Middle East respiratory syndrome coronavirus epidemiological and clinical criteria

Epidemiological criteria

- Patient has lived in or travelled to an area where it could have been acquired in the last 14 days (as of February 2016, Bahrain, Jordan, Iraq, Iran, Kingdom of Saudi Arabia, Kuwait, Oman, Qatar, United Arab Emirates, and Yemen).
 - OR
 - The patient has had close contact with a patient with MERS in the 14 days before the patient became ill and that patient had symptoms at the time of contact.
 - OR
 - The patient is a healthcare worker on ICU caring for patients with respiratory distress.
 - OR
 - The patient is part of a cluster of epidemiologically linked cases requiring ICU admission.
- AND

Clinical case description

- The patient has a fever >38 °C or history of fever and cough and has evidence of disease of the lung parenchyma (e.g. chest X-ray changes) with no alternative explanation.

ICU, Intensive care unit; MERS, Middle East respiratory syndrome. From Public Health England, 2018

Americas, Europe and Asia. The outbreak terminated that year, with only small numbers of cases occurring since. Many experts predict that SARS will re-emerge.

Middle East respiratory syndrome coronavirus

This novel coronavirus was first identified in 2012 and causes Middle East respiratory syndrome (MERS). The clinical picture ranges from asymptomatic infection to severe respiratory distress and death. Common symptoms include fever, cough and shortness of breath (Box 36.1). Some patients have gastro-intestinal symptoms such as diarrhoea; pneumonia is common but not universal. In 36% of identified cases, the patients have died (WHO, 2017). Camels appear to be a common host. Human-to-human transmission requires close contact, but there has been transmission to healthcare workers, and there have been nosocomial outbreaks (WHO, 2017). The risk in these patients is low, but they should be tested to exclude the possibility (Public Health England, 2018). Treatment is still under investigation and is currently supportive and includes supplemental oxygen and ventilation if required. No antiviral drugs are recommended at present.

Cystic fibrosis

Cystic fibrosis (CF) is an inherited, autosomal-recessive disease which, at the cellular level, is caused by a defect in the transport of ions in and out of cells. This leads to changes in the consistency and chemical composition of exocrine secretions. In the lungs, this is manifest by the production of very sticky, tenacious mucus which is difficult to clear by mucociliary action. The production of such mucus leads to airway obstruction and infection. These repeated infections lead to lung damage and bronchiectasis,

which in turn predisposes to further infection. The pattern in CF is of a progressive decline in lung function with episodes of acute worsening known as pulmonary exacerbations. The features of these exacerbations include increased cough, increased sputum production, shortness of breath, chest pain, loss of appetite and decline in respiratory function.

Infective organisms

It had been thought that the microbiology of respiratory infections in cystic fibrosis involved a few key pathogens, but this is now acknowledged over recent years to be increasingly complex.

H. influenzae is frequently encountered in early childhood and has been reported to be the most common organism at 1 year of age. LRTI is sometimes difficult to distinguish from upper respiratory tract colonisation. As in healthy children, most of the infections in children with cystic fibrosis are with non-capsulate strains. *S. aureus* is a common pathogen and may be isolated from early infancy. In the UK, continuous anti-staphylococcal prophylaxis is recommended up to the age of 3, although some centres continue beyond this time. Prophylaxis has been with flucloxacillin, but MRSA rates vary between units and this may affect the choice of agent.

P. aeruginosa is the most common pathogen isolated from people with cystic fibrosis, and its prevalence increases with age. It is possible to clear 80% of early infections with aggressive antibiotic therapy (e.g. ciprofloxacin and an inhaled aminoglycoside) and so delay the onset of chronic colonisation. Once chronic colonisation with *P. aeruginosa* is established, it is associated with faster decline in lung function, increased hospitalisation and reduced survival. Long-term suppressive therapy with inhaled antibiotics is used in these patients to slow the decline in lung function.

An important feature of those *P. aeruginosa* strains which infect patients with cystic fibrosis is their production of large amounts of alginate, a polymer of mannuronic and glucuronic acid. This seems to be a virulence factor for the organism because it inhibits opsonisation and phagocytosis and enables the bacteria to adhere to the bronchial epithelium, thus inhibiting clearance. It does not confer additional antibiotic resistance. Strains which produce large amounts of alginate have a wet, slimy appearance on laboratory culture media and are termed 'mucoïd' strains.

P. aeruginosa acquisition by CF patients had been thought to involve sporadic acquisition of environmental strains. However, some strains of *P. aeruginosa* are transmissible between CF patients. Guidelines recommend molecular fingerprinting to identify these epidemic strains (Cystic Fibrosis Trust Microbiology Laboratory Standards Working Group, 2010).

Other Gram-negative bacteria can also infect the lungs of patients with CF, with the *Burkholderia cepacia* complex being the most important. Outbreaks of these organisms occurred in CF centres in the 1980s and 1990s, leading to many deaths. Therefore, interaction between non-related CF patients, either socially or in healthcare settings, is strongly discouraged. Colonisation with genomovar IIIA of the *B. cepacia* complex (*cenocepacia*) precludes lung transplantation because of high postoperative mortality rates. Correct identification of the organism is therefore

vital, and because biochemical methods are unreliable, PCR methods are recommended (Cystic Fibrosis Trust Microbiology Laboratory Standards Working Group, 2010). The impact of other Gram-negative bacteria and also of organisms such as anaerobes which had traditionally not been thought to be pathogenic is still unresolved.

In recent years there has been an increase in the number of patients in Europe and the USA found to be colonised with non-tuberculous mycobacteria. Transmission of *Mycobacterium abscessus* complex has been recorded (Cystic Fibrosis Trust *Mycobacterium abscessus* Infection Control Working Group, 2013). Poorer outcomes after lung transplantation have been described in patients colonised with *M. abscessus* (Floto et al., 2015). The *Mycobacterium avium* complex is most frequently isolated, but the number of *M. abscessus* complex isolated is increasing rapidly. There are concerns that this may be related to widespread use of azithromycin prophylaxis. Consensus guidelines from the European Cystic Fibrosis Society and the US Cystic Fibrosis Foundation recommend annual screening for carriage of non-tuberculous mycobacteria and strict infection control precautions (Floto et al., 2015).

Fungi have also been increasingly recognised as important pathogens in cystic fibrosis. Aspergillus colonisation leading to allergic bronchopulmonary aspergillosis (ABPA) has been recognised for many years, but it has now also been suggested that it can cause exacerbations by producing a fungal bronchitis. *Scedosporium apiospermum* and *Wangiella (Exophiala) dermatitidis* are being isolated more commonly (Cystic Fibrosis Trust Antibiotic Working Group, 2009).

Treatment

Although this section concentrates on antibiotic therapy, it should be noted that other treatments such as physiotherapy play a vital part. In addition, lung transplantation can be lifesaving.

Acute respiratory exacerbations of CF caused by *P. aeruginosa* are usually treated with dual antibiotic therapy with two agents that act by different mechanisms (Table 36.3). The length of treatment course is usually 2 weeks. Sensitivity testing of *Pseudomonas* spp. and other non-fermenting Gram-negative bacilli should not be used in isolation to guide treatment because it is frequently unreliable in this setting. The choice of antibiotics will therefore be guided by the patient's response.

B. cepacia complex is often very difficult to treat, and strains may be resistant to all available antibiotics. Under these circumstances, combination therapy is often required.

The use of inhaled (usually nebulised) antibiotics as an adjunct to parenteral therapy has attracted attention, both for treatment of acute exacerbations and for longer-term use in an attempt to reduce the pseudomonal load. Agents which have been administered in this way include colistin, aminoglycosides and aztreonam. The best evidence that long-term administration can be beneficial comes from a large multi-centre trial of nebulised tobramycin (Moss, 2001). Patients were randomised to receive once-daily nebulised tobramycin or placebo in on-off cycles for 24 weeks, followed by open-label tobramycin to complete 2 years of study. Nebulised tobramycin was safe and well tolerated and was associated with a reduction in hospitalisation and

Table 36.3 Antibiotics with activity against *Pseudomonas*

Antibiotic	Comment
β-Lactams and related drugs	
Ureidopenicillins	Piperacillin, formulated in combination with the β-lactamase inhibitor tazobactam, is the only one of these agents currently available in the UK.
Cephalosporins	Ceftazidime is the third-generation cephalosporin active against <i>Pseudomonas</i> ; it is very active against other Gram-negative bacilli but has rather lower activity against Gram-positive bacteria. Ceftobiprole is a new cephalosporin with activity against <i>Pseudomonas</i> and MRSA.
Carbapenems	Broad-spectrum agents with good Gram-negative activity. Imipenem was the first of these drugs, but CNS toxicity and its requirement for combination with the renal dipeptidase inhibitor cilastatin have largely led to its replacement by meropenem. Doripenem is a newer carbapenem with similar activity to meropenem. Ertapenem has poor activity against <i>Pseudomonas aeruginosa</i> .
Monobactams	Aztreonam is the only monobactam available and offers good activity against Gram-negative organisms but no activity against Gram-positive organisms.
Other antibiotic classes	
Aminoglycosides	Gentamicin and tobramycin have very similar activity against <i>Pseudomonas</i> ; tobramycin is perhaps slightly more active. Netilmicin is less active, whereas amikacin may be active against some gentamicin-resistant strains.
Quinolones	Ciprofloxacin can be given orally and parenterally, but as with ceftazidime, resistance can develop while the patient is on treatment. Other quinolones, such as ofloxacin, its L-isomer levofloxacin, and moxifloxacin, have better Gram-positive spectrum but concomitantly less activity against <i>Pseudomonas</i> .
Polymyxins	Colistin (polymyxin E) can be given by inhalation and intravenously; it is usually reserved for more resistant cases due to its toxicity.
CNS, Central nervous system; MRSA, methicillin-resistant <i>Staphylococcus aureus</i> .	

improvements in lung function. This was at the expense of a degree of tobramycin resistance, although this did not appear to be clinically significant. In patients who are intolerant of nebulised treatment, tobramycin and colistin dry powder inhalers can be used (NICE, 2013b).

Case studies

Case 36.1

A 40-year-old woman, Mrs LH, presents to her primary care doctor with a 1-week history of sore throat. She is normally fit and well and has had no other symptoms other than some lethargy.

Questions

1. What are the likely causes of Mrs LH's sore throat?
2. Should Mrs LH be prescribed antibiotics?

The primary care doctor decides to prescribe a 10-day course of penicillin V to cover a possible streptococcal infection. Two weeks later, the patient returns. Mrs LH is feeling worse and is now experiencing difficulty in swallowing. Examination of her throat reveals widespread white plaques.

3. What is the likely diagnosis?
4. What other investigations might be indicated?

Answers

1. A viral aetiology is the most likely cause. These are usually the same viruses that cause colds. Bacterial infection with group A streptococci usually presents with a more severe infection. The Centor score can be used to help determine whether bacterial infection is likely; because there is no tonsillar exudate, history of fever, tender anterior surgical lymphadenopathy or adenitis and no cough, the score would be 0, indicating that bacterial infection is unlikely.
2. Antibiotics are not recommended for routine use. Treatment is directed at symptomatic relief, and most people recover within 7 days.
3. The likely cause of Mrs LH's symptoms is oral candidiasis. The presence of dysphagia is concerning and raises the question of oesophageal involvement. If the dysphagia is significant, hospital admission may be indicated, and endoscopy may be required to elucidate the extent of the infection.
4. Mrs LH maybe immunocompromised, and this must be considered. Therefore, all patients with oral candidiasis should be offered HIV testing (British HIV Association et al., 2008).

Case 36.2

A 65-year-old man, Mr. NP, is found collapsed at home. He is brought into hospital. His family said that he complained of flu-like symptoms a few days before. Mr. NP is pyrexial, tachypnoeic, tachycardic and hypoxic. On examination, he is found to have reduced air entry at the right base.

Questions

1. What is the likely diagnosis?
2. What are the possible infecting organisms?
3. What empirical antibiotics would you choose?

Answers

1. Mr NP is likely to have community-acquired pneumonia.
2. The most likely causative organisms are *S. pneumoniae* and *H. influenzae*. However, *S. aureus* should also be considered in post-influenza pneumonia.
3. The choice of treatment for Mr NP should be guided by the 'CURB' 65 score. Given the history, the CURB 65 score is likely to be at least 3, indicating severe disease. A broad-spectrum β -lactam, such as co-amoxiclav, and a macrolide antibiotic are usually used. The β -lactam should be given intravenously initially.

Case 36.3

A 4-year-old girl, Miss GR, attends an appointment with her primary care doctor. Her mother explains that Miss GR is complaining of ear pain over the past 2 days. She is systemically well and playing in the consultation room. On examination she is afebrile, but the tympanic membrane is inflamed.

Questions

1. What is the likely diagnosis?
2. Should Miss GR be prescribed antibiotics?

Answers

1. It is likely that Miss GR has otitis media.
2. Immediate antibiotic treatment should not be necessary given that the infection is unilateral and the patient is over 2 years old. However, a delayed prescription could be considered, dated for 2 days after the consultation if the girl has not improved. Amoxicillin for 7 days would be a reasonable choice. The dose would depend on the patient's weight.

Case 36.4

A 30-year-old man, Mr SH, is found collapsed at home. He had complained of a sore throat over the past few days. On arrival at hospital, Mr SH is pyrexial (38.5 °C), hypotensive with a blood pressure of 80/50 mmHg and tachycardic with a heart rate of 130 beats/min.

Questions

1. What is the likely diagnosis?
2. What antibiotics should be prescribed for Mr SH?
3. What other treatments could be considered?

Answers

1. Invasive group A streptococcal infection seems the most likely diagnosis based on the clinical presentation.
2. A β -lactam antibiotic, for example, amoxicillin 1 g three times a day i.v. and clindamycin up to 1200 mg four times a day

depending on weight, would be the usual therapy for a severe group A streptococcal infection. Because the patient has presented in septic shock, a broader-spectrum combination such as piperacillin and tazobactam and clindamycin would be used until the causative organism had been identified. The clindamycin could be stopped once the patient has stabilised, usually after 48–72 hours.

If a group A streptococcus is isolated from clinical samples, the therapy can be rationalised to amoxicillin. Amoxicillin would usually be given for 10 days, but this could be switched to oral therapy once the patient has been afebrile for 24 hours, his haemodynamic parameters have returned to normal, and his inflammatory markers are falling.

3. Intravenous immunoglobulin has been used in group A streptococcal infection causing toxic shock. A single dose of 2 g/kg should be prescribed.

Case 36.5

A 72-year-old man, Mr AD, with a known history of COPD presents at the hospital emergency department with increasing breathlessness. Mr AD has a productive cough of cream-coloured sputum, which is normal for him. He has not noticed an increase in purulence or volume. Chest X-ray showed hyperinflated lungs but no focal consolidation, and a diagnosis of acute exacerbation of COPD was made.

Questions

1. Does Mr AD require antibiotics?
2. What investigations would inform the diagnosis?

Answers

1. Many exacerbations of COPD are non-infective. Therefore, antibiotics should be reserved for when sputum has become more purulent.
2. The diagnosis of an exacerbation of COPD is clinical. Sputum cultures should only be performed if antibiotics are required and if the patient is unwell enough to require referral to secondary care or if an initial empirical course of treatment has been ineffective.

Case 36.6

A 7-year-old girl, Miss TL, is seen in the hospital paediatric outpatient clinic for a routine appointment. She is known to have cystic fibrosis and has had several exacerbations in the past which have been treated with flucloxacillin. On this visit, Miss TL is stable, but the report of sputum culture received 2 days after the clinic shows a growth of *P. aeruginosa*.

Questions

1. What treatment should be started?
2. What other options are available?
3. One week later, you receive a telephone call from Miss TL's parents that she has become unwell. They suspect Miss TL has another chest infection. What agents might be appropriate for treating this infection?

Answers

1. Pseudomonas colonisation is associated with more rapid decline in lung function, and therefore decolonisation should be attempted, for example, using ciprofloxacin 20 mg/kg twice a day for 14 days and an inhaled aminoglycoside.
2. Non-pharmacological measures such as physiotherapy should also be included.
3. Combination treatment is usually favoured, depending on individual susceptibility results. This might include a β -lactam antibiotic such as ceftazidime or piperacillin/tazobactam in combination with an aminoglycoside such as tobramycin. In this case, Miss TL became unwell while on the original decolonisation regime; therefore, an alternative regime would be indicated.

Case 36.7

A 4-year-old boy, Master SW, presents with bouts of paroxysmal coughing which often end in vomiting. The previous week, Master SW had been unwell, with coryzal symptoms. Master SW has missed several of his standard vaccinations because his parents were concerned about 'overloading' his immune system.

Questions

1. What is the likely diagnosis?
2. What treatment should Master SW be offered?
3. What public health measures are necessary?

Answers

1. Pertussis should be considered as a possible diagnosis. This could be confirmed by culture or PCR if Master SW has been unwell for less than 2 weeks or by oral fluid IgG testing if he has been unwell for more than 2 weeks.
2. A 3-day course of azithromycin or a 7-day course of erythromycin or clarithromycin is the usual treatment for pertussis.
3. Pertussis is a notifiable disease, and in England, the local health protection team should be informed when the diagnosis is suspected. Because pertussis is highly infectious, Master SW should be excluded from nursery until 5 days after he starts treatment or 21 days after the cough started in line with [Public Health England \(2016c\)](#) guidance.

37 Urinary Tract Infections

Neil J. B. Carbarns

Key points

- Urinary tract infection (UTI) is one of the most common complaints seen in general practice, is one of the most common reasons for prescribing antibiotics and accounts for about one-third of hospital-acquired infections.
- *Escherichia coli* is the most frequent pathogen, accounting for more than three-quarters of community-acquired UTIs.
- Antimicrobial sensitivity patterns are changing. *E. coli* and other bacteria are becoming increasingly resistant to amoxicillin, cephalosporins, trimethoprim and the quinolones, both in healthcare-related and community-acquired infection.
- Symptoms are variable; many UTIs are asymptomatic and some present atypically, particularly in children and the elderly.
- The concept of significant bacteriuria (at least 100,000 organisms/mL of urine) is generally used to distinguish between contamination and infection, but fewer organisms than this can still cause symptoms and disease. One-third of young women with cystitis have lower counts.
- Asymptomatic UTI should be treated in children and pregnant women, but first it should be confirmed by having two urine cultures with significant numbers of the same pathogen. Treatment options are reduced because some antibiotics are contraindicated in these patient groups.
- Catheter-related UTI should be treated only when the patient has systemic evidence of infection.
- A 3-day treatment course is usually sufficient in uncomplicated lower UTI in women. Longer, 7- to 14-day courses are recommended for men, children and pregnant women.
- Although it is not always necessary to send urine samples for laboratory analysis unless empirical treatment fails, they provide local epidemiology and antibiotic resistance data. Urine dipsticks for pyuria and bacteriuria are useful screening tests.
- Antibiotic prophylaxis may be beneficial in women with recurrent UTIs and in children with structural or functional abnormalities. Non-antimicrobial prevention measures include probiotics and cranberry products.

The term urinary tract infection (UTI) usually refers to the presence of organisms in the urinary tract together with symptoms, and sometimes signs, of inflammation. However, it is more precise to use one of the following terms.

- *Significant bacteriuria*: defined as the presence of at least 100,000 bacteria/mL urine. A quantitative definition such as this is needed because small numbers of bacteria are normally found in the anterior urethra and may be washed out into urine samples. Counts of fewer than 100 bacteria/mL are

normally considered to be urethral contaminants unless there are exceptional clinical circumstances, such as a sick immunosuppressed patient.

- *Asymptomatic bacteriuria*: significant bacteriuria in the absence of symptoms in the patient.
- *Cystitis*: a syndrome of frequency, dysuria and urgency, sometimes with suprapubic tenderness, which usually suggests infection restricted to the lower urinary tract, that is, the bladder and urethra.
- *Urethral syndrome*: a syndrome of frequency and dysuria in the absence of significant bacteriuria with a conventional pathogen.
- *Acute pyelonephritis*: an acute infection of one or both kidneys with flank pain, tenderness and fever. Usually, the lower urinary tract is also involved.
- *Chronic pyelonephritis*: a potentially confusing term used in different ways. It can refer to continuous excretion of bacteria from the kidney, to frequent, recurring infection of the renal tissue or to a particular type of pathology of the kidney seen microscopically or by radiographic imaging, which may or may not be caused by infection. Although chronic infections of renal tissue are relatively rare, they do occur in the presence of kidney stones and in tuberculosis.
- *Relapse and reinfection*: relapse is recurrence of a UTI caused by the same organism that caused the original infection. Reinfection is recurrence caused by a different organism and is, therefore, a new infection.
- *Urosepsis*: includes clinical evidence of UTI with two or more criteria of a systemic inflammatory response, for example, abnormal temperature, white blood cell count, heart rate or respiratory rate.

Epidemiology

UTIs are among the most common infectious diseases occurring in either the community or healthcare setting. Uncomplicated UTIs typically occur in healthy adult non-pregnant women, whereas complicated UTIs are found in either sex and at any age, frequently associated with structural or functional urinary tract abnormalities.

Infants

UTI is a problem in all age groups, although its prevalence varies markedly. In infants up to 6 months of age, symptomatic UTI has

a prevalence of about 2 cases per 1000 and is much more common in boys than in girls. In addition to these cases, asymptomatic UTI is much more common than this, occurring in around 2% of boys in their first few months of life.

Children

In preschool children, UTIs become more common and the sex ratio reverses, such that the prevalence rate is 5% in girls and 0.5% in boys. In older children, the prevalence of bacteriuria falls to 1.2% among girls and 0.03% among boys. Overall, about 3–5% of girls and 1–2% of boys will experience a symptomatic UTI during childhood. However, in girls, about two-thirds of UTIs are asymptomatic. The occurrence of bacteriuria during childhood appears to correlate with a higher incidence of bacteriuria in adulthood.

Adults

When women reach adulthood, the prevalence of bacteriuria rises to between 3% and 5%. Each year, about a quarter of these women with bacteriuria clear their infections spontaneously and are replaced by an equal number of newly infected women, who are often those with a history of previous infections. On average, about 10% of adult women have a symptomatic UTI each year, and more than half of adult women report that they have had a symptomatic UTI at some time. Two to five percent of women have recurrent UTIs, with the peak age of incidence in their early 20s and with a genetic predisposition. UTI is uncommon in young healthy men, with 0.5% of adult men having bacteriuria. Structural or functional abnormality is associated with UTI in men. The rate of symptomatic UTI in men rises progressively with age, from 1% annually at age 18 to 4% at age 60 years.

Elderly

In the elderly of both sexes, the prevalence of bacteriuria increases dramatically, reaching at least 20% among women and 10% among men. Asymptomatic bacteriuria in older persons does not seem to have any harmful effects, and there is no evidence that treating it is beneficial, including no decrease in urinary incontinence. Therefore, routine treatment of asymptomatic bacteriuria in older persons is not indicated (Nicolle, 2009).

Aetiology and risk factors

More than 95% of uncomplicated UTIs are caused by a single bacterial species. In acute uncomplicated UTI acquired in the community, *Escherichia coli* is by far the most common causative bacterium, being responsible for about 80% of infections. The remaining 20% are caused by other Gram-negative enteric bacteria such as *Klebsiella* and *Proteus* species, and by Gram-positive cocci, particularly enterococci and *Staphylococcus saprophyticus*. The latter organism is almost entirely restricted to infections in young, sexually active women.

Recurrent and complicated UTIs associated with underlying structural abnormalities, such as congenital anomalies, neurogenic bladder and obstructive uropathy, are often caused by more resistant organisms such as *Pseudomonas aeruginosa*, *Enterobacter* and *Serratia* species. In complicated UTI there is an increased rate of isolation of multiple organisms. Organisms such as these are also more commonly implicated in hospital-acquired urinary infections, including those in patients with poor urinary catheter care, which are an important source of cross-infection.

Rare causes of urinary infection, nearly always in association with structural abnormalities or catheterisation, include anaerobic bacteria and fungi. Urinary tract tuberculosis is an infrequent but important diagnosis that may be missed through lack of clinical suspicion. A number of viruses are excreted in urine and may be detected by culture or nucleic acid amplification methods, but symptomatic infection is confined to immunocompromised patients, particularly children following peripheral blood stem cell transplant, in whom adenoviruses and polyomaviruses such as BK virus are associated with haemorrhagic cystitis.

In hospitals, a major predisposing cause of UTI is urinary catheterisation. With time, even with closed drainage systems and scrupulous hygiene, bacteria can be found in almost all catheters, and this is a risk of the development of symptomatic infection.

Pathogenesis

There are three possible routes by which organisms might reach the urinary tract: the ascending, blood-borne and lymphatic routes. There is little evidence for the last route in humans. Blood-borne spread to the kidney can occur in bacteraemic illnesses, most notably *Staphylococcus aureus* septicaemia, but by far the most frequent route is the ascending route.

In women, UTI is preceded by colonisation of the vagina, perineum and periurethral area by the pathogen, which then ascends into the bladder via the urethra. Uropathogens colonise the urethral opening of men and women. That the urethra in women is shorter than in men and the urethral meatus is closer to the anus are probably important factors in explaining the preponderance of UTI in females. Further, sexual intercourse appears to be important in forcing bacteria into the female bladder, and this risk is increased by the use of diaphragms and spermicides, which have both been shown to increase *E. coli* growth in the vagina. Whether circumcision reduces the risk of infection in adult men is not known, but it markedly reduces the risk of UTI in male infants.

Organism

E. coli causes most UTIs, and although there are many serotypes of this organism, only a few of these are responsible for a disproportionate number of infections. Although there are as yet no molecular markers that uniquely identify uropathogenic *E. coli*, some strains possess certain virulence factors that enhance their ability to cause infection, particularly infections of the upper urinary tract. Recognised factors include bacterial surface structures called P-fimbriae, which mediate adherence to glycolipid

receptors on renal epithelial cells, possession of the iron-scavenging aerobactin system, and increased amounts of capsular K antigen, which mediates resistance to phagocytosis.

Host

Although many bacteria can readily grow in urine, and Louis Pasteur used urine as a bacterial culture medium in his early experiments, the high urea concentration and extremes of osmolality and pH inhibit growth. Other defence mechanisms include the flushing mechanism of bladder emptying, because small numbers of bacteria finding their way into the bladder are likely to be eliminated when the bladder is emptied. Moreover, the bladder mucosa, by virtue of a surface glycosaminoglycan, is intrinsically resistant to bacterial adherence. Presumably, in sufficient numbers, bacteria with strong adhesive properties can overcome this defence. Finally, when the bladder is infected, white blood cells are mobilised to the bladder surface to ingest and destroy invading bacteria. The role of humoral antibody-mediated immunity in defence against infection of the urinary tract remains unclear. Genetic susceptibility of individual patients to UTI has been reviewed (Lichtenberger and Hooton, 2008).

Abnormalities of the urinary tract

Any structural abnormality leading to the obstruction of urinary flow increases the likelihood of infection. Such abnormalities include congenital anomalies of the ureter or urethra, renal stones and, in men, enlargement of the prostate. Renal stones can become infected with bacteria, particularly *Proteus* and *Klebsiella* species, and thereby become a source of 'relapsing' infection. Vesicoureteric reflux is a condition caused by failure of physiological valves at the junction of the ureters and the bladder which allows urine to reflux towards the kidneys when the bladder contracts. It is probable that vesicoureteric reflux plays an important role in childhood UTIs that lead to chronic renal damage (scarring) and persistence of infection. If there is a diminished ability to empty the bladder such as that due to spinal cord injury, there is an increased risk of bacteriuria.

Clinical manifestations

Most UTIs are asymptomatic. Symptoms, when they do occur, are principally the result of irritation of the bladder and urethral mucosa. However, the clinical features of UTI are extremely variable and to some extent depend on the age of the patient.

Infants

Infections in newborns and infants are often overlooked or misdiagnosed because the signs may not be referable to the urinary tract. Common but non-specific presenting symptoms include failure to thrive, vomiting, fever, diarrhoea and apathy. Further, confirmation may be difficult because of problems in obtaining adequate specimens. UTI in infancy and childhood is a major risk factor for the development of renal scarring, which in turn

is associated with future complications such as chronic pyelonephritis in adulthood, hypertension and renal failure. It is therefore vital to make the diagnosis early, and any child with a suspected UTI should receive urgent expert assessment.

Children

Children older than 2 years with UTI are more likely to present with some of the classic symptoms such as frequency, dysuria and haematuria. However, some children present with acute abdominal pain and vomiting, and this may be so marked as to raise suspicions of appendicitis or other intra-abdominal pathology. Again, however, it is extremely important that the diagnosis of UTI is made promptly to pre-empt the potential long-term consequences. National guidance has been published in the UK on paediatric UTIs to promote a more consistent clinical practice by ensuring prompt, accurate diagnosis and appropriate management (National Institute for Health and Care Excellence [NICE], 2007). A key feature of the guidance is that children with unexplained fever should have their urine tested within 24 hours and attention is given to avoiding over- or under-diagnosis, appropriate investigation and the prompt start of antibiotic treatment.

Adults

In adults, the typical symptoms of lower UTI include frequency, dysuria, urgency and haematuria. Acute pyelonephritis (upper UTI) usually causes fever, rigors and loin pain in addition to lower tract symptoms. Systemic symptoms may vary from insignificant to extreme malaise. Importantly, untreated cystitis in adults rarely progresses to pyelonephritis, and bacteriuria does not seem to carry the adverse long-term consequences that it does in children.

In about 40% of women with dysuria, urgency and frequency, the urine sample contains fewer than 100,000 bacteria/mL. These patients are said to have the urethral syndrome. Some have a true bacterial infection but with relatively low counts (100–1000 bacteria/mL). Some have urethral infection with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, mycoplasmas or other 'fastidious' organisms, any of which might give rise to symptoms indistinguishable from those of cystitis. In others, no known cause can be found by conventional laboratory techniques. It is important to consider the possibility of urinary tract tuberculosis, because special methods are necessary for its detection. Sometimes the symptoms are of non-infectious origin, such as menopausal oestrogen deficiency or allergy. However, most cases of urethral syndrome will respond to standard antibiotic regimens as used for treating confirmed UTI.

Elderly

Although UTI is frequent in the elderly, most cases are asymptomatic, and even when present, symptoms are not diagnostic because frequency, dysuria, hesitancy and incontinence are fairly common in elderly people without infection. Further, there may be non-specific systemic manifestations such as confusion and falls, or alternatively the infection may be the cause of deterioration in pre-existing conditions such as diabetes mellitus or

congestive cardiac failure, whose clinical features might predominate. UTI is one of the most frequent causes of admission to hospital among the elderly.

Investigations

The key to successful laboratory diagnosis of UTI lies in obtaining an uncontaminated urine sample for microscopy and culture. Contaminating bacteria can arise from skin, vaginal flora in women and penile flora in men. Patients therefore need to be instructed in how to produce a midstream urine sample (MSU). For women, this requires careful cleansing of the perineum and external genitalia with soap and water. Uncircumcised men should retract the foreskin. This is followed by a controlled micturition in which about 20 mL of urine from only the middle portion of the stream is collected, the initial and final components being voided into the toilet or bedpan. Understandably, this is not always possible and many so-called MSUs are in fact clean-catch specimens in which the whole urine volume is collected into a sterile receptacle and an aliquot transferred into a specimen pot for submission to the laboratory. These are more likely to contain urethral contaminants. In very young children, special collection pads for use inside nappies or stick-on bags are useful ways of obtaining a urine sample. Occasionally, in-and-out diagnostic catheterisation or even suprapubic aspiration directly from the bladder is necessary.

For primary care doctors located some distance from a laboratory, transport of specimens is a problem. Specimens must reach the laboratory within 1–2 hours or should be refrigerated; otherwise, any bacteria in the specimen will multiply and might give rise to a false-positive result. Methods of overcoming bacterial multiplication in urine include the addition of boric acid to the container and the use of dip-slides, in which an agar-coated paddle is dipped into the urine and submitted directly to the laboratory for incubation. Both of these alternatives have difficulties. For the boric acid technique, it is important that the correct amount of urine is added to the container to achieve the appropriate concentration of boric acid (1.8% w/v), because the chemical has significant antibacterial activity when more concentrated. When the dip-slide is used, no specimen is available on which to do cell counts.

Concerns about the relative expense and slow turnaround time of urine microscopy and culture have stimulated interest in alternative diagnostic strategies. Some advocate a policy of empirical antimicrobial treatment in the first instance and reserve investigation only for those cases who do not respond. Others are in favour of using cheaper, more convenient screening tests, for example, urine dipsticks. It is important to be aware that there is no rapid screening test that will reliably detect all UTIs. Urine microscopy and culture remain the standard by which other investigations are measured.

Dipsticks

Dipsticks for rapid near-patient testing for urinary blood, protein, nitrites and leucocyte esterase are usually used, although there

are concerns that these are reliable only when applied to fresh urine samples tested at the point of care. Assessment of colour changes on dipsticks can be subjective, and automated reading systems have been developed to assist interpretation. Generally, the negative predictive value is better than the positive predictive value, so their preferred use is as screening tests to identify those specimens which are least likely to be infected and which therefore do not require culture. A perfectly valid alternative is just to hold the specimen up to the light: Specimens that are visibly clear are very likely to be sterile.

The leucocyte esterase test detects enzyme released from leucocytes in urine and is approximately 90% sensitive at detecting white blood cell counts greater than $10/\text{mm}^3$. It will be positive even if the cells have been destroyed because of delays in transport to a laboratory. However, vitamin C and antibiotics in the urine such as cephalosporins, gentamicin and nitrofurantoin may interfere with the reaction. Although the presence of leucocytes is common in UTIs, it may also occur in other conditions. Particularly in children, white blood cells can be present for many reasons, including fever alone.

The nitrite test (also called the Griess test) detects urinary nitrite made by bacteria that can convert excreted dietary nitrate used as a food preservative to nitrite. Although the coliform bacteria that commonly cause UTI can be detected in this way, some organisms cannot, for example, enterococci, group B streptococci, *Pseudomonas*, because they do not contain the converting enzyme. In addition, the test depends on sufficient nitrate in the diet and on allowing enough time, at least 4 hours, for the chemical conversion to occur in the urine. Performance of the dipstick test is generally less diagnostic in infants and younger children than in the older age groups, and this may relate in part to the small capacity and frequent emptying of the infant bladder, resulting in lower numbers of organisms and less pyuria. The use of dipsticks alone for the diagnosis of UTI is not recommended for children younger than 3 years (NICE, 2007). The inability of the test to detect group B streptococci also makes it a relatively inappropriate test for screening for asymptomatic bacteriuria in pregnancy, in which this organism assumes particular importance as a cause of neonatal sepsis.

Although a negative dipstick test for leucocytes and nitrites can quite accurately predict absence of infection, their absence does not necessarily predict non-response to antibiotic treatment, and further research is needed on this. Some experts consider that detection of nitrites in a symptomatic patient should prompt initiation of treatment (Gopal Rao and Patel, 2009). An algorithm for the use of dipstick testing in uncomplicated UTI in adult women is set out in Fig. 37.1.

There are other rapid methods for detecting bacteriuria, such as tests for interleukin-8, and no shortage of data concerning their sensitivity and specificity, but the optimal strategy will always be a compromise between accuracy, speed, convenience and cost, and is likely to be very different for different settings and populations.

Microscopy

Microscopy is the first step in the laboratory diagnosis of UTI and can be readily performed in practice. A drop of uncentrifuged

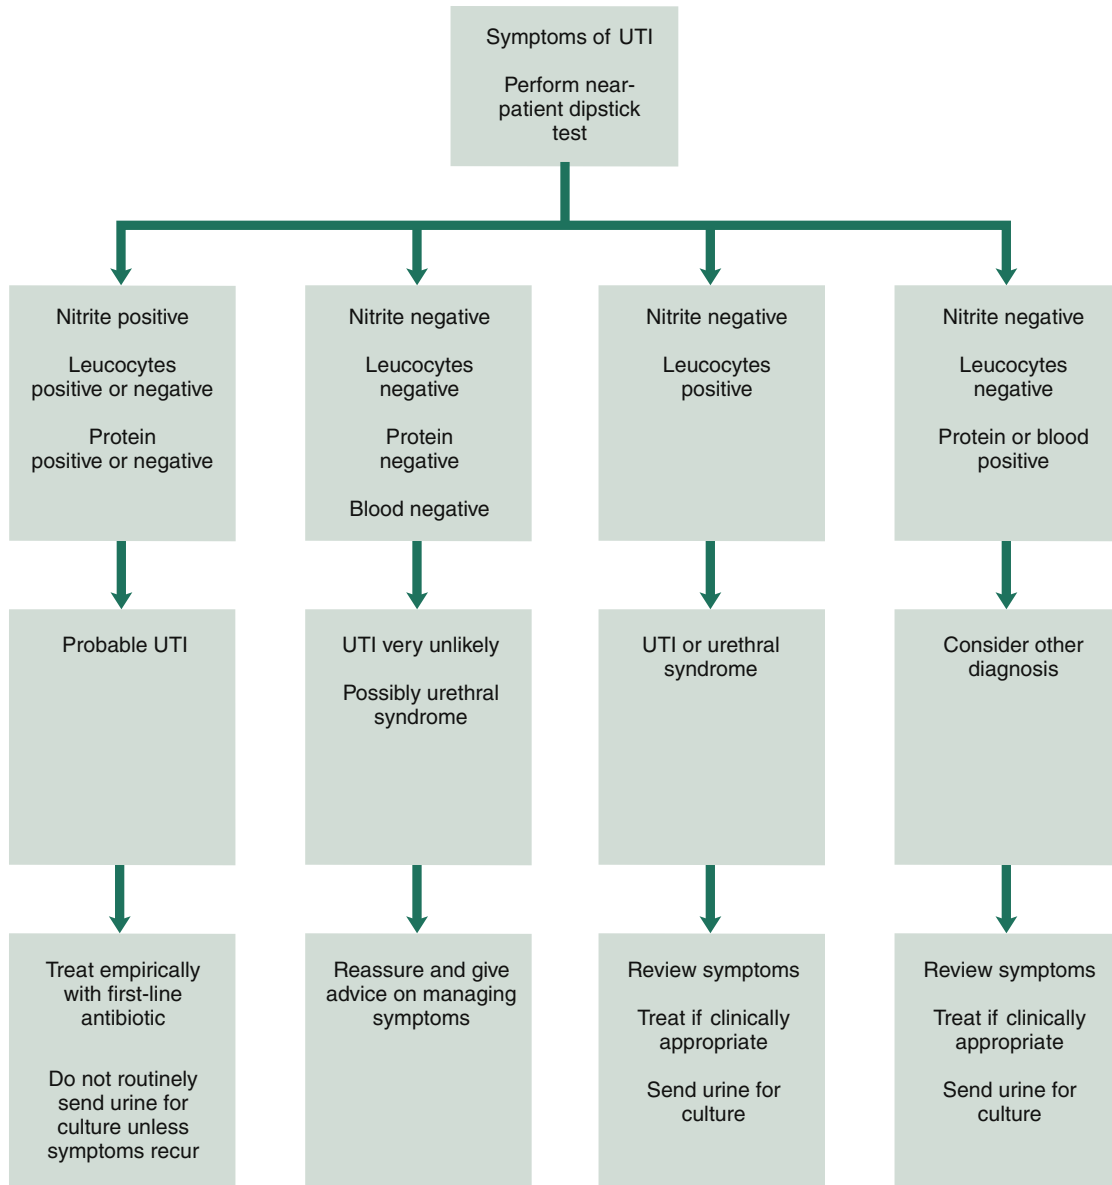

Fig. 37.1 Algorithm for diagnosis of acute uncomplicated urinary tract infection (UTI) in adult women.

urine is placed on a slide, covered with a coverslip and examined under a 40× objective. Excess white cells are usually seen in the urine of patients with symptomatic UTI, and more than 10 per high-power field is abnormal. Notably, there are other methods in common use, and laboratories may report white cell counts per microlitre (mm^3) of urine or per millilitre. Automated machinery for microscopy of urine is increasingly used and offers increased precision and handling capacities of more than 100 specimens/h. Although there is a substantial capital cost to such equipment, it is offset by savings in labour and bacterial culture materials. One feature of this equipment is that it is generally much more sensitive in detecting cells, so much so that laboratories using such systems will have a much higher number for significant results (e.g. greater than 50 rather than greater than 10 white cells per mm^3).

It is important not to be too rigid in the interpretation of the white cell count. UTI may occur in the absence of pyuria,

particularly at the extremes of age, in pregnancy and in pyelonephritis. Red blood cells may be seen, as may white cell casts, which are suggestive of pyelonephritis. As a rule of thumb, the presence of at least one bacterium per field correlates with 100,000 bacteria/mL.

Culture

Bladder urine is normally sterile, but when passed via the urethra, it is inevitable that some contamination with the urethral bacterial flora will occur. This is why it is important that laboratories quantify the number of bacteria in urine specimens. In work carried out more than 40 years ago, it was demonstrated that patients with UTI usually have at least 100,000 bacteria/mL, whereas in patients without infection, the count is usually less than 1000 bacteria/mL. Between these figures lies a grey area, and it should

be appreciated that the MSU is not an infallible guide to the presence or absence of urinary infection. True infections may be associated with low counts, particularly when the urine is very dilute because of excessive fluid intake or where the pathogen is slow growing. Although the quantitative criterion for 'significant' bacteriuria is generally taken as greater than 100,000/mL, in some specific groups, it is less: for men, it is greater than 1000/mL, and for women with symptoms of UTI, it is greater than 100/mL (Scottish Intercollegiate Guidelines Network [SIGN], 2012).

Most genuine infections are caused by one single bacterial species; mixed cultures usually suggest contamination. If a patient is taking an antibiotic when a urine specimen is obtained for culture, growth of bacteria may be inhibited. The laboratory may perform a test to detect antimicrobial substances in the urine, and this may be useful information to clarify circumstances in which the culture is negative but a significant pyuria is present.

Treatment

Although many, and perhaps most, cases clear spontaneously given time, symptomatic UTI usually merits antibiotic treatment to eradicate both symptoms and pathogen. Asymptomatic bacteriuria may or may not need treatment depending upon the circumstances of the individual case. Bacteriuria in children and in pregnant women requires treatment, as does bacteriuria present when surgical manipulation of the urinary tract is to be undertaken, because of the potential complications. On the other hand, in non-pregnant, asymptomatic bacteriuric adults without any obstructive lesion, screening and treatment are probably unwarranted in most circumstances. Unnecessary treatment will lead to selection of resistant organisms and puts patients at risk of adverse drug effects including bowel infection with *Clostridium difficile*, which has been particularly associated with the use of quinolones, cephalosporins and co-amoxiclav. A number of common management problems are summarised in Table 37.1.

Non-specific treatments

Advising patients with UTI to drink a lot of fluids is common practice on the theoretical basis that more infected urine is removed by frequent bladder emptying. This is plausible, although not evidence based. Some clinicians recommend urinary analgesics such as potassium or sodium citrate, which alkalinise the urine, but these should be used as an adjunct to antibiotics. They should not be used in conjunction with nitrofurantoin, which is active only at acidic pH.

Antimicrobial chemotherapy

The principles of antimicrobial treatment of UTI are the same as those of the treatment of any other infection: From a group of suitable drugs chosen on the basis of efficacy, safety and cost, select the agent with the narrowest possible spectrum and administer it for the shortest possible time. In general, there is no evidence that bactericidal antibiotics are superior

Table 37.1 Common management problems with urinary tract infections

Problem	Comments
Asymptomatic infection	Asymptomatic bacteriuria should be treated where there is a risk of serious consequences (e.g. in childhood), where there is renal scarring, and in pregnancy. Otherwise, treatment is not usually required.
Catheter in situ, patient unwell	Systemic symptoms may result from catheter-associated UTI and should respond to antibiotics, although the catheter is likely to remain colonised. Local symptoms such as urgency are more likely to reflect urethral irritation than infection.
Catheter in situ, urine cloudy or smelly	Unless the patient is systemically unwell, antibiotics are unlikely to achieve much and may give rise to resistance. Interventions of uncertain benefit include bladder washouts or a change of catheter.
Penicillin allergy	Clarify 'allergy': vomiting or diarrhoea are not allergic phenomena and do not contraindicate penicillins. Penicillin-induced rash is a contraindication to amoxicillin, but cephalosporins are likely to be tolerated. Penicillin-induced anaphylaxis suggests that all β -lactams should be avoided.
Symptoms of UTI, but no bacteriuria	Exclude urethritis, candidosis, etc. Otherwise, likely to be urethral syndrome, which usually responds to conventional antibiotics.
Bacteriuria, but no pyuria	May suggest contamination. However, pyuria is not invariable in UTI and may be absent particularly in pyelonephritis, pregnancy, neonates, the elderly, and <i>Proteus</i> infections.
Pyuria but no bacteriuria	Usually, the patient has started antibiotics before taking the specimen. Rarely, a feature of unusual infections (e.g. anaerobes, tuberculosis).
Urine grows <i>Candida</i>	Usually reflects perineal candidosis and contamination. True candiduria is rare and may reflect renal candidosis or systemic infection with candidaemia.
Urine grows two or more organisms	Mixed UTI is unusual; mixed cultures are likely to reflect perineal contamination. A repeat should be sent unless this is impractical (e.g. frail elderly patients), in which case best guess treatment should be instituted if clinically indicated.
Symptoms recur	May represent relapse or reinfection. A repeat urine culture should be performed shortly after treatment.

UTI, Urinary tract infection.

to bacteriostatic agents in treating UTI, except perhaps in relapsing infections. Blood levels of antibiotics appear to be unimportant in the treatment of lower UTI; what matters is the concentration in the urine. However, blood levels probably are important in treating pyelonephritis, which may progress to bacteraemia. Drugs suitable for the oral treatment of cystitis include trimethoprim; the β -lactams, particularly amoxicillin, co-amoxiclav and cefalexin; fluoroquinolones such as ciprofloxacin, norfloxacin and ofloxacin; and nitrofurantoin. Where intravenous administration is required, suitable agents include β -lactams such as amoxicillin and cefuroxime, quinolones, and aminoglycosides such as gentamicin.

In renal failure, it may be difficult to achieve adequate therapeutic concentrations of some drugs in the urine, particularly nitrofurantoin and quinolones. Further, accumulation and toxicity may complicate the use of aminoglycosides. Penicillins and cephalosporins attain satisfactory concentrations and are relatively non-toxic, and are therefore the agents of choice for treating UTI in the presence of renal failure.

Antibiotic resistance

Antimicrobial resistance is a major concern worldwide. The susceptibility profile of commonly isolated uropathogens has been constantly changing. Highly antibiotic-resistant organisms such as *Acinetobacter* and coliform bacteria of many species that produce extended-spectrum β -lactamase (ESBL) enzymes have emerged in recent years. They are particularly of concern as a cause of UTI in community-based patients because oral treatment options are limited. Previously, most ESBL-producing bacteria were hospital-acquired and occurred in specialist units.

ESBL-producing bacteria are clinically important because they produce enzymes that destroy almost all commonly used β -lactams except the carbapenem class, rendering most penicillins and cephalosporins largely useless in clinical practice. Some ESBL enzymes can be inhibited by clavulanic acid, and combinations of an agent containing it, for example, co-amoxiclav, with other oral broad-spectrum β -lactams, for example, cefixime or cefpodoxime, have been used to treat UTIs caused by ESBL-producing *E. coli*. These combinations are unlicensed and their effectiveness is variable.

In addition, many ESBL-producing bacteria are multiresistant to non- β -lactam antibiotics as well, such as quinolones, aminoglycosides and trimethoprim, narrowing treatment options. ESBL *E. coli* is often pathogenic, and a high proportion of infections result in bacteraemia with resultant mortality. Some strains cause outbreaks both in hospitals and in the community. Empirical treatment strategies may need to be reviewed in settings where ESBL-producing strains are prevalent, and it may be considered appropriate to use a carbapenem in seriously ill patients until an infection has been proved not to involve an ESBL producer.

Recently, even more resistant strains have emerged in India and Pakistan, with subsequent transfer to the UK, that carry a gene for a novel New Delhi metallo- β -lactamase-1 that also confers resistance to carbapenems. This *bla*_{NDM-1} gene was mostly found among *E. coli* and *Klebsiella*, which were highly resistant to all antibiotics except to colistin and tigecycline, which is not

effective for UTI because it is chemically unstable in the urinary tract (Kumarasamy et al., 2010).

Uncomplicated lower urinary tract infections

The problem with empirical treatment is that more than 10% of the healthy adult female population would receive an antibiotic each year. The use of antibiotics to this extent in the population has implications for antibiotic resistance, a major focus of public health policy worldwide. This highlights the tension between maximising the benefit for individuals and minimising antibiotic resistance at a population level. Strategies have included diagnostic algorithms to predict more precisely who has a UTI, as well as issuing delayed prescriptions (Mangin, 2010).

Therapeutic decisions should be based on accurate, up-to-date antimicrobial susceptibility patterns. Among almost 2500 *E. coli* isolates in a European multicentre survey, the resistance rates were 30% for amoxicillin, 15% for trimethoprim, 3.4% for co-amoxiclav, 2.3% for ciprofloxacin, 2.1% for cefadroxil and 1.2% for nitrofurantoin (Kahlmeter, 2003). These figures are lower than most routine laboratory data would suggest, but it should be remembered that the experience of diagnostic laboratories is likely to be biased by the overrepresentation of specimens from patients in whom empirical treatment has already failed. It is important to be aware of local variations in sensitivity pattern and to balance the risk of therapeutic failure against the cost of therapy.

Adults

The preference for best guess therapy would seem to be a choice between trimethoprim, an oral cephalosporin such as cefalexin, co-amoxiclav or nitrofurantoin, with the proviso that therapy can be refined once sensitivities are available. The quinolones are best reserved for treatment failures and more difficult infections, because overuse of these important agents is likely to lead to an increase in resistance, as has been seen in countries such as Spain and Portugal. These recommendations are summarised in Table 37.2.

Other drugs that have been used for the treatment of UTI include co-trimoxazole, pivmecillinam, fosfomycin and earlier quinolones such as nalidixic acid. Co-trimoxazole was recognised as a cause of bone marrow suppression and other haematological side effects, and in the UK, its use is greatly restricted. Further, despite superior activity in vitro, there is no convincing evidence that it is clinically superior to trimethoprim alone in the treatment of UTI caused by strains susceptible to both. Pivmecillinam is an oral prodrug that is metabolised to mecillinam, a β -lactam agent with a particularly high affinity for Gram-negative penicillin-binding protein 2 and a low affinity for commonly encountered β -lactamases, and which therefore has theoretical advantages in the treatment of UTI. Pivmecillinam has been extensively used for cystitis in Scandinavian countries, where it does not seem to have led to the development of resistance, and for this reason, there have been calls for wider recognition of its usefulness, particularly for UTI caused by ESBL-producing strains. Fosfomycin is a broad-spectrum antibiotic with pharmacokinetic and pharmacodynamic properties that favour its use for treatment of cystitis

Table 37.2 Oral antibiotics used for lower urinary tract infections

Antibiotic	Dose (adult)	Side effects	Contraindications	Comments
Amoxicillin	250–500 mg three times a day	Nausea, diarrhoea, allergy	Penicillin hypersensitivity	High levels of resistance (>50%) in <i>Escherichia coli</i> not used empirically
Co-amoxiclav	375–625 mg three times a day	See amoxicillin	See amoxicillin	Amoxicillin in combination with clavulanic acid
Cefalexin	250–500 mg four times a day	Nausea, diarrhoea, allergy	Cephalosporin hypersensitivity, porphyria	
Trimethoprim	200 mg twice a day	Nausea, pruritus, allergy	Pregnancy, neonates, folate deficiency, porphyria	
Nitrofurantoin	50 mg four times a day	Nausea, allergy, rarely pneumonitis, pulmonary fibrosis, neuropathy	Renal failure, neonates, porphyria, glucose-6-phosphate dehydrogenase deficiency	Modified-release form may be given as 100 mg twice daily; inactive against <i>Proteus</i>
Ciprofloxacin	100–500 mg twice a day	Rash, pruritus, tendinitis	Pregnancy, children	Reserve for difficult cases

with a single oral dose (Falagas et al., 2010). Finally, older quinolones such as nalidixic acid and cinoxacin were once widely used, but generally these agents have given ground to the more active fluorinated quinolones.

Duration of treatment

The question of duration of treatment has received much attention. Traditionally, a course of 7–10 days has been advocated, and this is still the recommendation for treating men, in whom the possibility of occult prostatitis should be borne in mind. For women, though, there has been particular emphasis on the suitability of short-course regimens such as 3-day or even single-dose therapy. The consensus of an international expert working group was that 3-day regimens are as effective as longer regimens in the cases of trimethoprim and quinolones. β -Lactams have been inadequately investigated on this point, but short courses are generally less effective than trimethoprim and quinolones, and nitrofurantoin requires further study before definite conclusions can be drawn. Single-dose therapy, with its advantages of cost, adherence and the minimisation of side effects, has been used successfully in many studies but in general is less effective than when the same agent is used for a longer period.

In the urethral syndrome, it is worth trying a 3-day course of one of the agents mentioned earlier. If this fails, a 7-day course of tetracycline could be tried to deal with possible chlamydia or mycoplasma infection.

Children

In children, the risk of renal scarring is such that UTI should be diagnosed and treated promptly, even if asymptomatic. The drugs of choice include β -lactams, trimethoprim and nitrofurantoin. Quinolones are relatively contraindicated in children because of the theoretical risk of causing cartilage and joint problems. Children should be treated for 7–10 days.

Renal scarring occurs in 5–15% of children with UTI, who should be identified so that appropriate treatment can be instituted. Unfortunately, the subgroup at high risk cannot be predicted, and for this reason, many clinicians choose to investigate all children with UTI, for example, using ultrasound and radioisotope scanning.

Acute pyelonephritis

Patients with pyelonephritis may be severely ill and, if so, will require admission to hospital and initial treatment with a parenteral antibiotic. Suitable agents with good activity against *E. coli* and other Gram-negative bacilli include cephalosporins such as cefuroxime and ceftazidime, some penicillins such as co-amoxiclav, quinolones, and aminoglycosides such as gentamicin (Table 37.3). A first-choice agent would be parenteral cefuroxime, gentamicin or ciprofloxacin. When the patient is improving, the route of administration may be switched to oral therapy, typically using a quinolone. Conventionally, treatment is continued for 10–14 days, although shorter courses of 7 days have been proven effective in patients who are less severely ill at the outset.

In hospital-acquired pyelonephritis, there is a risk that the infecting organism may be resistant to the usual first-line drugs. In such cases it may be advisable to start a broad-spectrum agent such as ceftazidime, ciprofloxacin or meropenem.

Relapsing urinary tract infection

The main causes of persistent relapsing UTI are renal infection, structural abnormalities of the urinary tract and, in men, chronic prostatitis. Patients who do not respond positively on a 7- to 10-day course should be given a 2-week course, and if that fails, a 6-week course can be considered. Structural abnormalities may need surgical correction before a cure can be maintained. It is essential that prolonged courses (i.e. >4 weeks) are managed

Table 37.3 Parenteral antibiotics used for pyelonephritis

Antibiotic	Dose (adult)	Side effects	Contraindications	Comments
Cefuroxime	750 mg three times a day	Nausea, diarrhoea, allergy	Cephalosporin hypersensitivity, porphyria	Implicated in <i>Clostridium difficile</i> diarrhoea
Ceftazidime	1 g three times a day	See cefuroxime	See cefuroxime	See cefuroxime
Co-amoxiclav	1.2 g three times a day	Nausea, diarrhoea, allergy	Penicillin hypersensitivity	
Gentamicin	80–120 mg three times a day or 5 mg/kg once daily	Nephrotoxicity, ototoxicity	Pregnancy, myasthenia gravis	Monitor levels
Ciprofloxacin	200–400 mg twice a day	Rash, pruritus, tendinitis	Pregnancy, children	Implicated in <i>Clostridium difficile</i> diarrhoea
Piperacillin with tazobactam	4.5 g three times a day	Nausea, allergy	Penicillin hypersensitivity	
Meropenem	500 mg three times a day	Nausea, rash, convulsions		Reserve for multiresistant cases

under bacteriological control, for example, with monthly cultures. In men with prostate gland infection, it is appropriate to select antibiotics with good tissue penetration such as trimethoprim and the fluoroquinolones.

Catheter-associated infections

In most large hospitals, 10–15% of patients have an indwelling urinary catheter. Even with the very best catheter care, most will have infected urine after 10–14 days of catheterisation, although most of these infections will be asymptomatic. Antibiotic treatment will often appear to eradicate the infecting organism, but as long as the catheter remains in place, the organism, or another more resistant one, will quickly return. The principles of antibiotic therapy for catheter-associated UTI are therefore as follows:

- Do not treat asymptomatic infection.
- If possible, remove the catheter before treating symptomatic infection.

Although it often prompts investigation, cloudy or strong-smelling urine is not *per se* an indication for antimicrobial therapy. In these situations, saline or antiseptic bladder washouts are often performed, but there is little evidence that they make a difference. Similarly, encrusted catheters are often changed on aesthetic grounds, but it is not known whether this reduces the likelihood of future symptoms.

Following catheter removal, bacteriuria may resolve spontaneously, but more often it persists (typically for longer than 2 weeks in more than half of patients) and may become symptomatic, although usually it will respond well to short-course treatment.

Antimicrobial catheters

Several different types of novel catheters with anti-infective properties have been developed with the aim of reducing the ability of bacteria to adhere to the material, which should lead

to a decreased incidence of bacteriuria and symptomatic infection. Several studies of the effect of incorporating antibiotics such as rifampicin and minocycline or silver-based alloys into the catheter have shown benefit. Although clearly more costly than standard catheters, economic evaluation shows silver alloy catheters to be cost efficient when used in patients who need catheterisation for several days. The effect of these catheters on clinical outcomes such as bacteraemia remains to be determined.

Bacteriuria of pregnancy

The prevalence rate of asymptomatic bacteriuria of pregnancy is about 5%, and about a third of these women proceed to development of acute pyelonephritis, with its attendant consequences for the health of both mother and pregnancy. Further, there is evidence that asymptomatic bacteriuria is associated with low birth weight, prematurity, hypertension and pre-eclampsia. For these reasons, it is recommended that screening be carried out, preferably by culture of a properly taken MSU, which should be repeated if positive for confirmation (NICE, 2008).

Rigorous meta-analysis of published trials has shown that antibiotic treatment of bacteriuria in pregnancy is effective at clearing bacteriuria, reducing the incidence of pyelonephritis and reducing the risk of preterm delivery. The drugs of choice are amoxicillin or cefalexin or nitrofurantoin, depending on the sensitivity profile of the infecting organism. Co-amoxiclav is cautioned in pregnancy because of relative lack of clinical experience in pregnant women. Trimethoprim is contraindicated without folate supplementation (particularly in the first trimester) because of its theoretical risk of causing neural tube defects through folate antagonism. Nitrofurantoin should be avoided close to the time of expected delivery because of a risk of haemolysis in the baby. Ciprofloxacin is contraindicated because it may affect the growing joints. There are insufficient data concerning short-course

therapy in pregnancy, and 7 days of treatment remains the standard. Patients should be followed up for the duration of the pregnancy to confirm cure and to ensure that any reinfection is promptly addressed.

Prevention and prophylaxis

There are a number of folklore and naturopathic recommendations for the prevention of UTI. Most of these have not been put to statistical study, but at least they are unlikely to cause harm.

Cranberry juice

Cranberry juice (*Vaccinium macrocarpon*) has long been thought to be beneficial in preventing UTI, and this has been studied in a number of clinical trials. Cranberry is thought to inhibit adhesion of bacteria to urinary tract cells on the surface of the bladder. In sexually active women, a daily intake of 750 mL of cranberry juice was associated with a 40% reduction in the risk of symptomatic UTI in a double-blinded 12-month trial. Many studies have been criticised for methodological flaws, and currently there is only limited evidence that cranberry juice is effective at preventing recurrent UTI. There have been no randomised controlled trials of the use of cranberry products (juice, tablets or capsules) in the treatment of established infection, or comparing it with established therapies such as antibiotics for preventing infection. In spite of the suggestive *in vitro* data and early reviews that suggested a benefit of cranberry for UTI, recent meta-analyses are conflicting in their support of its efficacy. A Cochrane review of 24 studies concluded that there was only a slight but nonsignificant reduction in the occurrence of symptomatic UTI overall (Jepson et al., 2012). However, another review of 13 studies concluded that cranberry-containing products are associated with a protective effect against UTIs (Wang et al., 2012).

A hypothetical benefit in using cranberry instead of antibiotics for this purpose is a reduced risk of the development of antibiotic-resistant bacteria. A significant hazard is an interaction of cranberry with warfarin, with a risk of bleeding episodes, and available products are not available in standardised formulations. Further, cranberry juice is unpalatable unless sweetened with sugar and therefore carries a risk of tooth decay, although ironically it is reported to prevent dental caries by blocking adherence of plaque bacteria to teeth.

Antibiotic prophylaxis

In some patients, mainly women, reinfections are so frequent that long-term antimicrobial prophylaxis with specific antibiotics is indicated. If the reinfections are clearly related to sexual intercourse, then a single dose of an antibiotic after intercourse is appropriate. In other cases, long-term, low-dose prophylaxis may be beneficial. One dose of trimethoprim (100 mg) or nitrofurantoin (50 mg) at night will suffice. These drugs are unlikely to lead to the emergence of resistant bacteria, although breakthrough

infection with strains intrinsically resistant to the chosen prophylactic antibiotic is possible.

Children

In children, recurrence of UTI is common and the complications potentially hazardous, so many clinicians recommend antimicrobial prophylaxis following documented infection. The evidence in favour of this practice is not strong, and although it has been shown to reduce the incidence of bacteriuria, there is no good-quality evidence that prophylactic antibiotics are effective in preventing further symptomatic UTIs, and they have not been shown to reduce the incidence of renal scarring complications, which are the most important outcomes for the patient (Mori et al., 2009). Further, important variables remain to be clarified, such as when to begin prophylaxis, which agent to use and when to stop. Guidelines have abandoned the time-honoured recommendation for routine antibiotic prophylaxis following a first infection, although it may be considered when there is recurrent UTI (NICE, 2007).

Although evidence is limited for some recommendations, there are many common-sense general measures aimed at reducing the risk of recurrence of infection, particularly in girls. They include advice on regular bladder emptying, cleaning the perineal/anal area from front to back after urinating, treating constipation adequately and avoiding both bubble baths and washing the hair in the bath.

Case studies

Case 37.1

Mr FG, a 70-year-old man, has consulted his primary care doctor three times in the past 3 months and seems to have the same *E. coli* infection on each occasion. A short course of antibiotics clears up the symptoms, but a clinical relapse is soon apparent. Mr FG is admitted to hospital for transurethral resection of the prostate and 2 days after the operation he becomes unwell with rigors, fever and loin pain. Microscopy of his urine shows more than 200 white cells/mm³. Blood cultures are taken and rapidly become positive, with Gram-negative bacilli seen on microscopy.

Questions

1. Is there any way of predicting which UTIs are likely to go on to cause further problems such as pyelonephritis or prostatitis?
2. What antibiotic therapy is indicated now?

Answers

1. Progression of a simple UTI is much more common in patients other than young women. Foreign bodies such as catheters and stents, or physiological problems such as neurogenic bladder increase the risk of a complicated UTI. In men, persistent or recurrent infection with the same organism is highly suggestive of prostatitis and should prompt an extended course of treatment. Pyelonephritis is more difficult to predict. Frequency, dysuria and haematuria indicate lower tract infection. Fever, vomiting, rigors and flank pain are more suggestive of upper renal tract involvement.

2. Mr FG should be started on intravenous antibiotic therapy for presumed prostatitis or pyelonephritis and consequent bacteraemia. The antibiotic should cover Gram-negative organisms found in the hospital environment such as *Klebsiella*, *Enterobacter* and *Pseudomonas*. Appropriate agents would be piperacillin-tazobactam, ceftazidime, ciprofloxacin or meropenem. An alternative would be an aminoglycoside such as gentamicin, provided the patient has satisfactory renal function.

Case 37.2

A pregnant woman, Ms SL, aged 26 years is found to have bacteriuria at her first antenatal visit. No white or red cells are seen in her urine. Urine culture demonstrates *E. coli* at a count of more than 100,000 bacteria/mL, sensitive to trimethoprim, nitrofurantoin and cefalexin, but resistant to amoxicillin. Other than a degree of urinary frequency, which Ms SL ascribes to the pregnancy itself, the patient does not complain of any urinary symptoms.

Question

Does Ms SL need antibiotic treatment, and if so, which medicines could be safely prescribed?

Answer

Ms SL may be correct that her urinary frequency is a consequence of pregnancy. However, because of the consequences of untreated infection during pregnancy, even asymptomatic bacteriuria should be treated. A repeat urine specimen should be obtained to confirm the persistent finding of more than 100,000 bacteria/mL, and treatment started with either cefalexin or co-amoxiclav for 7 days. Trimethoprim should be avoided during early pregnancy because of its theoretical risk of teratogenicity, and nitrofurantoin should be avoided in late pregnancy because it may cause neonatal haemolysis. Following treatment, Ms SL should be reviewed throughout the pregnancy to ensure eradication of the bacteriuria and to permit early treatment of any relapse or reinfection.

Case 37.3

A 2-year-old boy is admitted to hospital with vomiting and abdominal pain. His mother reports that he was treated for a UTI 6 months previously but was not investigated further at the time. A clean-catch urine sample shows more than 50 white cells/mm³, and bacteria are seen on microscopy.

Question

What action should be taken?

Answer

It seems that this child is suffering from a recurrent UTI. An intravenous antibiotic such as cefuroxime should be started, because the child will not tolerate oral antibiotics at present. If the organism proves to be sensitive to amoxicillin, the treatment could be changed accordingly. Further investigations, for example, ultrasonography and radioisotope scan, may be carried out to determine any underlying cause of the infection and to look for already established renal scarring. The child may require long-term prophylaxis to prevent a further recurrence.

Case 37.4

Mrs EH, a 62-year-old woman, has been troubled by recurrent symptoms of UTI. She has been taking an oral oestrogen preparation for menopausal symptoms for some years. She is currently on an orthopaedic ward and catheterised because of incontinence. Mrs EH is afebrile but has been confused since her hip replacement 5 days earlier; she remains on cefuroxime, which was started as prophylaxis at the time of the operation. The urine in her catheter bag is cloudy, has a high white cell count and grows *Enterococcus faecalis* sensitive to amoxicillin but resistant to cephalosporins.

Questions

1. How should Mrs EH be managed?
2. In older women, is there any association with the use of different types of oestrogen delivery systems and UTIs?

Answers

1. Mrs EH's confusion may have a number of causes, including her recent surgery, sleep disturbance, drug toxicity, deep venous thrombosis or infection. If, following clinical examination and investigation, which should include blood cultures, her catheter-associated infection is thought to be contributing to her systemic problems, it should be treated with amoxicillin. If possible, the catheter should be removed, even if this is inconvenient for the nursing staff. Unless it has been prescribed for another indication, the cefuroxime is achieving nothing and may be stopped.
2. In post-menopausal women, there have been trials assessing the merits of topical oestrogen creams. Topical intravaginal oestriol cream has significant benefits in reducing the number of UTIs in those suffering recurrent infections. In a placebo-controlled trial, the rate of UTI was 12-fold less in the group receiving active oestrogen cream. This effect is not seen with oral oestrogens (Perrotta et al., 2008).

Case 37.5

Ms MD, a 45-year-old woman, suffers from recurrent episodes of cystitis. Examination is unremarkable. On the occasions when a specimen has been sent, the urine has contained few white cells and no significant growth of organisms.

Question

How should the patient be managed?

Answer

Ms MD is suffering from the urethral syndrome, in which symptoms of infection are not associated with objective evidence of UTI. It may be felt necessary to investigate her to exclude less common causes of UTI such as herpes simplex virus, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, *Mycoplasma hominis* and *Lactobacilli*. Otherwise, her symptoms are likely to respond to conventional courses of antibiotics. Consider non-infective causes, for example, psychological factors or trauma from intercourse.

Case 37.6

Ms LT, a 23-year-old woman, has recurrent symptoms of UTI temporally related to sexual intercourse, despite following advice to empty her bladder as soon as possible after sex.

Question

What do you think of the use of antibiotics such as trimethoprim for women who get recurrent problems after sexual intercourse?

Answer

Post-coital voiding does not have any prospective data to support it, but it is a simple, harmless intervention. Long-term continuous antimicrobial prophylaxis is unquestionably an effective treatment but may be overtreating those in whom UTIs follow intercourse. Post-coital prophylaxis, a single dose within 2 hours of intercourse, has the advantage of using less antibiotic overall. One small, placebo-controlled, double-blind trial assessed the efficacy of post-coital cotrimoxazole in preventing recurrent UTI and found that 12% of the active treatment patients developed a UTI in 6 months, compared with 82% of the control group. Other studies have shown nitrofurantoin, cefalexin and ciprofloxacin also to be effective.

Case 37.7

A 45-year-old woman, Mrs DG, was hospitalised in India a few weeks ago while undergoing cosmetic surgery. She now has

severe symptoms of UTI and is admitted to hospital with a diagnosis of 'urosepsis'.

Question

What particular consideration is there in relation to the potential for Mrs DG's UTI to be an antibiotic-resistant strain?

Answer

Hospitalised patients in a number of countries are at risk of becoming colonised with coliform bacteria that are extremely resistant to commonly used antibiotics, as well as to those that are often used empirically for patients with sepsis. In the Indian subcontinent there have been particular problems with strains that are resistant to the carbapenem class of antibiotics such as meropenem, because the bacteria produce a transmissible hydrolyzing carbapenemase enzyme. Such strains are usually resistant to virtually all classes of antibiotics and it may be necessary to administer intravenous combination therapy including colistin or fosfomycin. Patients who have been hospitalised in areas where such resistant strains are prevalent should be screened for potential carriage of the organism if readmitted to hospital so that assiduous infection control precautions can be implemented.

38 Gastro-Intestinal Infections

Jim Gray

Key points

- There are many different microbial causes of gastro-intestinal infections.
- Gastroenteritis is the most common syndrome of gastro-intestinal infection, but some gastro-intestinal pathogens can cause systemic infections.
- Fluid and electrolyte replacement is the mainstay of management of gastroenteritis.
- Antibiotic resistance in gastro-intestinal pathogens is an escalating problem.
- Most cases of gastroenteritis that occur in developed countries are mild and self-limiting and do not require antibiotic therapy. Unnecessary use of antibiotics simply promotes antibiotic resistance.
- Antibiotic therapy should be considered for patients with underlying conditions that predispose to serious or complicated gastroenteritis, or where termination of faecal excretion of pathogens is desirable to prevent further spread of the infection.
- *Clostridium difficile* is a very important cause of diarrhoea in hospitals. Strict control measures are required; cases are usually initially treated with oral metronidazole or oral vancomycin.
- Fidaxomicin is a new treatment for *C. difficile* that may be associated with a lower recurrence rate. Faecal microbiota transplantation is another treatment option that is becoming mainstream.
- Antibiotic therapy is also essential for life-threatening systemic infections, such as enteric fever.
- Where possible, antibiotic therapy should be delayed until a microbiological diagnosis has been established.

Gastro-intestinal infections represent a major public health and clinical problem worldwide. Many species of bacteria, viruses and protozoa cause gastro-intestinal infection, resulting in two main clinical syndromes. Gastroenteritis is a non-invasive infection of the small or large bowel that manifests clinically as diarrhoea and vomiting. Other infections are invasive, causing systemic illness, often with few gastro-intestinal symptoms. *Helicobacter pylori* and its association with gastritis, peptic ulceration and gastric carcinoma are discussed in [Chapter 12](#).

Epidemiology and aetiology

In Western countries, the average person probably experiences one or two episodes of gastro-intestinal infection each year.

Infections are rarely severe, and the vast majority of cases never reach medical attention. Nevertheless, they are of considerable economic importance. In the UK, viruses, especially noroviruses, are the most common cause of gastroenteritis. *Campylobacter*, followed by non-typhoidal serovars of *Salmonella enterica*, are the most common reported causes of bacterial gastroenteritis. Cryptosporidiosis is the most commonly reported parasitic infection. In developing countries, the incidence of gastro-intestinal infection is at least twice as high and the range of common pathogens is much wider. Infections are more often severe and represent a major cause of mortality, especially in children.

Gastro-intestinal infections can be transmitted by consumption of contaminated food or water or by direct faecal–oral spread. Airborne spread of viruses that cause gastroenteritis also occurs. The most important causes of gastro-intestinal infection, and their usual modes of spread, are listed in [Table 38.1](#). In developed countries, the majority of gastro-intestinal infections are food-borne. Farm animals are often colonised by gastro-intestinal pathogens, especially *Salmonella* and *Campylobacter*. Therefore, raw foods such as poultry, meat, eggs and unpasteurised dairy products are commonly contaminated and must be thoroughly cooked to kill such organisms. Raw foods also represent a potential source of cross-contamination of other foods, through hands, surfaces or utensils that have been inadequately cleaned. Food handlers who are excreting pathogens in their faeces can also contaminate food. This is most likely when diarrhoea is present, but continued excretion of pathogens during convalescence also represents a risk. Food handlers are the usual source of *Staphylococcus aureus* food poisoning, where toxin-producing strains of *S. aureus* carried in the nose or on skin are transferred to foods. Bacterial food poisoning is often associated with inadequate cooking and/or prolonged storage of food at ambient temperature before consumption. Water-borne gastro-intestinal infection is primarily a problem in countries without a sanitary water supply or sewerage system, although outbreaks of water-borne cryptosporidiosis occur from time to time in the UK. The spread of pathogens such as *Shigella* or enteropathogenic *Escherichia coli* (*E.coli*) by the faecal–oral route is favoured by over-crowding and poor standards of personal hygiene. Such infections in developed countries are most common in children and can cause troublesome outbreaks in paediatric wards, nurseries and residential children’s homes.

Treatment with broad-spectrum antibiotics alters the bowel flora, creating conditions that favour superinfection with microorganisms (principally *Clostridium difficile*) that can cause diarrhoea. *C. difficile* infection (CDI) may be associated with any

Table 38.1 Important causes of gastro-intestinal infection, their modes of spread and pathogenic mechanisms

Causative agent	Chief mode(s) of spread	Pathogenic mechanisms
Bacteria		
<i>Campylobacter</i>	Food, especially poultry, milk	Mucosal invasion, enterotoxin
<i>Salmonella enterica</i> , non-typhoidal serovars	Food, especially poultry, eggs, meat	Mucosal invasion, enterotoxin
<i>Salmonella enterica</i> serovars Typhi and Paratyphi	Food, water	Systemic invasion
<i>Shigella</i>	Faecal–oral	Mucosal invasion, enterotoxin
<i>Escherichia coli</i>		
Enteropathogenic	Faecal–oral	Mucosal adhesion
Enteraggregative	Faecal–oral, food	Mucosal toxicity
Enterotoxigenic	Faecal–oral, food, water	Enterotoxin
Enteroinvasive	Faecal–oral, food	Mucosal invasion
Verotoxin-producing	Food, especially meat	Verotoxin
<i>Staphylococcus aureus</i>	Food, especially meats, dairy produce	Emetic toxin
<i>Clostridium perfringens</i>	Food, especially meat	Enterotoxin
<i>Bacillus cereus</i>		
Short incubation period	Food, especially rice	Emetic toxin
Long incubation period	Food, especially meat and vegetable dishes	Enterotoxin
<i>Vibrio cholerae</i> O1, O139	Water	Enterotoxin
<i>Vibrio parahaemolyticus</i>	Seafoods	Mucosal invasion, enterotoxin
<i>Clostridium difficile</i>	Faecal–oral (nosocomial)	Cytotoxin, enterotoxin
<i>Clostridium botulinum</i>	Inadequately heat-treated canned/preserved foods	Neurotoxin
Protozoa		
<i>Giardia lamblia</i>	Water	Mucosal invasion
<i>Cryptosporidium</i>	Water, animal contact	Mucosal invasion
<i>Entamoeba histolytica</i>	Food, water	Mucosal invasion
Viruses		
Rotavirus, norovirus, astrovirus, sapovirus, adenovirus	Food, faecal–oral, respiratory secretions	Small-intestinal mucosal damage

antibiotic, but clindamycin, the cephalosporins and the fluoroquinolones are most commonly implicated. CDI is most common in patients with serious underlying disease and in the elderly. Although some sporadic cases are probably due to overgrowth of endogenous organisms, person-to-person transmission also occurs in hospitals and care homes, sometimes resulting in large outbreaks.

Pathophysiology

Development of symptoms after ingestion of gastro-intestinal pathogens depends on two factors. First, sufficient organisms must be ingested and then survive host defence mechanisms; and second, the pathogens must possess one or more virulence mechanisms to cause disease.

Host factors

Healthy individuals possess a number of defence mechanisms that protect against infection by enteropathogens. Therefore, large numbers of many pathogens must be ingested for infection to ensue; for example, the infective dose for *Salmonella* is typically around 10^5 organisms. Other species, however, are better able to survive host defence mechanisms; for example, infection with *Shigella* or verotoxin-producing *E. coli* (VTEC) can result from ingestion of fewer than 100 organisms. VTEC (principally *E. coli* O157) are especially important because of the risk of the life-threatening complication haemolytic uraemic syndrome (HUS).

Gastric acidity

Most microorganisms are rapidly killed at normal gastric pH. Patients whose gastric pH is less acidic, as, for example, following treatment with antacids or ulcer-healing drugs, are more susceptible to gastro-intestinal infections. There is a particularly strong association between proton pump inhibitor use and CDI.

Intestinal motility

It is widely held that intestinal motility helps to rid the host of enteric pathogens, and that anti-motility agents are therefore potentially hazardous in patients with infective gastroenteritis. Despite this, self-medication with antidiarrhoeals is commonly practised, and in otherwise healthy individuals is probably safe.

Resident microflora

The resident microflora of the lower gastro-intestinal tract, largely composed of anaerobic bacteria, help to resist colonisation by enteropathogens.

Immune system

Phagocytic, humoral and cell-mediated elements are important in resistance to different pathogens. Individuals with inherited or acquired immunodeficiencies are therefore susceptible to specific gastro-intestinal infections, depending on which components of their immune system are affected.

Organism factors

The first requirement of gastro-intestinal pathogens is that they are able to adhere to the gut wall and colonise the intestine. The symptoms of gastro-intestinal infection can then be mediated by various mechanisms (see Table 38.1).

Toxins

Toxins produced by gastro-intestinal pathogens can be classified as enterotoxins, neurotoxins and cytotoxins. Enterotoxins act on intestinal mucosal cells to cause net loss of fluid and electrolytes. The classic enterotoxin-mediated disease is cholera, the result of infection with toxigenic serotypes of *Vibrio cholerae*. Many other

bacteria produce enterotoxins, including enterotoxigenic *E. coli* and *Clostridium perfringens*. The emetic toxins of *S. aureus* and *Bacillus cereus* are neurotoxins that induce vomiting by an action on the central nervous system. The symptoms of botulism are mediated by a neurotoxin that blocks release of acetylcholine at nerve endings. Cytotoxins cause mucosal destruction and inflammation (see later). The pathogenicity of *C. difficile* is mediated by two exotoxins, TcdA and TcdB, both of which are potent cytotoxic enzymes that damage the human colonic mucosa. Verotoxins are potent cytotoxins that cause direct damage to small-vessel endothelial cells, which is exacerbated by stimulation of production of inflammatory mediators by non-endothelial cells. This causes multiorgan microvascular injury, expressed most commonly as haemorrhagic colitis and HUS.

Mucosal damage

Cytotoxins are important in mediating mucosal invasion, but other mechanisms are also involved. Enteropathogenic *E. coli* causes diarrhoea by damaging microvilli when it adheres to the intestinal mucosa. Organisms such as *Shigella* and enteroinvasive *E. coli* express surface proteins that facilitate mucosal invasion. Diarrhoea due to mucosal damage may be caused by reduction in the absorptive surface area or the presence of increased numbers of immature enterocytes which are secretory rather than absorptive.

Systemic invasion

The lipopolysaccharide outer membrane and possession of an antiphagocytic outer capsule are important virulence factors in invasive *Salmonella* infections.

Clinical manifestations

Many cases of gastro-intestinal infection are asymptomatic or cause subclinical illness. Gastroenteritis is the most common syndrome of gastro-intestinal infection, presenting with symptoms such as vomiting, diarrhoea and abdominal pain. The term 'dysentery' is sometimes applied to infections with *Shigella* (bacterial dysentery) and *Entamoeba histolytica* (amoebic dysentery), where severe colonic mucosal inflammation causes frequent diarrhoea with blood and pus. Table 38.2 lists the most important causative agents of gastroenteritis together with a brief description of the typical illness that each causes. However, the symptoms experienced by individuals infected with the same organism can differ considerably. This is important because it means that it is rarely possible to diagnose the cause of gastroenteritis on clinical grounds alone.

Gastro-intestinal manifestations of infection with VTEC range from non-bloody diarrhoea to haemorrhagic colitis. In addition, VTEC are the most important cause of HUS, a serious complication which is most common in young children and the elderly. HUS is defined by the triad of microangiopathic haemolytic anaemia, thrombocytopenia and acute renal dysfunction. The mortality rate is about 5%, and up to half of the survivors suffer long-term renal damage.

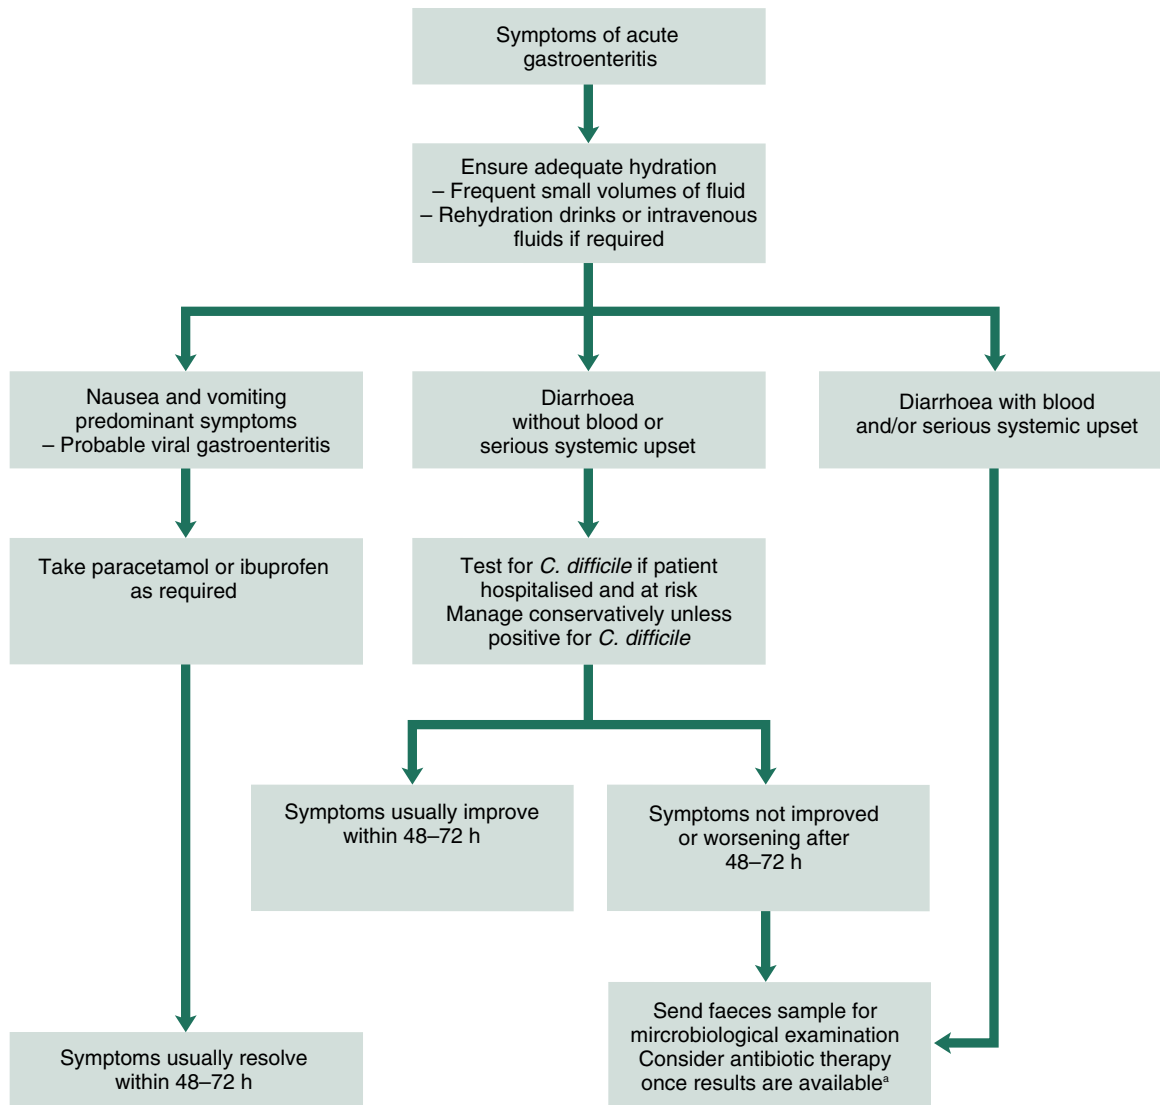

Table 38.2 Characteristic clinical features of various causes of gastroenteritis

Causative agent	Incubation period	Symptoms (syndrome)
<i>Campylobacter</i>	2–5 days	Bloody diarrhoea Abdominal pain Systemic upset
<i>Salmonella</i>	6–72 h	Diarrhoea and vomiting Fever; may be associated bacteraemia
<i>Shigella</i>	1–4 days	Diarrhoea, fever (bacillary dysentery)
<i>Escherichia coli</i>		
Enteropathogenic	12–72 h	Infantile diarrhoea
Enteroaggregative	1–3 days	Childhood diarrhoea, traveller's diarrhoea
Enterotoxigenic	1–3 days	Traveller's diarrhoea
Enteroinvasive	1–3 days	Similar to <i>Shigella</i>
Verotoxin-producing	1–3 days	Bloody diarrhoea (haemorrhagic colitis) Haemolytic uraemic syndrome
<i>Staphylococcus aureus</i>	4–8 h	Severe nausea and vomiting
<i>Clostridium perfringens</i>	6–24 h	Diarrhoea
<i>Bacillus cereus</i>		
Short incubation period	1–6 h	Vomiting
Long incubation period	6–18 h	Diarrhoea
<i>Vibrio cholerae</i> O1, O139	1–5 days	Profuse diarrhoea (cholera)
<i>Vibrio parahaemolyticus</i>	12–48 h	Diarrhoea, abdominal pain
<i>Clostridium difficile</i>	Usually occurs during/just after antibiotic therapy	Diarrhoea, abdominal pain, pseudomembranous enterocolitis
<i>Giardia lamblia</i>	1–2 weeks	Watery diarrhoea
<i>Cryptosporidium</i>	2 days to 2 weeks	Watery diarrhoea
<i>Entamoeba histolytica</i>	2–4 weeks	Diarrhoea with blood and mucus (amoebic dysentery), liver abscess
Viruses	1–2 days	Vomiting, diarrhoea Systemic upset

The clinical spectrum of CDI ranges from asymptomatic carriage to life-threatening pseudomembranous colitis (so called because yellow-white plaques or membranes consisting of fibrin, mucus, leucocytes and necrotic epithelial cells are found adherent to the inflamed colonic mucosa).

Enteric fever, resulting from infection with *S. enterica* serovars Typhi and Paratyphi, presents with symptoms such as headache, malaise and abdominal distension after an incubation period of 3–21 days. During the first week of the illness, the temperature

gradually increases, but the pulse characteristically remains slow. Without treatment, during the second and third weeks, the symptoms become more pronounced. Diarrhoea develops in about half of cases. Examination usually reveals splenomegaly, and a few erythematous macules (rose spots) may be found, usually on the trunk. Serious gastro-intestinal complications such as haemorrhage and perforation are most common during the third week. Symptoms begin to subside slowly during the fourth week. In general, paratyphoid fever is less severe than typhoid fever.

^aAntibiotic therapy may have to be commenced empirically if patient has serious systemic upset

Fig. 38.1 Pathway for the investigation and management of patients with symptoms of acute gastroenteritis.

Botulism typically presents with autonomic nervous system effects, including diplopia and dysphagia, followed by symmetrical descending motor paralysis. There is no sensory involvement.

Gastro-intestinal infections are often followed by a period of convalescent carriage of the pathogen. This usually lasts for no more than 4–6 weeks but can be for considerably longer, especially for *Salmonella*.

Investigations

Many cases of gastroenteritis outside hospital are mild and short-lived, and microbiological investigation may not be necessary. However, investigations are always recommended where antibiotic therapy is being considered (Fig. 38.1), where

there are public health concerns (e.g. if the sufferer works in the food industry) and for gastro-intestinal infections in hospitalised patients.

The mainstay of investigation of diarrhoeal illness is examination of faeces. Conventional faecal microbiology is one of the most complex aspects of diagnostic microbiology. A range of different, often labour-intensive techniques have been required to test for different bacteria, viruses and protozoa. However, laboratory diagnostic strategies are changing; increasingly laboratories are using molecular methods (e.g. multiplex polymerase chain reaction [PCR]) to detect the full range of enteric pathogens (bacteria, viruses and parasites) more quickly and more accurately than by conventional methods. Results can be available in as little as an hour, compared with 2 or more days with conventional methods, which can assist with antibiotic stewardship and infection prevention and control.

Conventionally, bacterial infections have been diagnosed by stool culture. Various selective culture media designed to suppress growth of normal faecal organisms and/or enhance the growth of a particular pathogen are used. When sending specimens to the laboratory, it is important that details of the age of the patient, the clinical presentation and recent foreign travel are provided so that appropriate media for the likely pathogens can be selected.

A two-stage approach is recommended for diagnosis of CDI. Diarrhoeal stools are screened for the presence of glutamate dehydrogenase (GDH) antigen, an inexpensive, sensitive, but non-specific test; PCR is also suitable as an initial screening test, but it is more expensive. Samples that are positive for GDH, or by PCR, are then tested for *C. difficile* toxin. Patients who are toxin-positive have CDI; those who are GDH- or PCR-positive are *C. difficile* excretors. *C. difficile* excretors are at risk of development of CDI, especially if they are exposed to antibiotics; they also present an infection-control risk because they may spread toxigenic *C. difficile* to other patients who may develop CDI. Sigmoidoscopy is used to diagnose pseudomembranous colitis.

Various other procedures are sometimes useful in investigating patients with suspected bacterial gastroenteritis. Blood cultures should be taken from patients with severe systemic upset and are especially important when enteric fever is suspected. In enteric fever, the causative organism may also be cultured from urine or bone marrow. In *S. aureus* and *B. cereus* food poisoning, the pathogen can sometimes be isolated from vomitus. In cases of food poisoning, suspect foods may also be cultured. In general, serological investigations are of little value in the diagnosis of bacterial gastroenteritis. However, demonstration of serum antibodies to *E. coli* O157 can be helpful in confirming the cause of the HUS. Botulism is diagnosed by demonstration of toxin in serum.

Parasitic infestations are conventionally detected by microscopic examination of faeces, but PCR appears to be more sensitive. Molecular methods have to a large extent superseded electron microscopy and immunological tests for detection of enteric viruses.

Treatment

Many gastro-intestinal infections are mild and self-limiting and never reach medical attention. Where treatment is required, there are three main therapeutic considerations. Fluid and electrolyte replacement is the cornerstone of treatment of diarrhoeal disease. Most patients can be managed with oral rehydration regimens, but severely dehydrated patients require rapid volume expansion with intravenous fluids. Symptomatic treatment with antiemetics and anti-motility (antidiarrhoeal) agents is sometimes used, especially as self-medication. Antimicrobial agents may be useful both in effecting symptomatic improvement and in eliminating faecal carriage of pathogens, and therefore reducing the risk of transmitting infection to others.

Antiemetics and antidiarrhoeal drugs are discussed in [Chapters 35 and 14](#), respectively. This chapter focuses on the place of antibiotic therapy in gastro-intestinal infections.

Antibiotic therapy

The requirement for antibiotic treatment in gastro-intestinal infection depends on the causative agent, the type and severity of symptoms, and the presence of underlying disease. Antibiotics are ineffective in some forms of gastroenteritis, including bacterial intoxications and viral infections. For many other infections, such as salmonellosis and campylobacteriosis, effective agents are available, but antimicrobial therapy is often not clinically necessary. Serious infections, such as enteric fever, always require antibiotic therapy.

Conditions for which antibiotic therapy is not available or not usually required

The symptoms of *S. aureus* and short incubation period *B. cereus* food poisoning and botulism are usually caused by ingestion of preformed toxin, and therefore antibiotic therapy would not influence the illness. Pathogens such as *C. perfringens*, *Vibrio parahaemolyticus*, and enteropathogenic *E. coli* usually cause a brief, self-limiting illness that does not require specific treatment.

None of the presently available antiviral agents are useful in gastroenteritis caused by viruses such as rotaviruses or noroviruses. Although most viral infections are self-limiting, chronic infections can occur in immunocompromised patients. Where possible, immunosuppression should be reduced. Immunoglobulin-containing preparations, administered orally or directly into the duodenum via a nasogastric tube, have also been reported to be effective in managing chronic viral gastroenteritis in immunocompromised patients. As well as human serum immunoglobulin, antibodies from other species (e.g. immunised bovine colostrum) have been used. Immunotherapy of viral gastroenteritis for severely immunocompromised patients remains experimental. Where these preparations are used, dosages and frequency of administration of immunoglobulin preparations must be determined locally, based on expert opinion ([Pammi and Haque, 2011](#)). Occasionally, where viruses such as cytomegalovirus or adenoviruses cause enteritis in immunocompromised patients, antiviral treatment, under specialist supervision, may be indicated.

At least one study has found that the risk of HUS in children with diarrhoea caused by VTEC was much higher in those who received antibiotics ([Wong et al., 2000](#)). On that basis, it is advised in the UK that antibiotics are contraindicated in children with VTEC infection ([National Collaborating Centre for Women's and Children's Health, 2009](#)). However, it has been suggested that some antibiotics, especially fosfomycin and quinolones, may prevent the development of HUS, and these treatments are used in some other countries ([Corogeanu et al., 2012](#)).

Conditions for which antimicrobial therapy may be considered

The place for antibiotics in the management of uncomplicated gastroenteritis due to bacteria such as *Salmonella* and

Campylobacter is not clear-cut. Certain antibiotics are reasonably effective in reducing the duration and severity of clinical illness and in eradicating the organisms from faeces. However, many microbiologists are cautious about the widespread use of antibiotics in diarrhoeal illness because of the risk of promoting antibiotic resistance (Pollack et al., 2013). Another difficulty with respect to antibiotic prescribing is that it is not usually possible to determine the aetiological agent of diarrhoea on clinical grounds, and stool culture takes at least 48 hours. Although an aetiological diagnosis can be established much faster using PCR, antibiotic susceptibility results are not provided. Patients with severe illness, especially systemic symptoms, may require antibiotic therapy before the aetiological agent, or its antibiotic susceptibilities, are established. In such circumstances, a fluoroquinolone antibiotic such as ciprofloxacin would usually be the most appropriate empiric agent, at least in patients in whom CDI is considered unlikely or has been excluded. Otherwise, it is reasonable to limit antibiotic use to microbiologically proven cases where there is serious underlying disease and/or continuing severe symptoms. Antibiotics may also be used to try to eliminate faecal carriage, for example, in controlling outbreaks in institutions, or in food handlers who may be prevented from returning to work until they are no longer excreting gastro-intestinal pathogens.

Campylobacteriosis. Erythromycin is effective in terminating faecal excretion of *Campylobacter*. Some studies have shown that treatment commenced within the first 72–96 hours of illness can also shorten the duration of clinical illness, especially in patients with severe dysenteric symptoms. The recommended dosage for adults is 250–500 mg four times a day orally for 5–7 days, and for children 30–50 mg/kg/day in four divided doses. Clarithromycin 250–500 mg (children <1 year of age, 7.5 mg/kg; 1–2 years, 62.5 mg; 3–6 years, 125 mg; 7–9 years, 5–7 days) twice a day orally or azithromycin 500 mg (children 10 mg/kg) once daily for 3 days is also effective. Ciprofloxacin, at a dosage of 500 mg twice daily orally for adults, may also be effective in *Campylobacter* enteritis. However, resistance rates to erythromycin have generally remained less than 5%, whereas resistance to ciprofloxacin has emerged, exceeding 10% in the UK and 50% in some other countries (Dingle et al., 2005).

Salmonellosis. Most cases of *Salmonella* gastroenteritis are self-limiting, and antibiotic therapy is unnecessary. However, antimicrobial therapy of salmonellosis is routinely recommended for infants younger than 6 months and immunocompromised patients, who are susceptible to complicated infections. Most antibiotics, even those with good in vitro activity, do not alter the course of uncomplicated *Salmonella* gastroenteritis. However, the fluoroquinolones, such as ciprofloxacin, can often shorten both the symptomatic period and the duration of faecal carriage. Ciprofloxacin resistance is now seen in up to 10% of non-typhoidal serovars of *S. enterica* in some countries but is still uncommon in the UK (Al-Mashhadani et al., 2011). The recommended dosage of ciprofloxacin for adults is 500 mg twice daily orally for 1 week. Fluoroquinolones are not licensed for this indication in children, although there is increasing evidence that they can safely be given to children. The recommended dosage of ciprofloxacin in childhood is 7.5 mg/kg twice daily orally. Trimethoprim at a dosage of 25–100 mg twice daily orally may be used in children if it is preferred not to use a fluoroquinolone.

Ciprofloxacin given orally at a dosage of 500–750 mg twice daily in adults (7.5–12.5 mg/kg twice daily in children) or 200 mg intravenously twice daily in adults (5–7.5 mg/kg twice daily in children) is recommended for invasive salmonellosis. Alternative agents include ampicillin or amoxicillin, trimethoprim or chloramphenicol (see later section Enteric Fever). However, resistance to these agents is more common than resistance to ciprofloxacin, and they are not recommended as empiric therapy.

***E. coli* infections.** Most cases of enteropathogenic *E. coli*-associated diarrhoea are self-limiting and are managed conservatively; indeed, until recently few microbiology laboratories in Western countries have tested for these bacteria. However, increasingly laboratories are using PCR tests to investigate samples from patients with diarrhoea, and some of the commercially available PCR panels test for enteropathogenic *E. coli*. Consequently, some patients with chronic diarrhoea are now being reported to have enteropathogenic *E. coli*, the significance of which is uncertain (Duda-Madej et al., 2013). Specialist advice should be obtained before considering treatment of such patients. On the basis that enteroinvasive *E. coli* are closely related to *Shigella* and cause a similar clinical syndrome, similar therapy may be appropriate. Antibiotic therapy for traveller's diarrhoea caused by enterotoxigenic or enteroaggregative *E. coli* infections is often unnecessary, but troublesome symptoms will often respond to a single dose of ciprofloxacin or azithromycin; the need for further doses depends on clinical response. Alternatively, a 3- to 5-day course of trimethoprim may be given, although resistance is becoming increasingly common in some areas. Rifaximin is a new non-absorbable antibiotic that is available in a number of countries. It appears to be as effective as ciprofloxacin in treating *E. coli*-predominant traveller's diarrhoea but is ineffective in patients with inflammatory or invasive enteropathogens (Hopkins et al., 2014). The dosage for adults is 200 mg three times per day for 3 days.

Conditions for which antimicrobial therapy is usually indicated

Shigellosis. *Shigella sonnei*, which accounts for most cases of shigellosis in the UK and most other industrialised countries, usually causes a mild, self-limiting illness. Even if not required on clinical grounds, antibiotic therapy for shigellosis is usually recommended to eliminate faecal carriage, and therefore prevent person-to-person transmission. In contrast with salmonellosis, a number of antibiotics may be effective in shortening the duration of illness and terminating faecal carriage. This is especially true of strains of *S. sonnei* that are endemic in industrialised countries, whereas in developing countries, *Shigella* species that are multiple antibiotic resistant are an increasing problem. The fluoroquinolones are highly effective in shigellosis, and resistance is rare; therefore, they are often considered to be the treatment of choice, especially in adults and/or for treating imported infections. The dosage of ciprofloxacin is 500 mg twice daily orally in adults (7.5 mg/kg twice daily in children). Amoxicillin is an alternative first-line drug for *S. sonnei* infections acquired in the UK, where around 90% of isolates are susceptible. The dosage of amoxicillin is 250–500 mg three times daily in adults and 62.5–125 mg three times daily in children. Azithromycin (doses as for campylobacteriosis) is increasingly

recommended as an alternative agent for shigellosis, especially in children (Jain et al., 2005). Third-generation cephalosporins such as ceftriaxone are another option for severe shigellosis. Trimethoprim resistance is now common, so this agent can no longer be recommended as empiric therapy. Antibiotic therapy is usually given for a maximum of 5 days.

Enteric fever. Treatment should be commenced as soon as a clinical diagnosis of enteric fever is made. Fluoroquinolones have been widely used as the first-choice treatment for typhoid and paratyphoid fevers. When treating isolates that are fully sensitive, the clinical response is at least as rapid as with the older treatments, there is a lower relapse rate and convalescent faecal carriage is shortened. However, the proportion of isolates with reduced susceptibility to fluoroquinolones has increased to around 75%. Although most of these isolates have minimum inhibitory concentration values below those regarded as fully resistant, treatment failures have been reported. For this reason, fluoroquinolones are no longer recommended as first-line treatment unless it is known that the isolate is fully sensitive. Resistance to other antibiotics that have been commonly used to treat enteric fever, such as co-trimoxazole, chloramphenicol and ampicillin, is now frequent. These agents therefore cannot be recommended as alternatives to fluoroquinolones for empiric treatment of enteric fever, but may be useful in patients with bacterial isolates that are confirmed as sensitive. Doses of ciprofloxacin are as outlined for non-typhoidal salmonellosis. The usual dosage of chloramphenicol is 50 mg/kg/day in four divided doses, and for ampicillin 100 mg/kg/day in four divided doses. Two weeks of antibiotic therapy is usually recommended, although shorter courses of ciprofloxacin (7–10 days) may be as effective.

The majority of cases of enteric fever diagnosed in the UK are related to travel to the Indian subcontinent, where multi-drug resistance is common (Wain et al., 2015). Third-generation cephalosporins are the recommended first-choice agents to treat such infections, for example, cefotaxime (100–150 mg/kg daily in two to four divided doses in children; 6–8 g daily in three to four divided doses in adults) or ceftriaxone (50–80 mg/kg/day in children; 1–2 g/day in adults). Alternative agents for multidrug-resistant strains are intravenous carbapenems or oral azithromycin at a dosage of 20 mg/kg/day (maximum 1000 mg) for at least 5 days. Time taken for clearance of bacteraemia may be longer with azithromycin, but the relapse rate appears to be lower than with β -lactam antibiotics.

Chronic carriers of Salmonella. Patients may become chronic carriers after *Salmonella* infection, especially in the presence of underlying biliary tract disease. Oral ciprofloxacin 500–750 mg twice daily continued for 2–6 weeks is usually effective in eradicating carriage and has largely superseded the use of oral amoxicillin at a dosage of 3 g twice daily.

Cholera. Fluid and electrolyte replacement is the key aspect of the management of cholera. However, antibiotics do shorten the duration of diarrhoea, and therefore reduce the overall fluid loss, and rapidly terminate faecal excretion of the organism. Effective agents include tetracyclines, erythromycin, trimethoprim, ampicillin or amoxicillin, chloramphenicol, ciprofloxacin and furazolidone. However, antibiotic resistance is being increasingly seen; in particular, *V. cholerae* O139 is

intrinsically resistant to furazolidone and trimethoprim. The choice of antibiotics is therefore governed by knowledge of local resistance patterns, which may vary between outbreaks. Tetracycline 250 mg four times daily or doxycycline 100 mg once daily by mouth is probably the most widely used therapy in adults. Ampicillin, amoxicillin or erythromycin is generally the preferred agent for children. Although clinical cure can be achieved after a single dose of antibiotics, treatment is usually given for 3–5 days to ensure eradication of *V. cholerae* from faeces.

C. difficile infection. The first objective is to diagnose CDI as soon as possible so that appropriate treatment and infection control measures can be put in place. Clinicians must consider the diagnosis in any patient in whom there is no clear alternative diagnosis for his or her diarrhoea. Stool samples must be sent to the laboratory immediately, and the laboratory must make testing available 7 days per week. Once the diagnosis is confirmed, attention must be paid to the patient's hydration and nutrition, non-essential antibiotic therapy or gastro-intestinal active drugs must be stopped and the patient's condition closely monitored. Although mild cases may resolve without specific therapy, treatment of all hospitalised patients with diarrhoea due to *C. difficile* is recommended, to shorten the duration of illness and to reduce environmental contamination and, therefore, the risk of nosocomial transmission.

Oral metronidazole 400 mg three times daily for 10 days is widely used as the first-line treatment for mild-to-moderate CDI. For severe CDI, oral vancomycin is recommended at a dosage of 125 mg four times daily for 10 days. In patients who are unable to take oral medication, either drug can be administered via a nasogastric tube. However, there is growing evidence that vancomycin is superior to metronidazole in CDI of all grades of severity (Nelson et al., 2017). Where there is no response to initial treatment, the dosage of vancomycin can be increased up to 500 mg four times daily, together with intravenous metronidazole 500 mg three times daily. Oral fidaxomicin 200 mg twice a day for 10 days was approved for CDI treatment in Europe in 2012. This drug is considerably more expensive than vancomycin, which is itself more expensive than metronidazole. Fidaxomicin has been shown in clinical trials to be at least non-inferior to vancomycin for the initial cure of CDI, but is clearly associated with a lower rate of recurrence. It is therefore recommended for treatment of patients deemed to be at high risk of recurrence; individual hospitals must make their own assessment of the cost-effective use of fidaxomicin (Wilcox, 2013).

Recurrence of symptoms occurs in about 20% of patients treated for CDI. Although some recurrences are due to germination of spores that have persisted in the colon since the original infection, it is recognised that some of these cases are due to reinfection, rather than relapse caused by the original strain (Loo et al., 2004). Most recurrences do respond to a further 10- to 14-day course of metronidazole or vancomycin, but increasingly fidaxomicin is seen as first-line treatment for this indication. A few patients experience repeated recurrences. Faecal microbiota transplantation is being increasingly used in managing these patients. However, questions remain concerning regulatory matters, donor selection, the optimal mixture of the transplant and the preferred route of administration.

Pharmaceutical approaches to managing patients with multiple recurrences where fidaxomicin has failed include:

- a supervised trial of anti-motility agents alone (if there are no abdominal symptoms or signs of severe CDI),
- tapering or pulse therapy with oral vancomycin given for 4–6 weeks,
- a 2-week course of oral vancomycin 125 mg four times daily and oral rifampicin 300 mg twice daily,
- intravenous immunoglobulin, especially if the patient's albumin status worsens.

Trial data do not currently support the use of probiotics for the treatment or prevention of CDI (Department of Health and Health Protection Agency, 2009).

Cryptosporidiosis. Cryptosporidiosis in immunocompetent individuals is generally self-limiting. However, in immunosuppressed patients, severe diarrhoea can persist indefinitely and can even contribute to death. HIV-infected patients who are receiving highly active antiretroviral therapy now have a much lower incidence of cryptosporidiosis due to immune reconstitution and possibly a direct anti-cryptosporidium effect of protease inhibitors. There is no reliable antimicrobial therapy. Azithromycin, which is readily prescribable, is partially effective at a dosage of 500 mg once daily (10 mg/kg once daily in children). Treatment should be continued until *Cryptosporidium* oocysts are no longer detectable in faeces (typically 2 weeks), to minimise the risk of relapse post-treatment. Occasionally, therapy has to be continued indefinitely to prevent relapse. Most other agents that have been recommended for treatment of cryptosporidiosis, for example, nitazoxanide, spiramycin, paromomycin and letrazuril, are not licensed in the UK. These can usually be sourced from special-order manufacturing or importing companies (Smith and Corcoran, 2004). Of these agents, nitazoxanide has US Food and Drug Administration approval in the USA and has been shown to be effective in clinical trials at a dosage of 500 mg twice daily (adults and children aged ≥ 12 years) for 3 days (children 1–3 years: 100 mg twice daily; 4–11 years: 200 mg twice daily). Clinical cure rates of 72–88% have been reported in immunocompetent patients (Fox and Saravolatz, 2005), but are probably lower in immunosuppressed patients.

Giardiasis. Metronidazole is the treatment of choice for giardiasis. Various oral regimens are effective, for example, 400 mg three times daily (7.5 mg/kg in children) for 5 days, or 2 g/day (children: 500 mg to 1 g) for 3 days. Alternative treatments are tinidazole 2 g as a single dose, or mepacrine hydrochloride 100 mg (2 mg/kg in children) three times daily for 5–7 days. Nitazoxanide is a new thiazolide antiparasitic drug (discussed in the earlier Cryptosporidiosis section) that has also been licensed for treatment of giardiasis in some countries, but is not currently available in the UK. A single course of treatment for giardiasis has a failure rate of up to 10%. A further course of the same or another agent is often successful. Sometimes repeated relapses are due to reinfection from an asymptomatic family member. In such cases, all affected family members should be treated simultaneously.

Amoebiasis. The aim of treatment in amoebiasis is to kill all vegetative amoebae and also to eradicate cysts from the bowel lumen. Metronidazole is highly active against vegetative amoebae and is commonly the treatment of choice for acute amoebic dysentery and

amoebic liver abscess. The dosage for adults is 800 mg (children 100–400 mg) three times daily for 5–10 days. To eradicate cysts, metronidazole therapy is followed by a 5-day course of diloxanide furoate 500 mg three times daily (20 mg/kg daily in three divided doses for children). Tinidazole has been shown to reduce clinical failure and be better tolerated than metronidazole (Gonzales et al., 2009). The dosage of tinidazole for adults is 2 g daily for 2–3 days, and for children is 50–60 mg/kg daily for 3 days.

Asymptomatic excretors of cysts living in areas with a high prevalence of *E. histolytica* infection do not merit treatment because most individuals quickly become reinfected. However, asymptomatic excretors of cysts in Europe or North America are usually treated with diloxanide furoate for 5–10 days; metronidazole and tinidazole are relatively ineffective in this situation.

Patient care

Individuals who are excreting gastro-intestinal pathogens are potentially infectious to others. Liquid stools are particularly likely to contaminate the hands and the environment. All cases of gastro-intestinal infection should be excluded from work or school at least until the patients are symptom free; hospitalised patients should be isolated in a single room. Patients should be advised on general hygiene, and in particular, on thorough handwashing and drying after visiting the toilet and before handling food.

In most countries, many gastro-intestinal infections are statutorily notifiable. Following notification, the authorities will judge whether the implications for public health merit investigation of the source of infection, contact screening or follow-up clearance stool samples from the original case.

Common therapeutic problems in the management of gastro-intestinal infection are summarised in Table 38.3. Problems associated with specific gastro-intestinal infections are summarised in Table 38.4.

Case studies

Case 38.1

A 12-year-old boy, Master RH, is admitted to hospital with a history of fever, weight loss and malaise 1 week after returning from visiting relatives in Pakistan. Whilst there he was diagnosed as having typhoid fever, and although details are sketchy, it seems that Master RH received treatment with ciprofloxacin. The only other medical history of note is that he experienced an anaphylactic reaction after taking penicillin 4 years ago. Twenty-four hours after admission, *S. enterica* serovar Typhi is isolated from a blood culture.

Questions

1. Why might Master RH not have fully responded to the treatment given in Pakistan?
2. Which antibiotic would now be most appropriate as empiric therapy?

Table 38.3 Practice points: general problems with treatment of gastro-intestinal infections

Problems	Resolution
Difficult or impossible to make a rapid aetiological diagnosis	New rapid and more sensitive diagnostic techniques (polymerase chain reaction) are being introduced Hospital laboratories are expected to offer rapid testing for <i>Clostridium difficile</i> 7 days per week
Antibiotic resistance in bacterial causes of gastroenteritis is increasing in prevalence	With no or few antibiotic agents on the horizon, good antibiotic stewardship is essential to preserve the effectiveness of existing treatments
Clinical effectiveness and cost-effectiveness of antibiotic therapy for many bacterial gastro-intestinal infections are not clearly established	Without reliable data showing benefit, antimicrobial therapy is not used in the majority of infections
No specific therapies for viral gastroenteritis	Infections in otherwise healthy individuals are generally self-limiting
Up to 20% of patients with <i>C. difficile</i> infection experience at least one recurrence	Fidaxomicin is a new treatment for <i>C. difficile</i> infection that may be associated with a lower rate of recurrence
Few other recent improvements in the diagnosis of bacterial or parasitic infections	Various non-evidence-based experimental treatments have been used to manage immunocompromised patients with protracted diarrhoea; faecal microbiota transplantation is being increasingly used to manage <i>C. difficile</i> infection
Acute illness may be followed by a period of non-infective diarrhoea	Cautious use of antidiarrhoeal medication may be indicated at this stage

Table 38.4 Practice points: problems with treatment of specific gastro-intestinal infections

Infection	Antibiotic	Problems	Resolution
Campylobacteriosis	Macrolides (e.g. erythromycin)	Not always effective, especially if commenced >72 h after onset of symptoms	Reserve therapy for cases where symptoms are severe or worsening at time of diagnosis
	Ciprofloxacin ^a	Up to 50% of strains are resistant	Use only as a second-line agent for isolates that have been shown to be sensitive
Salmonellosis	Ciprofloxacin ^a	Not always effective Resistance is increasing	Reserve therapy for cases where symptoms are severe or worsening at time of diagnosis
Enteric fever	Ciprofloxacin ^a	Resistance is increasing	None of these agents is now considered to be a suitable first-line therapy for enteric fever in the UK
	Ampicillin or amoxicillin	Resistance to these agents is now common	
	Chloramphenicol	Higher incidence of chronic carriage and relapse than with ciprofloxacin Resistance is now common	
Shigellosis	Trimethoprim	Resistance is increasing	Therapy should be guided by antibiotic sensitivities of the isolate; most trimethoprim-resistant strains are ciprofloxacin sensitive
<i>Clostridium difficile</i>	Metronidazole	Relapse rate up to 20%	Repeat course of treatment, or treatment with another agent, e.g. fidaxomicin, or consider faecal microbiota transplantation
	Vancomycin (oral)	More expensive than metronidazole Risk of promoting vancomycin-resistant enterococci Relapse rate up to 20%	Reserve for more serious cases; in the case of relapse, repeat course of treatment, or treatment with another agent, e.g. fidaxomicin, or consider faecal microbiota transplantation
Cryptosporidiosis	Azithromycin or nitazoxanide	Not always effective	Long-term therapy may be required to control symptoms

^aCiprofloxacin is not licensed for general paediatric use; it is widely used to treat gastro-intestinal infections in children.

Answers

1. Strains of *S. enterica* serovar Typhi that have reduced susceptibility to fluoroquinolones are common in the Indian subcontinent. Although these strains are not usually fully fluoroquinolone resistant, treatment failures have been reported, even when an appropriate dose regimen has been used. In this case, there is not even any assurance that the treatment regimen in Pakistan was adequate.
2. Given the lack of assurance of the adequacy of the ciprofloxacin treatment in Pakistan, one option would be to re-treat with ciprofloxacin. However, given the high likelihood that the strain will have reduced susceptibility to ciprofloxacin, it would be more logical to use an alternative agent. Of those, carbapenems and cephalosporins are β -lactam antibiotics that would be best avoided, given the history of anaphylaxis following penicillin exposure. Azithromycin would appear therefore to be the empiric treatment of choice in this case. If the patient was seriously unwell and/or unable to take oral medication, then a carbapenem antibiotic might have to be used under specialist supervision.

Case 38.2

A mother brings her 6-year-old daughter, Miss MF, to her primary care doctor because she has a 2-day history of bloody diarrhoea and abdominal pain. The family had been on a farm visit the previous weekend and had eaten food when there. The mother is anxious for her child to be treated with antibiotics because they will be going on their summer holiday in 1 week.

Questions

1. Give three possible infective causes of Miss MF's symptoms.
2. How should the primary care doctor respond to the mother's request for antibiotics?

Answers

1. The two commonest bacterial gastro-intestinal infections, campylobacteriosis and salmonellosis, can both present in this way. Many other bacterial and protozoan causes of gastroenteritis can also cause similar symptoms. One bacterium that is especially important to consider in this case, where there is a history of a farm visit, is *E. coli* O157. Every effort should be made to obtain a stool sample from the patient for microbiological examination.
2. It would not be appropriate to treat Miss MF's symptoms empirically with antibiotics for a number of reasons. Firstly, antibiotic therapy may make no difference to the speed of clinical resolution. Secondly, where antibiotics are justified, the choice of drug will depend on the aetiological agent. Thirdly, antibiotics are contraindicated in infection with *E. coli* O157, which must feature in the differential diagnosis in this case.

Case 38.3

An adult liver transplant patient, Mr EJ, presented with diarrhoea (up to 15 times per day), which has been ongoing for 10 days since he returned from a camping holiday. The microbiology laboratory has just called to say that *Cryptosporidium* oocysts were seen in his faeces sample.

Question

What treatment management can be offered to Mr EJ?

Answer

There is no reliable antimicrobial therapy for cryptosporidiosis. Azithromycin is readily prescribable, and as such may be used at a dosage of 500 mg once daily as a first-choice agent. If symptoms do abate, treatment should be continued until *Cryptosporidium* oocysts are no longer detectable in faeces (typically 2 weeks), to minimise the risk of relapse post-treatment. Occasionally, therapy has to be continued indefinitely to prevent relapse. Of the alternative agents for treatment of cryptosporidiosis, nitazoxanide appears to be the most effective. Although not licensed in the UK, it can usually be sourced from special-order manufacturing or importing companies. However, nitazoxanide treatment is also not always effective in patients who are unable to mount an appropriate immune response.

Case 38.4

A businessman, Mr JM, is planning a short trip to Egypt. During previous visits to the area, he has experienced troublesome diarrhoea despite being careful about hygiene. Although the diarrhoea has not made him seriously unwell, it has caused him considerable inconvenience during business discussions.

Question

Are there any antimicrobials that Mr JM could take to prevent this problem?

Answer

Although traveller's diarrhoea is not usually serious, it can cause considerable inconvenience whether the sufferer is travelling for leisure or business reasons. Simple measures that can help prevent traveller's diarrhoea include taking care with food and drinks (only bottled water from reputable sources should be used). There are two approaches to antibiotic use in traveller's diarrhoea. Either the drug can be taken prophylactically to try to prevent development of diarrhoea, or treatment can be commenced with the onset of diarrhoea. The latter approach is generally preferred because it limits unnecessary exposure to antibiotics, and the response to treatment is usually rapid. However, there are instances such as in this case where the inconvenience of even short-lived diarrhoea may be great enough to justify use of prophylaxis.

The choice of antibiotics for traveller's diarrhoea has been made more complicated by the increasing prevalence of antibiotic resistance in many developing countries. Drugs such as amoxicillin or trimethoprim no longer have a role. A fluoroquinolone, such as ciprofloxacin, still represents a reasonable first choice, with azithromycin as a possible alternative in areas where fluoroquinolone resistance is known to be common. For travellers from countries where it can be prescribed, rifaximin may be the agent of choice. For travellers to areas where infections such as amoebic dysentery or giardiasis are common, it may be appropriate to take a supply of metronidazole that can be started if there is no response to the first-line antibacterial prophylaxis.

Case 38.5

A 75-year-old woman, Mrs CS, on an elderly care ward experiences watery diarrhoea and abdominal pain 4 days after commencing therapy with ciprofloxacin for a urinary tract infection. *C. difficile* toxin is detected in a stool sample. She has had two previous episodes of CDI in the past year.

Question

How should Mrs CS be managed?

Answer

Firstly, treatment with ciprofloxacin should be discontinued. Four-day antibiotic therapy for a urinary tract infection will often suffice, but if further treatment is required, an antibiotic that is less likely to disturb the bowel flora should be prescribed. Secondly, Mrs CS requires treatment for her CDI. Metronidazole is often regarded as

the preferred first-line treatment for mild-to-moderate CDI, whereas oral vancomycin would be a more expensive, but possibly more effective, alternative; either treatment would be an option here. However, because Mrs CS has recurrent CDI, many prescribers would now choose to treat with fidaxomicin. Although fidaxomicin is much more expensive, it is associated with a lower risk of CDI recurrence. Another treatment option that would be considered in some centres is faecal microbiota transplantation. Mrs CS should be closely monitored for the frequency and severity of the diarrhoea to ensure that she does not experience life-threatening complications of CDI. Finally, the patient should be isolated to reduce the risk of spread of the infection.

39 Infective Meningitis

Jim Gray

Key points

- The causative agents of meningitis are related to the age of the patient and the presence of underlying disease.
- The most common cause of early-onset neonatal meningitis is the group B streptococcus. Other important causes of neonatal meningitis include *Escherichia coli* and *Listeria monocytogenes*.
- Outside the neonatal period, *Neisseria meningitidis* and *Streptococcus pneumoniae* are the major causes of infective meningitis, accounting for around 75% of confirmed cases.
- Antibiotic treatment of meningitis requires attainment of adequate concentrations of bactericidal antibiotics in the cerebrospinal fluid.
- Suitable empiric therapies for neonatal meningitis are ampicillin or amoxicillin, combined with a third-generation cephalosporin such as cefotaxime.
- Increasing multidrug resistance in Gram-negative bacteria means that carbapenem antibiotics, especially meropenem, have an increasing role in the empiric treatment of neonatal meningitis.
- Increasing resistance to penicillins and concerns about the toxicity of chloramphenicol have led to the widespread use of cefotaxime or ceftriaxone as empiric therapy for meningitis outside the neonatal period.
- Because of the potentially rapid progression of the disease, patients with suspected meningococcal infection should receive emergency therapy with penicillin before admission to hospital.
- Close contacts of patients with meningococcal, and in some circumstances *Haemophilus influenzae* type b disease, should receive chemoprophylaxis and be considered for immunisation.
- There is increasing evidence of the benefit of steroids as adjunctive therapy in the management of some forms of bacterial meningitis.
- Introduction into the routine immunisation schedule of vaccines against *H. influenzae* type b, *N. meningitidis* group C and common *S. pneumoniae* serotypes has markedly reduced the incidence of meningitis caused by these bacteria. Immunisation against *N. meningitidis* group B was introduced in the UK in 2015.

The brain and spinal cord are surrounded by three membranes, which from the outside inwards are the dura mater, the arachnoid mater and the pia mater. Between the arachnoid mater and the pia mater, in the subarachnoid space, is found the cerebrospinal fluid (CSF) (Fig. 39.1). This fluid, of which there is around 150 mL in a normal individual, is secreted by the choroid plexuses

and vascular structures, which are in the third, fourth and lateral ventricles. CSF passes from the ventricles via communicating apertures to the subarachnoid space, after which it flows over the surface of the brain and the spinal cord (see Fig. 39.1). The amount of CSF is controlled by resorption into the bloodstream by vascular structures in the subarachnoid space, called the arachnoid villi. Infective meningitis is an inflammation of the arachnoid and pia mater associated with the presence of bacteria, viruses, fungi or protozoa in the CSF. Meningitis is one of the most emotive of infectious diseases, and for good reason: even today, infective meningitis is associated with significant mortality and risk of serious sequelae in survivors.

Aetiology and epidemiology

The annual incidence of acute bacterial meningitis in developed countries is 2–5 per 100,000 of the population. Viruses are the most common cause of meningitis, but because laboratory confirmation of the aetiological agent is often not achieved there are no reliable data on the incidence of viral meningitis.

Bacterial meningitis

Although bacterial meningitis occurs in all age groups, it is predominantly a disease of young children, with 40–50% of all cases occurring in the first 4 years of life. The pattern of micro-organisms causing meningitis is related to the age of the patient and the presence of underlying disease. Development of vaccines against the major causes of bacterial meningitis has dramatically changed the epidemiology of the condition outside the neonatal period. Following the introduction of vaccination against *Haemophilus influenzae* type b (Hib) into national childhood immunisation programmes in the early 1990s, invasive disease meningitis caused by that pathogen has almost been eliminated. Routine vaccination against *Streptococcus pneumoniae* and *Neisseria meningitidis* serogroup C (MenC) was subsequently adopted, and in 2015 the UK became the first country in the world to introduce the *N. meningitidis* serogroup B (MenB) vaccine into a national childhood immunisation programme (Salisbury and Ramsay, 2013).

N. meningitidis is the most common cause of bacterial meningitis from infancy through to middle age, with peaks of incidence in the less than 5-year age group and in adolescents. There are several serogroups of *N. meningitidis*, including A, B, C, W135

Fig. 39.1 The meninges covering the brain and spinal cord and the flow of cerebrospinal fluid (arrowed). (Modified from Ross and Wilson [1981], and reproduced with permission of Elsevier Ltd.)

and Y. In the late 20th century, serogroups B and C accounted for 60–65% and 35–40% of infections in the UK, respectively. However, with the introduction of vaccination against MenC into the routine immunisation programme in 1999, serogroup B now accounts for well more than 80% of all meningococcal disease. Moreover, in recent years an increase in other serogroups, especially W135, has been observed; based on this rise the former adolescent MenC dose has been replaced with a quadrivalent ACWY conjugate vaccine. The same vaccine is available to protect travellers to countries where other serogroups predominate, for example, in Africa and the Middle East where serogroups A and W135 prevail.

S. pneumoniae is the most common cause of meningitis in adults older than 45 years, but almost half of all cases of pneumococcal meningitis occur in children younger than 5 years. It has a poorer outcome than meningococcal meningitis. Vaccination against the most common serotypes of *S. pneumoniae* using a conjugate vaccine was added to the routine childhood immunisation programme in the UK in 2006; the original 7-valent vaccine was then replaced by a 13-valent vaccine in the spring of 2010. A different 23-valent polysaccharide vaccine is available for certain patient groups at risk of pneumococcal infection.

Hib was once the major cause of bacterial meningitis in children aged 3 months to 5 years but, as noted earlier, has been almost eliminated in the UK and other developed countries since the introduction of the vaccine.

Although patients with meningococcal or Hib meningitis are potentially infectious, most cases of meningitis due to these bacteria are acquired from individuals who are asymptomatic nasopharyngeal carriers (Health Protection Agency, 2012; Public Health England, 2013). People who live in the same household as a patient with meningococcal disease have a 500- to 1200-fold increased risk of development of infection if they do not receive chemoprophylaxis. Susceptible young children who are household contacts of an individual with Hib disease have a similarly increased risk of becoming infected. Epidemics of meningococcal disease sometimes occur. In developed countries, these take the form of clusters of cases among people living in close proximity (e.g. in schools or army camps) or in a particular geographical area. In Africa, large epidemics with many thousands of cases occur, usually during the dry season.

In the neonatal period, group B streptococci are the most common cause of bacterial meningitis. Other causes of neonatal meningitis include *Escherichia coli* and other *Enterobacteriaceae*, and rarely, *Listeria monocytogenes*. Most cases of early-onset infection (within the first 7 days of life) are acquired from the maternal genital tract around the time of delivery; late-onset infections may still be maternal in origin, but they can also be acquired from a variety of other sources.

L. monocytogenes is also an occasional cause of meningitis in immunocompromised patients. Meningitis can also occur as a complication of neurosurgery, especially in patients who have ventriculoatrial or ventriculoperitoneal shunts. Coagulase-negative staphylococci are the major cause of shunt-associated meningitis, but other bacteria are important, including *Enterobacteriaceae* and *Staphylococcus aureus*. Meningitis caused by *S. aureus* may also be secondary to trauma, or local or haematogenous spread from another infective focus. Meningitis may also be a feature of multisystem bacterial diseases such as syphilis, leptospirosis and Lyme disease.

The decline in the incidence of tuberculous meningitis in developed countries has mirrored the fall in the incidence of tuberculosis in these countries. Tuberculous meningitis may occur as part of the primary infection or as a result of recrudescence of a previous infection.

Viral meningitis

Human enteroviruses, such as echoviruses and Coxsackie viruses, account for about 70% of cases of viral meningitis in the UK. Parechoviruses are another important cause of meningitis in

infants, especially neonates. Herpes simplex and varicella zoster viruses account for most other cases. Occasional causes of viral meningitis include mumps virus and human immunodeficiency viruses (HIVs).

Fungal meningitis

In Europe, fungal meningitis is rare in individuals without underlying disease. *Candida* species are an occasional cause of shunt-associated meningitis. *Cryptococcus neoformans* emerged as an important cause of meningitis in patients with late-stage HIV infection and other severe defects of T-cell function. With greater use of fluconazole for oral candidiasis, and especially the advent of highly active antiretroviral therapy, cryptococcosis has become much less common in developed countries. However, in sub-Saharan African countries with the highest HIV prevalence, cryptococcus is the leading cause of infective meningitis. In certain other areas of the world, infections with fungi such as *Coccidioides immitis* and *Histoplasma capsulatum* are endemic.

Pathophysiology

Most cases of bacterial meningitis are preceded by nasopharyngeal colonisation by the causative organism. In most colonised individuals, infection will progress no further, but in susceptible individuals, the organism invades the submucosa by circumventing host defences (e.g. physical barriers, local immunity, phagocytes) and gains access to the central nervous system (CNS) by invasion of the bloodstream and subsequent haematogenous seeding of the CNS. Other less common routes by which micro-organisms can reach the meninges include:

- direct spread from the nasopharynx;
- blood-borne spread from other foci of colonisation or infection;
- abnormal communications with the skin or mucous membranes, for example, skull fractures, anatomical defects or a meningocoele;
- spread from an infected adjacent focus, for example, brain abscess, tuberculoma, infected paranasal air sinus or infection of the middle ear.

Once in the subarachnoid space, the infection spreads widely and incites a cascade of meningeal inflammation. The cerebral tissue is not usually directly involved, although cerebral abscess may complicate some types of meningitis.

The micro-organisms that most frequently cause meningitis are capable of doing so because they have a variety of virulence factors, including mechanisms for:

- attachment to host mucosal surfaces,
- evasion of phagocytosis and other host defences,
- meningeal invasion,
- disruption of the blood–brain barrier,
- induction of pathophysiological changes in the CSF space,
- secondary brain damage.

Overall, the net result of infection is vascular endothelial injury and increased blood–brain barrier permeability leading to the entry of many blood components into the subarachnoid space. This contributes to cerebral oedema and elevated CSF protein

levels. In response to the cytokine response, neutrophils migrate from the bloodstream into the CSF. Cerebral oedema contributes to intracranial hypertension and a consequent decrease in cerebral blood flow. Anaerobic metabolism ensues, which contributes to increased lactate and decreases glucose concentrations. If this uncontrolled process is not modulated by effective treatment, transient neuronal dysfunction or permanent neuronal injury results.

Clinical manifestations

Acute bacterial meningitis usually presents with sudden-onset headache, neck stiffness, photophobia, fever and vomiting. On examination, Kernig's sign may be positive. This is resistance to extension of the leg when the hip is flexed, due to meningeal irritation in the lumbar area. Where meningitis is complicated by septicaemia, there may be septic shock. The presence of a haemorrhagic skin rash is highly suggestive, but not pathognomonic, of meningococcal infection. Untreated patients with bacterial meningitis deteriorate rapidly, with development of seizures, focal cerebral signs and cranial nerve palsies. Finally, obtundation and loss of consciousness herald death.

In infants with meningitis, the early physical signs are usually non-specific and include fever, diarrhoea, lethargy, feeding difficulties and respiratory distress. Focal signs such as seizures or a bulging fontanelle usually only occur at a late stage.

Viral meningitis usually presents with acute onset of low-grade fever, headache, photophobia and neck stiffness. Unless encephalitis develops, patients usually remain alert and oriented.

Although tuberculous and fungal meningitis sometimes present acutely, these infections typically have a more indolent course. The early stages of the diseases are dominated by general symptoms such as malaise, apathy and anorexia. As they progress, symptoms and signs more typical of meningitis usually appear.

Diagnosis

The definitive diagnosis of meningitis is established by detection of the causative organism and/or demonstration of biochemical changes and a cellular response in CSF. CSF is obtained by lumbar puncture, where a needle is inserted between the posterior space of the third and fourth lumbar vertebrae into the subarachnoid space. Before performing lumbar puncture, the possibility of precipitating or aggravating existing brain herniation in patients with intracranial hypertension must be considered. A computed tomography (CT) scan should be performed before undertaking lumbar puncture if any neurological abnormalities are present.

In health, the CSF is a clear colourless fluid which, in the lumbar region of the spinal cord, is at a pressure of 50–150 mm H₂O. There may be up to 5 cells/microlitre, the protein concentration is up to 0.4 g/L and the glucose concentration is at least 60% of the blood glucose (usually 2.2–4.4 mmol/L). [Table 39.1](#) shows how the cell count and biochemical measurements can be helpful in determining the type of organism causing meningitis.

In bacterial and fungal meningitis, organisms may be visible in Gram-stained smears of the CSF. The common causes of bacterial meningitis are easily distinguished from each other by their

Table 39.1 Cellular and biochemical responses in different forms of infective meningitis

Type of meningitis	Cell count	Protein (g/L)	Glucose
Bacterial	Predominantly polymorphs, 500–2000 per microlitres (lymphocytes may predominate in early or partially treated cases)	1–3	<50% blood glucose
Tuberculous	Predominantly lymphocytes, 100–600 per microlitres	1–6	<50% blood glucose
Viral	Predominantly lymphocytes, 50–500 per microlitres	0.5–1	Usually normal
Cryptococcal	Predominantly lymphocytes, 50–1000 per microlitres	1–3	<50% blood glucose

Gram stain appearance. Special stains, such as the Ziehl–Neelsen method, are necessary to visualise mycobacteria. However, only small numbers of mycobacteria are present in the CSF in tuberculous meningitis, and direct microscopy is often unrevealing. Although cryptococci can be visualised by Gram staining, they are often more easily seen with India ink staining, which highlights their prominent capsules.

Regardless of the microscopic findings, CSF should be cultured to try to confirm the identity of the causative organism and to facilitate further investigations such as antibiotic sensitivity testing and typing. Special cultural techniques are required for mycobacteria, fungi and viruses. Cultures of other sites are sometimes helpful. In suspected bacterial meningitis, blood for culture should always be obtained. Bacteraemia occurs in only 10% of patients with meningococcal meningitis but is more common in most other forms of meningitis. In suspected meningococcal disease, culture of a nasopharyngeal swab may be helpful because antibiotic penetration at this site is less. It increases the chances of isolating meningococci when antibiotics were administered to the patient before presentation to hospital.

Non-culture-based methods are increasingly used to investigate the aetiology of meningitis. Molecular amplification techniques, such as polymerase chain reaction (PCR), have been widely used for some years now to detect specific pathogens, especially meningococci, pneumococci, *Mycobacterium tuberculosis* and various viruses, including herpes simplex viruses and enteroviruses. An important recent development has been the introduction of multiplex PCR tests that can detect 10 or more different bacterial, viral or fungal CNS pathogens in the same assay, giving results in about 1 hour.

Serum antibodies to *N. meningitidis* and various viruses may be detected, but these investigations usually depend on demonstration of seroconversion between two samples collected a week or more apart and are, therefore, undertaken more for public health than clinical reasons. Patients with tuberculous meningitis may have a positive Mantoux test or an interferon- γ release assay.

Drug treatment

Acute bacterial meningitis is a medical emergency that requires urgent administration of antibiotics. Other considerations in some forms of meningitis include the use of adjunctive therapy such as steroids and the administration of antibiotics to prevent secondary cases.

Antimicrobial therapy

Pharmacokinetic considerations

The antimicrobial therapy of meningitis requires attainment of adequate levels of bactericidal agents within the CSF. The principal route of entry of antibiotics into CSF is by the choroid plexus; an alternative route is via the capillaries of the central nervous system into the extracellular fluid and hence into the ventricles and subarachnoid space (see Fig. 39.1). The passage of antibiotics into CSF is dependent on the degree of meningeal inflammation and integrity of the blood–brain barrier created by capillary endothelial cells, as well as the following properties of the antibiotic:

- lipid solubility (the choroidal epithelium is highly impermeable to lipid-insoluble molecules),
- ionic dissociation at blood pH,
- protein binding,
- molecular size,
- concentration of the drug in the serum.

Antimicrobials fall into three categories according to their ability to penetrate the CSF:

- those that penetrate even when the meninges are not inflamed, for example, chloramphenicol, metronidazole, isoniazid and pyrazinamide;
- those that generally penetrate only when the meninges are inflamed, and are used in high doses, for example, most β -lactam antibiotics, the quinolones and rifampicin;
- those that penetrate poorly under all circumstances, including the aminoglycosides, vancomycin and erythromycin.

Recommended regimens

Clinical urgency determines that empirical antimicrobial therapy will usually have to be prescribed before the identity of the causative organism or its antibiotic sensitivities are known. Consideration of the epidemiological features of the case, together with microscopic examination of the CSF, is often helpful in identifying the likely pathogen. However, empiric therapy is usually with broad-spectrum antimicrobial therapy to cover all likely pathogens, at least until definitive microbiological information is available. For the purpose of selecting empiric antimicrobial therapy, patients with acute bacterial meningitis can be categorised into four broad groups: neonates and infants younger than 3 months; immunocompetent older infants, children and adults; immunocompromised patients; and those with ventricular shunts.

Table 39.2 Suitable antibiotic regimens for treatment of acute bacterial meningitis in different age groups

Age group	First-choice antibiotic therapy	Alternative therapies
Neonates, aged <8 days	Ampicillin 50 mg/kg twice daily or amoxicillin 25 mg/kg twice daily and cefotaxime 50 mg/kg twice daily or ceftazidime 50 mg/kg twice daily	Benzylpenicillin 50 mg twice daily and ampicillin 50 mg/kg twice daily or amoxicillin 25 mg/kg twice daily and gentamicin 2.5 mg/kg twice daily ^a
Neonates, aged 8–28 days	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily and cefotaxime 50 mg/kg three times daily or ceftazidime 50 mg/kg three times daily	Meropenem 40 mg/kg two or three times daily ^b
Infants, aged 1–3 months	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily and cefotaxime 50 mg/kg three times daily or ceftriaxone 75–100 mg/kg once daily	
Infants and children, aged >3 months ^c	Cefotaxime 50 mg/kg three times daily or ceftriaxone ^d 75–100 mg/kg once daily	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily or benzylpenicillin ^e 30 mg/kg 4-hourly and chloramphenicol ^f 12.5–25 mg/kg four times daily
Adults	Cefotaxime ^g 2 g three times daily or ceftriaxone ^{d,g} 2–4 g once daily	Benzylpenicillin 2.4 g 4-hourly or ampicillin 2–3 g four times daily or amoxicillin 2 g three or four times daily and chloramphenicol ^f 12.5–25 mg/kg four times daily

^aBenzylpenicillin is suitable for treating group B streptococcus meningitis, but this regimen is not recommended for Gram-negative bacterial meningitis.
^bUse meropenem where multidrug-resistant Gram-negative bacterial meningitis is suspected or confirmed.
^cCalculated doses for children should not exceed maximum recommended doses for adults.
^dCeftriaxone should not be administered to neonates within 48 h of completion of infusions of calcium-containing solutions; caution should be exercised in older age groups.
^eBenzylpenicillin is inactive against *Haemophilus influenzae* and should therefore not be used in children aged <5 years.
^fMonitoring of serum chloramphenicol levels is recommended, especially in children aged <4 years.
^gAdd ampicillin or amoxicillin to cover *Listeria monocytogenes* in elderly patients or where Gram-positive bacilli seen in cerebrospinal fluid.

Antibiotics for meningitis in neonates and infants younger than 3 months. The most important pathogens in neonates include group B streptococci, *E. coli* and other *Enterobacteriaceae* and *L. monocytogenes*. Where meningitis in a neonate is suspected, the recommended empiric treatment is with a third-generation cephalosporin, usually cefotaxime, along with amoxicillin or ampicillin (Galiza and Heath, 2009). Cephalosporins penetrate into CSF better than aminoglycosides, and their use in Gram-negative bacillary meningitis has contributed to a reduction in mortality rate to less than 10%. Where neonates present with sepsis without evidence of meningitis it is common practice to prescribe an aminoglycoside, such as gentamicin, together with benzylpenicillin, ampicillin or amoxicillin (in early-onset sepsis), or flucloxacillin (in late-onset sepsis) as empiric therapy. This cephalosporin-sparing approach is preferred because cephalosporins are potent selectors of antibiotic-resistant bacteria such as methicillin-resistance *S. aureus* (MRSA), vancomycin-resistant enterococci and multidrug-resistant Gram-negative bacteria (MDRGNB), and also predispose to secondary candidiasis. If a baby treated with a penicillin and aminoglycoside combination is subsequently suspected or confirmed to have meningitis, then their antibiotic therapy should be altered to ensure good CSF penetration of antibiotics (National Institute for Health and Care Excellence, 2012). Likewise, empiric antibiotic therapy must be reviewed in all cases of neonatal meningitis once a pathogen has been identified. MDRGNB are becoming more prevalent, especially as a cause of hospital-acquired infection.

These bacteria include AmpC and extended-spectrum β -lactamase producers that are resistant to cephalosporins; a carbapenem, such as meropenem, is the usual treatment of choice for such infections. Suitable dosages are listed in Table 39.2.

In infants outside the immediate neonatal period, the classic neonatal pathogens account for a decreasing number of cases of meningitis, and the common bacteria of meningitis in childhood become increasingly important. Amoxicillin or ampicillin plus cefotaxime or ceftriaxone is the recommended treatment. Therapy with amoxicillin or ampicillin and gentamicin is unsuitable for this age group because it provides inadequate cover against *H. influenzae*.

Antibiotics for meningitis in older infants, children and adults. Antimicrobial therapy has to cover *S. pneumoniae*, *N. meningitidis* and, in children younger than 5 years, *H. influenzae* (Brouwer et al., 2010). Achievable antibiotic CSF concentrations are compared with the susceptibilities of the common agents of meningitis in Table 39.3. Third-generation cephalosporins, such as cefotaxime or ceftriaxone, are now widely used in place of the traditional agents of choice, chloramphenicol, ampicillin, amoxicillin and penicillin (see Table 39.2). This change has stemmed from concern over the rare but potentially serious adverse effects of chloramphenicol and the emergence of resistance to penicillin, ampicillin and chloramphenicol among *S. pneumoniae* and *H. influenzae* in particular. Chloramphenicol resistance and reduced susceptibility to penicillin have also been reported in

Table 39.3 Achievable cerebrospinal fluid concentrations of antibiotics in meningitis and minimum inhibitory concentration values for common central nervous system pathogens

Antibiotic	CSF/serum ratio	Peak CSF level (mg/L)	MIC ₉₀ (mg/L)		
			<i>N. meningitidis</i>	<i>H. influenzae</i>	<i>S. pneumoniae</i>
Ampicillin	1:10	10	0.02	0.25	0.05
Benzylpenicillin	1:20	1.5	0.02	1.0	0.02
Cefotaxime	1:20	10	0.01	0.06	0.25
Ceftriaxone	1:15	15	0.01	0.06	0.12
Chloramphenicol	1:2	15	1.0	1.0	2.5

CSF, Cerebrospinal fluid; MIC₉₀, minimum concentration of antibiotic that is inhibitory for 90% of isolates.

N. meningitidis. The third-generation cephalosporins, cefotaxime or ceftriaxone, have a broad spectrum of activity that encompasses not only the three classic causes of bacterial meningitis, but also many other bacteria that are infrequent causes of meningitis. Because of the potential for calcium chelation in vivo, ceftriaxone must not be administered within 48 hours of the completion of infusions of calcium-containing solutions in neonates. The risk of precipitation is much lower in patients more than 28 days of age. Nevertheless, caution should still be exercised when treating older age groups, especially in the early treatment of meningococcal infections (where calcium-containing products are commonly used for resuscitation).

Cephalosporins are inactive against *L. monocytogenes*, and amoxicillin or ampicillin should be added where it is possible that the patient may have listeriosis, for example, in elderly patients, or where Gram-positive bacilli are seen on Gram stain; it is not necessary to routinely prescribe ampicillin or amoxicillin in all cases of suspected bacterial meningitis. Although earlier-generation cephalosporins such as cefuroxime achieve reasonable CSF penetration and are active against the agents of meningitis in vitro, they do not effectively sterilise the CSF and should not be used to treat meningitis. Addition of vancomycin should be considered for patients who have received recent prolonged or frequent antibiotic therapy, or who have travelled to an area with a high prevalence of penicillin-resistant pneumococci in the preceding 3 months.

In meningitis due to *N. meningitidis* and *H. influenzae*, prompt administration of chemoprophylaxis to close contacts of the case

should be prescribed to eliminate nasopharyngeal carriage and hence reduce the risk of secondary cases.

***N. meningitidis*.** In view of the potentially rapid clinical progression of meningococcal disease with a non-blanching rash, it is recommended that treatment should begin with the emergency administration of benzylpenicillin. Primary care clinicians should give penicillin while arranging transfer of the patient to hospital. The dose is 1200 mg for adults and children aged 10 years and older, 600 mg for children aged 1–9 years and 300 mg for children younger than 1 year. Ideally this should be given intravenously. The intramuscular route is less likely to be effective in shocked patients but can be used if venous access cannot be obtained. The only contraindication is in people who have a clear history of anaphylaxis after a previous dose; a history of a rash following penicillin is not a contraindication.

Strains of *N. meningitidis* with reduced sensitivity to penicillin are well known and presently account for 5–10% of isolates in Europe and the USA. In general, these cases respond to treatment with adequate doses of benzylpenicillin, and failure of penicillin treatment has rarely been reported. Nevertheless, cefotaxime and ceftriaxone are now widely used in preference to benzylpenicillin or chloramphenicol. Meningococcal meningitis should be treated for 7 days.

***S. pneumoniae*.** Benzylpenicillin was once widely regarded as the treatment of choice for pneumococcal meningitis. However, pneumococci resistant to penicillin have emerged across the world, presenting a major therapeutic challenge in view of the severity of pneumococcal meningitis.

Although currently only about 5% of pneumococci in the UK are penicillin resistant, the frequency of resistance is increasing, and resistance rates of more than 50% have been reported in other countries, including Spain, Hungary and South Africa. Penicillin resistance in pneumococci is defined in terms of the minimum inhibitory concentration (MIC) of penicillin. Most strains have an MIC value of 0.1–2.0 mg/L and are defined as having moderate resistance; strains with an MIC value of more than 2 mg/L are considered highly resistant. This distinction is relevant for less serious infections with moderately resistant strains, which may still respond to adequate doses of some β -lactam antibiotics, such as cefotaxime, ceftriaxone or a carbapenem. However, the clinical outcome of meningitis with penicillin-resistant pneumococci treated with a β -lactam antibiotic as monotherapy is less good. For this reason many guidelines, including those produced by the Infectious Diseases Society of America, have for some years recommended therapy with a combination of a third-generation cephalosporin and vancomycin (McIntosh, 2005). This approach has not been adopted universally in the UK but should certainly be considered for patients who might have acquired their infection in a location where the incidence of penicillin resistance is high. Where vancomycin is given intravenously to treat meningitis, it is important to aim for trough serum levels of 15–20 mg/L because of the limited CSF penetration of vancomycin. Another problem is the emergence of pneumococci that are tolerant to vancomycin; that is, they are able to survive, but not proliferate, in the presence of vancomycin. Although such strains are uncommon, the outcome of meningitis treated with vancomycin is poor (Cottagnoud and Tauber, 2004).

Other antibiotics may be useful in treating pneumococcal meningitis. Use of rifampicin in combination with a cephalosporin and/or vancomycin is sometimes recommended, but there are few data confirming this improves the response rate in either penicillin-sensitive or -resistant pneumococcal meningitis. The dosage of rifampicin is 600 mg twice daily in adults or 10 mg/kg (maximum 600 mg) twice daily in children. Chloramphenicol is a suitable alternative to penicillin for treatment of meningitis due to penicillin-sensitive strains, for example, in patients who are penicillin allergic. However, chloramphenicol is not recommended for treating penicillin-resistant pneumococcal meningitis: although isolates may appear to be sensitive to chloramphenicol on routine laboratory testing, bactericidal activity is often absent, and the clinical response is usually poor.

Consideration of alternative antibiotics for treatment of penicillin-resistant pneumococcal meningitis is largely based on case reports rather than clinical trials. Success has been reported with meropenem as monotherapy and in conjunction with rifampicin. Moxifloxacin is a new-generation quinolone antibiotic with enhanced activity against Gram-positive bacteria, including *S. pneumoniae*, that is a suitable second-line agent for treating penicillin-resistant pneumococcal meningitis. Linezolid has excellent CSF penetration but does not have bactericidal activity, and clinical experience in treating meningitis has been variable (Rupprecht and Pfister, 2005).

The unpredictable nature of the response to therapy of penicillin-resistant pneumococcal meningitis means that patients require close observation during treatment, for example, monitoring of C-reactive protein. Repeat examination of CSF during therapy should also be considered.

Box 39.1 Indications for chemoprophylaxis in contacts of cases of infection with *Neisseria meningitidis* or *Haemophilus influenzae* type b

N. meningitidis

- Household and other close contacts (boyfriends/girlfriends) during the 7 days before onset of illness, irrespective of vaccination status (Prophylaxis is usually initiated as soon as possible by clinicians caring for the patient.)
 - The index case when able to take oral medication and before discharge from hospital, unless the disease has already been treated with ceftriaxone (Those treated with cefotaxime should still receive prophylaxis because it is not known that cefotaxime eradicates carriage.)
 - Healthcare workers whose mouth or nose was directly exposed to large-particle droplets/secretions from the respiratory tract of a probable or confirmed case of meningococcal disease during acute illness until completed 24 h of systemic antibiotics (Prophylaxis should only be initiated after consultation with hospital infection control team or public health doctor.)
 - Other contacts (Prophylaxis should be initiated by a public health doctor.)
 - School pupils in the same dormitory or university students sharing a kitchen in a hall of residence
 - Schools, nurseries, universities and other closed communities where two or more linked cases have occurred
- Vaccination is also recommended for close contacts (other than healthcare workers) of cases of serogroups A, C, W135 and Y.

Invasive Hib infection

- Household and other close contacts where there is a vulnerable person in the household (any child aged <10 years or an immunosuppressed or asplenic person of any age) (Prophylaxis usually initiated as soon as possible by clinicians caring for the patient.)
 - The index case (if age <10 years) when able to take oral medication and before discharge from hospital
 - Other contacts: prophylaxis is rarely necessary and should only be initiated by a public health physician
- Vaccination is also recommended for the index patient and vulnerable household contacts.

H. influenzae. A third-generation cephalosporin, such as cefotaxime or ceftriaxone, is generally the treatment of choice for *H. influenzae* meningitis. These agents have superseded the traditional therapies of chloramphenicol and/or ampicillin or amoxicillin.

Other bacteria. Meningitis in immunocompetent individuals is rarely due to other bacteria. The definitive treatment for these individuals should be determined on an individual basis in light of careful clinical and microbiological assessment.

Chemoprophylaxis against meningococcal and *H. influenzae* type b infection. In meningococcal meningitis, spread between family members and other close contacts is well recognised; these individuals should receive chemoprophylaxis as soon as possible, preferably within 24 hours. Sometimes, chemoprophylaxis may be indicated for other contacts, but the decision to offer prophylaxis beyond household contacts should be made only after obtaining expert advice (Box 39.1). Of the antibiotics conventionally used to treat meningococcal infections, only ceftriaxone reliably eliminates nasopharyngeal carriage; where another antibiotic has been used for treatment, the index case also requires chemoprophylaxis. A number of antibiotics are suitable as prophylaxis (Box 39.2).

Box 39.2 Recommended prophylactic regimens for contacts of cases of infection with *Neisseria meningitidis* or *Haemophilus influenzae* type b

Meningococcal infection	
<i>Ciprofloxacin</i> ^a (oral)	
Children aged 1 month to 4 years	125 mg as a single dose
Children aged 5–12 years	250 mg as a single dose
Adults	500 mg as a single dose
<i>Rifampicin</i> (oral)	
Children aged <1 year	5 mg/kg twice daily on 2 consecutive days
Children aged 1–12 years	10 mg/kg (maximum 600 mg) twice daily on 2 consecutive days
Adults	600 mg twice daily on 2 consecutive days
<i>Azithromycin</i> ^a (oral)	
Pregnant women	500 mg as a single dose
<i>Ceftriaxone</i> ^a (intramuscular)	
Children aged <12 years	125 mg as a single dose
Adults	250 mg as a single dose
Invasive Hib infection	
<i>Rifampicin</i> (oral)	
Children aged 1–3 months	10 mg/kg once daily for 4 days
Children aged >3 months	20 mg/kg once daily (maximum 600 mg) for 4 days
Adults	600 mg once daily for 4 days
<i>Ceftriaxone</i> ^a (intravenous or intramuscular)	
Children aged <12 years	50 mg/kg once daily for 2 days
Adults	1 g once daily for 2 days

^aNot licensed for this indication.

Ciprofloxacin is recommended for contacts of all ages (including pregnant and breastfeeding women) because of the convenience of single-dose administration, and unlike rifampicin, it does not interact with oral contraceptives and is readily available in community pharmacies. Although anaphylactoid reactions have been reported to occur in individuals receiving ciprofloxacin as chemoprophylaxis, none of these reactions have been fatal. If the strain is confirmed as group C (or A, W135 or Y), vaccination is normally offered to contacts who were given prophylaxis. Currently group B vaccination is not recommended for contacts. Appropriate immunisation should be given to any eligible unimmunised or partially immunised index case according to the recommended national schedule.

Chemoprophylaxis against Hib infection is usually indicated only for contacts where there is a vulnerable individual in the household (see Box 39.1). Only rifampicin has been proved to be effective in eliminating nasopharyngeal carriage (see Box 39.2). Ceftriaxone is recommended as an alternative agent if an individual is unable to tolerate or experiences an adverse reaction to rifampicin. Vulnerable individuals who are household contacts should also receive vaccination against Hib. The index case (if

aged <10 years) should always receive rifampicin to eliminate nasopharyngeal carriage before discharge from hospital and should be considered for immunisation as follows.

Unimmunised or partially immunised index cases younger than 10 years (or of any age with asplenia or splenic dysfunction) should complete their primary course of Hib immunisation.

Fully vaccinated index cases are managed as follows (Public Health England, 2013):

- Age 5–10 months: Give one dose of Hib vaccine before discharge from hospital to cover them until they receive their routine 12-month booster dose.
- Older infants and children aged less than 10 years: Measure anti-Hib antibodies 4 weeks post-infection and give an additional dose of Hib vaccine if antibody levels are less than 1 mg/mL. If this is not feasible, give a dose of Hib vaccine before discharge from hospital.
- Aged ≥10 years with asplenia or splenic dysfunction: Give an extra dose of Hib vaccine if they completed their scheduled Hib immunisation more than 1 year previously.

Antibiotics for meningitis in special groups

Immunocompromised host. In the immunocompromised patient with neutropenia, the meninges can become infected. Possible causes of meningitis include *Enterobacteriaceae* and *Pseudomonas aeruginosa*, as well as the classic bacterial causes of meningitis. The choice of therapy is governed by the need to attain broad-spectrum coverage, using agents with good CSF penetration. Meropenem may now be the drug of choice for meningitis in this setting, although many other regimens are also appropriate.

Patients with cellular immune dysfunction are vulnerable to meningitis caused by *L. monocytogenes* and *C. neoformans*. Ampicillin or amoxicillin, along with cefotaxime or ceftriaxone, is recommended as empirical antibacterial therapy for meningitis in these patients. Definitive treatment of listeria meningitis is normally with high-dose ampicillin (3 g four times daily) or amoxicillin (2 g four times daily), with the addition of gentamicin to obtain a synergistic effect. The most appropriate treatment for patients who are penicillin allergic – or in the rare circumstance of infection with a strain that is ampicillin resistant – is uncertain and specialist microbiological advice should be sought. Specific therapies for cryptococcal meningitis are described in detail later in this chapter.

Patients who have had a splenectomy are susceptible to invasive infections with encapsulated bacteria, including *S. pneumoniae* and Hib. Standard therapy with either cefotaxime or ceftriaxone is appropriate.

Post-neurosurgery meningitis. The majority of cases are aseptic meningitis secondary to a local inflammatory reaction to blood breakdown products or to tumor antigens, but it is not usually possible to distinguish between aseptic meningitis and infective meningitis until culture results are available after 48–72 hours. Post-operative infective meningitis is usually due to micro-organisms introduced into the meninges at the time of surgery. The range of potential pathogens is wide, with staphylococci, enteric bacteria (e.g. *E. coli*) and respiratory bacteria (e.g. *Haemophilus* species) each accounting for around one-third of cases. Broad-spectrum empiric therapy, usually with a carbapenem antibiotic, is indicated; vancomycin should be added if the patient is at risk of infection with MRSA

Table 39.4 Antimicrobial regimens for treatment of shunt meningitis

Type of infection	First-choice antibiotic regimen	Other antibiotic regimens	Duration of therapy before reshunting
Internal shunt infection caused by Gram-positive bacteria	Intraventricular vancomycin + intravenous or oral rifampicin	Substitute flucloxacillin or intravenous vancomycin for rifampicin in cases of rifampicin resistance, except in the case of enterococci, where an aminoglycoside (e.g. gentamicin) should be used	7–10 days intravenous
External shunt infection caused by <i>Staphylococcus aureus</i>	As mentioned in the section, 'Shunt-associated meningitis', with the addition of intravenous flucloxacillin	Substitute intravenous vancomycin for flucloxacillin in the case of meticillin resistance (meticillin-resistant <i>S. aureus</i>)	12–14 days
<i>Enterobacteriaceae</i>	Intravenous cefotaxime ± an aminoglycoside + intraventricular aminoglycoside	Substitute ceftazidime or meropenem for cefotaxime in the case of cefotaxime resistance	14 days
Polymicrobial ventriculoperitoneal shunt infections	Intravenous amoxicillin, metronidazole, cefotaxime ± intravenous and/or intraventricular aminoglycoside	Seek specialist advice	14 days
<i>Candida</i>	Intravenous amphotericin B + flucytosine	Intravenous fluconazole or voriconazole ± flucytosine	10–14 days (antifungal fungal therapy should continue for 1 week after reshunting)

(Alnimr, 2012). Antibiotic therapy should be reviewed once culture results are available, to determine whether treatment can be discontinued (if a diagnosis of aseptic meningitis is established) or de-escalated.

Shunt-associated meningitis. Patients who have a ventricular shunt are at increased risk of meningitis. Shunt-associated infections are classified according to the site of initial infection. Internal infections, where the lumen of the shunt is colonised, constitute the majority of cases. External shunt infections involve the tissues surrounding the shunt. Most internal shunt infections are caused by coagulase-negative staphylococci. *S. aureus* and *Enterobacteriaceae* account for most external infections. It is generally held that management of shunt infections should include shunt removal, as well as systemic therapy with or without intraventricular antibiotics (Wells and Allen, 2013). Although the need for shunt removal has been questioned (Arnell et al., 2007), there is also evidence that shunts that are not removed are associated with subsequent shunt revisions because of complications from the infection. Appropriate antimicrobial regimens are listed in Table 39.4.

Tuberculous meningitis. The outcome in tuberculous meningitis relates directly to the severity of the patient's clinical condition on commencement of therapy. A satisfactory response demands a high degree of clinical suspicion such that appropriate chemotherapy is initiated early, even if tubercle bacilli are not demonstrated on initial microscopy. Most currently used antituberculous agents achieve effective concentrations in the CSF in tuberculous meningitis. Detailed discussion of antituberculous therapy is given in Chapter 41. Adjunctive steroid therapy is of value in patients with more severe disease, for example, in the presence of increased intracranial pressure,

altered consciousness, focal neurological findings, spinal block and tuberculous encephalopathy. However, routine use of steroids is not recommended. They may suppress informative changes in the CSF and interfere with antibiotic penetration by restoring the blood–brain barrier. Early neurosurgical management of hydrocephalus by means of a ventriculoperitoneal or ventriculoatrial shunt is also important in improving the prospects for neurological recovery.

Cryptococcal meningitis. The standard treatment of cryptococcal meningitis is amphotericin B. Traditionally, amphotericin B deoxycholate has been the preferred formulation given intravenously at a dose of 0.7–1.0 mg/kg per day. However, there is growing evidence that lipid formulations of amphotericin B are as effective, with less nephrotoxicity; AmBisome at a dosage of 4 mg/kg per day or Abelcet at a dosage of 5 mg/kg per day are suitable alternatives to amphotericin B deoxycholate (Nelson et al., 2011). Amphotericin B formulations should be combined with flucytosine 100 mg/kg per day in four divided doses. Addition of flucytosine results in quicker clearance of yeasts from the CSF and may be associated with an improved clinical outcome. Therapy with amphotericin B and flucytosine is normally continued for 6–10 weeks. As an alternative to prolonged therapy with two potentially toxic drugs, 2 weeks of therapy with amphotericin B and flucytosine may be given, followed by consolidation therapy with fluconazole 400 mg/day for at least 10 weeks. Initial treatment with fluconazole 400–800 mg/day plus flucytosine is clinically inferior to amphotericin B-based regimens, and in any case is no better tolerated than amphotericin B-based regimens. Regular haematological and biochemical monitoring is recommended during treatment, along with measurement of serum concentrations of flucytosine (which should not exceed 80 mg/L).

The clinical response to treatment of cryptococcal meningitis is slow, and it often takes 2 or 3 weeks to sterilise the CSF. Monitoring of intracranial pressure is essential, with large-volume CSF drainage indicated if the opening pressure reaches 250 mmHg. Serial CSF cultures are occasionally helpful in following the response to treatment, but monitoring of cryptococcal antigen titres in serum or CSF is of little value.

Patients with HIV infection who are treated for cryptococcal meningitis should then receive fluconazole indefinitely, or at least until immune reconstitution occurs. The dosage of fluconazole may be reduced to 200 mg/day, depending on the patient's clinical condition (Bicanic and Harrison, 2004). Itraconazole offers less good CSF penetration than fluconazole and is clinically inferior. However, it is sometimes used as maintenance therapy at a dosage of 200–400 mg/day for patients who are unable to tolerate fluconazole. Clinical data with newer triazoles, such as voriconazole and posaconazole, remain limited, but these agents may be useful, especially in the rare situation of fluconazole-resistant cryptococcal meningitis. The echinocandin class of antifungals does not possess useful activity against *Cryptococcus*.

Viral meningitis. None of the currently available antiviral agents has useful activity against human enteroviruses, the commonest causes of viral meningitis (Big et al., 2009). Fortunately, however, the condition is usually self-limiting. The viruses that commonly cause this condition, herpes simplex and varicella zoster meningoencephalitis, are treated with high-dose aciclovir 10 mg/kg three times daily for at least 10 days (adults and children aged ≥ 12 years). For younger children, the recommended dosages are 20 mg/kg three times daily for infants up to age 3 months and 500 mg/m² three times daily for those aged 3 months to 12 years.

Steroids as adjunctive therapy in bacterial meningitis. In pharmacological doses, corticosteroids, and in particular dexamethasone, regulate many components of the inflammatory response and also lower CSF hydrostatic pressure. However, by reducing inflammation and restoring the blood–brain barrier, they may reduce CSF penetration of antibiotics. The benefits of steroids in the initial management of meningitis caused by *M. tuberculosis* and Hib are well established, although in other forms of bacterial meningitis the evidence has been less compelling. However, a 2015 Cochrane review of corticosteroid use for acute bacterial meningitis concluded that corticosteroids significantly reduced hearing loss and neurological sequelae without serious adverse effects, although they did not reduce overall mortality (Brouwer et al., 2015). The use of adjunctive intravenous dexamethasone is now recommended for children and adults with community-acquired bacterial meningitis, regardless of bacterial aetiology. Adjunctive therapy should ideally be initiated within 4 hours of the first dose of antibiotic; do not start dexamethasone more than 12 hours after starting antibiotics (National Institute for Health and Care Excellence, 2015). The recommended dosage for adults is 10 mg intravenously four times daily for 4 days (for children 0.15 mg/kg four times daily for 4 days).

Intrathecal and intraventricular administration of antibiotics. Intrathecal administration, that is, administration into the lumbar subarachnoid space, of antibiotics was once widely used to supplement levels attained by concomitant systemic therapy. However, there is little evidence for the efficacy of this route of delivery, and it is now rarely used. In particular, it produces only

Table 39.5 Daily doses (mg) of gentamicin and vancomycin for intraventricular administration

Antibiotic	Adult	Child ≥ 2 years old	Child < 2 years old
Gentamicin	1.0 ^b	1.0	1.0
Vancomycin	15–20	10 ^c	10 ^c

^aIf cerebrospinal fluid is not draining freely, reduce dose frequency to once every 2–3 days.
^bDose can be increased to up to 5 mg in the most severe cases.
^cReduce dose to 5 mg if ventricular size is reduced, or increase to 15–20 mg/day if ventricular size is increased.

low concentrations of antibiotic in the ventricles and, therefore, does little to prevent ventriculitis, one of the most serious complications of meningitis. Direct intraventricular administration of antibiotics in meningitis is important in certain types of meningitis, especially where it is necessary to use an agent (e.g. vancomycin or an aminoglycoside) that penetrates CSF poorly (Shah et al., 2004). The most common situation is in shunt-associated meningitis, where multiple antibiotic-resistant coagulase-negative staphylococci are the major pathogens, and where conveniently the patient will often have an external ventricular drain through which antibiotics can be administered.

There are considerable differences in recommended doses of antibiotics for intrathecal or intraventricular administration. A dose of 15–20 mg vancomycin per day is recommended for treatment of shunt-associated meningitis in adults with an extraventricular drain and 10 mg/day for neonates and children. The paediatric dose may need to be reduced to 5 mg/day if ventricular size is reduced, or increased to 15–20 mg/day if the ventricular size is increased. In all patients, the dose frequency should be decreased to once every 2–3 days if CSF is not draining freely. The CSF vancomycin concentration should be measured after 3–4 days, aiming for a trough concentration less than 10 mg/L. Recommended doses of antibiotics are otherwise largely based on anecdotal experience (Table 39.5).

Patient care

Common problems in the treatment of meningitis are set out in Table 39.6.

Prevention of person-to-person transmission

Patients with meningitis may be infectious to others. Neonates with meningitis usually have generalised infections, and the causative organisms can often be isolated from body fluids and faeces. Babies with meningitis should therefore be isolated to prevent infection spreading to other patients. Patients with meningococcal or Hib meningitis should be isolated until after at least 48 hours of antibiotic therapy. Contacts of these patients may be asymptomatic carriers and potentially infectious to others and/or at risk of development of invasive infection themselves. Chemoprophylaxis and vaccination can reduce these risks. Patients with most other types of meningitis do not represent a

Table 39.6 Practice points in infective meningitis

Infection	Antibiotic	Common problems	Resolution
Bacterial meningitis	Chloramphenicol	Risk of serious toxicity, especially in neonates	Avoid use if possible Close monitoring of serum levels where use essential
Neonatal meningitis	Aminoglycosides (e.g. gentamicin)	Poor CSF penetration provides unreliable activity for Gram-negative bacterial meningitis Unpredictable neonatal pharmacokinetics (especially preterm neonates)	Substitute with, or add, an antibiotic with better CSF penetration (e.g. a cephalosporin) Close monitoring of serum levels
<i>Streptococcus pneumoniae</i> meningitis	Penicillin Cefotaxime or ceftriaxone Vancomycin (intravenous)	Resistance is increasing Treatment failure in meningitis due to penicillin-resistant strains Unreliable CSF penetration	Use cefotaxime or ceftriaxone ± vancomycin as empiric therapy Add rifampicin or vancomycin Consider one of the newer antibiotics with good activity against multidrug-resistant Gram-positive bacteria
<i>Listeria monocytogenes</i> meningitis	Any	Relapse rate up to 10% after short courses of therapy	Give prolonged therapy (usually 3–4 weeks)
Cryptococcal meningitis	Amphotericin B Flucytosine Fluconazole	High incidence of side effects, e.g. fever, nausea, vomiting, anaemia, hypokalaemia, impaired renal function Risk of side effects, e.g. deranged liver function, bone marrow depression Low cure rate when used as monotherapy (except as consolidation therapy)	Change to lipid-based preparation of amphotericin B, or replace with fluconazole Close monitoring of serum levels Combine with flucytosine

CSF, Cerebrospinal fluid.

significant infectious hazard, and enhanced infection control precautions are not usually necessary.

Case studies

Case 39.1

A 3-week-old preterm infant was born at 25 weeks gestation and is being cared for on the hospital neonatal intensive care unit. He becomes unwell, with poor feeding, fever and increasing drowsiness. Sepsis, with possible meningitis, is diagnosed, and the baby is commenced empirically on amoxicillin and cefotaxime. A lumbar puncture reveals 1200 white blood cells/microlitre (80% of which are polymorphs) and low glucose and elevated protein levels, but no organisms are seen on a Gram-stained smear of the CSF.

On the following day the microbiology laboratory telephones the unit to tell them that Gram-negative bacilli have been grown from blood cultures and the CSF culture; the baby has not improved clinically.

Questions

1. What are the most likely aetiological agents in a 3-week-old baby with acute purulent meningitis?
2. Why might the baby's condition not have improved 24 hours after commencing antibiotic therapy?
3. Would you change the baby's antibiotic therapy once it was known that the baby had Gram-negative sepsis and meningitis?

Answers

1. At 3 weeks of age, the possible causes of meningitis include neonatal pathogens (group B streptococci, *E. coli* and *L. monocytogenes*), nosocomial pathogens such as *S. aureus* and Gram-negative bacilli, and even occasionally the usual causes of meningitis in older infants (especially *N. meningitidis* and *S. pneumoniae*). Most group B streptococcal disease presents in the first few days of life, whilst listeria meningitis is very uncommon, meaning that of the neonatal pathogens there is a greater likelihood of Gram-negative bacillary meningitis. Indeed on the second day it was confirmed that the baby did have Gram-negative bacillary meningitis.
2. Gram-negative sepsis is a serious condition, and it may take longer than 24 hours for a baby to begin to recover. However, it is important to consider the possibility of infection with multidrug-resistant Gram-negative bacteria (MDRGNB). Bacteria such as *E. coli*, *Klebsiella*, *Enterobacter* or *Serratia* may produce β -lactamases that destroy cephalosporins. *P. aeruginosa* is another Gram-negative bacterium that is always resistant to cefotaxime.
3. If the baby's condition is stable, it might be reasonable to observe him closely and defer any review of antibiotic treatment until more microbiology results are available. However, many prescribers would change antibiotic therapy to a carbapenem at this stage; this would be mandatory if either the baby's condition had deteriorated, or if the baby was known to be colonised with an MDRGNB.

Case 39.2

Mr HP, a 70-year-old man, is being treated for meningitis caused by *S. pneumoniae* that is moderately resistant to penicillin (MIC

value 1.0 mg/L). Despite 7 days of treatment with intravenous vancomycin and cefotaxime, there has been little improvement in his clinical condition. A CT scan has shown meningeal inflammation consistent with meningitis, but no evidence of intracranial complications that might explain his poor clinical response. The most recent trough (pre-dose) serum vancomycin concentration was 5.3 mg/L.

Questions

1. Why might there have been an inadequate response to treatment with cefotaxime and vancomycin?
2. What options are there to modify Mr HP's antimicrobial therapy?

Answers

1. Cefotaxime alone may not adequately treat meningitis caused by penicillin-resistant pneumococci. CSF penetration of vancomycin is poor; the serum vancomycin concentration in this case is low, meaning that there is little prospect of drug concentration in the CSF being effective. Even if the vancomycin concentration in CSF were adequate, the infection may be due to a vancomycin-tolerant strain of *S. pneumoniae*. Tolerant strains appear fully sensitive to vancomycin by routine laboratory antimicrobial susceptibility sensitivity testing.
2. It is important to optimise Mr HP's treatment as quickly as possible. He might respond to increasing the dose of vancomycin with or without addition of rifampicin. However, these strategies give little assurance of success. It would probably be preferable to switch to an alternative agent. Meropenem would not be a good choice, and certainly not as monotherapy, because there has already been an inadequate response to another β -lactam antibiotic. Linezolid or a quinolone with good activity against Gram-positive bacteria (e.g. moxifloxacin) would be the most appropriate drugs.

Case 39.3

Mr KT, an 18-year-old man, is referred as an emergency with suspected meningitis. He was given intravenous penicillin by the primary care doctor before admission to hospital. On examination he is fully conscious, and neck stiffness is elicited. He is haemodynamically stable, and no rash is present.

Questions

1. What investigations would you undertake to establish the diagnosis?
2. What treatment would you give Mr KT?
3. What further action will be required if a diagnosis of meningococcal meningitis is either confirmed or considered likely?

Answers

1. Blood cultures and a nasopharyngeal swab for culture should be collected. There are no clinical contraindications to lumbar puncture, and in most centres this would be undertaken without a prior CT scan. The white cell count and glucose and protein concentrations in the CSF should be measured. A Gram stain should be undertaken, which may give immediate information on the likely identity of the pathogen, as well as culture. Blood and CSF should be tested for *N. meningitidis* and *S. pneumoniae* by PCR. In the

UK these tests are provided by national reference laboratories. In addition, some laboratories may undertake multiplex PCR testing or antigen testing locally to try to establish an early aetiological diagnosis.

2. Antibiotic treatment should be with a third-generation cephalosporin (cefotaxime or ceftriaxone). The latter should be entirely safe to use in this situation given that it sounds unlikely that the patient will have required resuscitation with calcium-containing fluids. There is no clinical indication to add amoxicillin. In addition, adjunctive therapy with dexamethasone (IV 10 mg four times a day for 4 days), for which there appear to be no contraindications, should be considered.
3. Meningitis is a notifiable disease. If a diagnosis of meningococcal meningitis is considered likely, then chemoprophylaxis should be offered to the patient and to close contacts as soon as possible (preferably within 24 hours) to eliminate nasopharyngeal carriage and prevent secondary cases. If a diagnosis of meningococcal disease is confirmed, immunisation may also be indicated for the contacts, depending on the strain's serogroup.

Case 39.4

Mrs GT, an 88-year-old woman who lives on her own, presents with a 3-day history of fever, headache and vomiting, and a 1-day history of altered consciousness. She was taking seven different drugs, including furosemide for heart failure. On examination she was ill-looking and had altered consciousness (Glasgow Coma Scale score 9/15). She was febrile (39.2 °C) and had marked neck stiffness. The remainder of the physical examination was unremarkable.

A brain CT scan demonstrated no parenchymal abnormality. For further assessment, a lumbar puncture was then performed. CSF analysis showed leucocytosis (90% polymorphs), high protein concentration and low glucose level with a decreased CSF/serum glucose ratio. No organisms were seen on Gram or acid-fast stains.

Questions

1. What are the likely causes of Mrs GT's meningitis?
2. What antimicrobial treatment would you prescribe?
3. If after 24 hours Gram-positive bacteria were isolated from the CSF, how would this change your management?

Answers

1. The CSF findings (polymorph leucocytosis, low glucose) are strongly suggestive of bacterial meningitis. Increasing life expectancy means we are likely to see more cases like this. As well as possibly being due to one of the usual causes of bacterial meningitis, the elderly are at greater risk of listeria meningitis. Tuberculous meningitis is unlikely because the history of illness is relatively brief.
2. Empiric treatment with amoxicillin or ampicillin together with a third-generation cephalosporin (e.g. cefotaxime) would be appropriate.
3. Isolation of Gram-positive bacilli is consistent with listeria meningitis. The treatment of listeria meningitis is with high-dose amoxicillin or ampicillin, combined with an aminoglycoside (e.g. gentamicin). In this patient the dose of amoxicillin or ampicillin will need to be based on an assessment of her renal function. The decision to add an aminoglycoside will need to consider the risks for toxicity in an elderly patient who is receiving furosemide, as well as the clinical condition of the patient. Because cephalosporins are high-risk antibiotics for *Clostridium difficile*, this treatment should be discontinued.

40 Surgical Site Infection and Antimicrobial Prophylaxis

Philip Howard and Jonathan Sandoe

Key points

- Surgical site infection is a major cause of mortality and morbidity.
- Development of surgical site infection is a complex process influenced by host, operative and microbial factors.
- The microbial cause of surgical site infection varies with type of procedure, but Enterobacteriaceae (coliforms) have replaced *Staphylococcus aureus* as the predominant organism grown from surgical site infections for many procedures.
- Surveillance of surgical site infection is necessary to benchmark and improve prevention strategies.
- Antimicrobial prophylaxis is just one of many approaches to reduce surgical site infection.
- Not all operations require antimicrobial prophylaxis.
- Antimicrobial prophylaxis should be used only where there is evidence of efficacy or expert consensus that benefits outweigh risks.
- The choice of antimicrobial prophylaxis depends on the operation, pharmacokinetics, pharmacodynamics and patient factors.
- The timing of antimicrobial administration is key to reducing surgical site infection.
- Pharmacists are unlikely to see many patients before surgery; they must therefore develop systems to ensure that appropriate antimicrobial prophylaxis is given at the right time.

Surgery is the branch of medical science that treats injury or disease, or improves bodily function through operative procedures. Surgery has been used for thousands of years but has always been complicated to some extent by infection. Currently, surgery is an integral part of the management of many medical conditions and remains the definitive treatment for many cancers. Infections developing at the site of invasive surgical procedures are frequently referred to as surgical site infections. Surgical site infections occur when pathogenic microorganisms contaminate a surgical wound, multiply and cause tissue damage. The term ‘surgical site infection’ encompasses not only infection at the site of incision, but also infections of implants, prosthetic devices and adjacent tissues involved in the operation.

Epidemiology

In England, more than 11 million operations and interventions are undertaken each year. More than 50% of these are performed as day cases, and many patients are admitted on the day of surgery (Health and Social Care Information Centre, 2016).

Healthcare-associated infections (HCAIs), including surgical site infections, complicate around 6% of all hospital admissions (Health Protection Agency, 2012). Surgical site infections are of major clinical importance because they account for 14–16% of all HCAIs (Health Protection Agency, 2012; Health Protection Scotland, 2015; Public Accounts Committee, 2009) and are associated with considerable morbidity and mortality. One-third of peri-operative deaths are related to surgical site infections (Astagneau et al., 2001). It has been estimated that surgical site infections double the length of hospital stay (Coello et al., 2005). Although surgical site infections can be common in some procedures, the incidence can be minimised by the care provided before and after the operation, together with the skill of the surgeon (Health Protection Scotland, 2015).

Surveillance

Monitoring the incidence of surgical site infections is hampered by the lack of agreed measuring systems. In particular, to monitor the rates of surgical site infection within an organisation, or to benchmark between organisations, there needs to be a standard approach to diagnosis. Criteria for such a definition have been developed by the Centers for Disease Control and Prevention (Mangram et al., 1999), and these are presented in Table 40.1. More detailed surgical site infection scoring systems have been developed, but these are time consuming to use.

Mandatory surveillance for surgical site infections in orthopaedic surgery in the UK was introduced in 2004. In addition, Scotland and Wales monitor caesarian section surgical site infections (<http://www.hps.scot.nhs.uk> and <http://www.wales.nhs.uk>). England has a voluntary reporting system for a broader range of operations (<https://www.gov.uk/guidance/surgical-site-infection-surveillance-service-ssiss>). All report their findings annually. Many surgical site infections, especially those involving prosthetic joints, often develop late (>28 days post-operation), so post-discharge surveillance schemes are essential. Patients need to be aware how a surgical site infection may present after discharge from hospital. Surveillance of surgical site infections and feedback to the surgical team has been shown to reduce rates of infection (Gastmeier et al., 2005).

Table 40.1 Criteria for defining surgical site infection (Mangram et al., 1999)

Type	Level	Signs and symptoms
Superficial incisional	Skin and subcutaneous tissue	Localised (Celsian) signs such as redness, pain, heat or swelling at the site of the incision or by the presence of pus within 30 days
Deep incisional	Fascial and muscle layers	Presence of pus or an abscess, fever with tenderness of the wound, or a separation of the edges of the incision exposing the deeper tissues within 30 days (or 1 year if an implant is used)
Organ or space infection	Any part of the anatomy other than the incision that is opened or manipulated during the surgical procedure, e.g. joint or peritoneum	Loss of function of a joint, abscess in an organ, localised peritonitis or collection; ultrasound or computed tomography scans confirm infection; within 30 days of surgery if no implant is used or within 1 year of surgery if an implant is used.

Fig. 40.1 Schematic representation of the anatomical classification of surgical site infection (Horan et al., 1993). (Reproduced with permission from the University of Chicago Press.)

Risk factors

Surgical site infections can be categorised into three groups: superficial incisional, deep incisional and organ or space (Fig. 40.1). Whether a wound infection occurs after surgery depends on a complex interaction among the following:

- procedure-related factors, for example, implantation of foreign bodies, degree of trauma to host tissues and experience of surgeon;
- patient-related factors, for example, host immunity, nutritional status and the presence or absence of diabetes;
- microbial factors (tissue adherence and invasion);
- peri-operative antimicrobial prophylaxis.

A system to stratify operative wounds by the expected level of bacterial contamination (Table 40.2) was developed to help predict likely infection rates (Mangram et al., 1999). A number of other factors have also been found to affect the incidence of surgical site infection and are discussed later.

Prosthetic implants

Medical implants have a detrimental effect on host defences such that a lower bacterial count is needed to initiate infection. Hence there is a greater risk of infection during implant surgery. Bacteria growing on an abiotic surface, such as a prosthetic hip implant or heart valve, together with a protective layer of microbial polymers are known as a biofilm (Donlan and Costerton, 2002). Antimicrobials are frequently ineffective against microorganisms growing in biofilms, making treatment of implant infections problematic and their prevention even more important.

Duration of surgery

The longer the operation, the greater the risk of wound infection. This, in turn, may be influenced by the experience (Fig. 40.2), speed and skill of the surgeon, and is additional to the classification of the operation by risk of infection, for example, clean, contaminated, dirty or infected.

Patient-related factors

A number of patient-related factors are known to influence the likelihood of developing a surgical site infection and include the following:

- wound potential for infection, for example, clean, contaminated, dirty or infected site,
- physical status of patient (Table 40.3),
- duration of procedure.

For each surgical procedure, a score of 0–3 is allocated to represent the number of risk factors present. Patients with a score of 0 are at the lowest risk of development of a surgical site infection, whereas those with a score of 3 have the greatest risk (Table 40.4). Use of this risk index allows comparison of similar patient groups in terms of surgical site infection risk over time. The risk index is a significantly better predictor of surgical wound risk than the traditional wound classification system and performs well across a broad range of operative procedures.

Table 40.2 Classification of surgical procedures by risk of infection (Mangram et al., 1999)

Type of procedure	Definition	Wound infection rate (%)	Example	Need for prophylaxis
Clean	Atraumatic; no inflammation encountered, no break in technique; gastro-intestinal, genitourinary and respiratory tracts not entered	1.5–4.2	Inguinal hernia repair	Not usually required
Contaminated	Gastro-intestinal or respiratory tract entered but without spillage; oropharynx, appendectomy, sterile genitourinary or biliary tract entered; minor break in technique	<10	Cholecystectomy (no spillage)	Usually required
Clean-contaminated	Acute inflammation; infected bile or urine; gross spillage from gastro-intestinal tract; major lapse in technique; fresh traumatic wound (12–24 h)	10–20	Appendicectomy	Required
Dirty and infected	Established infection; transection of clean tissues to enable collection of pus; traumatic wound with retained devitalised tissue; faecal contamination; delayed treatment	20–40	Sigmoid colectomy (Hartmann's procedure) for faecal peritonitis	Treatment required (not prophylaxis)

ST = Speciality registrar grade, number represents years of training

Fig. 40.2 Surgical site infection (SSI) rate by grade of operator for orthopaedic surgery in 2008 (Health Protection Scotland, 2009). (Reproduced with kind permission from Health Protection Scotland.)

Other factors

There are a number of other risk factors that may increase the risk of a surgical site infection (Table 40.5) for an individual patient, but the impact has not been quantified to the same extent as the risk factors discussed earlier. Some are modifiable; others such as age are not.

Table 40.3 American Society of Anesthesiology classification of physical status (Mangram et al., 1999)

American Society of Anesthesiology score	Physical status
1	A normal, healthy patient
2	A patient with mild systemic disease
3	A patient with a severe systemic disease that limits activity but is not incapacitating
4	A patient with an incapacitating systemic disease that is a constant threat to life
5	A moribund patient who is not expected to survive 24 h with or without operation

Table 40.4 Risk index based on presence of co-morbidity and duration of operation (Culver et al., 1991)

Risk index	Infection rate (%)
0	1.5
1	2.9
2	6.8
3	13.0

Table 40.5 Patient and operative risk factors for surgical site infection

Patient risk factors	Operative risk factors
Advanced age	Tissue ischaemia
Malnutrition	Lack of haemostasis
Obesity	Tissue damage, e.g. crushing by surgical instruments
Concurrent infection	Presence of necrotic tissue
Diabetes mellitus	Presence of foreign bodies including surgical materials
Liver impairment	
Renal impairment	
Immune deficiency states	
Prolonged preoperative stay	
Blood transfusion	
Smoking	

Smoking

Smoking increases the risk of development of a wound infection (Myles et al., 2002). The mechanism is not known, but tobacco use may delay wound healing via the vasoconstricting effects of nicotine, and thus increase the risk of infection (Myles et al., 2002). Smoking cessation for 30 days prior to surgery is recommended because it decreases post-operative morbidity and mortality (Sharma et al., 2013).

Diabetes mellitus

Long-term diabetes does not appear to have any impact on the risk of development of a surgical site infection. However, peri-operative fluctuations in blood glucose for up to 48 hours have been shown to double the infection risk in cardiac patients (Latham et al., 2001).

Age

Increasing age is associated with an increased risk of surgical site infection. However, there is debate whether age serves simply as a marker for underlying disease or whether the decline in immune function with age is the significant factor. A study of 72,000 patients in the USA, which adjusted for hospital type, procedure, duration, wound class and physical status of the patient, showed a 1.1% increase in surgical site infection per year of age from the age of 18–65 years, but a 1.2% decrease in individuals older than 65 years (Kaye et al., 2005). In contrast, the findings of the English surgical site infection surveillance scheme (Fig. 40.3) indicated that the chance of acquiring a surgical site infection was 37% higher for a 65-year-old person compared with a 45-year-old person (Health Protection Agency, 2008).

Pathogenesis

Most surgery involves an incision through one of the body's protective barriers, typically the skin or other epithelial surface

Fig. 40.3 Relative risk of surgical site infection (SSI) by age group, 2003–2007, adjusted for surgical category (reference age group is <45 years) (Health Protection Agency, 2008). (Reproduced with kind permission from Health Protection Agency.)

such as the conjunctiva or tympanic membrane. When intact, these provide an excellent barrier to entry of both exogenous and endogenous bacteria. Other epithelial surfaces including the mucosal surfaces of the gastro-intestinal and genitourinary tracts, when intact, prevent entry of the luminal contents into the surrounding tissues and organs.

Any surgical operation will breach at least one of the surfaces mentioned and allow entry of bacteria. Whether an infection follows, depends on the ability of other defences to kill the invading bacteria. Important host mechanisms include antibodies, complement and phagocytes.

Development of a surgical site infection depends on survival of the contaminating microorganism in a wound site at the end of a surgical procedure, the pathogenicity and number of these microorganisms, and the host's immune response. Most microorganisms are from the host (endogenous), but they are occasionally introduced via surgical instruments, the environment or contaminated implants (exogenous). The likely invading microorganism varies according to the type of surgery (Table 40.6). Data for England from 2004 to 2016 show that Enterobacteriaceae (coliforms) have replaced *Staphylococcus aureus* as the predominant organism grown from surgical site infections for many procedure types (Public Health England, 2016). They accounted for 28% of all surgical site infections and were the prominent cause of surgical site infections in two categories: large-bowel surgery (53%) and coronary artery bypass graft (26%). *S. aureus* has steadily decreased to 13% from 39% in 2006/2007 (Fig. 40.4), primarily because of a reduction in methicillin-resistant *S. aureus* (MRSA) strains. The proportion of MRSA reduced from 25% to 4% of all *S. aureus* cases. Infection control measures including the introduction of mandatory MRSA screening for elective patients in 2009 may have contributed to this because known or previous MRSA carriers can be 'decolonised'.

The proportion of surgical site infections caused by *S. aureus* was highest in open reduction of long-bone fracture (44%), followed by knee prosthesis (42%), then hip hemiarthroplasty (34%) (Public Health England, 2016).

Table 40.6 Likely pathogens in post-operative wound infections

Category of surgery	Most likely pathogen(s)
Clean	
Cardiac/vascular/orthopaedic	Coagulase-negative staphylococci, <i>Staphylococcus aureus</i> , Gram-negative bacilli
Breast	<i>S. aureus</i>
Clean-contaminated	
Burns	<i>S. aureus</i> , <i>Pseudomonas aeruginosa</i>
Head and neck	<i>S. aureus</i> , <i>Streptococcus</i> spp., anaerobes (from oral cavity)
Gastro-intestinal tract	Coliforms, anaerobes (<i>Bacteroides fragilis</i>)
Urogenital tract	Coliforms, <i>Enterococcus</i> spp.
Dirty	
Ruptured viscera	Coliforms, anaerobes (<i>B. fragilis</i>)
Traumatic wound	<i>S. aureus</i> , <i>Streptococcus pyogenes</i> , <i>Clostridium</i> spp.

Prevention of surgical site infection

The evidence that supports interventions to minimise surgical site infection has been highlighted in national guidelines (National Institute for Health and Care Excellence [NICE], 2017) and categorised into four areas: information to patients, preoperative phase, peri-operative phase and post-operative phase (Table 40.7). When selecting antimicrobial prophylaxis regimens or evaluating potential prophylaxis failures, it is important to ensure that all four aspects of prevention have been addressed.

Antimicrobial prophylaxis

In the early 1960s, it was demonstrated, using a guinea-pig model, that surgical-wound infection could be reduced by administration of an antimicrobial just before an incision was made, but the beneficial effect disappeared if antimicrobial administration was delayed by 3–4 hours after the incision (Burke, 1961). Since then, many clinical trials have indicated the benefit of maintaining adequate antimicrobial tissue levels from the time of initial surgical incision until closure.

There are potential adverse consequences to the administration of antimicrobials for both the individual and the population. For the individual, side effects range from antimicrobial-associated diarrhoea or thrush to life-threatening allergic reactions. From the population perspective, the development of antimicrobial

resistant bacteria is a concern. Antimicrobial prophylaxis should, therefore, only be offered to patients when there is evidence or, in the absence of evidence, expert consensus that the potential benefits of prophylaxis outweigh the risks.

The numbers of patients who need to be treated with antimicrobial agents to prevent one infection in the different types of surgery are presented in Table 40.8.

The infection risk associated with a particular surgical procedure and evidence of efficacy should be used to determine whether antimicrobial prophylaxis is to be administered. Not all surgical procedures warrant antimicrobial prophylaxis.

Choice of antimicrobial

Once it has been determined that antimicrobial prophylaxis is required, the next step is to select an appropriate agent(s). The choice of antimicrobial should take into account the following:

- likely infecting organisms (procedure specific);
- local susceptibility of potential pathogens to antimicrobials;
- pharmacokinetics, for example, penetration of antimicrobial to the site(s) in question;
- patient allergy to penicillins or other antimicrobials;
- administration time (bolus better than infusion);
- drug cost;
- carriage of resistant organisms, for example, MRSA;
- prevalence of *Clostridium difficile* infection in hospital.

The majority of clinical trials that have demonstrated the benefit of antimicrobial prophylaxis are outdated and probably do not reflect current surgical practice. First- and second-generation cephalosporins (cefazolin and cefuroxime) have been the mainstay of agents studied (Bratzler et al., 2013). There are advantages and disadvantages with using cephalosporins. The advantages include a low anaphylaxis risk, but they have the disadvantage of excessive or inadequate spectrum of cover depending on the operation (Morgan, 2006) and a strong association with *C. difficile* infection. Many antimicrobials used in prophylaxis have not been extensively studied in clinical trials but are selected on a theoretical basis of their antimicrobial spectrum (Tables 40.9–40.11).

Timing and duration

The timing of antimicrobial administration is one of the most important aspects of prophylaxis delivery. Animal studies, and latterly clinical observational studies, have shown that prophylaxis is most effective when given immediately before an operation (within 30 minutes of induction of anaesthesia), so that antimicrobial activity is present for the duration of the operation and for about 4 hours afterwards. Antimicrobials given too early prior to surgery are associated with prophylaxis failure, presumably because serum and tissue levels are not sustained during the surgical procedure. Similarly, for each hour antimicrobial administration was delayed after the start of the operation there was an increased rate of wound infection (Classen et al., 1992). This suggests bacterial replication, once commenced, cannot be eliminated by antimicrobial regimens designed for prophylaxis. The microbiological basis for these observations is likely to be that bacterial reproduction at a logarithmic rate follows a lag phase of relatively little increase in bacterial population. The

Fig. 40.4 Surgical site infection (SSI) isolated organisms 2004–16 (Public Health England, 2016). CoNS, Coagulase negative *Staphylococcus*; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin sensitive *S. aureus*. (Reproduced with permission from Public Health England.)

Table 40.7 Recommendations for the prevention and treatment of surgical site infections (NICE, 2017)

Category	Recommendation
Information for patients and carers	How to recognise a surgical site infection and what to do
Preoperative phase	Patient preparation: preoperative washing, hair removal, nasal methicillin-resistant <i>S. aureus</i> decontamination and bowel preparation Antimicrobial prophylaxis guidance Staff preparation and theatre movement
Intra-operative phase	Operating team preparation Patient skin preparation Maintaining patient homeostasis Wound dressings
Postoperative phase	Dressing and cleansing the wound Antimicrobial treatment for surgical site infection Debridement of surgical site infections

lag phase for wound infection bacteria lasts typically 3–4 hours. If bacteria inoculated into a wound can be killed or inhibited by antimicrobials given early, the immune system can kill the remaining organisms. However, if antimicrobials are given only when the growth curve has entered the logarithmic phase, the chances of successful prophylaxis are reduced.

Formerly, protocols for prophylaxis extended for several post-operative days. Now, single-dose schedules are

increasingly common with greater emphasis on ensuring immediate preoperative administration. Because surgery may be delayed at short notice, sometimes between the time the patient leaves the ward and arrives at the theatre, it is sensible for the responsibility for administration of antimicrobials to be transferred from ward staff to the operating team, allowing prophylaxis to be given around the time of induction of anaesthesia.

National guidelines recommend administration of prophylactic antimicrobials on starting anaesthesia, or earlier if a tourniquet is being used (NICE, 2017). Fig. 40.5 represents the two major studies undertaken to identify the optimum time for administration of prophylaxis. Both studies determined that post-incision administration of antimicrobials significantly increased the risk of surgical site infection (Classen et al., 1992; Steinberg et al., 2009). A large randomised controlled trial of pre-operative prophylaxis in more than 5000 general, vascular and orthopaedic surgical patients has recently found there was no difference in surgical site infection rates between patients given their preoperative antibiotics in the operating theatre (median time before administration 16 minutes) or in the anaesthetic room (median time to administration 42 minutes) (Weber et al., 2017). Historically, the only occasion where antimicrobial administration has been delayed to after the incision is caesarian section, where antimicrobials are given after cross-clamping the umbilical cord to prevent drug delivery to the neonate. However, it is recognised that this does not provide the mother with adequate tissue levels at the time of incision, and several studies have shown that antimicrobials can be given safely before incision without adversely affecting the neonate (Mackeen et al., 2014; Sullivan et al., 2007; Thigpen et al., 2005).

Table 40.8 Example of number needed to treat for antimicrobial prophylaxis (SIGN, 2014)

Type of surgery	Operation	NNT	Outcome
Upper GI surgery	Stomach and duodenal surgery	5	Wound infection
Lower GI surgery	Colorectal surgery	4	Wound infection and intra-abdominal abscesses
Obstetric	Caesarian section	19	Wound infection
Orthopaedic	Arthroplasty (hip replacement)	42	Hip infection

Number needed to treat is the number of patients who need to be treated to prevent one infection compared with receiving no antimicrobials.
GI, Gastro-intestinal.

Table 40.9 Antimicrobial susceptibility of common pathogens

Surgical site infection for a skin wound at any site	
<i>Staphylococcus aureus</i>	Highly variable (30–60% susceptible) to flucloxacillin; therefore, meticillin-resistant <i>S. aureus</i> screening essential
β-Haemolytic streptococci	90% susceptible to penicillins, macrolides or clindamycin
Additional pathogens by site of infection	
Head and neck surgery	
Oral anaerobes	95% susceptible to metronidazole or co-amoxiclav
Operations below the diaphragm	
Anaerobes	95% susceptible to metronidazole or co-amoxiclav
<i>Escherichia coli</i> and other Enterobacteriaceae	80–90% of <i>E. coli</i> sensitive to cefuroxime, co-amoxiclav (or other β-lactam with inhibitor combination) or gentamicin
Insertion of a prosthesis, graft or shunt	
Coagulase-negative <i>Staphylococcus</i> (CNS) <i>S. aureus</i> , diphtheroids	Two-thirds of CNS are meticillin resistant, but β-lactams may still be used but preferably with a second agent with staphylococcal cover, e.g. gentamicin, or a glycopeptide used instead see above for <i>S. aureus</i> .

Table 40.10 Microorganisms commonly isolated from surgical site infections and prophylactic antimicrobials used in common surgical procedures (Prtak and Ridgway, 2009)

Surgical procedure	Most common microorganisms	Examples of prophylactic intravenous antimicrobials
Gastro-intestinal		
Bowel flora		
• Upper gastro-intestinal tract	<i>Staphylococcus aureus</i> , Gram-negative bacilli	Co-amoxiclav or cefuroxime or gentamicin
• Biliary	<i>S. aureus</i> , Gram-negative bacilli (enterococci, anaerobes)	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole
• Colorectal/appendicectomy	<i>S. aureus</i> , Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole

Table 40.10 Microorganisms commonly isolated from surgical site infections and prophylactic antimicrobials used in common surgical procedures (Prtak and Ridgway, 2009)—cont'd

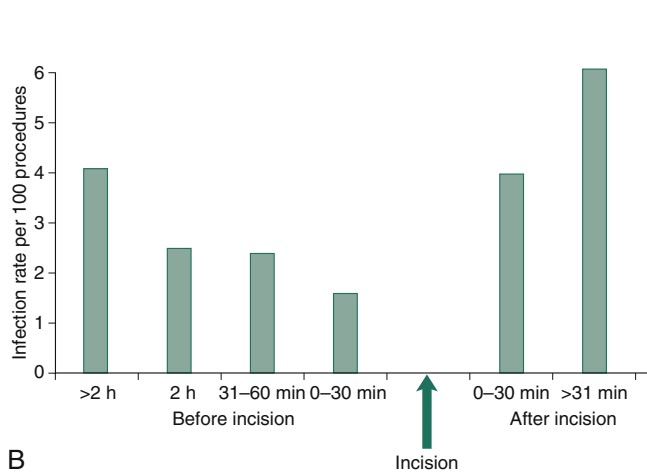

Surgical procedure	Most common microorganisms	Examples of prophylactic intravenous antimicrobials
Urogenital		
• Transrectal biopsy	<i>S. aureus</i> , Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole
• Transurethral resection of prostate	<i>S. aureus</i> , Gram-negative bacilli, enterococci	Co-amoxiclav or cefuroxime or gentamicin
Obstetric/gynaecological		
• Caesarean section	<i>S. aureus</i> , Gram-negative bacilli, streptococci (anaerobes)	Co-amoxiclav or cefuroxime and metronidazole
• Hysterectomy	<i>S. aureus</i> , Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole
Vascular		
• Reconstructive arterial surgery	Skin flora: primarily staphylococci	Co-amoxiclav or cefuroxime
• Amputation	<i>S. aureus</i> , anaerobes if gangrenous	Co-amoxiclav or cefuroxime and metronidazole or vancomycin and metronidazole
Orthopaedic		
• Joint replacement surgery	Skin flora: primarily staphylococci	Co-amoxiclav or cefuroxime or flucloxacillin and gentamicin
If patient has previously had methicillin-resistant <i>S. aureus</i> or is at high risk (e.g. nursing home resident), use teicoplanin or other glycopeptide. For β -lactam allergy, replace co-amoxiclav or cefuroxime with teicoplanin with or without ciprofloxacin.		

Table 40.11 Suggested cephalosporin-free antimicrobial prophylaxis for surgical site infection

Type of surgery	Suggested antimicrobials	Alternatives for penicillin allergy
Cardiothoracic	Flucloxacillin +/- gentamicin	Teicoplanin or co-trimoxazole
ENT, maxillofacial and oral	Amoxicillin + metronidazole or co-amoxiclav	Clarithromycin +/- metronidazole or clindamycin
Gynaecology	Gentamicin + metronidazole	
Lower GI	Gentamicin + metronidazole	
Obstetrics	Co-amoxiclav	Clarithromycin +/- metronidazole or clindamycin
Orthopaedic	Flucloxacillin +/- gentamicin	Teicoplanin or co-trimoxazole
Thoracic	Flucloxacillin or co-amoxiclav	
Upper GI	Gentamicin	
Urology	Gentamicin	
Vascular	Flucloxacillin +/- gentamicin (+metronidazole for amputations)	Co-trimoxazole or teicoplanin
ENT, Ears, nose and throat; GI, gastro-intestinal. Adapted from SIGN (2014).

B

Fig. 40.5 Timing of antimicrobial prophylaxis administration and infection rate. Study A: The timing of prophylactic administration of antibiotics and the risk of surgical wound infection (Classen et al., 1992). Study B: Trial to reduce antimicrobial prophylaxis errors (Steinberg et al., 2009). (Taken from Mandell et al. [2010]. Reproduced with kind permission of Elsevier.)

When a tourniquet is used during orthopaedic procedures to minimise bleeding, the antimicrobial should be infused before inflating the tourniquet. This ensures adequate tissue levels are achieved at the site of surgery (Bratzler et al., 2013).

Certain practical issues should be considered when selecting an antimicrobial, for example, the requirement for intravenous infusion or safe intravenous bolus administration. An antimicrobial, which requires to be administered over a long period, for example, vancomycin 1 g over nearly 2 hours, is much less likely to be given completely compared with teicoplanin, which is administered as a bolus.

To improve the timing of antimicrobial prophylaxis administration, the World Health Organization (WHO) has introduced a question in their surgical safety checklist. The question ‘Has antimicrobial prophylaxis been given within the last 60 minutes?’ is to be asked aloud before incision (WHO, 2009).

Repeat doses

Although single-dose prophylaxis regimens are widely advocated (Department of Health and Health Protection Agency, 2008; NICE, 2017; Scottish Intercollegiate Guideline Network [SIGN], 2014),

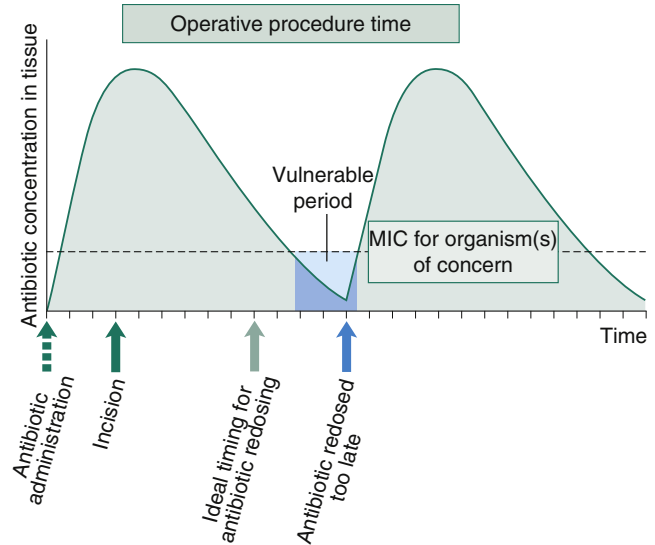

Fig. 40.6 Schematic presentation of tissue antibiotic concentration over time (Mandell et al., 2010). MIC, Minimum inhibitory concentration. (Reproduced with kind permission of Elsevier.)

many surgeons continue to use prolonged courses of ‘prophylaxis’ often for several days, without a clear evidence base. For some procedures, the optimum duration of prophylaxis is not known and 24- to 48-hour prophylaxis is considered acceptable, for example, for open heart surgery (SIGN, 2014).

Where single-dose prophylactic regimens have been adopted, the need for dosage adjustment in patients with reduced ability to excrete the drug (usually because of renal impairment) becomes unnecessary. This is because it is unlikely that single doses will have significant dose-related adverse effects. Although the half-life of many drugs used is relatively short (1–2 hours in normal volunteers), surgical patients often have slower clearance of antimicrobials from the blood. This concept will probably also hold true for prophylactic regimens lasting up to 48 hours.

There are some situations in which it is necessary to prescribe additional doses of antibiotics to achieve the aim of adequate tissue levels at the time of wound closure. The additional doses may be needed when there is significant blood loss (>1500 mL) because plasma is effectively diluted by intra-operative transfusions and fluid replacement. Long operations may also need extra antimicrobial doses during the operation, but additional doses post-operatively do not provide an additional prophylactic benefit.

Antimicrobial administration by hospital theatre staff has practical implications for the route of administration. Ward-based administration of prophylaxis can be given orally if appropriate preparations exist, but this is impractical in sedated or unconscious patients. The oral route tends to suffer from variable absorption, especially in the presence of anaesthetic premedication, and this also makes it unsatisfactory. The intravenous route is the most reliable way of ensuring effective serum levels and is the only route supported by a substantial body of evidence.

A schematic model for the tissue concentration time profile of an antimicrobial agent used to prevent surgical site infection is presented in Fig. 40.6. After an initial dose of the antimicrobial agent, tissue concentrations reach their peak rapidly, with a

Table 40.12 Time for peri-operative re-dosing of antimicrobials

Antimicrobials	Peak serum level (mg/L)	Half-life (h)	Time to redose (h)
Cefuroxime 1.5 g i.v.	100	1–2	4
Ciprofloxacin 400 mg i.v.	4.6	3–7	8
Co-amoxiclav 1.2 g	Unknown	1.4 AM/1.1 CL	2
Co-trimoxazole 960 mg i.v.	9 TMP/105 SMX	11 TMP/9 SMX	12
Flucloxacillin 1 g i.v.	120–350	0.75–1.5	3
Gentamicin	N/A as many doses used	2–3	6 unless >2 mg/kg; then do not redose
Metronidazole 500 mg i.v.	20–25	6–8	8
Vancomycin 1 g i.v.	20–50	4–8	12
Teicoplanin 400 mg i.v.	20	90–157	12

AM, Amoxicillin; CL, clavulanic acid; i.v., intravenous; N/A, not applicable; SMX, sulfamethoxazole; TMP, trimethoprim.
Adapted from [Bratzler et al. \(2013\)](#).

subsequent decline over time. The goal of prophylaxis is for the antimicrobial tissue concentration to remain above the minimum inhibitory concentration for the specific pathogens at the time of incision and throughout the procedure. The antimicrobial should be re-administered during prolonged procedures to prevent a period where tissue concentrations are less than the minimum inhibitory concentration (grey area). Failure to re-administer antimicrobials appropriately may result in a period during which the wound is vulnerable. Recommendations for peri-operative re-dosing schedules are presented in [Table 40.12](#). General guidance is to repeat doses of antimicrobials at intervals of one to two half-lives; however, not all guidance recommends repeat dosing outside of cardiac surgery ([SIGN, 2014](#)).

β-Lactam allergy

Penicillin and cephalosporin antibiotics have been the cornerstone of antimicrobial prophylaxis to prevent surgical site infections. Patients reported to be allergic to β-lactam antibiotics or other antimicrobials need to be carefully assessed, because alternatives may not be optimal. Alternatives are often glycopeptides, for example, teicoplanin or vancomycin, which are more expensive, often need to be given by infusion (vancomycin) and can increase selection for resistant bacteria. The prevalence of true penicillin allergy in the general population is unknown. The incidence rate of self-reported penicillin allergy is approximately 10%, with the frequency of life-threatening anaphylaxis estimated at 0.01–0.05% (or 1–5 in 10,000) ([NICE, 2014](#)). More than 80% of patients with a self-reported allergy to penicillin have no evidence of allergy on skin testing. Important details of an allergic reaction include signs, symptoms, severity, history of prior reaction, time course of allergic event, temporal proximity to administered drug, route of administration, other medication being taken and adverse events to other medication ([Park and Li, 2005](#)). Reactions to penicillins and other β-lactams can occur because of allergy

to the parent compound or its metabolites. The cross-sensitivity between penicillins and cephalosporins is unknown but has been variably reported to be up to 10%. Early cephalosporin preparations were contaminated with penicillins probably leading to an overestimate of cross-sensitivity ([Saxon et al., 1987](#)). As the generation of the cephalosporin increases, the likelihood of cross-sensitivity decreases ([Pichichero and Casey, 2007](#)). Those with a penicillin allergy showed an increased risk of allergic reaction to a first-generation cephalosporin. First-generation cephalosporins share a similar side chain to penicillin and amoxicillin. However, cross-sensitivity to second- and third-generation cephalosporins was lower. The different side chains appear to play a more dominant role than the β-lactam ring in allergy.

Prospective studies have shown that the cross-reactivity to carbapenems and monobactams is very small. It is around 1% for imipenem and meropenem, and no cross-reaction has been reported for penicillins and aztreonam ([Frumin and Gallagher, 2009](#)).

The increased use of penicillins rather than first- or second-generation cephalosporins for surgical site infection prophylaxis is increasing the potential for adverse reactions. In addition, the current nomenclature for penicillin combinations, for example, co-amoxiclav, can often make it more difficult for staff to recognise penicillin-containing antimicrobials. Current guidance on the use of β-lactams in patients with penicillin allergy is detailed in [Table 40.13](#).

Topical or local antimicrobial prophylaxis

Many surgical procedures involving the use of implants or prostheses now use topical antimicrobials to prevent late surgical site infection. Examples include antimicrobial-loaded cement for fixing hip and knee joint replacements into bone. Gentamicin and clindamycin are the only antimicrobials in commercially available products in the UK. Surgeons do add other antimicrobial agents, especially if replacing an infected prosthesis with choice based on prior knowledge of the pathogen and its sensitivity profile.

Table 40.13 Guidance on the use of β -lactam antibiotics in patients with penicillin allergy recommended by British National Formulary (Joint Formulary Committee, 2017)

Allergic reaction	Action
Immediate hypersensitivity reaction to a penicillin	Avoid penicillins and cephalosporins
Minor rash, localised or widespread but delayed (>72 h)	Avoid penicillins, but cephalosporins are safe to use

In vascular surgery, synthetic grafts bonded with or soaked in rifampicin are frequently used, despite evidence showing that there was no decrease in infection rates at 1 month and 2 years (Stewart et al., 2006). There is some evidence to support the local delivery of gentamicin into wounds via collagen fleece impregnated with gentamicin, and further research into this was recommended; however, two recent randomised controlled trials have shown it not to be efficacious (Bennett-Guerrero et al., 2010a, 2010b). The use of topical cefotaxime in contaminated surgery has been shown not to decrease peritonitis and should not be used.

Case studies

Case 40.1

A patient is due to have an elective total hip replacement. As part of the routine, pre-admission screening is done, during which swab samples are taken. The patient is identified as being MRSA-positive. The patient receives a 5-day course of nasal mupirocin and topical chlorhexidine washes as 'decolonisation therapy' prior to the admission. The unit normally uses single-dose co-amoxiclav as prophylaxis.

Question

Should there be a change to the routine antimicrobial prophylaxis for this patient?

Answer

A change to the routine antimicrobial prophylaxis should be recommended because co-amoxiclav is not active against MRSA. The commonly used terms 'decolonisation therapy' and 'MRSA eradication' falsely give the impression that this regimen eradicates MRSA carriage. In reality, it should be called 'suppression therapy' because these agents reduce the numbers of bacteria present but often fail to eradicate MRSA carriage. *S. aureus* is still a common cause of surgical site infection, and this patient remains at risk of an MRSA surgical site infection. As a consequence, an agent that is active against MRSA should be used. Glycopeptides are the recommended antimicrobial class in this situation, and there are two options: teicoplanin and vancomycin. Vancomycin needs to be given as an infusion at a maximum rate of 10 mg/min, which means that administering a 1 g dose will take nearly 2 hours and may be impractical before skin incision. Teicoplanin can be given as a bolus and so is the best choice. Where bone cement is required to secure the prosthesis, a commercially prepared bone

cement containing gentamicin should also be used. Ideally, all antimicrobial prophylaxis guidelines or protocols should contain an option for MRSA-positive patients. Administration of appropriate regimens is facilitated by MRSA screening of all elective patients.

Case 40.2

A patient with a severe allergy to penicillin is admitted for a hemicolectomy for cancer of the colon. The unit uses a single-dose co-amoxiclav regimen as antimicrobial prophylaxis for large-bowel surgery.

Question

The junior hospital doctor asks your advice as to the antimicrobials to use instead of co-amoxiclav? What advice would you give?

Answer

Colorectal surgery still carries one of the highest surgical site infection rates of up to 10% for elective procedures. The usual bacteria found in these surgical site infections are *S. aureus*, Gram-negative bacilli (e.g. *Escherichia coli*) and anaerobes. Options for treatment include gentamicin and metronidazole, or ciprofloxacin and metronidazole; centres that have a problem with *C. difficile* infection may prefer to use the former regimen.

Case 40.3

Mrs AJ, a 73-year-old woman, is seen in pre-admission clinic for assessment prior to a knee replacement. She has recently had *C. difficile* infection in the community after being treated with a 1-week course of co-amoxiclav. She is asymptomatic now. The surgical team is reluctant to use its usual antimicrobial prophylaxis regimen of co-amoxiclav, or cefuroxime or ciprofloxacin.

Question

The anaesthetist assessing Mrs AJ in the pre-assessment clinic asks your advice about what to prescribe. Mrs AJ is currently being screened for MRSA. What advice would you give?

Answer

The most common pathogens in knee replacement surgical site infections are *S. aureus* and coagulase-negative staphylococci, although infection rates are low. Depending on the result of the MRSA screening test, there will be different answers. If Mrs AJ is colonised with MRSA, she could receive a single dose of teicoplanin. Options for prophylaxis include flucloxacillin with gentamicin or teicoplanin, although the latter does not cover Gram-negative bacteria. The use of gentamicin-containing cement would be recommended.

Case 40.4

Mr LP, a 72-year-old man, is due for elective transurethral resection of the prostate (TURP) and is currently well with no signs of a urinary tract infection. Routine prophylaxis for surgical site infections on the unit is co-amoxiclav. The patient is known to have had a mitral valve replacement 2 years ago.

Question

You are asked whether the antimicrobial prophylaxis should be amended because of his valve replacement? What advice would you give?

Answer

NICE guidelines no longer recommend routine prophylaxis for patients at risk of endocarditis who are undergoing investigations

involving the oral, gastro-intestinal or urogenital tract, in the absence of local infection (NICE, 2015). The usual prophylaxis for TURP should be recommended. If the patient had a urinary tract infection, this should ideally be treated before surgery.

41 Tuberculosis

Toby Capstick and Paul Whitaker

Key points

- Clinical manifestations of active tuberculosis (TB) disease are varied because *Mycobacterium tuberculosis* can infect any organ in the body, but common non-specific symptoms include malaise, weight loss, fever and night sweats.
- Diagnosis of TB is based on the context of clinical signs and symptoms and investigations such as radiography and microbiological results.
- Risk factors for TB include close contact with an infectious person, living in a country with a high incidence of TB, immunocompromise because of drugs or disease and previous under-treatment of TB.
- Treatment of active TB with single anti-TB drugs must never be attempted, and a single drug must never be added to a failing regimen, because of the risks for development of further drug resistance.
- Adherence to the full treatment course is essential to achieve cure, prevent relapse, prevent the development of drug resistance and prevent transmission to other people.
- Fixed-dose combination drugs are preferred to using separate drugs because they reduce pill burden and prevent selective non-adherence.
- Adverse effects of anti-TB drugs are common. Patients should be advised on common and serious adverse drug reactions, how to manage them and when to refer to their named healthcare professional.
- All patients should have a risk assessment for their likely adherence, and Directly Observed Therapy should be considered for patients thought likely to be non-adherent.
- The management of drug-resistant TB is highly complex and should only be managed by a multidisciplinary team with experience in managing such cases.

Introduction

Tuberculosis (TB) is a bacterial infection caused by *Mycobacterium tuberculosis* complex. It is a global problem and still accounts for millions of deaths every year. Unfortunately, the burden of TB disproportionately affects developing countries, and this effect is also compounded by co-infection with HIV. Advances in diagnostics and treatment have led to a reduction in TB mortality by 47% since 1990, with an estimated 53 million lives saved between 2000 and 2016. However, many new challenges are facing healthcare systems. The biggest concern has been the increase in multidrug-resistant tuberculosis (MDR-TB).

In 2006, the emergence of extensively drug-resistant tuberculosis (XDR-TB) was also reported. The treatment of drug-resistant TB is complex, costlier and of a longer duration than drug-susceptible cases.

Adequate and effective treatment is essential, both clinically for patients and also to control TB, because the Bacille Calmette-Guérin (BCG) vaccine does not prevent infection. Successful control depends on a close working collaboration between clinical, microbiological, pharmacy, infection control and public health teams in managing patients and their contacts.

Epidemiology

The global incidence of TB has declined steadily with rates now around 18% lower than in 2000. Reporting of patients with TB to national surveillance systems is variable between countries, but it is estimated that 10.4 million people experienced symptoms of TB worldwide in 2016 ([World Health Organization \[WHO\], 2017](#)); this number includes more than 1 million children. Ten percent of all patients were also positive for HIV. In 2016, despite the fact that all patients can potentially be cured, 1.3 million people died. In addition, a further 374,000 had TB-HIV co-infection (deaths among HIV-positive TB cases are classified as HIV deaths according to *International Classification of Diseases*, 10th Revision). Alongside HIV, TB remains a leading cause of death worldwide.

The highest annual incidence of TB (>100 cases per 100,000 population) is seen in sub-Saharan Africa, India and Southeast Asia. Intermediate rates of TB (26–100 cases/100,000) occur in China, South America, Eastern Europe and northern Africa. Lower rates (<25 cases per 100,000 inhabitants) occur in the USA, Western Europe, Canada, Japan and Australia.

In 2016, it was estimated that 490,000 cases of MDR-TB occurred; however, only about a quarter of these were detected and reported. Almost half of all of these cases occurred in India, China and the Russian Federation. In some areas of the world more than one in four people have drug-resistant TB; this is a problem especially in Eastern European countries such as Belarus and Lithuania.

A total of 5664 TB cases were reported in England during 2016 ([Public Health England, 2017](#)). The overall incidence across all population groups was 10.2 per 100,000 population. This rate has declined over the past 5 years because of a reduction in migrants

from high-incidence countries, as well as improved pre-entry TB screening. The majority of TB cases in the UK were in the population born outside of the UK. The incidence amongst UK-born individuals remains stable at around 3.2 per 100,000 population.

Aetiology

M. tuberculosis complex contains five different species; however, it is *M. tuberculosis*, *M. bovis* and *M. africanum* that are associated with human disease. *M. tuberculosis* is the most notable cause of TB and accounts for the majority of cases worldwide. *M. africanum* is responsible for up to half of the cases of TB in West Africa but is not a major pathogen outside of this geographical area. *M. bovis* is the causative organism in bovine TB and accounts for between 5% and 10% of human TB. Its impact has fallen since the introduction of pasteurised milk. Both *M. bovis* and *M. africanum* can give rise to clinical features of disease that are indistinguishable from *M. tuberculosis*.

TB is an airborne disease, and the source of infection is from another individual with active pulmonary disease. Patients should be considered infectious if they have sputum smear-positive pulmonary disease (i.e. they produce sputum containing sufficient tubercle bacilli to be seen on microscopic examination of a sputum smear) or laryngeal TB. Patients with smear-negative pulmonary disease, on three sputum samples, are less infectious than those who are smear positive. When coughing, droplets containing the tubercle bacilli are aerosolised and subsequently inhaled by other people. The greatest risk is to prolonged, mainly household contacts.

Inhalation of *M. tuberculosis* and deposition in the lungs leads to one of three possible outcomes: immediate clearance of the organism, primary active disease, or latent infection (with or without subsequent reactivation of disease). Active TB develops in around 10% of patients who do not clear the organism, and latent TB develops in around 90%. In latent TB the infectious bacilli trigger an immune response and T lymphocytes become sensitised to the mycobacterium. The immune system forms granulomas around the infection to limit spread, and these latent bacilli can remain in this state for a long period. If there is a change in the inflammatory response, then the latent bacilli can be released, triggering reactivation of disease. It is estimated that there are 2 billion people worldwide who have latent TB and are at risk of reactivation. There is a 10% lifetime risk that latent TB will reactivate; however, factors that further increase the risk include HIV, immunosuppressant drugs, diabetes mellitus, chronic kidney disease and poor nutrition. The estimated annual risk of TB in those with HIV infection and TB co-infection is around 10%, as opposed to a 10% lifetime chance in someone infected with TB, but not HIV.

Clinical features

The classic symptoms related to TB are those of prolonged (>2 weeks) respiratory symptoms. These usually include chronic cough, weight loss, fevers and night sweats. Patients can be productive of purulent sputum as well as haemoptysis (Lawn and

Zumla, 2011). Although this accounts for the majority of cases, between 10% and 40% of individuals can have extrapulmonary disease. In these patients they will often have the systemic symptoms of TB, such as weight loss and sweats, but will have focal signs and symptoms elsewhere. Common sites for extrapulmonary TB include the lymph nodes, pleura, skeletal sites, abdominal sites and the central nervous system (CNS). In the UK the commonest sites for extrapulmonary TB are the lymph nodes in the neck and the chest. Miliary TB is the widespread dissemination throughout the body due to spread through the bloodstream and is seen in around 3% of TB cases. It is more common in infants and the elderly, as well as immunocompromised individuals. In miliary TB the CNS is affected in around 20% of cases.

In patients with HIV the manifestations of TB can be atypical. Extrapulmonary disease is more common, and patients with advanced HIV can have very few signs and symptoms despite extensive and disseminated TB.

Diagnosis

Latent infection

Screening for latent *M. tuberculosis* infection is indicated for groups in which the prevalence of latent infection is high or in those who are at higher risk of reactivation. High-risk groups include foreign-born persons from endemic areas and contact screening during an investigation of an active TB case. The diagnosis and treatment of latent TB is important because this will result in a reduction in the numbers of active infectious cases in the future.

There are two ways of identifying latent TB: the first is a tuberculin skin test and the second an interferon- γ release assay (IGRA). Both methods are a test of the person's immunological memory against TB.

The only tuberculin skin test now used is the Mantoux test. The standard Mantoux test consists of an intradermal injection of 2 TU of Statens Serum Institute tuberculin RT23 in 0.1 mL of solution for injection. The results are read 48–72 hours later, although a valid reading can be obtained up to 96 hours later. The transverse diameter of the area of induration is measured with a ruler and the result recorded in millimetres. A diameter of induration ≥ 5 mm is considered positive and represents an immune response against the tuberculin (National Institute for Health and Care Excellence [NICE], 2016). A false-positive result can be caused by previous BCG vaccination or nontuberculous environmental mycobacterium. A false-negative result can occur if the patient has a lowered immune system and cannot mount an inflammatory response.

The IGRA measures the immune response following the exposure of the patient's blood cells to proteins from *M. tuberculosis*. After incubation for 16–24 hours the levels of interferon- γ are quantified. The advantages include that it is not affected by prior BCG vaccination and no second visit is required to read the test.

If either the tuberculin skin test or the IGRA is positive, an assessment of the patient has to be made to ensure he or she has no features of active TB. Only when it is confirmed that the patient is symptom free and has a normal chest radiograph can he or she be confirmed as having latent disease.

Active tuberculosis

Awareness of TB amongst healthcare professionals is essential for its control. Early diagnosis, especially of pulmonary TB, followed by prompt commencement of treatment can reduce the period of infectivity to other people, especially susceptible contacts, who might be at risk of the more serious forms of TB disease. TB should be considered part of the differential diagnosis in a range of clinical presentations. These include cough, pleural effusions, lymphadenopathy, skeletal pain, abdominal pain and fever of unknown origin.

Basic investigations include sputum microbiology, as well as chest radiograph; however, with the complexity of presentations many patients will require more extensive diagnostics to confirm TB. Confirmation is important to avoid unnecessary treatment, as well as to obtain appropriate specimens for testing drug susceptibilities. At present there is only a limited role for IGRAs and tuberculin skin testing in the diagnosis of active disease.

Microbiological testing

Sputum microscopy and mycobacterial culture are considered to be the gold standard tests for the diagnosis of pulmonary disease. The staining and microscopy of the sputum smear is a reliable and cost-effective way of identifying a patient with active TB. If positive, there is usually a high burden of disease, and these patients are more infectious. A negative smear cannot be relied upon and, in many cases, because *M. tuberculosis* is a slow-growing organism, culture positivity can take several weeks. A minimum of three sputum samples, one of which needs to be from early morning, should be collected from patients with suspected pulmonary TB. In many patients, treatment will be commenced on clinical suspicion before cultures become positive.

If conventional culture methods are used, such as the Lowenstein–Jensen medium, growth may take between 3 and 8 weeks. Modern liquid cultures can produce results more quickly, often in 1–3 weeks. Once the culture does become positive it allows for drug-susceptibility patterns to be identified, allowing appropriate treatment.

More recently, polymerase chain reaction–based tests can also detect *M. tuberculosis* complex in clinical specimens. These assays use nucleic acid probes to amplify specific target RNA or DNA. Using these probes, it is possible, with high sensitivity, to identify both *M. tuberculosis* and rifampicin resistance mutations (*rpoB* gene). These tests do not replace routine culture, but they may shorten the time interval before effective treatment is commenced.

In patients who do not have pulmonary TB, samples can be collected and processed in a similar way. These may include fluid from pleural effusions or tissue biopsies, for example, from lymph nodes. In tissue biopsies it is also possible to send them for histological diagnosis, and the typical features seen in TB are those of caseating granulomatous inflammation.

Radiology

Chest radiography is an essential part of the diagnostic workup in TB. It is important both for the initial diagnosis as well as to risk stratify, to determine how infectious the patient may be. Classic features on chest radiograph include focal infiltration of the upper

Fig. 41.1 Chest radiograph of a 45-year-old male patient with sputum heavily smeared positive for *Mycobacterium tuberculosis*. Chest radiograph shows increased airspace shadowing in both upper lobes with a cavity in the right upper lobe.

Fig. 41.2 Computed tomography (CT) of a 45-year-old male patient with sputum heavily smeared positive for *Mycobacterium tuberculosis*. CT scan shows thick-walled 4-cm cavity and nodular inflammation in the right upper lobe.

lobes, often with cavitation and lymph node enlargement (Fig. 41.1). However, in many cases, the features are not typical and may present with masses, nodules and pleural effusions. In patients with HIV atypical chest radiograph appearances are common.

Chest computed tomography (CT) is more sensitive than plain chest radiography and has a role in the atypical or the subtler cases (Fig. 41.2). In these cases the CT scan may indicate further investigations, such as bronchoscopy, to obtain microbiological samples.

Further imaging may also be required depending upon the presentation or symptoms, for example, a CT or magnetic resonance imaging scan of the brain in someone with neurological symptoms.

Public health action

TB is a statutorily notifiable communicable disease in the UK. Cases should be notified on clinical suspicion by the attending

doctor to the local authority or a local Public Health England centre for communicable disease control. Notification enables public health action to be initiated and involves investigation of prolonged, close contacts who might be at risk of infection, mainly those living in the same household as the patient, to assess them for latent or active TB disease. It may also enable the source of the infection to be found and treated.

Latent TB infection is not infectious and does not require notification.

Bacille Calmette-Guérin Vaccination

The BCG vaccine contains a live attenuated strain of *M. bovis* and is 70–80% effective against the most severe forms of TB, such as TB meningitis in children, but is less effective in adults. The current (Public Health England, 2013) UK vaccination strategy targets the at-risk population rather than the entire UK population. In brief, BCG immunisation is offered to infants at high risk of TB exposure (e.g. those living in local areas of high incidence or with close relatives from high-incidence countries), children (where active TB is excluded) who are contacts of people diagnosed with pulmonary TB and people younger than 35 years who are at occupational risk of TB (e.g. healthcare workers, veterinary staff, prison staff and staff of hostels for homeless people).

Treatment

The aims of TB treatment are the following:

- cure the patient of TB disease,
- prevent death from active TB,
- prevent relapse of disease,
- prevent development of drug resistance,
- prevent the transmission of the disease to other patients or contacts.

M. tuberculosis is a slow-growing obligate pathogen that exists in different populations, making it difficult to target with antibacterials. It exists mostly as extracellular actively growing organisms, slowly growing organisms within macrophages under microaerobic and acidic conditions, and as dormant organisms in anaerobic conditions. The presence of organisms in pulmonary cavities, caseous necrotic foci or pus may reduce antibiotic penetration. Antibacterial activity may be reduced by the persistence of organisms within low pH environments, their long generation time, dormancy and low metabolic activity. Consequently, treatment of TB requires combinations of several anti-TB drugs, because monotherapy is liable to generate resistance, as demonstrated in the original trials of streptomycin. If untreated there is a 5-year mortality rate of 65%.

Drug-sensitive tuberculosis

Most patients with drug-sensitive TB can be treated in outpatient settings and do not require admission to hospital. The treatment

of fully sensitive TB requires the use of four first-line anti-TB drugs: isoniazid, rifampicin, pyrazinamide and ethambutol (NICE, 2016). Streptomycin was previously used as an alternative to ethambutol but is no longer recommended for uncomplicated cases.

Isoniazid and rifampicin are the most effective bactericidal drugs, and they are most effective at preventing the emergence of drug resistance. Rifampicin and pyrazinamide have sterilising activity and kill semi-dormant persistent bacteria, and pyrazinamide is particularly effective in acid environments. Ethambutol is bacteriostatic and may prevent or delay the emergence of resistant strains.

Most patients with a fully sensitive strain of TB (including adults and children regardless of whether they are HIV positive) require a 6-month course of isoniazid and rifampicin, supplemented with pyrazinamide and ethambutol for the first 2 months (NICE, 2016). This is often referred to as the ‘standard recommended regimen’, and the use of fixed-dose combination (FDC) regimens (e.g. Voractiv, Rifater and Rifinah) is recommended to reduce pill burden and improve adherence. The recommended doses of first-line drugs are listed in Table 41.1.

Active tuberculosis without central nervous system involvement

The ‘standard recommended regimen’ is recommended for all people with active TB without CNS involvement. This includes pulmonary TB, which is defined as TB affecting the lungs, pleural cavity, mediastinal lymph nodes or larynx, and those with all forms of extrapulmonary TB, for example, peripheral lymph node, bone and joint, pericardial and disseminated (including miliary) TB.

Glucocorticoids are also recommended in the treatment of pericardial TB (at an initial dosage of prednisolone 60 mg daily (1 mg/kg/day in children) and then gradually tapered after 2–3 weeks (NICE, 2016).

Active tuberculosis with central nervous system involvement

Active TB affecting the CNS is associated with high rates of morbidity and mortality, and thus treatment is extended to 12 months, that is, 12 months of isoniazid and rifampicin, supplemented with pyrazinamide and ethambutol for the first 2 months. Rifampicin, isoniazid and ethambutol penetrate the cerebrospinal fluid (CSF) poorly; rifampicin achieves CSF concentrations that are only 10–20% of that in the blood. Isoniazid has good CSF penetration in patients with inflamed meninges, but achieves CSF concentrations that are only 20% of that in the blood when the meninges are not inflamed. Ethambutol has poor CSF penetration and may only be useful when the meninges are inflamed.

Glucocorticoids are also recommended for the treatment of TB of the CNS because they have been demonstrated to reduce mortality and disabling residual neurological deficit (Prasad and Singh, 2008). High doses of prednisolone or dexamethasone are recommended, with NICE recommending an initial dosage in adults of intravenous dexamethasone

Table 41.1 First-line antituberculosis drugs

Drug	Preparations	Daily unsupervised dose		Daily supervised dose	
		Adults	Children	Adults	Children
Individual drugs					
Isoniazid	Oral: 50 mg, 100 mg tablets Liquid (as a manufactured special) Parenteral: 50 mg/2 mL ampoules	300 mg once a day Consider 5 mg/kg once a day if low body weight	10 mg/kg (max. 300 mg) once a day	15 mg/kg (max. 900 mg) three times a week	15 mg/kg (max. 900 mg) three times a week
Rifampicin	Oral: 150 mg, 300 mg capsules 100 mg/5 mL syrup Parenteral: 600 mg powder for reconstitution	<50 kg: 450 mg once a day ≥50 kg: 600 mg once a day	15 mg/kg (max. 450 mg if <50 kg; 600 mg if ≥50 kg) once a day	600–900 mg three times a week	15 mg/kg (max. 900 mg) three times a week
Pyrazinamide ^a	Oral: 500 mg tablets Liquid (as a manufactured special)	<50 kg: 1.5 g once a day ≥50 kg: 2 g once a day	35 mg/kg (max. 1.5 g if <50 kg; 2 g if ≥50 kg) once a day	<50 kg: 2 g three times a week ≥50 kg: 2.5 g three times a week	50 mg/kg (max. 2 g if <50 kg; 2.5 g if ≥50 kg) three times a week
Ethambutol ^{a,b}	Oral: 100 mg, 400 mg tablets	15 mg/kg once daily	20 mg/kg once daily	30 mg/kg three times per week	30 mg/kg three times per week
Fixed-dose combination drugs					
Voractiv	Oral: rifampicin 150 mg, isoniazid 75 mg, pyrazinamide 400 mg, ethambutol hydrochloride 275 mg	30–39 kg: 2 tablets daily 40–54 kg: 3 tablets daily 55–69 kg: 4 tablets daily ≥70 kg: 5 tablets daily	Not recommended	Not recommended	Not recommended
Rifater	Oral: rifampicin 120 mg, isoniazid 50 mg, pyrazinamide 300 mg	<40 kg: 3 tablets daily 40–49 kg: 4 tablets daily 50–64 kg: 5 tablets daily ≥65 kg: 6 tablets daily	Not recommended	Not recommended ^c	Not recommended
Rifinah	Oral: Rifinah 300/150 mg (rifampicin 300 mg, isoniazid 150 mg) Rifinah 150/100 mg (rifampicin 150 mg, isoniazid 100 mg)	<50 kg: Rifinah 150/100 mg 3 tablets daily ≥50 kg: Rifinah 300/150 mg 2 tablets daily	Not recommended ^d	Not recommended ^c	Not recommended
^a Dose adjustment may be required in renal impairment. ^b Use IBW plus 40% of the excess weight in markedly obese patients. <ul style="list-style-type: none"> • Male IBW (kg) = 50 + (2.3 × height in cm above 152.4)/2.54 (i.e. IBW = 50 kg + 2.3 kg for each inch over 5 feet). • Female IBW (kg) = 45.5 + (2.3 × height in cm above 152.4)/2.54 (i.e. IBW = 45.5 kg + 2.3 kg for each inch over 5 feet) ^c The BNF for Children advises that the use of Rifinah or Rifater in older children may be considered outside of license, provided that the respective dose of each drug is appropriate for the weight of the child. ^d Rifinah is often used in supervised regimens to reduce tablet burden, but may require additional isoniazid to make up the full dose. max., Maximum; IBW, ideal body weight.					

Table 41.2 Treatment regimens for mono-resistant tuberculosis (NICE, 2016)

Drug resistance	Initial phase (2 months' duration)	Continuation phase
Rifampicin	Treat using multidrug-resistant tuberculosis regimen	
Isoniazid	Rifampicin, pyrazinamide, ethambutol	Rifampicin and ethambutol for 7 months (up to 10 months in extensive disease)
Pyrazinamide	Rifampicin, isoniazid, ethambutol	Rifampicin and isoniazid for 7 months
Ethambutol	Rifampicin, isoniazid, pyrazinamide	Rifampicin and isoniazid for 4 months

0.3–0.4 mg/kg once daily, then gradually tapered over 4–8 weeks (NICE, 2016).

Drug-resistant tuberculosis

Drug-resistant TB is most commonly caused by non-adherence to the full treatment regimen, prescribing of inappropriate treatment regimens or lack of availability of high-quality drugs. In one meta-analysis, the risk of development of MDR-TB in patients in whom treatment was unsuccessful after being prescribed an inappropriate treatment regimen was increased 27-fold (van der Werf et al., 2012). Although the number of drug-resistant cases of TB in the UK is relatively low, resistance to anti-TB drugs is becoming an increasing problem in many countries including the UK.

There are varying degrees of drug resistance that are encountered:

- mono-resistance: resistance to one anti-TB drug;
- MDR-TB: resistance to at least isoniazid and rifampicin;
- XDR-TB: resistance to any fluoroquinolone, and at least one injectable second-line drug (capreomycin, kanamycin or amikacin), in addition to multidrug resistance.

The treatment of drug-resistant TB is complex, with a paucity of randomised controlled trials to guide treatment regimen selection, and second-line anti-TB drugs are generally less effective than first-line drugs and often have poor adverse effect profiles.

Mono-resistant tuberculosis

In 2016 in England, 7.5% of cases had resistance to at least one first-line antibiotic, comprising 7.0% resistant to isoniazid, 1.7% to rifampicin, 1.2% to ethambutol and 0.6% to pyrazinamide (Public Health England, 2017). Treatment of mono-resistant TB requires the remaining first-line anti-TB drugs to be used for longer durations, as outlined in Table 41.2.

Multidrug-resistant tuberculosis

The treatment of MDR-TB is complex and requires prolonged courses of treatment. Only specialist doctors with experience in treating drug-resistant TB should manage these cases. Newly diagnosed patients require admission to hospital into a negative pressure isolation room until they become non-infectious, to prevent transmission to other people. Because the precise pattern of

drug resistance can be highly variable in MDR-TB, there are limited clinical trials to guide treatment decisions and drug regimens need to be individualised. The treatment of MDR-TB is significantly more expensive than treating drug-sensitive TB, with drug costs of approximately £18,000 for a 20-month course of treatment compared with £260 for standard treatment. However, the costs of prolonged admissions, outpatient clinic appointments, staffing and testing will drive overall costs much higher.

MDR-TB is relatively uncommon in the UK, with just 1.5% cases reported in England in 2016 (Public Health England, 2017). Because there are relatively few doctors in the UK with experience in managing MDR-TB, it is recommended that cases are registered with the British Thoracic Society MDR-TB Clinical Advice Service to allow other registered healthcare professionals to provide advice. Guidelines for managing MDR-TB have been produced by the WHO (2016), and drug information is available from the UK TB Drug Monographs (<http://www.tbdrugmonographs.co.uk>).

Treatment regimens for MDR-TB are based on known drug sensitivity data, and it is of critical importance that just one drug is not added to failing treatment regimens, because this could result in further resistance developing to the new drug. The principles of treating MDR-TB with second-line drugs (Table 41.3) are complex, but treatment regimens usually comprise at least five effective drugs during the intensive phase (WHO, 2016):

- one group A drug: a fluoroquinolone (moxifloxacin most effective);
- one group B drug: a parenteral agent (amikacin or capreomycin);
- two group C drugs: prothionamide, cycloserine linezolid or clofazimine;
- usually pyrazinamide (unless resistant);
- if five drugs cannot be selected, one drug from group D2 (bedaquiline or delamanid) and others from group D3 (e.g. *p*-aminosalicylic acid, meropenem-clavulanate) are used;
- ethambutol and/or high-dose isoniazid may be used in addition.

The intensive phase of treatment should last 8 months, at which time the parenteral agent is stopped and the remaining drugs continued for a total of 20 months. If the regimen appears to be failing (often an indicator of poor adherence or increased resistance), at least two new drugs should be commenced. This is because adding a single drug is liable to result in further resistance developing.

Table 41.3 Second-line antituberculosis drugs (WHO, 2016)

WHO grouping	Drug	Route	Adults ^a	Children ^a
Group A: fluoroquinolones	Levofloxacin (not licensed to treat TB in the UK)	Oral	10–15 mg/kg once daily (usually 750–1000 mg once daily)	Age >5 years: 10–15 mg/kg once daily Age ≤5 years: 7.5–10 mg/kg twice a day (limited experience)
	Moxifloxacin (not licensed to treat TB in the UK)	Oral, intravenous	Usual dose 400 mg once daily WHO recommendations for MDR-TB short course regimen (safety of the higher doses not verified): Weight <30 kg: 400 mg once a day Weight 30–50 kg: 600 mg once a day Weight >50 kg: 800 mg once a day	7.5–10 mg/kg once a day
Group B: second-line injectable agents	Streptomycin (unlicensed in the UK)	Intravenous	Age ≤59 years: 15 mg/kg daily (usual max. 1 g daily, but can be increased if necessary in large, muscular adults) Age >59 years: 10 mg/kg daily (max. 750 mg daily) All ages: after initial period: 15 mg/kg three times per week	20–40 mg/kg daily (max. 1 g daily) After initial period: 20–40 mg/kg three times per week
	Amikacin (not licensed to treat TB in the UK)	Intravenous or intramuscular injection	Age ≤59 years: 15 mg/kg daily (usual max. 1 g daily, but can be increased if necessary in large, muscular adults) Age >59 years: 10 mg/kg daily (max. 750 mg daily) All ages: after initial period: 15 mg/kg three times per week	15–22.5 mg/kg daily (usual max. 1 g daily) After initial period: 15–30 mg/kg three times per week
	Capreomycin	Intramuscular injection There is experience using as an intravenous infusion	Age ≤59 years: 15 mg/kg daily (usual max. 1 g daily, but can be increased if necessary in large, muscular adults) Age >59 years: 10 mg/kg daily (max. 750 mg daily) All ages: after initial period: 15 mg/kg three times per week	15–30 mg/kg daily (usual max. 1 g daily) After initial period: 15–30 mg/kg three times per week
Group C: other core second-line agents	Prothionamide (unlicensed in the UK)	Oral	15–20 mg/kg (max. 1 g) once daily Once-daily dosing is preferred to maximise peak levels, particularly for daily doses ≤750 mg; consider twice-daily dosing if patients are unable to tolerate once-daily regimens	15–20 mg/kg (max. 1 g) once daily Once-daily dosing is preferred to maximise peak levels, particularly for daily doses ≤750 mg; consider twice-daily dosing if patients are unable to tolerate once-daily regimens
	Cycloserine	Oral	Initially 250 mg twice a day, increased to 500 mg twice a day depending on serum concentrations. The usual target dose is 10–20 mg/kg/day once or twice per day; max. 1 g/day	The usual target dose is 10–20 mg/kg/day once or twice per day; max. 1 g/day
	Linezolid (not licensed to treat TB in the UK)	Oral, intravenous	600 mg once a day Consider reducing to 300 mg once daily if serious adverse effects develop	Age ≤11 years: 10 mg/kg three times daily Age >11 years: 10 mg/kg twice daily (max. 600 mg in 24 h)
	Clofazimine (unlicensed in the UK)	Oral	100–200 mg once daily Doses of 200 mg daily for 2 months, then 100 mg daily have been used	Limited data, recommendation is based on experience and expert opinion and suggests 1 mg/kg/day

Continued

Table 41.3 Second-line antituberculosis drugs (WHO, 2016)—cont'd

WHO grouping	Drug	Route	Adults ^a	Children ^a
Group D: add-on agents	Bedaquiline	Oral	400 mg daily for the first 2 weeks, followed by 200 mg three times per week for the remaining 22 weeks	Not recommended; limited experience
	Delamanid	Oral	100 mg twice a day for 24 weeks	Not recommended; limited experience
	<i>p</i> -Aminosalicylic acid	Oral	150 mg/kg/day in two to four divided doses; usual dose is 8–12 g/day	200–300 mg/kg/day <i>p</i> -Aminosalicylic acid is only available in 4 g sachets; the GranuPAS brand comes with a dosage scoop graduated in milligrams to aid dosing in children
	Co-amoxiclav (not licensed to treat TB in the UK)	Oral, intravenous	Oral: 625 mg three times daily Intravenous: 1.2 g three times daily	Limited data, consult the UK TB Drug monographs
	Imipenem/cilastatin (not licensed to treat TB in the UK)	Intravenous	Body weight >50 kg: 1 g twice a day Body weight (≤50 kg): 15 mg/kg twice a day (dose is based on the imipenem component)	20–40 mg/kg (max. 2 g) three times a day
	Meropenem (not licensed to treat TB in the UK)	Intravenous	1 g three times a day Should be used in combination with clavulanate (as co-amoxiclav) 625 mg three times a day	1 month to 12 years: 20–40 mg/kg every 8 h (max. 6000 mg in 24 h)
	Thiacetazone (unlicensed in the UK)	Oral	150 mg once daily	No information

^aConsult product literature or the UK TB Drug monographs (<http://www.tbdrugmonographs.co.uk>) for dose adjustment recommendations in marked obesity, renal impairment, or in response to serum levels.
max., Maximum; TB, tuberculosis; WHO, World Health Organization.

An alternative, shorter 9- to 12-month regimen has been proposed by WHO (2016) for patients with MDR-TB who have not previously been treated with second-line drugs and in whom resistance to fluoroquinolones and second-line injectable agents has either been excluded or is considered highly unlikely. In Western Europe, this regimen is likely to be suitable only for a minority of patients based on current drug-resistance patterns.

The short regimen comprises two phases of treatment:

- 4-month intensive phase (extended up to a maximum of 6 months in case of lack of sputum smear conversion): gatifloxacin (or moxifloxacin), kanamycin, prothionamide, clofazimine, high-dose isoniazid, pyrazinamide and ethambutol;
- 5-month continuation phase: gatifloxacin (or moxifloxacin), clofazimine, pyrazinamide and ethambutol.

Extensively drug-resistant tuberculosis

There is a lack of evidence for suitable treatment regimens for people with XDR-TB, and very limited experience in the UK. Cases should be managed only at specialist TB centres, advice

should be sought from multidisciplinary teams, and cases must be registered with the British Thoracic Society MDR-TB Clinical Advice Service.

Treatment regimens are likely to comprise any or all remaining anti-TB drugs to which the isolate is likely to be sensitive, and drug costs may exceed £70,000. Bedaquiline and delamanid are two drugs with novel modes of action that have recently been licensed in the UK for the treatment of drug-resistant TB and may have a role when treating XDR-TB. Currently, however, there are very limited data on the safety of combining bedaquiline and delamanid in treatment regimens.

HIV/tuberculosis co-infection

Patients with TB/HIV co-infection should be managed by a multidisciplinary team that includes physicians with expertise in the treatment of both TB and HIV infection (Pozniak et al., 2011). First-line anti-TB drugs are recommended, and non-interacting antiretrovirals (ARVs) should be used where possible. TB treatment should only be modified where intolerance, severe toxicity or genotypic resistance limits ARV choice.

ARVs should ideally be commenced early during TB treatment, because delayed treatment may prolong or worsen immunosuppression. However, the treatment of HIV/TB co-infection is complicated because of overlapping toxicities, drug interactions, immune reconstitution disease and high pill burdens. Potential interactions between ARVs and anti-TB drugs must be checked before administration, using either manufacturer's summaries of product characteristics, the British HIV Association 2011 guidelines (Pozniak et al., 2011) on the treatment of TB/HIV co-infection or the University of Liverpool HIV drug interactions website (<http://www.hiv-druginteractions.org>).

The British HIV Association provides recommendations for commencing ARVs in patients with TB:

- CD4 less than 100 cells/microlitre: Start as soon as practical within 2 weeks after starting TB therapy, because there is an increased risk of further AIDS-defining events and increased mortality.
- CD4 100–350 cells/microlitre: Commence as soon as practical, but can wait until after completion of 2 months of TB treatment, especially when there are difficulties with drug interactions, adherence and toxicities.
- CD4 consistently greater than 350 cells/microlitre: Begin at physician discretion, because there is a low risk of HIV disease progression.

Latent tuberculosis infection

Latent TB infection can be successfully eradicated with appropriate courses of anti-TB drugs; however, these are not without risks due to their side effect profile. Treatment is recommended for children and adults aged up to 65 years, including those with HIV infection, confirmed to have latent TB infection after active TB disease is excluded (NICE, 2016). UK treatment regimens include either 3 months of isoniazid and rifampicin or 6 months of isoniazid alone.

The choice of treatment depends on each individual's circumstances, such that 3 months of isoniazid and rifampicin is recommended for people younger than 35 years, if hepatotoxicity is a concern after assessment of both liver function and risk factors, whereas 6 months of isoniazid alone may be preferred where drug interactions with rifamycins are a concern (e.g. with ARVs, contraceptives, immunosuppressants). Because the risk of hepatotoxicity increases with age, adults aged between 35 and 65 years should receive treatment only if there are no concerns of hepatotoxicity.

Treatment of latent TB infection in people who are contacts of patients with infectious MDR-TB is currently not recommended because of the lack of data demonstrating efficacy of any potential regimen.

Adverse effects

Paradoxical reactions

Occasionally patients treated for active TB may experience an exacerbation of signs or symptoms of disease (e.g. worsening lymph node swelling), or radiological manifestations of TB despite otherwise responding to anti-TB treatment. This is known

as a paradoxical reaction or immune reconstitution inflammatory syndrome, and is thought to be due to an exaggerated immune response to dead bacilli. Patients may respond to treatment with high-dose prednisolone, such as 30 mg once daily (increased if on rifampicin), which is gradually reduced after 1–2 weeks. Non-pharmacological treatment options include recurrent needle aspiration of lymph nodes or abscesses.

Adverse drug reactions

Side effects from anti-TB drugs are common and patients should be advised of the common and serious effects, and how to manage them. This may be supplemented with patient information leaflets (PILs) such as those produced by TB Alert (<http://www.tetruthabouttb.org/professionals/patient-support/>). Common and serious adverse drug reactions of first- and second-line anti-TB drugs are listed in Table 41.4.

In drug-sensitive TB, rifampicin will cause an orange-red discolouration of urine and other body secretions throughout treatment, but is harmless. Gastro-intestinal side effects, such as nausea and vomiting, are common, particularly with pyrazinamide, but also with rifampicin and isoniazid. Whilst this is often mild and transient, some patients may experience severe symptoms that require antiemetics. Skin reactions including itching and rashes may occur with any first-line anti-TB drug; mild cases may require antihistamines, but if severe may require treatment interruption or systemic corticosteroid treatment.

Rifampicin, isoniazid and pyrazinamide are all potentially hepatotoxic, and liver function tests (LFTs) should be checked before commencing treatment. Many centres will also recheck LFTs periodically throughout treatment. If transaminases rise greater than five times the upper limit of normal, or greater than three times normal with symptomatic liver disease, all potentially hepatotoxic drugs (i.e. rifampicin, isoniazid and pyrazinamide) should be stopped immediately. LFTs should be closely monitored and the advice of a liver specialist sought if necessary. If the patient is well and sputum smear negative (i.e. non-infectious), no treatment is required until after LFTs return to normal. However, if the patient is unwell or sputum smear positive, TB treatment must continue using two anti-TB drugs with low risk of hepatotoxicity, such as streptomycin and ethambutol, with or without a fluoroquinolone (levofloxacin or moxifloxacin). Once liver function has returned to normal, the first-line anti-TB drugs can be reintroduced sequentially at full dose over a period of no more than 10 days, usually in the order of ethambutol, isoniazid, rifampicin, then pyrazinamide. Some guidelines advise against reintroducing pyrazinamide if the hepatotoxic reaction was particularly severe and prolonged, but continuing with ethambutol, rifampicin and isoniazid initially and extending the course duration to 9 months.

Peripheral neuropathy is a rare side effect of isoniazid and is more common in patients who are malnourished, immunocompromised, diabetic, elderly, alcoholic or have renal impairment. At-risk groups should be prescribed prophylactic doses of pyridoxine 10–50 mg once a day, although some guidelines recommend prescribing pyridoxine routinely for all patients. If symptomatic neuropathy occurs, larger pyridoxine doses may be required.

Ethambutol can rarely cause optic neuritis, resulting in blurred vision or red/green colour blindness, and patients should be advised to report any changes in vision. The risk is increased with large dosages greater than 15 mg/kg/day and with prolonged courses. Visual acuity and colour vision should be checked using a Snellen chart and Ishihara plates at the start of treatment and during treatment.

Monitoring of treatment

Adherence is possibly the most important aspect of monitoring of anti-TB drug treatment. It can be assessed in community settings simply by patient interview, tablet counts, reviewing prescription collection data or even by taking urine samples to assess for a

red-orange colouration due to taking rifampicin, or with isoniazid urine test strips.

Anti-TB drugs are associated with a range of adverse effects that require routine monitoring. Routine tests for monitoring adverse effects of treatment include:

- urea and electrolytes, LFTs: repeated every 2–4 weeks for 2 months;
- baseline uric acid;
- baseline vitamin D level;
- baseline full blood count, clotting;
- HIV and hepatitis screen;
- baseline visual acuity and colour vision testing;
- nutritional assessment.

Table 41.4 Adverse drug reactions

WHO grouping	Drug	Common side effects	Serious side effects
First-line agents	Isoniazid	Neurological: peripheral neuropathy Hepatic: transient increases in LFTs	Dermatological: skin reactions, e.g. urticaria (uncommon) Haematological: agranulocytosis, megaloblastic anaemia, thrombocytopenia Hepatic: hepatotoxicity (rare) Immunological: drug-induced lupus (rare) Musculoskeletal: arthralgia, rhabdomyolysis Neurological: seizure, psychosis (rare)
	Rifampicin	Reddish discolouration of urine, sweat, sputum, tears Gastro-intestinal: anorexia, nausea, vomiting, heartburn Hepatic: transient increases in LFTs Flu-like syndrome	Haematological: agranulocytosis (rare), haemolytic anaemia (rare, usually intermittent therapy), thrombocytopenia (rare, usually high-dose/intermittent therapy) Hepatic: hepatotoxicity (rare) Renal: nephrotoxicity (rare)
	Pyrazinamide	Hyperuricaemia Arthralgia Gastro-intestinal: anorexia, nausea, vomiting Hepatic: transient increases in LFTs Dermatological: rash	Haematological: sideroblastic anaemia (rare), thrombocytopenia (rare) Hepatotoxicity
	Ethambutol	Endocrine: hyperuricaemia Gastro-intestinal: nausea, vomiting	Ophthalmic: Optic neuritis (1–6%; greatest risk at doses >25 mg/kg/day, or >2 months of treatment) Red/green colour blindness
Group A: fluoroquinolones	Fluoroquinolones (e.g. levofloxacin, moxifloxacin)	Cardiovascular: QTc prolongation (risk: hypokalaemia, proarrhythmic conditions, in combination QT-prolonging drugs) Gastro-intestinal: nausea, vomiting, diarrhoea Hepatic: transient increases in LFTs Other: dizziness, headache	Cardiovascular: QTc prolongation Dermatological: SJS or TEN (rare) Haematological: (uncommon) agranulocytosis, aplastic anaemia, haemolytic anaemia, thrombocytopenia Hepatic: acute hepatitis (rare) Immunological: anaphylaxis, immune hypersensitivity (uncommon) Metabolic: hypoglycaemia (in patients receiving hypoglycaemic drugs, uncommon) Musculoskeletal: tendon inflammation and rupture Neurological: seizures Renal: renal impairment (rare) Respiratory: extrinsic allergic alveolitis (rare) Other: serum sickness (rare)

Table 41.4 Adverse drug reactions—cont'd

WHO grouping	Drug	Common side effects	Serious side effects
Group B: second-line injectable agents	Injectable agents (e.g. amikacin, capreomycin, streptomycin)	<p>Nephrotoxicity: accumulation if renal impairment</p> <p>Ototoxicity: irreversible vestibulo-cochlear nerve damage</p> <p>Drug-induced eosinophilia (capreomycin): usually subsides with intermittent dosing</p>	<p>Dermatological: induration and local pain with intramuscular injection</p> <p>Endocrine: hypocalcaemia, hypomagnesaemia and hypokalaemia</p> <p>Neurological: neuromuscular blockade and respiratory paralysis (more common in neuromuscular disease; usually dose-related and self-limiting)</p> <p>Audiological: ototoxicity: auditory > vestibular (higher with amikacin, prolonged use and older age)</p> <p>Renal: nephrotoxicity (higher with prolonged use)</p>
Group C: other core second-line agents	Prothionamide	<p>Hepatic: transient increases in LFTs</p> <p>Gastro-intestinal: nausea, vomiting, diarrhoea, anorexia, excessive salivation, metallic taste, stomatitis, and abdominal pain</p>	<p>Hepatic: acute hepatitis (rare)</p> <p>Neurological (maybe increased with cycloserine): dizziness, encephalopathy, peripheral neuropathy</p> <p>Ophthalmic: optic neuritis (rare)</p> <p>Psychiatric: psychotic disturbances, depression</p> <p>Metabolic: gynaecomastia, hypoglycaemia, hypothyroidism</p>
	Cycloserine	<p>Neurological: confusion, disorientation, dizziness, somnolence (increased risk if peak serum level >35 mg/L)</p>	<p>Cardiovascular: sudden development of congestive heart failure (doses >1–1.5 g daily [rare])</p> <p>Dermatological: rash and photosensitivity, SJS (rare)</p> <p>Haematological: vitamin B₁₂ and/or folic acid deficiency, megaloblastic anaemia or sideroblastic anaemia (rare)</p> <p>Psychiatric: depression, seizure, psychotic disturbances (increased risk if peak serum level >35 mg/L)</p>
	Linezolid	<p>Gastro-intestinal: diarrhoea (4%), nausea (3%), vomiting</p> <p>Neurological: headache (2%)</p> <p>Infections: candidiasis, particularly oral and vaginal (1%)</p> <p>Hepatic: transient increases in LFTs</p>	<p>Metabolic: lactic acidosis</p> <p>Dermatological: urticaria, rash; (rare) bullous disorders, e.g. SJS and TEN</p> <p>Haematological: myelosuppression</p> <p>Neurological: peripheral neuropathy, seizure, serotonin syndrome</p> <p>Ophthalmic: optic neuropathy: risk with prolonged treatment</p>
	Clofazimine	<p>Dermatological: pink to brownish-black skin discolouration within 1–4 weeks in 75–100% of patients; gradually disappears within 6–12 months after stopping treatment. Ichthyosis and dry skin (8–38%), pruritus (5%), rash (1–5%), photosensitivity reactions (wear protective clothing and sunscreens)</p> <p>Gastro-intestinal (up to 50% of patients): abdominal pain, nausea, vomiting, diarrhoea, weight loss</p>	<p>Gastro-intestinal (<1%): bowel obstruction, gastrointestinal haemorrhage</p> <p>Ophthalmic: conjunctival pigmentation (38–57%), subjective dimness of vision (12.3%), and dry eyes, burning and other ocular irritation (24.6%)</p> <p>Psychiatric: reactive depression due to skin discolouration</p> <p>Other: splenic infarction, discolouration of body fluids</p>
	p-Aminosalicylic acid	<p>Gastro-intestinal: nausea, vomiting, diarrhoea, abdominal pain</p> <p>Immunological: hypersensitivity reactions (5–10%) including rash and fever</p>	<p>Metabolic: hypothyroidism</p> <p>Haematological: haemolytic anaemia (patients with G6PD deficiency), agranulocytosis, eosinophilia, leucopenia and thrombocytopenia</p> <p>Hepatic: acute hepatitis (rare)</p>

WHO grouping	Drug	Common side effects	Serious side effects
Group D: add-on agents	Bedaquiline	Arthralgia Chest pain Gastro-intestinal: nausea Neurological: headache Respiratory: haemoptysis	Cardiovascular: QTc prolongation (more common in hypokalaemia, proarrhythmic conditions, in combination with other drugs that prolong the QT interval such as clofazimine, fluoroquinolones or macrolides) Hepatic: increases in LFTs
	Delamanid	Dermatological: dermatitis and urticaria Gastro-intestinal: nausea, vomiting, diarrhoea Neurological: dizziness, insomnia, paraesthesia, tremor Respiratory: haemoptysis	Cardiovascular: QTc prolongation; increased risk if: hypoalbuminaemia (especially <28 g/L), known congenital prolongation of the QTc interval, any condition or concomitant drug that may prolong the QTc interval Haematological: anaemia, eosinophilia, thrombocytopenia, leucopenia Hepatic: increases in LFTs Metabolic: hypertriglyceridaemia, hypercholesterolaemia Psychiatric: psychotic disorder, agitation, anxiety, depression, restlessness
	<i>p</i> -Aminosalicylic acid	Gastro-intestinal: nausea, vomiting, diarrhoea, abdominal pain Immunological: hypersensitivity reactions (5–10%) including rash and fever	Metabolic: hypothyroidism Haematological: haemolytic anaemia (patients with G6PD deficiency), agranulocytosis, eosinophilia, leucopenia and thrombocytopenia Hepatic: acute hepatitis (rare)

G6PD, Glucose-6-phosphate dehydrogenase; LFT, liver function test; SJS, Stevens–Johnson syndrome; TB, tuberculosis; TEN, toxic epidermal necrolysis. Adapted from the UK TB Drug Monographs.

Drug interactions

Rifampicin is a potent inducer of cytochrome P450 enzymes, and drug interactions are common, resulting in accelerated drug metabolism and reduced plasma concentrations. An accurate medication history must be taken, including herbal and over-the-counter remedies. Common significant drug interactions frequently encountered in clinical practice, resulting in reduced efficacy, include opiate analgesics, anticoagulants, antiepileptics, antifungals, antivirals, corticosteroids, immunosuppressants and hormonal contraceptives.

The absorption of isoniazid and rifampicin is reduced in the presence of food, and both should both be taken on an empty stomach, 30–60 minutes before food or 2 hours after food.

Isoniazid is also associated with a possible increased risk of headache, sweating, palpitations, flushing and hypotension when eating certain foods rich in histamine or tyramine such as cheese, skipjack tuna or other tropical fish, or red wine. In practice, no dietary restrictions are usually required unless symptoms are experienced. This reaction is thought to be due to an exaggerated histamine poisoning reaction following inhibition of histamine metabolism, or to the sympathomimetic action of tyramine resulting from inhibition of monoamine oxidase.

Adherence

Ensuring full adherence to treatment is critical to achieving treatment success, because non-adherence risks not only treatment

failure, but also disease relapse, development of drug resistance and transmission to other people. Factors that affect adherence to treatment include communication barriers, size and number of tablets, adverse events of treatment and cost of prescriptions.

Approximately three-quarters of new cases of TB in England are born outside the UK ([Public Health England, 2017](#)), and language barriers may exist. Communication and adherence can be supported by the provision of PILs, such as those produced by TB Alert, which contain photographs of the tablets that the patient takes, and are available in a range of foreign languages.

To reduce tablet burden to support adherence, FDC tablets are recommended in TB treatment regimens, to prevent patients from being selective about which drugs to take and prevent drug resistance from developing, which may occur with separate drugs. Although there is a lack of evidence on adherence with different treatment regimens in TB, studies have demonstrated that FDC tablets are easier to swallow and more convenient to take than taking the four drugs given separately ([Bartacek et al., 2009](#)).

Supervised versus unsupervised treatment

Most patients diagnosed with active TB in the UK do not need to have their treatment supervised, but all should have a risk assessment for their likely adherence, and Directly Observed Therapy (DOT) should be considered for patients thought likely to be non-adherent. DOT should be considered for people who:

- have a history of non-adherence;
- have been treated previously;

- have a history of homelessness, drug or alcohol misuse;
- are currently in prison or have been in the past 5 years;
- have a major psychiatric, memory or cognitive disorder;
- are in denial of the diagnosis;
- have MDR-TB.

DOT is performed by directly observed swallowing of medication, and for drug-sensitive TB this is usually given three times weekly (often on Mondays, Wednesdays and Fridays) rather than daily (see doses in [Table 41.1](#)). Healthcare workers are usually responsible for observing medication being swallowed, although relatives or friends may be suitable observers in some situations. Although in the UK TB nurses frequently provide the DOT service, this can also be performed by community pharmacies as an enhanced service subject to local funding arrangements. The use of DOT (either given daily or intermittently) has been demonstrated to have similar outcomes in terms of cure and cure plus treatment completion in a systematic review ([Karumbi and Garner, 2015](#)).

Patient education

When commencing treatment, all patients should receive verbal and written information on their diagnosis, whether active or latent TB infection, and their treatment. Although all patients must be issued with a PIL provided by the manufacturer, these may be hard for some patients to read because of the complexity of language and size of the text. Consequently, many patients find the TB Alert PILs easier to read and understand, particularly because these are available in many languages.

Patients should be advised of the benefits of treatment, emphasising that complete adherence to treatment will ensure that they will be cured, but whilst they may begin to feel better within a few weeks, the full treatment course will take months to prevent relapse of disease. All patients should be advised that they may experience side effects, and whilst some may be harmless or temporary, others may be more serious and require the patient to contact a named healthcare professional.

Special circumstances

Renal disease

Several anti-TB drugs are eliminated by the renal route and consequently may require dose adjustment in moderate to severe kidney disease ([Milburn et al., 2010](#)). Of the first-line drugs, pyrazinamide and ethambutol should have their dose interval extended to three times weekly dosing in stage 4 and 5 chronic kidney disease, whereas isoniazid and rifampicin may be continued at the full daily dose. The dose and/or frequency of a number of second-line anti-TB drugs should also be adjusted, including all injectable agents, prothionamide, cycloserine and *p*-aminosalicylic acid. Patients with chronic kidney disease should be closely monitored for adverse effects, and therapeutic drug monitoring may be utilised to ensure that a safe and effective dose is used, particularly for ethambutol, aminoglycosides and cycloserine.

Liver disease

The incidence of active TB is increased in people with chronic liver disease, but is complicated by the fact that many anti-TB drugs are potentially hepatotoxic. The frequency of hepatotoxicity is also increased in the presence of liver cirrhosis, chronic hepatitis B and chronic hepatitis C. Such patients should be closely monitored with regular and frequent checks of LFTs, and treatment suspended if there is a rise in plasma aspartate aminotransferase or alanine aminotransferase greater than five times the upper limit of normal, or three to five times the upper limit if also symptomatic.

Pregnancy and breastfeeding

Active TB during pregnancy poses risks to both the mother and fetus, as well as to any close contacts. Complications of TB in pregnancy include spontaneous abortion, preterm labour, low birth weight and increased neonatal mortality. The first-line anti-TB drugs isoniazid, rifampicin, pyrazinamide and ethambutol are all considered compatible with use in pregnancy, and any risks of harm from these drugs are outweighed by the risks of untreated active TB. Many second-line drugs are not compatible with use in pregnancy, in particular the aminoglycosides, which are associated with hearing and/or balance problems.

Pregnant women who are diagnosed with latent TB infection may choose to delay commencing chemoprophylaxis until after delivery, provided that active TB is definitively excluded.

Breastfeeding is considered safe whilst taking anti-TB drugs, and all mothers should take supplemental pyridoxine 10–50 mg daily whilst taking isoniazid given the small risk of neurotoxicity to the feeding infant.

Elderly

The use of anti-TB drugs may be complicated in elderly patients because of the presence of comorbidities, drug interactions and increased incidence of adverse effects of treatment compared with younger people. In particular, healthcare professionals should be alert for the presence or worsening of renal or liver disease, and adverse effects of anti-TB drugs. Where necessary, doses may need to be adjusted and potential drug interactions managed by altering existing treatment plans.

Children

The treatment of TB in children is similar to that of adults, requiring a 2-month intensive phase of four drugs followed by a 4-month continuation phase of two drugs (extended to 12 months for TB affecting the CNS). See [Table 41.1](#) for recommended doses. Adverse effects of treatment tend to be less frequent in children than in adults, and consequently LFTs do not need to be routinely monitored unless there is clinical suspicion of hepatotoxicity. Furthermore, because isoniazid may cause pyridoxine deficiency, supplementation is recommended in children at higher risk of experiencing symptoms, particularly malnourished children, HIV-infected children, breastfeeding infants and pregnant adolescents.

Treatment in children is also complicated by the lack of availability of drug preparations suitable for use in children. Of the FDCs, Rifater (rifampicin, isoniazid, pyrazinamide) may not be appropriate as the dose of each drug is not suitable for recommended doses in children; Voractiv (rifampicin, isoniazid, pyrazinamide, ethambutol) is not licensed for children younger than 8 years or less than 30 kg body weight; and Rifinah (rifampicin, isoniazid) is licensed only for use in adults. Consequently children diagnosed with TB frequently receive treatment with the four anti-TB drugs given separately. However, some UK specialist paediatric TB centres do use FDCs, but only after careful consideration of individual doses, which may require dose supplementation with individual drugs.

There is a lack of suitable preparations to use if children are unable to swallow large tablets. Rifampicin syrup is the only licensed liquid preparation available for treating TB, whilst isoniazid, pyrazinamide and ethambutol must all be ordered as an unlicensed special.

Case studies

Case 41.1

Mr SD is a 25-year-old man with a history of drug use, for which he is prescribed daily supervised methadone. He was released from prison 2 years ago. He has been referred to a chest physician with a cough productive of sputum and a fever (2 months in duration). A sputum sample, obtained by his primary care doctor, is positive for acid, alcohol-fast bacilli, and a chest radiograph shows right upper lobe cavities. A diagnosis of TB is made.

Questions

1. What risk factors does Mr SD have for TB?
2. What effects might TB treatment have on methadone, and how should this be managed?
3. How should Mr SD's TB treatment be managed?

Answers

1. Mr SD may be at risk of TB because of his lifestyle. He has the potential for chronic poor health and nutrition due to drug and alcohol abuse, which could result in a weakened immune system. The risk of TB in prisoners and people who have recently been discharged from prison in the UK is not currently clear, although prisoners are more likely to have other risk factors for TB (such as social exclusion and drug abuse). Recently, TB in UK prisoners has increased.
2. Rifampicin is a potent inhibitor of cytochrome P450 enzymes and will accelerate the metabolism of methadone, which can result in withdrawal symptoms. It is likely that most patients will require significant increases in methadone dose (as much as twofold to threefold dose increases) whilst being prescribed rifampicin. Consequently, the drug addiction service that prescribes Mr SD's methadone should be advised of the TB diagnosis and asked to monitor withdrawal symptoms and adjust the methadone dose accordingly. An appointment with the drug addiction service should ideally be arranged within 24 hours of commencing TB treatment.

An alternative option would be to use rifabutin instead of rifampicin, because it appears to interact to a lesser extent.

3. Due to his history, Mr SD would be considered high risk of non-adherence to TB treatment, and a DOT regimen should be strongly considered. This could be provided by local TB nurses, or alternatively the community pharmacist who supervises Mr SD's methadone treatment could be asked to provide this role. Community pharmacists may provide DOT as an enhanced service, with an agreement between the TB service and pharmacist about each other's responsibilities, including when the pharmacist should refer back to the TB service, for example, because of side effects or non-adherence.

Case 41.2

Ms RW is a 28-year-old Lithuanian woman who has lived in England for 3 years. She has been referred to the TB clinic with a 2-month history of weight loss, fever, night sweats and productive cough. Chest X-ray shows upper lobe infiltrates and cavities on both sides. A diagnosis of pulmonary TB is made.

Questions

1. Is Ms RW at low or high risk of drug-resistant TB?
2. Should she be in isolation?
3. What microbiological investigations are required?
4. What treatment should she receive?

Answers

1. Data collated by the WHO show that 12% of new TB cases in Lithuania are MDR-TB (WHO, 2017). Consequently Ms RW would be assumed to be at high risk of having MDR-TB.
2. Because there is a high risk of MDR-TB, Ms RW should be admitted to a negative pressure isolation room until she is demonstrated to be either not drug-resistant or non-infectious.
3. Sputum samples should be taken and undergo smear to test for the presence of acid, alcohol-fast bacilli. If positive, they should then undergo rapid diagnostic nucleic acid amplification tests for rifampicin resistance. Tests should also be done to assess susceptibility to other drugs.
4. Treatment should incorporate at least four second-line anti-TB drugs that are likely to be effective, in addition to pyrazinamide. In the absence of any history of contact with other cases of drug-resistant TB, a suitable regimen is likely to initially comprise pyrazinamide, a fluoroquinolone (e.g. moxifloxacin), an injectable agent (e.g. capreomycin), prothionamide and cycloserine. This should be supplemented with pyridoxine, to reduce neurological side effects from cycloserine, and an antiemetic.

Case 41.3

Mr KP is a 40-year-old man who was born in India. Six weeks ago, he was referred to the TB clinic with a productive cough and fever. Chest X-ray film showed patchy upper lobe consolidation, and sputum smear was positive for acid, alcohol-fast bacilli. He was commenced on Voractiv treatment as an outpatient.

Mr KP subsequently failed to turn up for his weeks 2 and 4 outpatient appointments, and so the local TB nurses had scheduled a home visit, but Mr KP was not at home at the appointed time.

His wife was at home, and she telephoned Mr KP on his mobile phone so that the TB nurses could speak to him. He admitted that he had taken only a few days of treatment and did not intend to take any more. The TB nurses advised him that if he did not take his treatment, he would need to be admitted to hospital.

Questions

1. What form of TB does Mr KP have?
2. How can Mr KP be forced into hospital admission?
3. Which groups of healthcare staff should be involved in arrangements for his admission to hospital?

Answers

1. Mr KP has sputum-smear-positive pulmonary TB, and thus would be considered to be and potentially pose an infection risk to others.
2. In the UK legal measures are allowed for compulsory admission of people with infectious pulmonary TB under section 37 of the Public Health (Control of Disease) Act 1984. Two separate applications to the magistrates court are required for compulsory hospital admission: the first for the admission, and the second for detention under section 38 of the Public Health (Control of Disease) Act 1984. This allows an infectious person to be isolated and prevent transmission; however, compulsory treatment of TB is not allowed.
3. Because Mr KP is infectious, admission to a hospital side room is required. A multidisciplinary approach should be taken to prepare and plan for the compulsory admission, including the ward nursing staff, doctors and public health representatives. This should be discussed with the patient, including the reasons why he will need to be kept in isolation.

Case 41.4

Mr FR, a 50-year-old man being treated for pulmonary TB, is reviewed in the outpatient clinic at week 4 of his standard anti-tuberculous treatment (isoniazid, rifampicin, pyrazinamide and ethambutol). He reports feeling generally run-down with some increased nausea. Routine blood tests are performed and his alanine transaminase (ALT) has risen from 37 to 230 U/L.

Questions

1. Should Mr FR’s treatment be stopped?
2. What is the likely causative medicine?
3. How should the medicines be re-introduced?

Answers

1. Once the ALT has risen to five times the upper limit of normal (>200 U/L), then the medicines should be discontinued.
2. Unfortunately, all of the drugs used can cause liver toxicity. The least likely cause is ethambutol.
3. Mr FR’s liver function should be monitored off treatment to ensure it is returning to baseline. At the same time it is important to assess for factors that may have increased risk of liver toxicity, such as viral hepatitis. When the ALT is less than two times the upper limit of normal (<80 U/L) reintroduction can take place in a sequential fashion starting with ethambutol plus either isoniazid or rifampicin. Pyrazinamide is reintroduced last, because it may be the most likely culprit. Latest NICE guidelines (NICE, 2016) recommend that the reintroduction regimen should take place quickly over no more than 10 days.

42 HIV Infection

Sheena Castelino, Alison Grant and Katie Conway

Key points

- As a result of effective combination antiretroviral therapy (cART), infection with the human immunodeficiency virus (HIV) has changed from being a terminal illness to a long-term manageable chronic infection, and many people living with HIV can enjoy a good quality of life, with essentially normal life expectancy.
- Untreated infection with HIV leads to a progressive deterioration in the cellular immune response. After primary HIV infection (PHI), or 'seroconversion', the infected individual may appear asymptomatic for a number of years before experiencing development of symptomatic disease and/or acquired immune deficiency syndrome.
- Complications arising from untreated HIV infection can manifest in a variety of ways, usually as opportunistic infections or malignancies that are uncommon in the immunocompetent population.
- The aim of the treatment of HIV infection is to suppress viral replication to prevent further deterioration of the immune system and allow immune reconstitution, thereby reducing morbidity and mortality associated with chronic HIV.
- Currently available antiretroviral agents are classified by their mechanism of actions as nucleoside or nucleotide analogue reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, integrase inhibitors and entry inhibitors.
- Antiretroviral agents are given in combination, usually of at least three agents, to improve efficacy and reduce the development of viral resistance. A high level of adherence to therapy is vital to ensure efficacy and prevent the emergence of resistant virus.
- Treatment regimens have improved both in terms of efficacy and tolerability over time, with the majority of people living with HIV experiencing virological suppression and good treatment outcomes. There are some important toxicities related to ART, and drug–drug interactions remain a challenge, particularly when faced with an aging HIV population and increasing poly-pharmacy.
- Effective treatment and virological suppression also significantly reduce the onward transmission of HIV.

Epidemiology

In June 1981 five cases of *Pneumocystis jirovecii* (formerly known as *carinii*) pneumonia (PCP) were described in homosexual men in the USA. Reports of other unusual conditions, such as Kaposi's sarcoma (KS), followed shortly. In each of these patients, there was found to be a marked impairment of

cellular immune response, and so the term acquired immune deficiency syndrome, or AIDS, was coined. In 1984 a new human retrovirus, subsequently named human immunodeficiency virus (HIV), was isolated and identified as the cause of AIDS.

Although initially described in homosexual men, it soon became apparent that other population groups were affected, including intravenous drug users and individuals with haemophilia. During the first decade, the epidemic grew and the importance of transmission via heterosexual intercourse and from mother to child (vertical transmission) was increasingly recognised. There are two types of HIV: HIV-1, which is the predominant type worldwide; and HIV-2, which is less pathogenic and mainly found in West Africa.

Globally there are more than 36.9 million people living with HIV (UNAIDS, 2015), with the main burden of disease affecting sub-Saharan Africa. Heterosexual transmission of infection is most commonly seen worldwide. In the UK there are more than 100,000 people living with HIV and this number continues to rise, mainly because of effective HIV treatment, an aging HIV population and increased levels of testing. The number of those living with undiagnosed HIV has declined since 2010 (25% to 17% in 2014). There remain high and increasing levels of new infections amongst men who have sex with men (MSM), and prevention strategies are more important than ever. Amongst heterosexuals in 2014, the overall prevalence of HIV is 1 in 1000, but amongst black African men and women rates are 1 in 56 and 1 in 22, respectively. There are declining levels of new infections, in particular from those acquiring HIV abroad particularly from sub-Saharan Africa. However, there is a stable number of heterosexuals acquiring HIV within the UK. Within the heterosexual population, late diagnosis is still a significant problem. In 2014, 55% of cases were diagnosed late (i.e. CD4 cell count <350 cells/mm³), and therefore at a 10-fold increased risk of death over the next year compared with those diagnosed early. The increasing proportion of individuals with HIV who are living into older age leads to an increase in comorbidities, such as cardiovascular disease, osteoporosis and osteopaenia, cancer, cognitive impairment, and hepatic and renal dysfunction. It is postulated that HIV directly and some antiretroviral therapies may contribute to the development of these comorbidities.

The impact of treatment advances on reducing the incidence of AIDS-related illnesses and mortality has been dramatic. However, the absolute numbers of new AIDS diagnoses and HIV-related deaths in the UK have plateaued and are largely due to

late presentation, failure to diagnose HIV infection amongst the asymptomatic population and those disengaged from care.

Although the number living with HIV globally continues to rise, there are encouraging trends which include many low- and middle-income countries having declining incidence (35% decrease since 2000) and fewer AIDS-related deaths (42% decrease since 2004). There has also been an increase in access to available antiretroviral agents (ARVs; 84% increase since 2010). However, challenges remain, with 17.1 million people unaware of their infection and 22 million who still need access to treatment. In resource-poor settings, choice of agents and facilities for monitoring may be limited, and locally produced generic formulations are often used.

The virus has been isolated from a number of body fluids, including blood, semen, vaginal secretions, saliva, breast milk, tears, urine, peritoneal fluid and cerebrospinal fluid (CSF). However, not all of these are important in the spread of infection, and the predominant routes of transmission remain: sexual intercourse (anal or vaginal); sharing of unsterilised needles or syringes; blood or blood products in areas where supplies are not screened or treated; and vertical transmission in utero, during labour or through breastfeeding.

Pathogenesis

HIV, in common with other retroviruses, possesses the enzyme reverse transcriptase and consists of a lipid bilayer membrane surrounding the capsid (Fig. 42.1). Its surface glycoprotein molecule (gp120) has a strong affinity for the CD4 receptor protein found predominantly on the T helper/inducer lymphocytes. Monocytes and macrophages may also possess CD4 receptors in low densities and can therefore also be infected. The process of HIV entry is more complex than originally thought, and in addition to CD4 attachment, subsequent binding to co-receptors such as C-C chemokine receptor type 5 (CCR-5) or C-X-X chemokine receptor type 4 (CXCR-4) and membrane fusion also occur (Fig. 42.2).

After penetrating the host cell, the virus sheds its outer coat and releases its genetic material. Using the reverse transcriptase enzyme, the viral RNA is converted to DNA using nucleosides. The viral DNA is then integrated into the host genome in the cell nucleus, where it undergoes transcription and translation, enabling the production of new viral proteins. New virus particles are then assembled and bud out of the host cell, finally

Fig. 42.1 Structure of the human immunodeficiency virus.

maturing into infectious virions under the influence of the protease enzyme.

During primary HIV infection (PHI), there is a very high rate of viral turnover and a subsequent drop in CD4 count as these cells are depleted. As the host immune system responds to this

new infection, an equilibrium is then reached, which brings the level of the virus down to a 'set point', which is a relatively stable level of virus in the body and will vary between individuals. The CD4 count stabilises and may improve, but to a lower level than before infection occurred. At this stage the infection may appear

Fig. 42.2 Life cycle of human immunodeficiency virus (HIV) and the sites of action of currently available antiretroviral agents (in bold).

to be clinically latent, but in fact, as many as 10,000 million new virions are produced each day.

Over time, as chronic infection ensues, cells possessing CD4 receptors, particularly the T helper lymphocytes, are depleted from the body. The T helper cell is often considered to be the conductor of the 'immune orchestra', and thus as this cell is depleted, the individual becomes susceptible to a myriad of infections and tumours. The rate at which this immunosuppression progresses is variable, and the precise interaction of factors affecting it is still not fully understood. It is well recognised that some individuals rapidly develop severe immunosuppression, whereas others may have been infected with HIV for many years whilst maintaining a relatively intact immune system. It is likely that a combination of viral, host (genetic) and environmental factors contributes to this variation.

Clinical manifestations

Approximately 80% of individuals develop a flu-like illness during PHI, and this is characterised most commonly by a combination of some or all of the symptoms, such as fever, pharyngitis, rash, myalgia and headache/aseptic meningitis. Rarely, the degree of associated CD4 count depletion may be sufficient to result in development of an opportunistic illness such as oropharyngeal/oesophageal candidiasis or *P. jiroveci* pneumonia. During this stage testing is of great importance for the individual's health both to avoid late diagnosis and to reduce onward transmission of the virus because PHI is the most infectious phase.

Although the clinical course of HIV disease varies with each individual, there is a fairly consistent and predictable pattern that enables appropriate interventions and preventive measures to be adopted. Patients can be classified into one of three groups according to their clinical status: asymptomatic, symptomatic or AIDS. This clinical progression generally relates to a decline in CD4 count and advancing immunosuppression.

Asymptomatic disease usually follows PHI and can last for a number of years. Symptomatic disease is characterised by non-specific symptomatology such as fevers, night sweats, lethargy and weight loss, or by complications including oral candidiasis, oral hairy leucoplakia, and recurrent herpes simplex or herpes zoster infections. AIDS is defined by the diagnosis of one or more specific conditions including *P. jiroveci* pneumonia, *Mycobacterium tuberculosis* infection and cytomegalovirus (CMV) disease. The World Health Organization (WHO, 2007) has produced a comprehensive guide to the clinical staging of HIV/AIDS and a full list of HIV-related and AIDS-defining conditions.

The sequelae of untreated HIV infection can be broadly considered in five categories:

- infections that can occur in immunocompetent patients but tend to occur more frequently, more severely and often atypically in the context of underlying HIV infection, for example, *Salmonella*, herpes simplex and *M. tuberculosis*;
- opportunistic infections, that is, infections that would not normally cause disease in an immunocompetent host, for example, *P. jiroveci* pneumonia and CMV;
- malignancies, particularly those that occur rarely in the immunocompetent population, for example, KS and non-Hodgkin's lymphoma;

- direct manifestations of HIV infection, for example, HIV encephalopathy, HIV myelopathy and HIV enteropathy;
- consequences of chronic immune activation, including premature cardiovascular disease, neurocognitive dysfunction and bone mineral density loss.

Investigations and monitoring

Current and previous infections

The initial diagnosis of HIV infection is made using a fourth-generation serological test, which tests for HIV antibodies and antigen simultaneously, and will detect the vast majority of individuals who have been infected with HIV at 4 weeks after specific exposure. A further test at 8 weeks post-exposure need only be considered following an event assessed as carrying a high risk of infection. Many of the rapid 'point-of-care tests' which test in real time, using finger prick or saliva, test only for HIV antibodies and may miss early infection hence have a 'window period' and need to be repeated 3 months after exposure. After confirmation of HIV infection, the patient is usually tested for prior exposure to a number of potential pathogens, including syphilis; hepatitis A, B and C; CMV; varicella zoster virus (VZV) and *Toxoplasma gondii*. This can enable subsequent treatment (in the case of undiagnosed syphilis), vaccination (if no prior exposure to hepatitis A, hepatitis B or VZV), prevention (if no prior exposure to *Toxoplasma* and CMV) and prophylaxis (if previous exposure to *Toxoplasma*), and can aid subsequent diagnosis (according to CMV or *Toxoplasma* status).

CD4 count

The level of immunosuppression is most easily estimated by monitoring a patient's CD4 count. This measures the number of CD4⁺ T lymphocytes in a sample of peripheral blood. The normal range can vary between 500 and 1500 cells/mm³. As HIV disease progresses, the number of cells declines. Particular complications of HIV infection usually begin to occur at similar CD4 counts (Fig. 42.3), which can assist in differential diagnoses and enable the use of prophylactic therapies. For example, patients with a CD4 count less than 200 cells/mm³ should always be offered prophylaxis against *P. jiroveci* pneumonia. The CD4 count is also used to monitor response to antiretroviral treatment.

Viral load

The measurement of plasma HIV RNA (viral load) estimates the amount of circulating virus in the blood. This has been proven to correlate with prognosis, with a high viral load predicting faster disease progression (Mellors et al., 1997). Conversely, a reduction in viral load after commencement of antiviral therapy is associated with clinical benefit. This measure, in combination with the CD4 count, allows patients and clinicians to make informed decisions regarding which antiretrovirals to start, because some perform better at higher viral loads, to ensure that the medications are working (maintaining a fully suppressed viral load) and when to change antiretroviral therapies (i.e. virological failure), enabling the most effective use of such agents.

Fig. 42.3 Opportunistic complications of human immunodeficiency virus (HIV) infection and the CD4 count ranges at which they commonly occur.

Resistance testing

Certain mutations in the HIV virus confer resistance to certain antiretrovirals. Due to the implications of transmitted (primary) resistance, it is recommended that all patients have a genotypic HIV resistance test performed soon after diagnosis; this will ensure that appropriate initial therapy is selected. Further resistance tests should be performed at any subsequent virological failure to direct therapy choice.

Tropism testing

Viruses may enter the CD4 cell using the CCR5 co-receptor, the CXCR4 co-receptor or both co-receptors. Those that just use one co-receptor are known as CCR5-tropic or CXCR4-tropic viruses; those that can use both receptor types are called dual-tropic. Where a mixture of virus populations is present, the term mixed-tropic is used. Different methods of determining tropism are currently under evaluation. The tests must be performed in real time because viral tropism changes as the disease progresses. If CCR5 inhibitors are to be used, it is essential to determine that the virus is CCR5 tropic; that is, that there is no significant use of the CXCR4 receptor.

Drug treatment

The drug treatment of HIV disease can be classified as antiretroviral therapy, the management of opportunistic infections or malignancies, the management of ‘non-HIV-related’ comorbidities and

symptom control. For the first decade of the epidemic, most of the available drugs and therapeutic strategies were aimed at treating or preventing opportunistic complications and alleviating HIV-related symptoms. Since the advent of effective combination antiretroviral therapy (cART) the main aim is to suppress the HIV viral load, restore immune function and reduce the potential consequences of comorbidities. Unfortunately some opportunistic infections are still seen, as well as malignancies, often because of late diagnosis and because patients are from populations which are disengaged from care. Management of comorbidities is becoming much more important because the majority of people with HIV are living to an older age.

The speed at which new antiretroviral agents are developed means that there is often a lack of comprehensive data on drug interactions, side effects, etc. Thus, the ability to apply general pharmacological and pharmacokinetic principles, together with common sense, is required.

The treatment of many of the opportunistic complications of HIV comprises an induction phase of high-dose therapy, followed by maintenance and/or secondary prophylaxis using lower doses. This is due to the high rate of relapse or progression after a first episode of diseases such as *P. jiroveci* pneumonia, cerebral toxoplasmosis, systemic cryptococcosis and CMV retinitis. Where a cost-effective agent with an acceptable risk/benefit ratio exists, primary prophylaxis may be offered to individuals who are deemed to be at high risk of development of a particular opportunistic infection, for example, PCP prophylaxis. Discontinuation of prophylaxis, both primary and secondary, is

possible in individuals who demonstrate immunological restoration on cART.

Paradoxically, this immunological restoration may result in apparent clinical deterioration with opportunistic infections during the first few weeks after initiation of highly active antiretroviral therapy. This is known as immune reconstitution inflammatory syndrome and usually occurs in those with a low baseline CD4 count.

The goals of therapy in people living with HIV are to:

- improve the quality and duration of life,
- prevent deterioration of immune function and/or restore immune status,
- treat and/or prevent opportunistic infections,
- relieve symptoms.

Antiretroviral therapy

Antiretroviral therapy is one of the fastest evolving areas of medicine. The specific details of treatment will therefore continue to change as new drugs emerge, although it is likely that the following general principles will remain:

- A combination of three antiretroviral agents, selected on the basis of treatment history and resistance tests, should usually be prescribed to increase efficacy and reduce the development of drug-resistant virus.
- Treatment strategies should be adopted that sequence drug combinations, being mindful of potential cross-resistance and future therapy options.
- Given the crucial importance of a high level of adherence to these therapies, the regimen adopted for a particular individual should, wherever possible, be tailored to suit his or her daily lifestyle.

Many organisations, such as the British HIV Association (BHIVA), the European AIDS Clinical Society, the International AIDS Society and the WHO, produce regularly updated guidelines on the use of antiretroviral therapy. These guidelines include the most up-to-date considerations of:

- when to start therapy;
- what to start with;
- how to monitor, including use of therapeutic drug monitoring (TDM) and resistance testing;
- when to switch therapy;
- what therapy to switch to;
- treating individuals who have been highly exposed to multiple agents;
- managing individuals with significant comorbidities, for example, tuberculosis (TB) or hepatitis B/C.

Most studies that evaluate triple combinations of antiretrovirals have been designed with so-called surrogate marker endpoints, measuring the effect on laboratory parameters such as CD4 count and HIV viral load. These trials are generally smaller and shorter in duration than clinical endpoint studies that are powered to measure the impact on survival and disease progression. [Hammer et al. \(1997\)](#) undertook the first large clinical endpoint trial that demonstrated the superiority of a triple combination over dual therapy. Following the results of this trial, the standard approach, where treatment is indicated, has been to use a combination of at least three agents. The reduction

in morbidity and mortality associated with triple therapy has been confirmed in routine clinical practice, as well as in other trials (e.g. [Palella et al., 1998](#); [Smit et al., 2006](#)). Subsequent clinical trials have largely been for licensing purposes and/or have served to refine therapeutic choices rather than to change the paradigm of treatment. The concept of intermittent rather than continuous therapy was evaluated in the SMART study but shown to be linked with an increased risk of comorbidities not previously thought to be associated with HIV (such as cardiovascular disease, hepatic failure and renal failure), as well as HIV disease progression ([El-Sadr et al., 2006](#)).

There are studies which have evaluated novel strategies, such as monotherapy/dual-therapy approaches to reduce drug exposure and cost. The current BHIVA guidelines ([BHIVA, 2015](#)) advise triple therapy in those initiating cART and advise against boosted protease inhibitor (PI) monotherapy because of lower rates of virological efficacy ([Delfraissy et al., 2008](#)). Specific dual therapy can be used (darunavir [boosted with ritonavir] plus raltegravir) if there is a need to avoid certain nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), but with specific CD4 and viral load boundaries. Switching those patients who have achieved virological suppression because of toxicity, interactions or personal preference usually ensures patient adherence and subsequent maintenance on triple therapy. However, there are dual-therapy strategies should drug toxicities become problematic with a boosted PI plus lamivudine as the recommended alternative to triple therapy.

When to start therapy

Current UK guidelines ([BHIVA, 2015](#)) recommend starting antiretrovirals in all patients living with HIV regardless of their CD4 count. This is a change from previous guidelines, which recommended starting therapy when the CD4 count declined to ≤ 350 cells/mm³. This change was based on a large global study ([INSIGHT START Study Group, 2015](#)) which showed the risk of development of AIDS, serious non-AIDS events or death (combined as the primary endpoint) after 3 years was reduced by 57% in those who started at a higher CD4 count compared with patients who waited until their CD4 declined to ≤ 350 cells/mm³. In the UK, current funding is lagging behind guideline advice; therefore, patients are offered treatment with a CD4 ≤ 350 cells/mm³, hepatitis B/C co-infection and specific conditions (e.g. HIV-associated nephropathy, malignancy, pregnancy) and treatment as prevention. Treatment as prevention is the use of ARVs to suppress viral load to undetectable levels, to reduce the likelihood of onward transmission. This has been demonstrated to be highly effective in a number of large randomised control trials ([Cohen et al., 2011](#); [Rodger et al., 2014](#)).

Choosing and monitoring therapy

The majority of individuals are currently commenced on a combination of two NRTIs and a third agent: either a boosted PI, an integrase inhibitor (INI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI). The term 'boosted PI' refers to a combination of one PI combined with a low dosage (usually 100–200 mg once or twice daily) of ritonavir, another PI. The ritonavir

does not directly add to the antiretroviral activity of the regimen; it is used purely as a pharmacokinetic enhancer of the other PI, by increasing the maximum plasma concentration, C_{\max} , due to inhibition of cytochrome P450 enzymes and P-glycoprotein in the gut wall and/or extending the half-life ($t_{1/2}$) by inhibition of hepatic cytochrome P450 enzymes. Triple NRTI therapy is no longer recommended because it is associated with unacceptable rates of virological failure.

The aim of initial therapy is to achieve viral load suppression in the plasma to levels less than the detection limits of available assays (50 copies/mL). Such virological suppression is almost invariably accompanied by an elevation in CD4 count and clinical evidence of immune reconstitution. Whilst sustained suppression over many years is usually possible, viral rebound may occur and is often accompanied by the development of resistance to one or more agents in the combination. Upon confirmed virological failure, a resistance test is performed which will help to identify to which agents the virus may have adapted and the extent to which any such resistance mutations may confer cross-resistance to other available drugs. A second-line regimen is then constructed, wherever possible, utilising a new class of drug to which the individual has not previously been exposed. Upon virological failure of subsequent regimens, the available therapeutic options become increasingly complex, but with the availability of more agents targeting different parts of the virus life cycle, virological suppression is still usually possible and should remain the goal of treatment.

General prescribing guidelines for antiretrovirals are presented in [Box 42.1](#), whereas details of common side effects and interactions of the currently available agents are summarised in [Table 42.1](#).

The routine use of TDM is not recommended, but blood levels of PIs and NNRTIs should be measured in selected patients, for example, where there is liver impairment, suspected non-adherence, in pregnancy and children, or where there are concerns regarding potentially interacting drugs.

HIV mutates readily, and resistance to some antiretrovirals develops rapidly in the face of suboptimal treatment, for example, monotherapy or subtherapeutic blood levels. A high level of adherence to treatment is crucial to the sustained, successful outcome of antiretroviral regimens. In view of this, patients should be advised to take cART as close as possible to the same time every day and ideally within 2 hours of the agreed time each day. If they forget a dose, it should be taken as soon as they remember and then return to the original schedule. There are variations in the genetic barrier to resistance of different antiretrovirals. Many are fragile in terms of development of drug resistance in that a single point mutation will confer drug resistance, which can cross the drug class (NRTIs, NNRTIs and some INIs). cART with boosted PIs (particularly darunavir) and dolutegravir (INI) allow more latitude because it takes a number of mutations to reduce their efficacy and as such will be more appropriate for patients who struggle with adherence or who have historical drug resistance.

There has been significant progress over the years in reducing some of the physical burden of therapy, through the development of combination tablets and the use of strategies such as ritonavir boosting to reduce dietary restrictions and dosing frequency.

Box 42.1 General prescribing and monitoring information for antiretroviral agents

- The Liverpool University HIV Drug interaction website is an invaluable tool and should be consulted, and other clinicians managing people living with HIV should be informed of this resource (<http://www.hiv-druginteractions.org>).
- The Summary of Product Characteristics, current British National Formulary and national guidelines should be consulted when managing the treatment of an HIV-positive patient.
- Adverse events should be reported. With greater exposure and long-term use, it is likely that more adverse events will be recognised. Some of these may be class effects associated with particular groups of antiretrovirals and should therefore be monitored even in new agents within a class. Examples include dyslipidaemia and diabetes mellitus with PIs, mitochondrial myopathy and lipoatrophy with NRTIs, and rash with NNRTIs.
- There are limited data on the safety of many antiretroviral drugs when taken during pregnancy and their long-term effects on babies/children. Updated safety information from the Antiretroviral Pregnancy Register is published twice yearly. Caution should therefore be exercised with all agents. Treatment of women who are planning conception or who are pregnant must be discussed with the relevant experts and guidelines consulted ([BHIVA, 2014](#)). All pregnant women who are treated with antiretrovirals should be reported prospectively to the Antiretroviral Pregnancy Register.

Adherence aids such as pillboxes, medication record cards and alarms (e.g. on mobile phone) can also help to support adherence. However, practical issues are not the only barriers to adherence, and the individual's health beliefs and motivation, particularly around HIV and antiretroviral therapy, should also be addressed before treatment is commenced, because these are likely to have a significant impact on outcome ([Horne et al., 2004](#)). Although there is little evidence to demonstrate what the optimal interventions to improve adherence are, multidisciplinary and multi-agency approaches appear to be most useful ([Poppa et al., 2004](#)).

Treatment interruptions

For many reasons, including toxicity, cost and adherence, patients and clinicians have been interested in considering 'drug holidays' or treatment interruptions. However, this strategy is no longer recommended in routine practice ([El-Sadr et al., 2006](#)). It is now recognised that there are dangers associated with this approach because of CD4 decline, disease progression, mortality related to comorbidities, for example, cardiovascular disease, and viral load rebound associated with increased transmission risk and a seroconversion-like syndrome. Further, because different anti-HIV medications have different half-lives, there may be a risk of functional monotherapy, particularly with NNRTIs, and the development of resistance if combinations are stopped abruptly in an unplanned fashion.

Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) involves the use of antiretroviral drugs to prevent infection with HIV after possible

Table 42.1 Commonly used antiretroviral drugs: adult dosing information and general prescribing points

Drug and formulation	Dosage	Side effects	Main interactions/caution
NRTIs			
abacavir (ABC) 300 mg tablets 300 mg/15 mL oral solution Ziagen	300 mg twice a day/600 mg once a day	Nausea, vomiting, diarrhoea Rash (without systemic symptoms) Fatigue, fever, headache HSR: in clinical studies and post-marketing surveillance ~6–8% of patients developed this usually within the first 6 weeks (but may occur anytime) with symptoms indicating multi-organ system involvement – fever with or without a rash (maculopapular or urticarial), respiratory symptoms, gastro-intestinal symptoms, malaise, fever, myalgia, elevated LFTs; symptoms worsen with continued therapy and resolve on stopping; once suspected, the patient must not be rechallenged – a second reaction can be life threatening. The risk of HSR is high in patients who test positive for the HLAB*5701 allele; therefore, it should not be used in these patients Take with or without food	Caution with drugs inhibiting or metabolised by alcohol dehydrogenase or UDP transferase (i.e. disulfiram, chlorpromazine, isoniazid, chloral hydrate, alcohol, retinoids) Caution with potent enzyme inducers of UDP transferase (e.g. rifampicin, phenobarbitone, phenytoin) – may reduce levels of abacavir Monitor for evidence of withdrawal if given with methadone Abacavir and ribavirin share the same phosphorylation pathway and may compete for phosphorylation which could lead to a reduction in intracellular phosphorylated metabolite of ribavirin and reduced sustained virological response to hepatitis C treatment
emtricitabine (FTC) 200 mg capsule 10 mg/mL oral solution 200 mg capsule = 240 mg solution Emtriva	200 mg once a day Adjust dose in renal impairment CrCl < 50 mL/min	Headache, nausea and vomiting, diarrhoea, ↑ creatine kinase Insomnia, dizziness, neutropenia and anaemia, ↑ amylase, rash, ↑ LFTs Skin hyperpigmentation has been reported Take with or without food	Do not give concurrently with other cytidine analogues like lamivudine In patients co-infected with hepatitis B, discontinuation of emtricitabine may result in a rebound hepatitis – monitor LFTs and markers of HBV replication
lamivudine (3TC) 150 mg tablets 300 mg tablets 150 mg/15 mL oral solution EpiVir	150 mg twice a day/300 mg once a day Adjust dose in renal impairment CrCl < 50 mL/min	Headache, insomnia, nausea and vomiting, gastro-intestinal disorders, cough and nasal symptoms, neutropenia and anaemia (in combination with zidovudine), ↑ amylase, rash, alopecia, arthralgia Take with or without food	Avoid high-dose co-trimoxazole (trimethoprim increases lamivudine levels by 40%, dosage adjustment needed in renal impairment) In patients co-infected with hepatitis B, discontinuation of lamivudine may result in a rebound hepatitis – monitor LFTs and markers of HBV replication
zidovudine (AZT) 100 mg and 250 mg capsules Syrup 50 mg/5 mL Retrovir	250 mg twice a day/200 mg three times a day (up to 250 mg four times a day) Adjust dose in renal impairment CrCl ≤ 10 mL/min	Anaemia, neutropenia, leucopenia, myalgia, nausea and vomiting, anorexia, rash, headache, insomnia, nail and skin pigmentation Take with or without food	↑ Risk of myelotoxicity with ganciclovir, high-dose co-trimoxazole, pyrimethamine, dapsone, flucytosine, vinblastine, doxorubicin, interferon-α Caution with potentially nephrotoxic drugs – pentamidine, amphotericin, aminoglycosides, ribavirin Monitor if receiving phenytoin (reports of changes in phenytoin levels) Do not use with ribavirin (increased risk of anaemia) Clarithromycin reduces the absorption of zidovudine (give 2 h apart) Reports of lactic acidosis and mitochondrial toxicity

Table 42.1 Commonly used antiretroviral drugs: adult dosing information and general prescribing points—cont'd

Drug and formulation	Dosage	Side effects	Main interactions/caution
NTRTIs			
tenofovir disoproxil (TDF) 245 mg (tenofovir disoproxil fumarate 300 mg) Viread	245 mg once a day Adjust dose in renal impairment CrCl <50 mL/min Take with or after food	Gastro-intestinal upset (diarrhoea, flatulence, nausea and vomiting), renal impairment, hypophosphatemia, proximal tubulopathy (including Fanconi syndrome) have been reported, decrease in bone mineral density	Monitoring renal function recommended before starting and 2–4 weeks of treatment, at 3 months, and thereafter every 3–6 months; more frequent monitoring required in patients with renal impairment Avoid giving with potentially nephrotoxic drugs (e.g. pentamidine, amphotericin, aminoglycosides) Avoid concomitant use of cidofovir which is secreted by the same renal pathway as tenofovir In patients co-infected with hepatitis B, discontinuation of tenofovir disoproxil may result in a rebound hepatitis – monitor LFTs and markers of HBV replication
tenofovir alafenamide (TAF) Available only in combination products F/TAF 200 mg/10 mg emtricitabine 200 mg/tenofovir alafenamide 10 mg Descovy 200 mg/10 mg F/TAF 200 mg/25 mg emtricitabine 200 mg/tenofovir alafenamide 25 mg Descovy 200 mg/25 mg R/F/TAF 25 mg/200 mg/25 mg rilpivirine/emtricitabine/tenofovir alafenamide Odefsey emtricitabine 200 mg, elvitegravir 150 mg/cobicistat 150 mg/tenofovir alafenamide 10 mg Genvoya	F/TAF 200 mg/10 mg recommended with boosted PIs (e.g. atazanavir/ritonavir or darunavir/ritonavir or Kaletra) F/TAF 200 mg/25 mg recommended with unboosted third agents (e.g. dolutegravir, raltegravir, rilpivirine, efavirenz, nevirapine) F/TAF can be taken with or without food E/C/F/TAF should be taken with or after food R/F/TAF must be taken with a meal (390 kcal) TAF is not recommended if eGFR < 30 mL/min	Better safety profile on bone and kidneys relative to tenofovir disoproxil fumarate	In patients co-infected with hepatitis B, discontinuation of TAF may result in a rebound hepatitis – monitor LFT and markers of HBV replication
NNRTIs^a			
etravirine (ETR) 100 mg 200 mg Tablets Intelence	200 mg twice a day or 400 mg once a day Take with or after food The 100 mg tablets may be dispersed in water	Skin rash, diarrhoea, nausea, headache	Significantly reduces plasma concentrations of dolutegravir Can only be used with dolutegravir when co-administered with atazanavir/ritonavir, darunavir/ritonavir or lopinavir/ritonavir Clarithromycin levels reduced, but concentration of its active metabolite increased (which has reduced activity against <i>Mycobacterium avium</i> complex, so alternatives e.g. azithromycin, are recommended)

			<p>Reduces levels of anticonvulsants carbamazepine, phenobarbital, phenytoin</p> <p>Rifampicin decreases levels of etravirine</p> <p>Rifabutin decreases levels of etravirine and increases levels of rifabutin</p> <p>Reduces levels of antiarrhythmics</p> <p>Increases levels of warfarin</p> <p>Reduces levels of tacrolimus and ciclosporin</p> <p>Reduces the effect of hormonal contraceptives</p>
<p>efavirenz (EFV)</p> <p>200 mg capsules</p> <p>600 mg tablets</p> <p>efavirenz oral solution</p> <p>30 mg/mL</p> <p>600 mg tablet or capsule = 720 mg in 24 mL oral solution</p> <p>Sustiva</p>	<p>600 mg once a day</p> <p>Take at bedtime to minimise CNS side effects</p> <p>Take on an empty stomach to minimise the risk of CNS side effects</p>	<p>Skin rash, CNS effects (e.g. dizziness, light-headedness, insomnia, abnormal dreaming) – generally resolves after the first 2–4 weeks</p> <p>Depression</p> <p>Psychiatric adverse reactions</p>	<p>Do not give with terfenadine, astemizole, cisapride, triazolam, midazolam</p> <p>Efavirenz is an inducer of CYP3A4 and an inhibitor of other cytochrome P450 isoenzymes</p> <p>With clarithromycin ↑ risk of rash and 39% ↓ in clarithromycin concentration, whereas 34% ↑ in concentration of active metabolite of clarithromycin; therefore, use alternatives (e.g. azithromycin)</p> <p>Potential for increase or decrease in levels of phenytoin, phenobarbitone, carbamazepine, methadone – monitor for signs of withdrawal</p> <p>With rifampicin, 26% ↓ in efavirenz concentration; therefore, increase dosage of efavirenz to 800 mg once a day</p> <p>With rifabutin, decrease in rifabutin concentration – increase rifabutin dose by 50%</p> <p>Reduces levels of tacrolimus and ciclosporin</p> <p>Reduces the effect of hormonal contraceptives</p>
<p>rilpivirine (RPV)</p> <p>25 mg tablets</p> <p>Edurant</p>	<p>25 mg once a day</p> <p>Must be taken with a meal (390 kcal)</p>	<p>Skin rash, headache, dizziness, insomnia, depression, abdominal pain</p> <p>Causes mild decrease in creatinine clearance</p>	<p>Antacids (aluminium, magnesium, calcium) should be taken 2 h before or 4 h after rilpivirine</p> <p>Do not use with proton pump inhibitors (loss of therapeutic effect of rilpivirine); can use with H₂ antagonists if dosed once a day and given 12 h before or 4 h after rilpivirine</p>
<p>nevirapine (NVP)</p> <p>200 mg tablets</p> <p>400 mg prolonged-release tablets</p> <p>Suspension 10 mg/mL</p> <p>Viramune</p>	<p>200 mg once a day for 2 weeks (lead-in period to lessen the frequency of rash), then 200 mg twice a day or 400 mg prolonged release once a day</p> <p>Note: Dose escalation should not occur if rash observed during the lead-in period, until rash resolves</p> <p>Adjust dose in renal impairment CrCl < 20 mL/min</p> <p>With or without food</p>	<p>Skin rash (skin reactions including Stevens–Johnson syndrome and toxic epidermal necrolysis have been reported – discontinue immediately if severe or accompanied by constitutional symptoms [fever, blistering, oral lesions]), nausea, headache and abnormal LFTs</p> <p>Patients should be intensively monitored during the first 18 weeks to disclose the potential appearance of severe skin or hepatic reactions</p> <p>Do not initiate nevirapine in female adults if CD4 > 250 cells/mm³ and in male adults if CD4 count > 400 cells/mm³ and detectable HIV viral load because of the risk of serious and life-threatening hepatotoxicity</p>	<p>Not recommended with rifampicin; with rifabutin, monitor for toxicity – some patients may experience large increases in rifabutin levels because of high interpatient variability</p> <p>Nevirapine is a hepatic enzyme inducer; careful monitoring of the effectiveness of other drugs that are metabolised by the cytochrome P450 enzyme system is recommended when taken in combination</p> <p>Methadone levels may be reduced</p> <p>With warfarin has the potential to ↑ or ↓ coagulation time</p> <p>Reduces the effect of hormonal contraceptives</p>

Continued

Table 42.1 Commonly used antiretroviral drugs: adult dosing information and general prescribing points—cont'd

Drug and formulation	Dosage	Side effects	Main interactions/caution
PIs^b			
atazanavir (ATV) 150 mg capsules 200 mg capsules Reyataz	300 mg once a day + ritonavir 100 mg once a day Take with or after food	Nausea, vomiting, headache, diarrhoea, rash, scleral icterus and jaundice, fatigue Asymptomatic QTc prolongation Nephrolithiasis	Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with terfenadine, astemizole, pimozone, ergot derivatives, cisapride, quinidine, bepridil, quetiapine, alfuzosin Caution with amiodarone, lidocaine (↑ levels of these drugs) Caution with drugs known to induce PR prolongation on ECG Not recommended with simvastatin or lovastatin (↑ risk of myopathy including rhabdomyolysis); caution with atorvastatin Caution with sildenafil (↑ in sildenafil levels) With warfarin, monitor anticoagulation parameters Not recommended with apixaban, dabigatran and rivaroxaban (increase in concentration of anticoagulant) With diltiazem, ↓ initial dose of diltiazem by 50% and titrate; caution with verapamil (↑ verapamil levels) Levels of ketoconazole and itraconazole, ciclosporin, tacrolimus may be ↑ With tenofovir ↓ in atazanavir levels; must be used boosted (i.e. atazanavir 300 mg once a day with ritonavir 100 mg once a day) With efavirenz ↓ in atazanavir levels; use 400 mg atazanavir boosted with ritonavir 100 mg once a day Not recommended with nevirapine (↓ atazanavir levels) With antacids or products containing buffers, administer atazanavir + ritonavir 2 h before or 1 h after the buffered product (atazanavir levels reduced because of ↑ gastric pH) Do not give with proton pump inhibitors (e.g. with omeprazole 76% decrease in atazanavir levels due to increase in gastric pH); caution with H ₂ receptor antagonists; give atazanavir 2 h before or 10 h after ranitidine (which should be dosed as 300 mg once a day)
fosamprenavir (FPV) 700 mg tablets 50 mg/mL suspension Telzir	fosamprenavir 700 mg twice a day + ritonavir 100 mg twice a day Take with or after food	Nausea, vomiting, diarrhoea, headache, dizziness, rash Contains sulfonamide moiety – caution in sulfonamide allergy	Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with terfenadine, astemizole, pimozone, ergot derivatives, cisapride, quinidine, bepridil, quetiapine, alfuzosin, lidocaine Caution with amiodarone and other antiarrhythmics (darunavir ↑ levels of these) Not recommended with simvastatin or lovastatin (↑ risk of myopathy including rhabdomyolysis); caution with atorvastatin Caution with sildenafil (↑ in sildenafil levels) With warfarin, monitor anticoagulation parameters Not recommended with apixaban, dabigatran and rivaroxaban (increase in concentration of anticoagulant) Levels of ketoconazole and itraconazole, ciclosporin, tacrolimus may be ↑

<p>darunavir (DRV) 800 mg 600 mg Tablet 100 mg/mL suspension Prezista</p>	<p>darunavir 800 mg once a day + ritonavir 100 mg once a day darunavir 600 mg twice a day + ritonavir 100 mg twice a day (in patients with drug resistance) Take with or after food</p>	<p>Rash, nausea, vomiting, headache, dizziness, insomnia Contains sulfonamide moiety – caution in sulfonamide allergy</p>	<p>Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with terfenadine, astemizole, pimozone, ergot derivatives, cisapride, quinidine, bepridil, quetiapine, alfuzosin Caution with amiodarone, lidocaine (↑ levels of these drugs) Not recommended with simvastatin or lovastatin (↑ risk of myopathy including rhabdomyolysis); use lowest dose of atorvastatin Caution with sildenafil, dose of sildenafil should not exceed 25 mg in 48 h Levels of ketoconazole and itraconazole, ciclosporin, tacrolimus may be ↑ With warfarin, monitor anticoagulation parameters Not recommended with apixaban, dabigatran and rivaroxaban (increase in concentration of anticoagulant) Do not give with ticagrelor (increased levels of ticagrelor)</p>
<p>lopinavir/ritonavir (LPV/RTV) 200 mg/50 mg Tablets Liquid lopinavir 400 mg/ ritonavir 100 mg in 5 mL Kaletra</p>	<p>2 tablets twice a day/4 tablets once a day/5 mL twice a day Take with or after food</p>	<p>Nausea, vomiting, diarrhoea; increase in LFTs, triglycerides and cholesterol</p>	<p>Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with terfenadine, astemizole, midazolam, triazolam, pimozone, ergot derivatives, flecainide, propafenone, cisapride Not recommended with simvastatin or lovastatin (↑ risk of myopathy including rhabdomyolysis); caution with atorvastatin Caution with sildenafil, dose of sildenafil should not exceed 25 mg in 48 h With warfarin, monitor anticoagulation parameters Not recommended with apixaban, dabigatran and rivaroxaban (increase in concentration of anticoagulant) Levels of calcium channel blocking agents may be ↑ Levels of ketoconazole and itraconazole, ciclosporin, tacrolimus may be ↑ Dexamethasone, phenobarbitone, phenytoin, carbamazepine may ↓ lopinavir levels With methadone, methadone levels may be ↓ With clarithromycin, consider ↓ dose of clarithromycin if renal or hepatic impairment Because it contains ritonavir there is the risk of Cushing's syndrome with potent corticosteroids metabolised by cytochrome P450 pathways (e.g. triamcinolone, fluticasone, budesonide) and subsequent risk of iatrogenic adrenal suppression when corticosteroid is discontinued</p>

Continued

Table 42.1 Commonly used antiretroviral drugs: adult dosing information and general prescribing points—cont'd

Drug and formulation	Dosage	Side effects	Main interactions/caution
ritonavir (RTV) 100 mg tablets Solution 400 mg/5 mL Norvir	Used as a pharmacokinetic enhancer at a dosage of 100 mg once a day when taken in combination with atazanavir 300 mg once a day or darunavir 800 mg once a day 100 mg twice a day when taken with darunavir 600 mg twice a day Take with or after food	Nausea and vomiting, diarrhoea, asthenia, taste perversion, circumoral (around the mouth) and peripheral paraesthesia, fatigue and vasodilatation	Do not give with rifampicin and rifabutin Do not give with terfenadine, astemizole, cisapride, some sedatives (alprazolam, clorazepate, diazepam, flurazepam, triazolam, midazolam, zolpidem), some analgesics (piroxicam, dextropropoxyphene [contained in co-proxamol], pethidine), some antiarrhythmics (flecainide, amiodarone, quinidine, propafenone), clozapine, pimozide, bupropion, meperidine, ergot derivatives Caution with sildenafil, dose of sildenafil should not exceed 25 mg in 48 h Levels of ketoconazole and itraconazole, ciclosporin, tacrolimus may be ↑ With methadone or morphine, ↑ in methadone or morphine dose may be needed Do not give the oral solution with metronidazole (oral solution contains 40% alcohol), avoid with the capsules (12% alcohol) With theophylline, ↑ dose of theophylline may be required With warfarin, monitor anticoagulation parameters With clarithromycin, adjust dose of clarithromycin if renal impairment Not recommended with apixaban, dabigatran and rivaroxaban (increase in concentration of anticoagulant) Not recommended with salmeterol Risk of Cushing's syndrome with potent corticosteroids metabolised by cytochrome P450 pathways (e.g. triamcinolone, fluticasone, budesonide) and subsequent risk of iatrogenic adrenal suppression when corticosteroid is discontinued
Other pharmacokinetic enhancers			
cobicistat (COBI) 150 mg Tablet Tybost	150 mg once a day In combination with atazanavir 300 mg once a day or darunavir 800 mg once a day Take with or after food	Nausea, diarrhoea, fatigue	Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with amiodarone, quinidine, carbamazepine, phenobarbitone, phenytoin, ergot derivatives, cisapride, pimozide, midazolam, triazolam, lovastatin, simvastatin, alfuzosin, St. John's wort Not recommended with salmeterol, rivaroxaban With warfarin and dabigatran, monitor anticoagulation parameters Caution with sildenafil, dose of sildenafil should not exceed 25 mg in 48 h

			<p>Reduces eGFR due to inhibition of tubular secretion of creatinine</p> <p>Contains azo colouring agent sunset yellow which may cause allergic reactions</p> <p>Risk of adrenal suppression and Cushing's syndrome with corticosteroids metabolised by cytochrome P450 pathways (e.g. fluticasone, budesonide)</p> <p>Reduces the effect of hormonal contraceptives</p> <p>Concentration of immunosuppressants (e.g. ciclosporin and tacrolimus) may be increased</p> <p>Do not use with the herbal remedy St. John's wort</p> <p>Risk of Cushing's syndrome with potent corticosteroids metabolised by P450 pathways (e.g. triamcinolone, fluticasone, budesonide) and subsequent risk of iatrogenic adrenal suppression when corticosteroid is discontinued</p>
Entry inhibitor			
<p>enfuvirtide injection (T-20) 90 mg/mL Fuzeon</p>	<p>90 mg twice a day by subcutaneous injection (upper arm, anterior thigh or abdomen)</p> <p>Alternate sites</p> <p>Use immediately after reconstitution; if not used immediately, store in the fridge (2–8 °C) for a maximum of 24 h and protect from light</p>	<p>Injection-site reactions (discomfort/pain at the injection site, induration, erythema, nodules and cysts, pruritus), diarrhoea, nausea, peripheral neuropathy</p>	<p>No clinically significant interactions expected with products metabolised by cytochrome P450 enzymes</p>
<p>maraviroc (MVC) 150 mg tablets 300 mg tablets Celcentri</p>	<p>Confirm that virus is CCR5 tropic before starting maraviroc</p> <p>300 mg twice a day</p> <p>Reduce dosage to 150 mg once a day if CrCl < 80 mL/min and on a potent CYP3A4 inhibitor</p> <p>With efavirenz and rifampicin, increase dosage to 600 mg twice a day</p> <p>Take with or without food</p>	<p>Rash, abdominal pain, flatulence, nausea, depression, insomnia</p> <p>Delayed HSRs</p> <p>Cases of syncope caused by postural hypotension; caution in patients with severe renal impairment and in patients who have risk factors for or history of postural hypotension</p>	<p>With potent CYP3A inhibitors (e.g. cobicistat, rifabutin + PI, clarithromycin, itraconazole, ketoconazole), other PIs reduce dosage to 150 mg twice a day</p> <p>Not recommended with fosamprenavir/ritonavir</p> <p>Not recommended with St. John's wort</p>
Integrase inhibitors			
<p>raltegravir (RAL) 400 mg tablets Isentress</p>	<p>400 mg twice a day</p> <p>Take with or without food</p>	<p>Dizziness, headache, nausea and vomiting, insomnia, abnormal dreams, depression</p>	<p>Rifampicin reduces levels of raltegravir; if co-administration is unavoidable, double the dose of raltegravir</p> <p>Aluminium and magnesium hydroxide antacids reduce raltegravir levels – give 6 h apart</p>

Continued

Table 42.1 Commonly used antiretroviral drugs: adult dosing information and general prescribing points—cont'd

Drug and formulation	Dosage	Side effects	Main interactions/caution
dolutegravir (DTG) 50 mg tablets Tivicay	50 mg once a day Take with or without food	Headache, nausea and diarrhoea, rash, ↑ creatinine kinase, insomnia, abnormal dreams, depression 10–14% decrease in creatinine clearance	Efavirenz, etravirine, nevirapine and rifampicin decrease dolutegravir levels – increase dolutegravir dosage to 50 mg twice a day Magnesium, aluminium, calcium, iron and multivitamins should be taken 2 h after or 6 h before dolutegravir Metformin levels increase (area under the curve increased by 79% with dolutegravir 50 mg once a day) – adjust metformin dose when starting and stopping dolutegravir
elvitegravir (EVG) 85 mg tablets 150 mg tablets Vitekta	85 mg once a day (in combination with atazanavir 300 mg once a day/ritonavir 100 mg once a day or lopinavir 400 mg/ritonavir 100 mg twice a day) 150 mg once a day (in combination with darunavir 600 mg twice a day + ritonavir 100 mg twice a day or fosamprenavir 700 mg twice a day + ritonavir 100 mg twice a day) Take with or without food	Diarrhoea, nausea, headache, rash, fatigue	Do not give with rifampicin; with rifabutin, reduce dosage by 75% (if rifabutin dosage is 300 mg once a day, then reduce it to 150 mg three times a week) Do not give with carbamazepine, phenobarbitone, phenytoin, St. John's wort Magnesium- and aluminium-containing antacids and multivitamins should be separated 4 h apart from elvitegravir With warfarin, monitor anticoagulation parameters

This information is not exhaustive – refer to the Summary of Product characteristics for further information. For combination products, see the individual drugs.

^aNon-nucleoside reverse transcriptase inhibitors (NNRTIs) have a long half-life: Patients should be warned that if they discontinue them for whatever reason they should do so in consultation with their clinic which may recommend continuing the other drugs, e.g. the nucleotide analogue reverse transcriptase inhibitor (NRTI), for 2 weeks, or switching the NNRTI to a protease inhibitor (PI) for 2 weeks to prevent drug resistance. Do not use the herbal remedy St. John's wort.

^bProtease inhibitors (PIs) reports of new or exacerbated diabetes mellitus and hyperglycaemia. There are reports of lipodystrophy with PIs. There are reports of increased bleeding in patients with haemophilia with PIs. Do not use the herbal remedy St. John's wort with PIs. PIs reduce the effect of hormonal contraceptives.

CNS, Central nervous system; CrCL, creatinine clearance; ECG, electrocardiogram; eGFR, estimate of glomerular filtration rate; HBV, hepatitis B virus; HSR, hypersensitivity reaction; LFT, liver function test; PI, protease inhibitor; UDP, uridine diphosphate.

exposure, which may be recommended after occupational injuries (Department of Health, 2008) or sexual exposure (Cresswell et al., 2016). Whilst PEP is a largely unproven and unlicensed indication for the drugs used, it is supported by animal model data and case-control studies. Where recommended in guidelines, PEP is usually commenced as a 3- to 5-day starter regimen of two NRTIs and an INI (tenofovir disoproxil fumarate, emtricitabine and raltegravir), followed by an ongoing course for a total of 4 weeks post-exposure. It is believed this will reduce the likelihood of infection by at least 80%. The decision to prescribe or take PEP must reflect a careful risk-benefit evaluation.

Pre-exposure prophylaxis

Pre-exposure prophylaxis (PrEP) uses one or two antiretroviral drugs (tenofovir disoproxil fumarate +/- emtricitabine) to prevent acquisition of HIV in high-risk populations. Many studies (Grant et al., 2010; McCormack et al., 2015) have shown a reduction in those at risk of acquiring HIV; those with less efficacious results are generally attributable to lower levels of adherence. The PROUD study (Dolling et al., 2016) found that PrEP conferred higher protection than in placebo-controlled trials, reducing HIV incidence by 86% in a population with sevenfold higher HIV incidence than expected. Although available in many countries, PrEP is not currently funded by the National Health Service.

Women with HIV

In addition to the general points covered elsewhere in this chapter, there are specific issues for women with HIV. These include:

- Cervical screening should be carried out at least annually, to check for gynaecological manifestations of HIV because cervical intraepithelial neoplasia/cervical cancer has a higher incidence in women living with HIV.
- Drug interactions between antiretrovirals and some oral contraceptives and contraceptive implants are important and should be discussed with women.
- Guidelines are available from the Faculty of Sexual and Reproductive Healthcare Clinical Guidance (<http://www.fsrh.org>) on drugs that reduce contraceptive efficacy and from the University of Liverpool HIV drug interactions website (<http://www.hiv-druginteractions.org>).
- All ritonavir boosted PIs and the NNRTIs nevirapine and efavirenz may reduce the efficacy of hormonal contraception by enzyme induction.
- There is a potential reduction in efficacy of the progesterone-only subdermal implant etonogestrel (Nexplanon). The long-acting injectable progestones, depot medroxyprogesterone acetate (DMPA; Depo-Provera) and depot norethisterone enanthate (NET-EN; Noristerat), are not affected and can be used.
- There are no interactions with the intrauterine device (IUD) (copper coil) or the levonorgestrel-releasing intrauterine system (Mirena).
- The NRTIs etravirine, rilpivirine, raltegravir, dolutegravir and maraviroc do not have clinically significant interactions with hormonal contraceptives.

- A barrier method of contraception should also be recommended in addition to hormonal contraception, to prevent transmission of HIV and other sexually transmitted infections.
- Because women living with HIV are living longer, menopause and hormone replacement therapy (HRT) will become more of a prominent issue. There is currently a lack of data; therefore, potential drug interactions between HRT and ARVs need to be considered.

Mother-to-child transmission. The introduction of routine antenatal testing in the UK for HIV has made mother-to-child transmission a rare occurrence. Guidelines set out the management of HIV infection in pregnant women and the prevention of mother-to-child transmission (de Ruiter et al., 2014). In general, intervention reflects a risk-benefit evaluation between the efficacy of reducing transmission and the potential harmful effects to both mother and fetus.

The BHIVA pregnancy guidelines (2014) identify that women who require ART for their own health should commence treatment as soon as possible. Women who need ART solely to reduce transmission should start two NRTIs and a boosted PI by week 24 of pregnancy. Consideration should be given to starting ART at the beginning of the second trimester (viral load >30,000 copies/mL) or even earlier (viral load >100,000 copies/mL). Zidovudine monotherapy can be used in women planning a caesarean section who have a baseline viral load less than 10,000 copies/mL and a CD4 count greater than 350 cells/mm³. However, because the BHIVA (2015) guidelines for the treatment of HIV-1+ adults with antiretroviral therapy recommend starting ART at any CD4 count once they are ready to commit to taking therapy, this is likely to change.

Decisions regarding type of birth should be made after review of plasma viral loads at 36 weeks. Vaginal delivery is recommended if the plasma viral load is less than 50 copies/mL. A pre-labour caesarian section is recommended if plasma viral load is greater than 400 copies/mL. This should also be considered if plasma viral load is between 50 and 399, taking into account the decline of the HIV viral load trajectory time of ART, adherence issues, obstetric factors and the woman's views.

Infant post-exposure prophylaxis. Four weeks of zidovudine monotherapy is recommended if the maternal viral load is less than 50 copies/mL at 36 weeks' gestation and thereafter before delivery. Triple-drug therapy is recommended for all other circumstances. All infants should be exclusively formula fed from birth. Where a mother who is receiving effective ART and has repeated undetectable viral load chooses to breastfeed, this should be exclusive (except during the weaning period) and should be completed by the end of 6 months. This is because foods and fluids introduced to the gut of mixed-fed babies damage the bowel and may facilitate the entry into the body tissues of the HIV present in these mothers' breast milk. Maternal ART should be closely monitored up to 1 week after breastfeeding has ended.

Ethnicity

It is now recognised that ethnicity, as well as gender, can affect drug handling and response to treatment. This is due, in part, to epidemiological differences in gene expression. For example, reduced activity of cytochrome P450 2B6, one of the key enzymes involved in the metabolism of the NNRTI efavirenz, appears to

be more common amongst African than Caucasian individuals. These drugs, therefore, have a significantly longer plasma half-life in those affected, which may impact on efficacy, toxicity and treatment interruptions. The prevalence of the HLA*B5701 gene, associated with abacavir hypersensitivity, also varies in different ethnic groups, although the clinical implications of this have yet to be fully researched.

As pharmacogenomics becomes more widely incorporated into clinical trials and routine patient care, it is hoped that a greater understanding will be gained of differences in response to treatment, enabling treatment strategies to be individualised and optimised.

Nucleoside and nucleotide analogue reverse transcriptase inhibitors

NRTIs must be phosphorylated within host cells to be activated. The active form resembles the host nucleotides and is used in reverse transcriptase chain elongation. This false substrate terminates the chain and viral replication ceases.

The NRTIs commonly used are:

- abacavir (ABC; Ziagen),
- emtricitabine (FTC; Emtriva),
- lamivudine (3TC; Epivir),
- tenofovir disoproxil fumarate (TDF; Viread).

Combination formulations of NRTIs are also available:

- abacavir + lamivudine (Kivexa),
- tenofovir disoproxil fumarate + emtricitabine (Truvada).

Older NRTIs are rarely used, but patients may have been exposed to these in the past. These include:

- didanosine (ddI; Videx),
- stavudine (d4T; Zerit),
- zalcitabine (ddC; Hivid),
- zidovudine (AZT; Retrovir),
- zidovudine + lamivudine (Combivir),
- zidovudine + lamivudine + abacavir (Trizivir).

There are two mechanisms by which resistance to NRTIs can occur. The first involves mutations (e.g. M184V, K65R, Q151M) which occur at or near the drug-binding site of the reverse transcriptase gene conferring drug resistance. The second, known as pyrophosphorolysis, is when the chain-terminating residue is removed, enabling viral replication to resume.

Non-nucleoside reverse transcriptase inhibitors

NNRTIs inhibit the reverse transcriptase enzyme by binding to its active site. They do not require prior phosphorylation and can act on cell-free virions, as well as infected cells. The NNRTIs available include:

- efavirenz (EFV; Sustiva),
- etravirine (ETR; Intelence),
- nevirapine (NVP; Viramune),
- rilpivirine (RPV; Edurant),
- Delavirdine (DLV; Rescriptor) is no longer available, but patients may have been exposed to this in the past.

Resistance to NNRTIs occurs rapidly in incompletely suppressive regimens, and it is therefore essential that they are prescribed with at least two NRTIs or a combination of NRTIs and

PIs. Cross-resistance between nevirapine and efavirenz is high. Second-generation NNRTIs, like etravirine and rilpivirine, are active against some viruses resistant to nevirapine and efavirenz.

The NNRTIs have much longer plasma half-lives than PIs and NRTIs, so when stopping an NNRTI-containing combination, consideration should be given to either continuing the other agents for a period (e.g. 2 weeks after cessation of the NNRTI) or switching to a boosted PI before discontinuation.

Protease inhibitors

PIs bind to the active site of the HIV-1 protease enzyme, preventing the maturation of the newly produced virions so that they remain non-infectious. Commonly used PIs include:

- atazanavir (ATV; Reyataz),
- darunavir (DRV; Prezista),
- low-dose ritonavir (RTV; Norvir) as a booster (1100 mg) together with other PIs.

Less commonly used PIs include:

- fosamprenavir (FPV; Telzir),
- lopinavir co-formulated with ritonavir (LPV/RTV; Kaletra),
- saquinavir (SQV; Invirase).

Other PIs are no longer available, but patients may have been exposed to them in the past. These include:

- indinavir (IDV; Crixivan),
- nelfinavir (NFV; Viracept),
- tipranavir (TPV; Aptivus).

Second-generation PIs, like darunavir, are effective against many viruses resistant to the earlier PIs. Darunavir is used in first-line PI therapy as a once-daily boosted regimen (800 mg with 100 mg ritonavir); for patients with significant PI resistance, a higher dosage of 600 mg twice daily, boosted with ritonavir 100 mg twice a day is used. An alternative booster to ritonavir is cobicistat, which has no activity against HIV but is used as a booster at a dose of 150 mg once a day. Cobicistat is co-formulated with some PIs (e.g. darunavir [Rezolsta] and atazanavir [Evotaz]) and with an INI (e.g. elvitegravir [Genvoya and Stribild]).

Integrase inhibitors

INIs bind to the integrase enzyme, thus blocking the integration of viral DNA into host DNA. Raltegravir and elvitegravir have a lower genetic barrier to resistance than dolutegravir. In general, INIs must be used within a fully suppressive regimen to minimise the risk of drug resistance. INIs include:

- dolutegravir (DTG; Tivicay),
- raltegravir (RAL; Isentress),
- dolutegravir co-formulated with abacavir + lamivudine (Triumeq),
- elvitegravir (EVG) co-formulated with cobicistat + tenofovir disoproxil fumarate + emtricitabine (Stribild).

Entry inhibitors

There are currently two types of entry inhibitors: fusion inhibitors and CCR5 inhibitors. Fusion inhibitors block the structural rearrangement of HIV-1 gp41, and thus stop the fusion of the viral cell membrane with the target cell membrane, preventing viral

RNA from entering the cell. CCR5 inhibitors selectively bind to the human chemokine receptor CCR5, preventing CCR5-tropic HIV-1 from entering cells.

Enfuvirtide (T-20; Fuzeon), a fusion inhibitor, is administered subcutaneously and is primarily used in heavily treatment-experienced patients. The main side effect is injection-site reactions. The need to administer enfuvirtide by injection and the availability of other groups of drugs means it is rarely used.

Maraviroc (MVC; Celsentri), a CCR5 inhibitor, is indicated for use in patients with only CCR5-tropic virus, which is determined by a tropism test just before commencing treatment. It is usually used in patients with resistance to one or more other antiretroviral classes.

The different groups of drugs are co-formulated as fixed-dose combinations, and this helps reduce pill burden and may make them more acceptable to patients and also support adherence. Fixed-dose combinations are not suitable for patients with renal dysfunction who require dose modification. Currently available combinations include:

- Atripla (emtricitabine/tenofovir disoproxil fumarate/efavirenz),
- Eviplera (emtricitabine/tenofovir disoproxil fumarate/rilpivirine),
- Triumeq (abacavir/lamivudine/dolutegravir),
- Stribild (emtricitabine/tenofovir disoproxil fumarate/elvitegravir/cobicistat),
- Descovy (F/TAF; emtricitabine/tenofovir alafenamide),
- Odefsey (R/F/TAF; rilpivirine/emtricitabine/tenofovir alafenamide),
- Genvoya (E/C/F/TAF; elvitegravir/cobicistat/emtricitabine/tenofovir alafenamide),
- Rezolsta (darunavir/cobicistat),
- Evotaz (atazanavir/cobicistat),
- Dutrebis (raltegravir/lamivudine).

A combination not currently licensed in the UK is:

D/C/F/TAF: darunavir/cobicistat/emtricitabine/tenofovir alafenamide

As HIV drug patents expire many of these drugs are now available as cheaper generics with potential savings for drug budgets.

Toxicity of antiretroviral therapies

The availability and use of the different groups of antiretroviral drugs have led to decreased morbidity and mortality from HIV infection due to immune reconstitution and HIV viral suppression. However, there is also recognition of side effects and toxicities associated with ART. Patients who experience significant side effects may become non-adherent or refuse to take ART. A proactive approach to discussion with patients on how to recognise and manage side effects will support successful treatment (Max and Sherer, 2000). With all people living longer, managing ageing people living with HIV who have comorbidities requires healthcare staff to be mindful of the toxicities of ART and the impact of this on an ageing patient. Bone mineral density loss, kidney dysfunction, cardiovascular disease and neurocognitive disorders are more frequent in older patients, and these must be considered when choosing an HIV drug regimen.

Whilst there are many individual drug toxicities, there are also a number of class-specific or drug-related toxicities (Carr and Cooper, 2000).

Non-nucleoside reverse transcriptase inhibitors. Abacavir can cause a hypersensitivity reaction in 6–8% of individuals. The use of pharmacogenomics testing for HLA B*5701 status and only using abacavir in patients who are B*5701-negative has dramatically reduced the incidence of this hypersensitivity reaction (Mallal et al., 2008).

Tenofovir disoproxil fumarate can rarely cause proximal renal tubular dysfunction (Fanconi syndrome). This is characterised by glycosuria, hypophosphatemia and renal tubular acidosis from reduced bicarbonate reabsorption. Tenofovir disoproxil fumarate has also been shown to potentially reduce the estimate of glomerular filtration rate in certain patients. Caution should be observed when using tenofovir disoproxil fumarate in patients with pre-existing renal dysfunction or when patients are also taking other nephrotoxic drugs. Regular monitoring of renal function and checking for proteinuria is recommended for all patients receiving tenofovir disoproxil fumarate. Clinical observations have revealed a correlation between tenofovir disoproxil fumarate use and a reduction in bone mineral density, especially in young children and adolescents. This risk should be considered with patients who have risk factors for osteoporosis.

Tenofovir alafenamide is a novel targeted prodrug of tenofovir. It enters the cells, including HIV-infected cells, more efficiently and produces higher intracellular levels with lower doses. There are lower concentrations in the bloodstream and less exposure for the kidneys, bone and other organs and tissues. While the long-term clinical effects will be known by post-marketing surveillance, there is currently a strong suggestion that it is safer for the kidneys and bone than is tenofovir disoproxil fumarate.

The older NRTIs like didanosine, stavudine and zidovudine caused mitochondrial toxicity which may manifest as peripheral neuropathy, myopathy, lipodystrophy (fat loss particularly from the face, upper limbs and buttocks), hepatic steatosis, pancreatitis and lactic acidosis (McComsey and Lonergan, 2004). This is less common with the NRTIs which are now routinely prescribed (e.g. lamivudine, emtricitabine and tenofovir disoproxil fumarate).

Non-nucleoside reverse transcriptase inhibitors. NNRTIs cause rash, which frequently resolves early in therapy. In rare cases, Stevens–Johnson syndrome and toxic epidermal necrolysis have occurred. For patients who are taking nevirapine, the risk of rash is highest with a higher CD4 count; therefore, it should not be initiated if the CD4 count is greater than 250 cells/mm³ for women and greater than 400 cells/mm³ for men. There is also the small risk of serious hepatic toxicity. These factors make nevirapine a less favourable choice as first-line therapy.

Efavirenz is associated with central nervous system (CNS) toxicity including insomnia and mood problems. Caution is advised when considering initiating efavirenz in patients who have pre-existing depression or other mood problems. Patients with the homozygous G516T genotype of the enzyme CYP2B6 may metabolise it more slowly and have greater efavirenz exposure leading to higher rates of neuropsychiatric adverse reactions. The G516T genotype is more common in African individuals. Exposure to efavirenz is also significantly higher in women than in men and in non-Caucasian patients (Burger et al., 2006). This increased exposure is

independent of body composition, use of hormonal contraceptives that may inhibit the metabolism of efavirenz and genetic polymorphism, and further research is needed to identify other factors.

Protease inhibitors. All PIs are associated with metabolic abnormalities including dyslipidaemias, insulin resistance, diabetes, lipodystrophy (abnormal fat distribution particularly affecting the abdomen and neck) and are well reported in HIV studies (Smith et al., 2010). These abnormalities may result in risk of coronary and/or cerebral vascular morbidity and mortality which is increased because people living with HIV have chronic inflammation as a result of long-term exposure to the virus.

Cardiovascular risk associations of antiretroviral agents

Observational studies have reported an increased risk of myocardial infarct with abacavir (Worm et al., 2010). A US Food and Drug Administration (FDA) meta-analysis of 26 randomised controlled trials, however, showed no association between abacavir and myocardial infarct (Ding et al., 2012). In spite of this conflicting evidence and uncertainty, in clinical practice abacavir tends to be avoided in patients with high cardiovascular risk ($\geq 20\%$ risk over 10 years).

Cumulative exposure to the older PIs, Kaletra and indinavir, has also been associated with increasing risk of myocardial infarct. A similar association exists for fosamprenavir (Worm et al., 2010). No association has been reported between the use of atazanavir/ritonavir and the risk of myocardial infarct, and there was insufficient evidence to include darunavir/ritonavir in the analysis (Monforte et al., 2013).

Maraviroc can cause postural hypotension. Therefore, care should be taken in patients with a history of postural hypotension, renal impairment or those taking antihypertensives. In view of limited data, maraviroc should be used with caution in patients with high cardiovascular risk.

Identifying and managing cardiovascular risk is an essential part of HIV care. National Institute for Health and Care Excellence (NICE) recommends the QRISK2 calculator for the English population (NICE, 2014). There is no HIV-specific cardiovascular risk calculator for those of non-white ethnicity.

One approach suggested is to use the QRISK2 equation with a correction for HIV status of 1.6 (Islam et al., 2012). As in the general population, encouraging patients to adopt modifiable lifestyles including smoking cessation, healthy diets and exercise will reduce the risk. Baseline cardiovascular risk assessment is recommended by BHIVA, and an annual cardiovascular risk assessment is recommended if the patient is a smoker, is diabetic and or has a body mass index greater than 30 and age greater than 40 years.

People who are living with HIV are at higher risk of non-alcoholic fatty liver disease. Factors associated with this include older age, overweight and waist circumference, lipodystrophy, insulin resistance, previous use of the older NRTIs (e.g. ddI, d4T, AZT) or PI use (e.g. indinavir and ritonavir) (Capeau et al., 2012).

Specific HIV drug choice

HIV treatment usually involves a three-drug regimen that contains either an NNRTI or a PI plus a 'backbone' consisting of two NRTIs. When selecting an NRTI backbone, factors such as

efficacy, potential side effects and toxicities, patient preference and cost should be considered. Choosing the appropriate drug combination, monitoring patient parameters and switching to drugs that have a more favourable profile based on patient factors will ensure safety and success of treatment. Therefore, based on current evidence:

- Abacavir or abacavir-containing combinations (e.g. Kivexa) should be used with caution in patients whose baseline HIV viral load is greater than 100,000 copies/mL (except when used in combination with dolutegravir) because of the risk of virological failure. Abacavir-containing regimens should not be used in patients with high risk of CVD ($\geq 20\%$) and if they are HLA*B5701-positive.
- Rilpivirine should not be used in patients whose baseline HIV viral load is greater than 100,000 copies/mL because of the risk of virological failure.
- Tenofovir disoproxil fumarate should not be used in patients with stage 3–5 chronic kidney disease (CKD) or they have a high risk of progression to CKD. It should also be avoided in individuals older than 40 years with osteoporosis, a history of fragility fracture or a FRAX score greater than 20% (major osteoporotic fracture).
- There is a theoretical advantage of using emtricitabine rather than lamivudine because of its longer half-life and in vitro potency. It is also incorporated more efficiently into proviral DNA.
- Zidovudine/lamivudine is considered for use only in specific circumstances (e.g. short-term use in pregnancy) because of its association with mitochondrial toxicity.

Third agent choice. As similar critical treatment outcomes are obtained, atazanavir/ritonavir, darunavir/ritonavir, raltegravir, dolutegravir, rilpivirine and elvitegravir/cobicistat are all recommended in current guidelines. Rilpivirine is recommended only in patients whose baseline HIV viral load is less than 100,000 copies/mL. In patients who tend to be non-adherent to their HIV medicines and have treatment interruptions, a PI/ritonavir-based regimen is recommended because it may be associated with less frequent selection for drug resistance (BHIVA, 2015).

The availability and use of effective ARV combinations has resulted in a decline in the incidence of severe HIV-associated cerebral disease. However, subtle forms of brain disorders, known as HIV-associated neurocognitive disorders, remain prevalent. Attempts have been made to correlate the pharmacokinetics of ARVs with respect to CNS penetration (clinical effectiveness penetration scores) and CSF HIV-RNA with change in neurocognitive function. However, results have been conflicting. Table 42.2 shows the clinical effectiveness scores that have been assigned to the various HIV drugs. Based on limited evidence, switching to ARV combinations that have higher clinical effectiveness penetration scores may be considered in clinical practice in patients who have neurocognitive disorders (Letendre et al., 2010).

Local guidance may recommend the rationale for choosing third agents which would include patient acceptability to a particular regimen. Interventions to address adherence and potential barriers should be embedded in the roles of all members of the HIV multidisciplinary team. This should include being mindful of patient's beliefs that may affect adherence, patient preferences with regard to practical barriers (e.g. pill burden and tablet size) and

Table 42.2 Central nervous system penetration effectiveness of human immunodeficiency virus drugs

HIV drug group	CNS penetration effectiveness scores ^a			
	4	3	2	1
NRTIs	Zidovudine	Abacavir, emtricitabine	Lamivudine	Tenofovir
NNRTIs	Nevirapine	Efavirenz	Etravirine	
PIs		Darunavir/ritonavir Fosamprenavir/ritonavir Lopinavir/ritonavir	Atazanavir/ritonavir	Saquinavir/ritonavir
Entry inhibitors		Maraviroc		Enfuvirtide
Integrase inhibitors		Raltegravir		

^aA score of 4 is the highest and 1 is the lowest.

the requirement to take some medicines with food which can be restrictive to those with busy lifestyles. Accommodating medicine taking into account a patient's individual lifestyle and use of appropriate adherence aids should be considered. This would include the use of multi-compartment compliance aids (e.g. Dossette boxes). Peer support, use of buddies and outreach services into the community can also augment strategies to support adherence.

HIV drug–drug interactions

Absorption

The absorption of some HIV drugs may be altered by the presence or absence of food. For example, rilpivirine needs 390 kcal for optimal absorption. Increase in pH by antacids (aluminium, magnesium hydroxide, calcium carbonate), H₂ antagonists or proton pump inhibitors can reduce some HIV drug levels (e.g. atazanavir and rilpivirine). Chelation caused by polyvalent ions like calcium, magnesium or iron can reduce levels of some HIV drugs (e.g. dolutegravir and elvitegravir). It is therefore important that patients who are prescribed these medicines understand how to manage these drug–drug interactions, for example, timing separation when taking multivitamins containing iron and magnesium (4 hours apart from dolutegravir) or completely avoiding proton pump inhibitors like omeprazole with rilpivirine.

Metabolism

Some HIV drugs, especially NNRTIs and PIs, are metabolised by the cytochrome P450 enzyme system. The enzyme responsible for the majority of drug metabolism is CYP3A4, although CYP2C19 and CYP2D6 are also common. Table 42.3 shows the HIV drugs that are major CYP450 enzyme inducers, inhibitor and substrates. Drugs may interact with the CYP450 enzymes through induction, inhibition or acting as a substrate. Some drugs act as inducers and inhibitors of different CYP450 enzymes. CYP450 enzymes are in the liver and in the small intestine. Ritonavir inhibits CYP3A4 in the liver and the intestine. This is one of the mechanisms that allows

Table 42.3 HIV drugs that are major CYP450 enzyme inducers, inhibitors and substrates

Type of action	CYP enzyme			
	1A2	2C19	2D6	3A4
Inducers	Ritonavir	Ritonavir Efavirenz		Nevirapine Efavirenz Etravirine Ritonavir
Inhibitors	Atazanavir	Etravirine	Ritonavir Cobicistat	Protease inhibitors Cobicistat
Substrates		Etravirine		Nevirapine Efavirenz Elvitegravir Etravirine Rilpivirine Maraviroc Protease inhibitors Cobicistat

it to act as a pharmacokinetic booster. Drugs that inhibit CYP450 enzymes decrease the metabolism of other drugs metabolised by the same enzyme. This can result in higher drug levels and an increase in the potential for drug toxicities. Inhibition usually occurs quickly.

Induction of CYP450 enzymes causes increased clearance of drugs metabolised by the same enzyme, with the maximum effect taking 1–2 weeks. Some drugs, like nevirapine, induce their own metabolism, and the starting dose (200 mg once a day for 2 weeks) is increased after this period (400 mg once a day). The herbal remedy St. John's wort is a strong inducer of CYP3A

and will reduce levels of NNRTIs, PIs and cobicistat. Therefore, co-administration is not recommended.

The most important antiretroviral drugs to consider when evaluating drug–drug interactions are the pharmacoenhancers ritonavir and cobicistat. These agents can increase levels of many commonly used medicines including some statins, antidepressants, anticonvulsants, corticosteroids and cardiac drugs. One significant drug–drug interaction is between PIs and steroids metabolised by CYP3A enzymes (e.g. budesonide, fluticasone, methylprednisolone and triamcinolone). This interaction can result in adrenal insufficiency and iatrogenic Cushing’s syndrome (Saber *et al.*, 2013). Despite well-documented case reports, patients continue to inadvertently receive these combinations. Therefore, HIV healthcare staff should obtain a complete medication history for any patient exhibiting signs and symptoms of Cushing’s syndrome. Inhaled corticosteroids are used extensively in asthma and allergic rhinitis, and injectable corticosteroids in rheumatology and surgical patients.

Conducting a thorough medication history at each visit, including asking direct questions about prescribed medicines in other healthcare settings (e.g. by primary care doctors, other specialist hospital departments) and use of over-the-counter, herbal and recreational drugs is an important strategy in preventing significant drug–drug interactions which may result in virological failure or drug toxicity. Patients need to be counselled to explain that they are taking HIV medicines when in other healthcare settings to minimise this risk. Patient should also be advised to check drug–drug interactions before commencing new medicines.

Mycobacterium treatment results in complex drug–drug interactions. Rifampicin is a potent CYP3A4 inducer, although rifabutin has less effect. Therefore, rifabutin is the drug of choice in patients who require treatment for *M. tuberculosis* or *Mycobacterium avium* complex, to avoid significant reduction in HIV drug levels of, for example, nevirapine and the PIs. Rifampicin is also a strong inducer of the metabolising enzyme of the glucuronidation pathway UGT-1A1. Raltegravir is metabolised by UGT-1A1-mediated glucuronidation. Rifampicin will therefore reduce raltegravir levels, and co-administration is not recommended.

Tenofovir alafenamide (TAF) is a substrate for intestinal P-glycoprotein. Ritonavir and cobicistat both inhibit intestinal P-glycoprotein, thereby increasing tenofovir alafenamide exposure. For this reason a lower dose of tenofovir alafenamide (10 mg) is recommended when used with ritonavir- or cobicistat-boosted PIs. The standard dose of tenofovir alafenamide (25 mg) is recommended when administered with efavirenz, nevirapine, raltegravir, dolutegravir and maraviroc.

Excretion

Rilpivirine, dolutegravir and cobicistat inhibit renal transporters of creatinine, causing mild-to-moderate increase in serum creatinine and reduction in estimated creatinine clearance. Healthcare staff must correctly interpret these changes on initiating these drugs and differentiate this from clinically significant renal toxicities.

Tenofovir disoproxil fumarate undergoes active renal tubular secretion via organic anionic transporters in the renal proximal

tubule cells, and this plays a role in the aetiology of nephrotoxicity. Tenofovir alafenamide is not a substrate for organic anionic transporters and is likely to be associated with reduced tenofovir levels in the proximal renal tubule cells.

The NRTIs in general tend to be renally cleared and require dose modification in renal impairment.

Hepatitis B co-infection

Hepatitis B virus (HBV) co-infection is less likely to be cleared spontaneously and more likely to become chronic in the HIV-positive population. It is likely to be associated with higher hepatitis B DNA levels and faster fibrosis progression rate, end-stage liver disease and hepatocellular carcinoma (Wilkins *et al.*, 2013). People who are co-infected with HBV should be treated with tenofovir-, disoproxil-, fumarate-, and emtricitabine- or lamivudine-based cART, because these are effective against both HBV and HIV.

Response to hepatitis B vaccination is less with the standard dose; therefore, a higher dose (HBVAXPRO and Engerix B dose 40 micrograms, Fendrix 20 micrograms) is recommended (Geretti *et al.*, 2015).

Hepatitis C co-infection

Hepatitis C virus (HCV) co-infection is cleared spontaneously in an estimated 10–25% of people, and chronic infection of HCV will develop in the majority. Patients with HCV/HIV co-infection have higher hepatitis C RNA levels and an accelerated liver fibrosis progression rate. It increases the risk of hepatocellular carcinoma, which tends to occur at a younger age and within a shorter period since infection. A global epidemic of acute hepatitis in HIV-infected MSM has been observed in the past decade. Transmission appears to be associated with high-risk traumatic sexual practices, presence of sexually transmitted infections and recreational drug use.

Early ART initiation is recommended to slow the fibrosis progression rate. The ART regimen should be selected to suit the planned hepatitis C treatment. Efficacy, side-effect profile and the duration of treatment have significantly improved since the introduction of HCV direct-acting antiviral agents, with sustained virological response rates of more than 90%. The choice of regimen and duration of HCV treatment are based on HCV genotype, HCV RNA, liver fibrosis stage, prior treatment history and drug–drug interaction (NICE, 2015).

Opportunistic infections

Treatment guidelines are produced by many different countries and may differ slightly; one example of UK guidelines are those produced by the BHIVA. Examples of guidelines available from BHIVA are for the management of opportunistic infections (Nelson *et al.*, 2011), HIV-associated malignancies (Bower *et al.*, 2014), hepatitis viruses (Wilkins *et al.*, 2013) and TB (Pozniak *et al.*, 2011). Such guidance should be consulted for further detailed information on the management of people living with HIV.

Fungal infections

Pneumocystis jirovecii pneumonia

P. jirovecii is an atypical fungus causing pneumonia in immunocompromised individuals. It remains a major pathogen in those unaware of their HIV status, in people not seeking medical care for HIV and in those non-adherent to antiretroviral medication and/or prevention therapy (Miller and Huang, 2004; Morris and Gingo, 2015). It is thought to mainly cause clinical disease by exposure to an exogenous source, with likely transmission being via inhalation of airborne spores. In people living with HIV, PCP most commonly occurs in those with a CD4 T-cell count less than 200 cells/microlitre (or CD4 T-cell percentage <14%) (Nelson et al., 2011). Presentation is typically a gradual progression over several weeks, with principal symptoms being fatigue, fever, chills, sweats, non-productive cough and dyspnoea. Physical examination findings are non-specific and include fever, tachypnoea and tachycardia. Signs of pulmonary consolidation or changes in pulmonary signs are uncommon (Morris and Gingo, 2015; Nelson et al., 2011).

Presence of oxygen desaturation supports the diagnosis of PCP along with a typical chest radiographic appearance of bilateral interstitial shadowing; however, radiological imaging is not specific for PCP and can, in some cases, appear normal. Therefore, for a definitive diagnosis of PCP, this requires either an induced sputum for visualisation of the fungi (if routinely available) or bronchoscopic examination with bronchoalveolar lavage (BAL) (Morris and Gingo, 2015).

Treatment is instigated in patients with a proven diagnosis, or empirically where there is suspicion before confirmation (Table 42.4). Oxygen is essential for patients with compromised respiratory function. First-line therapy is high-dose trimethoprim-sulfamethoxazole (co-trimoxazole) for 21 days. In cases of co-trimoxazole intolerance, several alternative treatment choices are available.

Adjunctive corticosteroids should be given where PaO₂ <9.3 kPa or SpO₂ <92% to prevent further deterioration. Oral prednisolone is given at high doses for 21 days. Alternatively, intravenous methylprednisolone can be substituted if the patient is unable to take oral medication.

PCP can be prevented in people living with HIV by initiating ART, with the aim of restoring and preserving immunological function (Morris and Gingo, 2015). In patients with a CD4 T-cell count less than 200 cells/microlitre, CD4 T-cell percentage less than 14%, oral candidiasis or previous AIDS-defining illness, PCP prophylaxis should be started. First-line therapy is co-trimoxazole, which also provides prevention against toxoplasmosis; however, other regimens are available if this is contraindicated or not tolerated (see Table 42.4). Prophylaxis can be discontinued when CD4 T-cell count is sustained at greater than 200 cells/microlitre and suppression of HIV replication for more than 3 months on ART.

Oropharyngeal/oesophageal candidiasis

Candida species are common commensals in the general population, and candidiasis is a frequent manifestation of HIV infection, which may occur in early disease. It is usually characterised by white plaques on the oral mucosa, but may present

as erythematous patches or as angular cheilitis. If swallowing is difficult (dysphagia) or painful (odynophagia), oesophageal involvement may be suspected. Oesophageal candidiasis without oral plaques is not common; therefore, any patient presenting with oesophageal symptoms without oral candidiasis should be considered for alternative diagnoses (Nelson et al., 2011). Diagnoses of oral and oesophageal candidiasis are made clinically because microbiological confirmation is likely to give a positive result in the absence of clinical disease. Cultures should be requested only in patients who are not responding to standard treatment (Nelson et al., 2011).

Treatment regimens are described in Table 42.5. Systemic azole antifungals are first-line therapy for oral and oesophageal candidiasis with higher doses and longer treatment courses generally used in oesophageal candidiasis. Topical treatment with nystatin is effective for oropharyngeal candidiasis; however, it is associated with a slower clearance of yeast from the mouth and a higher relapse rate. First-line azole therapy is fluconazole with other azoles or antifungal classes being reserved in cases of drug resistance. Routine prophylaxis is not recommended and is associated with the emergence of resistance (Nelson et al., 2011).

Cryptococcus neoformans

Cryptococcus is an encapsulated yeast present in the environment. People become exposed to the yeast after inhalation of fungal spores, although this rarely causes infection in immunocompetent individuals (Centers for Disease Control and Prevention, 2015). In patients with a compromised immune system, the yeast can localise to the lungs and cause infection. This can rapidly disseminate to the blood and develop into cryptococcal meningitis (Nelson et al., 2011).

Symptoms are dependent on site of infection. Meningitis is the most common presentation in people who are living with HIV. Symptoms include fever and headache, often without the characteristic symptoms of meningism such as photophobia and neck stiffness. Raised intracranial pressure may be associated with nausea, vomiting, confusion and coma. Other symptoms may be respiratory secondary to pulmonary disease or dermatological lesions resembling molluscum in skin disease.

The principal test is serum cryptococcal antigen which, if negative, generally excludes disseminated disease. In the presence of a positive result, all patients should have a lumbar puncture for CSF culture after cerebral imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Manometry via lumbar puncture should be performed to exclude raised intracranial pressure. Blood cultures should also be performed and if positive for *Cryptococcus*, sensitivity testing may be performed if available (Nelson et al., 2011).

Treatment consists of an induction phase and a maintenance phase (Table 42.6). First-line treatment in the induction phase is intravenous liposomal formulation of amphotericin 4 mg/kg/day (once daily dosing) plus intravenous flucytosine 100 mg/kg/day (four times daily dosing). This is continued for at least 2 weeks or until CSF culture is negative for *Cryptococcus*. Liposomal amphotericin is the preferred formulation to reduce drug toxicity (Nelson et al., 2011).

Table 42.4 Treatment and prophylaxis of *Pneumocystis jirovecii* pneumonia

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Atovaquone	Treatment (mild to moderate): 750 mg PO twice daily (with food) for 21 days Prophylaxis (unlicensed indication): 750 mg PO twice daily (with food)	Anaemia, neutropenia, hyponatraemia, insomnia, headache, nausea, diarrhoea, vomiting, elevated liver enzyme levels, hypersensitivity reactions including angioedema, bronchospasm and throat tightness, rash, pruritus, urticaria, fever	Drugs known to reduce atovaquone: rifampicin, rifabutin, metoclopramide, efavirenz, boosted protease inhibitors, tetracycline Drugs known to be increased by atovaquone: zidovudine	LFTs, renal function, FBC	Absorption improved by taking with food (especially high-fat food); reduced by diarrhoea
Clindamycin	Treatment (severe): 600 mg IV/PO four times daily or 900 mg IV/PO three times daily for 21 days (given with primaquine 15–30 mg PO once daily)	Clindamycin: abdominal pain, diarrhoea, pseudomembranous colitis, abnormal LFTs, nausea, vomiting, rash, urticaria, blood dyscrasias, dysgeusia (IV), thrombophlebitis (IV) Primaquine: nausea, vomiting, methaemoglobinemia, haemolytic anaemia (especially in G6PD deficiency), bone marrow suppression	Neuromuscular blocking agents, erythromycin, neostigmine, pyridostigmine, oestrogens (risk of interaction is small)	LFTs, renal function, FBC, diarrhoea	Change in bowel habit should be investigated for <i>Clostridium difficile</i> Check G6PD status before use of primaquine
Co-trimoxazole (trimethoprim-sulfamethoxazole)	Treatment: Moderate to severe: 120 mg/kg/day IV/PO for 3 days, then reduced to 90 mg/kg/day for 18 days in three or four divided doses Mild to moderate: 1920 mg three times a day or 90 mg/kg/day in 3 divided doses for 21 days Prophylaxis: 480 mg (preferred) or 960 mg once daily or 960 mg three times a week	Hyperkalaemia, headache, nausea, diarrhoea, skin rash (rare: blood dyscrasias, drug fever, serious skin reactions, e.g. Stevens–Johnson syndrome and toxic epidermal necrolysis)	Ciclosporin (deterioration in renal function); rifampicin (can reduce plasma half-life of trimethoprim, although not thought to be significant); diuretics, in particular thiazide (increased risk of thrombocytopenia); pyrimethamine (risk of megaloblastic anaemia); warfarin (potentiates anticoagulant activity); phenytoin (prolongs phenytoin half-life); methotrexate (increases plasma levels of methotrexate); lamivudine (increases plasma levels of lamivudine in doses >960 mg); sulphonylureas (could potentiate hypoglycaemic effect)	LFTs, renal function, FBC, monitoring for rash	Caution in G6PD deficiency

Dapsone	<p>Treatment (mild to moderate): 100 mg PO once daily (given with trimethoprim 20 mg/kg/day PO for 21 days)</p> <p>Prophylaxis: 50–200 mg PO once daily (100 mg preferred)</p>	Rash, photosensitivity, pruritus, haemolysis and methaemoglobinaemia are rare in dosages >100 mg daily or in individuals not G6PD deficient, 'dapsone syndrome' may occur 3–6 weeks after therapy, anorexia, headache, hepatitis, jaundice, abnormal LFTs, insomnia, nausea, psychosis, tachycardia and vomiting are infrequent	Probenecid, rifampicin	LFTs, FBC	Check G6PD status before use
Pentamidine	<p>Treatment: 4 mg/kg IV once daily for 21 days</p> <p>Prophylaxis: 300 mg nebulised every 4 weeks</p>	<p>IV: leucopenia, thrombocytopenia, anaemia, azotaemia, hypoglycaemia, hyperglycaemia, hypocalcaemia, hypomagnesaemia, dizziness, hypotension, flushing, nausea, vomiting, taste disturbance, abnormal LFTs, rash, renal impairment, macroscopic haematuria; rare: pancreatitis, QT interval prolongation</p> <p>Nebulised: local respiratory reactions (including bronchospasm), taste disturbance, nausea</p>	Foscarnet, drugs that prolong QT interval	Renal function, blood glucose, blood pressure, LFTs, FBC, blood urea nitrogen, calcium and magnesium, ECG for QT interval prolongation	Nebulised: pretreat with a bronchodilator and use an appropriate nebuliser
ECG, Electrocardiogram; FBC, full blood count; G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous; LFT, liver function test; PO, oral.					

Table 42.5 Treatment of oropharyngeal/oesophageal candidiasis

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Azole antifungals					
Fluconazole	50–100 mg PO once daily for 7–14 days	Headache, abdominal pain, vomiting, diarrhoea, nausea, elevated LFTs, rash	Inducers and inhibitors of CYP3A4	LFTs	Duration of treatment will be less for oropharyngeal candidiasis Use with caution with medicines known to prolong QTc interval because some azole antifungals have been associated with prolongation of the QTc interval
Itraconazole	200 mg PO once daily for 7–14 days (or twice daily in fluconazole refractory candidiasis)	Headache, dyspnoea, abdominal pain, vomiting, nausea, diarrhoea, dysgeusia, elevated LFTs, rash, pyrexia	Inducers and inhibitors of CYP3A4	LFTs, FBC, renal function	Oral solution has higher bioavailability than capsule formulation
Voriconazole	Loading dose: IV: 6 mg/kg twice daily PO: 400 mg twice daily (if >40 kg) for 1 day Maintenance dosage: IV: 4 mg/kg twice daily PO: 200 mg twice daily (if >40 kg) for 7–14 days in total	Sinusitis, deranged FBC, peripheral oedema, hypoglycaemia, hypokalaemia, hyponatraemia, psychiatric disorders, headache, convulsion, syncope, tremor, hypertonia, paraesthesia, somnolence, dizziness, visual impairment, retinal haemorrhage, cardiac arrhythmias, hypotension, respiratory distress, diarrhoea, vomiting, abdominal pain, nausea, deranged LFTs, rash, alopecia, back pain, renal dysfunction, pyrexia	Inducers, inhibitors and substrates of CYP3A4, CYP2C19, CYP2C9	LFTs, FBC, renal function	Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole Use with caution with medicines known to prolong QTc interval because some azole antifungals have been associated with prolongation of the QTc interval
Posaconazole	Loading dose: 300 mg twice daily PO for 1 day Maintenance dosage: 300 mg once daily for 7–14 days in total	Neutropenia, anorexia, decreased appetite, hypokalaemia, hypomagnesaemia, paraesthesia, dizziness, somnolence, headache, dysgeusia, hypertension, nausea, vomiting, abdominal pain, diarrhoea, dyspepsia, dry mouth, flatulence, constipation, anorectal discomfort, deranged LFTs, rash, pruritus, pyrexia	Substrates of CYP3A4, rifabutin, efavirenz, fosamprenavir, phenytoin, digoxin, sulfonyleureas	LFTs, FBC, renal function	Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole Use with caution with medicines known to prolong QTc interval because some azole antifungals have been associated with prolongation of the QTc interval
Echinocandins					
Anidulafungin	Loading dose: 200 mg once daily IV for 1 day Maintenance dose: 100 mg once daily IV for 7–14 days in total	Hypokalaemia, hyperglycaemia, convulsions, headache, hypo/hypertension, bronchospasm, dyspnoea, diarrhoea, nausea, vomiting, abnormal liver function, rash, pruritus, increased creatinine	Nil	LFTs, renal function, blood sugar	Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole

Caspofungin	<p>Loading dose: 70 mg once daily IV for 1 day</p> <p>Maintenance dosage:</p> <p>>80 kg: 70 mg once daily IV</p> <p><80 kg: 50 mg once daily IV for 7–14 days in total</p>	<p>Local injection-site reactions including phlebitis, reduced haemoglobin, reduced white cell count, hypokalaemia, headache, dyspnoea, nausea, diarrhoea, vomiting, elevated LFTs, rash, pruritus, erythema, hyperhidrosis, arthralgia, pyrexia, chills</p>	<p>Ciclosporin, tacrolimus, rifampicin</p>	<p>LFTs, renal function, FBC</p>	<p>Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole</p>
Micafungin	<p>150 mg once daily IV (if >40 kg) for 7–14 days</p>	<p>Leukopenia, neutropenia, anaemia, hypokalaemia, hypomagnesaemia, hypocalcaemia, headache, phlebitis, nausea, vomiting, diarrhoea, abdominal pain, elevated LFTs, rash, pyrexia, rigors</p>	<p>Itraconazole, sirolimus, nifedipine, amphotericin</p>	<p>FBC, renal function, magnesium, calcium, LFTs</p>	<p>Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole</p>
Others					
Liposomal amphotericin	<p>1–3 mg/kg once daily IV for 7–14 days</p>	<p>Hypokalaemia, hyponatraemia, hypocalcaemia, hypomagnesaemia, hyperglycaemia, headache, tachycardia, hypotension, vasodilation, flushing, dyspnoea, nausea, vomiting, abnormal LFTs, rash, back pain, renal impairment, rigors, pyrexia, chest pain</p>	<p>Nephrotoxic medication, drugs that may potentiate hypokalaemia, antineoplastic agents</p>	<p>Renal function, magnesium, LFTs, FBC</p>	<p>Only for use in fluconazole resistance, where fluconazole has been shown to be ineffective or the patient is intolerant to fluconazole</p>
FBC, Full blood count; IV, intravenous; LFT, liver function test; PO, oral.					

Table 42.6 Treatment and maintenance of *Cryptococcal neoformans* meningitis

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Treatment					
Liposomal amphotericin + flucytosine	Liposomal amphotericin: 4 mg/kg IV once daily Flucytosine: 100 mg/kg/day PO/IV in 4 divided doses for at least 2 weeks (until negative CSF culture)	Amphotericin: hypokalaemia, hyponatraemia, hypocalcaemia, hypomagnesaemia, hyperglycaemia, headache, tachycardia, hypotension, vasodilation, flushing, dyspnoea, nausea, vomiting, abnormal LFTs, rash, back pain, renal impairment, rigors, pyrexia, chest pain Flucytosine: nausea, vomiting, diarrhoea, rash, haematological changes are more common when co-administered with amphotericin	Amphotericin: nephrotoxic medication, drugs that may potentiate hypokalaemia, antineoplastic agents Flucytosine: cytarabine, brivudine, sorivudine and analogues, phenytoin	Renal function, magnesium, LFTs, FBC Therapeutic drug monitoring may be considered with flucytosine	Amphotericin: a test dose of 1 mg is required before the first dose and if no hypersensitivity reaction after 30 min, the remainder of the dose can be given Pre-hydration with 0.9% sodium chloride may decrease nephrotoxicity
Fluconazole + flucytosine	Fluconazole: 400 mg PO/IV once daily (or twice daily in severe, life-threatening infections) Flucytosine: 100–150 mg/kg/day PO/IV in 4 divided doses for at least 2 weeks (until negative CSF culture)	Fluconazole: headache, abdominal pain, vomiting, diarrhoea, nausea, elevated LFTs, rash Flucytosine: nausea, vomiting, diarrhoea, rash, haematological changes are more common when co-administered with amphotericin	Fluconazole: inducers and inhibitors of CYP3A4 Flucytosine: cytarabine, brivudine, sorivudine and analogues, phenytoin	Fluconazole: LFTs Flucytosine: renal function, magnesium, LFTs, FBC Therapeutic drug monitoring may be considered with flucytosine	Considered as an alternative to amphotericin and flucytosine if this fails or is not tolerated
Voriconazole	Loading dose: IV: 6 mg/kg twice daily PO: 400 mg twice daily (if >40 kg) for 1 day Maintenance dose: IV: 4 mg/kg twice daily PO: 200 mg twice daily (if >40 kg) for at least 2 weeks (until negative CSF culture)	Sinusitis, deranged FBC, peripheral oedema, hypoglycaemia, hypokalaemia, hyponatraemia, psychiatric disorders, headache, convulsion, syncope, tremor, hypertonia, paraesthesia, somnolence, dizziness, visual impairment, retinal haemorrhage, cardiac arrhythmias, hypotension, respiratory distress, diarrhoea, vomiting, abdominal pain, nausea, deranged LFTs, rash, alopecia, back pain, renal dysfunction, pyrexia	Inducers, inhibitors and substrates of CYP3A4, CYP2C19, CYP2C9	LFTs, FBC, renal function	Only considered as an alternative to amphotericin and flucytosine if this fails or is not tolerated
Posaconazole	Loading dose: 300 mg twice daily PO for 1 day Maintenance dose: 300 mg once daily for at least 2 weeks (until negative CSF culture)	Neutropenia, electrolyte imbalance, anorexia, decreased appetite, hypokalaemia, hypomagnesaemia, paraesthesia, dizziness, somnolence, headache, dysgeusia, hypertension, nausea, vomiting, abdominal pain, diarrhoea, dyspepsia, dry mouth, flatulence, constipation, anorectal discomfort, raised LFTs, rash, pruritus, pyrexia, asthenia, fatigue	Substrates of CYP3A4, rifabutin, efavirenz, fosamprenavir, phenytoin, digoxin, sulphonylureas	LFTs, FBC, renal function	Only considered as an alternative to amphotericin and flucytosine if this fails or is not tolerated

Table 42.6 Treatment and maintenance of *Cryptococcal neoformans* meningitis—cont'd

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Maintenance					
Fluconazole	400mg PO once daily for 8–10 weeks, then reduced to 200 mg PO once daily and continued until CD4 T-cell count >100 cells/microlitre and an undetectable HIV viral load for at least 3 months	Headache, abdominal pain, vomiting, diarrhoea, nausea, elevated LFTs, rash	Inducers and inhibitors of CYP3A4	LFTs	In some cases it may be considered to continue 400 mg once daily regimen for duration of maintenance phase
Liposomal amphotericin	4mg/kg IV ONCE weekly continued until CD4 T-cell count >100 cells/microlitre and an undetectable HIV viral load for at least 3 months	Hypokalaemia, hyponatraemia, hypocalcaemia, hypomagnesaemia, hyperglycaemia, headache, tachycardia, hypotension, vasodilation, flushing, dyspnoea, nausea, vomiting, abnormal LFTs, rash, back pain, renal impairment, rigors, pyrexia, chest pain	Nephrotoxic medication, drugs that may potentiate hypokalaemia, antineoplastic agents	Renal function, magnesium, LFTs, FBC	Fluconazole is considered first line for maintenance because has been shown to be superior to amphotericin with less drug-related toxicities and lower relapse rates Pre-hydration with 0.9% sodium chloride may decrease nephrotoxicity

CSF, Cerebrospinal fluid; FBC, full blood count; IV, intravenous; LFT, liver function test; PO, oral.

First-line treatment in the maintenance phase is fluconazole 400 mg once daily for 8–10 weeks, then reduced to 200 mg once daily. In some cases the decision to continue 400 mg once daily therapy may be considered and has been associated with a lower rate of relapse (Nelson et al., 2011). Maintenance therapy has been shown to reduce the incidence of disease relapse and should be continued until immune function has been restored secondary to HIV treatment and CD4 T-cell count is greater than 100 cells/microlitre with an undetectable HIV viral load for at least 3 months.

Protozoal infections

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan and the most common cause of space-occupying lesions or cerebral abscesses in the brain in people who are living with HIV with a CD4 T-cell count less than 200 cells/microlitre. Humans acquire infection by eating animals with disseminated infection or by ingestion of oocytes shed in cat faeces that have contaminated soil, fruit, vegetables and water. Toxoplasmosis is then usually caused by reactivation of chronic infection acquired earlier in life

during periods of immunodeficiency. Cerebral abscesses develop over a number of days to weeks, and the patient will commonly present with neurological symptoms and sometimes seizures. An increase in intracranial pressure can cause headaches and vomiting (Nelson et al., 2011).

Radiological imaging of the brain performed by MRI is a more sensitive test and, therefore, the preferred method over CT scanning. However, if MRI is unavailable, then a CT scan should be performed. Abscesses are typically multiple, ring-enhancing lesions that may be associated with cerebral oedema and mass effect. A positive serum toxoplasma IgG represents prior infection, which may be a useful additional diagnostic tool because toxoplasmosis in people living with HIV is usually the result of reactivation.

First-line treatment is sulfadiazine and pyrimethamine, with calcium folinate to prevent pyrimethamine-induced myelosuppression. Acute treatment is continued for 6 weeks followed by maintenance therapy with lower doses of the same agents until CD4 T-cell count remains greater than 200 cells/microlitre for 6 months and suppression of HIV replication (Table 42.7). There is limited experience to guide therapy if first- and second-line agents cannot be tolerated; however, possible alternatives can be found in BHIVA guidelines. Corticosteroids are not routinely used but may

Table 42.7 Treatment and maintenance of toxoplasmosis

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Treatment					
Sulfadiazine + pyrimethamine (+ calcium folinate)	Sulfadiazine: 1.5 g PO four times daily (≤ 60 kg) or 2 g PO four times daily (> 60 kg) Pyrimethamine: 200 mg PO loading dose followed by 50 mg PO once daily (≤ 60 kg) or 75 mg PO once daily (> 60 kg) Calcium folinate: 15 mg PO once daily for 6 weeks	Sulfadiazine: blood disorders, hypersensitivity reactions, hypoglycaemia, hypothyroidism, depression, psychosis, hallucinations, neurological reactions, tinnitus, cough, dyspnoea, GI symptoms, hepatitis, jaundice, purpura, rash, crystalluria Pyrimethamine: anaemia, leucopenia, thrombocytopenia, headache, giddiness, vomiting, nausea, diarrhoea, rash, abnormal skin pigmentation, fever	Sulfadiazine: thiopentone anaesthetics, warfarin, sulphonylureas, clozapine, aspirin, ciclosporin, diuretics, methotrexate, oestrogen-containing oral contraceptives, probenecid Pyrimethamine: agents that depress folate metabolism, agents that cause myelosuppression, antacids, highly protein-bound drugs, methotrexate	LFTs, renal function, FBC	Ensure fluid intake of 2 L/day to reduce the risk of crystalluria Caution in G6PD deficiency Calcium folinate to counteract myelosuppressive effects of pyrimethamine
Clindamycin + pyrimethamine (+ calcium folinate)	Clindamycin: 600 mg PO/IV four times daily Pyrimethamine: 200 mg PO loading dose followed by 50 mg PO once daily (≤ 60 kg) or 75 mg PO once daily (> 60 kg) Calcium folinate: 15 mg PO once daily for 6 weeks	Clindamycin: abdominal pain, diarrhoea, <i>Pseudomembranous colitis</i> , abnormal LFTs, nausea, vomiting, rash, urticaria, blood dyscrasias, dysgeusia (IV), thrombophlebitis (IV) Pyrimethamine: anaemia, leucopenia, thrombocytopenia, headache, giddiness, vomiting, nausea, diarrhoea, rash, abnormal skin pigmentation, fever	Clindamycin: neuromuscular blocking agents, erythromycin, neostigmine, pyridostigmine, oestrogens (risk of interaction is small) Pyrimethamine: agents that depress folate metabolism, agents that cause myelosuppression, antacids, highly protein-bound drugs, methotrexate	LFTs, renal function, FBC, diarrhoea	Change in bowel habit should be investigated for <i>Clostridium difficile</i> Caution in G6PD deficiency Calcium folinate to counteract myelosuppressive effects of pyrimethamine
Maintenance					
Sulfadiazine + pyrimethamine (+ calcium folinate)	Sulfadiazine: 500 mg PO four times daily (preferred) or 1 g twice daily (if reduced adherence is suspected) Pyrimethamine: 25 mg PO once daily Calcium folinate: 15 mg PO once daily continued until CD4 T-cell count > 200 cells/microlitre for 6 months and suppression of HIV replication	Sulfadiazine: blood disorders, hypersensitivity reactions, hypoglycaemia, hypothyroidism, depression, psychosis, hallucinations, neurological reactions, tinnitus, cough, dyspnoea, GI symptoms, hepatitis, jaundice, purpura, rash, crystalluria Pyrimethamine: anaemia, leucopenia, thrombocytopenia, headache, giddiness, vomiting, nausea, diarrhoea, rash, abnormal skin pigmentation, fever	Sulfadiazine: thiopentone anaesthetics, warfarin, sulphonylureas, clozapine, aspirin, ciclosporin, diuretics, methotrexate, oestrogen-containing oral contraceptives, probenecid Pyrimethamine: agents that depress folate metabolism, agents that cause myelosuppression, antacids, highly protein-bound drugs, methotrexate	LFTs, renal function, FBC	Ensure fluid intake of 2 L/day to reduce the risk of crystalluria Caution in G6PD deficiency Calcium folinate to counteract myelosuppressive effects of pyrimethamine
Clindamycin + pyrimethamine (+ calcium folinate)	Clindamycin: 300 mg PO four times daily (preferred) or 600 mg three times daily (if reduced adherence is suspected) Pyrimethamine: 25 mg PO once daily Calcium folinate: 15 mg PO once daily continued until CD4 T-cell count > 200 cells/microlitre for 6 months and suppression of HIV replication	Clindamycin: abdominal pain, diarrhoea, <i>Pseudomembranous colitis</i> , abnormal LFTs, nausea, vomiting, rash, urticaria, blood dyscrasias, dysgeusia (IV), thrombophlebitis (IV) Pyrimethamine: anaemia, leucopenia, thrombocytopenia, headache, giddiness, vomiting, nausea, diarrhoea, rash, abnormal skin pigmentation, fever	Clindamycin: neuromuscular blocking agents, erythromycin, neostigmine, pyridostigmine, oestrogens (risk of interaction is small) Pyrimethamine: agents that depress folate metabolism, agents that cause myelosuppression, antacids, highly protein-bound drugs, methotrexate	LFTs, renal function, FBC, diarrhoea	Change in bowel habit should be investigated for <i>Clostridium difficile</i> Caution in G6PD deficiency Calcium folinate to counteract myelosuppressive effects of pyrimethamine

FBC, Full blood count; G6PD, glucose-6-phosphate dehydrogenase; GI, gastro-intestinal; IV, intravenous; LFT, liver function test; PO, oral.

be considered in patients where there is evidence of raised intracranial pressure. Adjunctive anticonvulsants may be indicated if a patient presents with or develops seizures; however, there is no evidence to support routine prescribing (Nelson et al., 2011).

Cryptosporidiosis

Cryptosporidium is a protozoan parasite, which is ubiquitous in the environment. Transmission is via ingestion of cryptosporidium oocysts from contaminated water supplies, which leads to transmission of the parasite. Transmission may also occur during sexual intercourse, particularly via the faecal-oral route. Symptoms are profuse, non-bloody watery diarrhoea. This may be accompanied by nausea, abdominal cramps and pyrexia.

Diagnosis is via detection of cryptosporidium oocysts in a stool sample. Several samples may need to be checked because oocyst excretion can be intermittent, especially in less severe infections (Nelson et al., 2011).

Treatment options are described in Table 42.8. No specific treatments are available that target cryptosporidium. Optimal management is to restore immune function via initiation of ART. Several therapeutic options have been investigated for treatment; however, low study numbers and lack of promising results in immunocompromised individuals make ART the first choice of management. If treatment is considered worth using, nitazoxanide is the preferred agent; however, it should be recognised that efficacy is limited in patients with compromised immune function. Patients should also be offered symptomatic and supportive therapy with fluid replacement, adequate hydration and anti-motility agents.

Bacterial infections

Mycobacterium tuberculosis

In individuals who are living with HIV, *M. tuberculosis* (TB) is characterised by increased likelihood of reactivation of latent disease, more rapid progression to clinical disease following acquisition, more frequent extrapulmonary manifestations of TB and more rapid progression of HIV disease if the individual is not receiving ART. The management of co-infection with TB and HIV requires specialist knowledge, and it is therefore mandatory to involve specialists in both HIV and respiratory and/or infectious diseases (Nelson et al., 2011).

Both clinical and radiographic presentation of TB may be atypical. Patients may have a normal chest radiograph and a

sputum-smear-negative result with positive culture. Definitive diagnosis is reliant on culture of the organism from biological specimens but may be complicated by atypical clinical features and reduced response to tuberculin testing. It is often necessary to initiate treatment empirically. Molecular diagnostics can rapidly confirm if acid-fast bacilli from a body fluid smear test are not TB, which may avoid unnecessary treatment and infection-control measures. The increased incidence of multidrug-resistant TB and the emergence of extremely drug-resistant disease are a cause for concern and raise many infection-control issues. They also highlight the need for antibiotic therapy driven by bacteriological sensitivities (Nelson et al., 2011).

Recommendations for the treatment of *M. tuberculosis* are similar to those in HIV-negative adults, and the appropriate guidelines should be consulted, for example, NICE (2016). The potential for drug–drug interactions and overlapping toxicities are greater in those receiving ART, and this should be considered when initiating *M. tuberculosis* treatment (Table 42.9). Further information can be obtained from the University of Liverpool HIV drug interaction website (<http://www.hiv-druginteractions.org>).

M. avium intracellulare/*M. avium* complex

M. avium intracellulare (MAI) or *M. avium* complex (MAC) are commonly found in the environment and are thought to enter individuals via the respiratory route and gastro-intestinal tract. With the increasing use of ART, the incidence of MAI/MAC has decreased significantly in people who are living with HIV because it typically occurs in severe immunosuppression with CD4 T-cell count less than 50 cells/microlitre. Infection usually presents as a systemic febrile illness with sweating, fatigue, abdominal pain, weight loss and diarrhoea. Lymphadenopathy, hepatosplenomegaly and/or splenomegaly may be present. Clinical presentation may vary with site of infection, for example, pulmonary MAI/MAC may present with respiratory symptoms (Temesgen, 2015). Diagnosis should be made based on culture of the organism from blood and sputum samples. In specific cases, it may be necessary for further investigations such as lung or lymph node tissue biopsy or bone marrow aspirate.

First-line treatment should be with a macrolide antibiotic (azithromycin is preferred secondary to less drug–drug interaction potential than other macrolide antibiotics), ethambutol and, ideally, rifabutin as a third agent. Treatment should be continued for at least 12 months and until individuals remain culture-negative, asymptomatic and have a sustained CD4 T-cell count greater than 100 cells/microlitre for at least 3 months (Nelson et al., 2011).

Table 42.8 Treatment of cryptosporidium

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Nitazoxanide	500 mg orally twice daily for 3 days; course duration may be required for up to 12 weeks	Abdominal pain, diarrhoea, nausea, vomiting, headache	Nil known	Full blood count, liver function tests, renal function	Take with food

Table 42.9 Drug–drug interactions between antiretroviral therapy and rifampicin/rifabutin

Antiretroviral	Rifampicin	Rifabutin
NRTIs/NTRTIs		
There are no interaction with any NRTIs/NTRTIs and rifamycins	Use standard doses	Use standard doses
NNRTIs		
Efavirenz	Efavirenz levels decreased: Consider increasing efavirenz dosage to 800 mg once daily in patients >50 kg (may also consider TDM)	Rifabutin levels decreased: Increase daily dose of rifabutin by 50%
Nevirapine	Nevirapine levels decreased: Do not co-administer	Rifabutin levels increased: Use standard doses Caution: High intersubject variability means some patients may experience larger increases and may be at risk of rifabutin toxicity
Etravirine	No data available: Do not co-administer	Limited data: Use standard doses Caution: Etravirine and rifabutin levels both decreased
Rilpivirine	Rilpivirine levels decreased: Do not co-administer	Rilpivirine levels decreased: Increase rilpivirine dose by 100%
Protease inhibitors		
Atazanavir/ritonavir	Atazanavir levels decreased: Do not co-administer	Rifabutin levels increased: Reduce rifabutin dosage to 150 mg three times weekly (TDM advised because this dosage may be too low in some patients)
Darunavir/ritonavir	Darunavir levels decreased: Do not co-administer	Rifabutin levels increased: Reduce rifabutin dosage to 150 mg three times weekly (TDM advised because this dose may be too low in some patients)
Fosamprenavir/ritonavir	Fosamprenavir levels decreased: Do not co-administer	Rifabutin levels increased: Reduce rifabutin dosage to 150 mg three times weekly (TDM advised because this dose may be too low in some patients)
Lopinavir/ritonavir	Lopinavir levels decreased: Do not co-administer	Rifabutin levels increased: Reduce rifabutin dosage to 150 mg three times weekly (TDM advised because this dose may be too low in some patients)
Saquinavir/ritonavir	Saquinavir levels decreased: Do not co-administer	Rifabutin levels increased: Reduce rifabutin dosage to 150 mg three times weekly (TDM advised because this dose may be too low in some patients)
Integrase inhibitors and entry inhibitors		
Dolutegravir	Dolutegravir levels decreased: Increase dolutegravir dosage to 50 mg twice daily	Use standard doses
Elvitegravir/cobicistat	Elvitegravir and cobicistat levels decreased: Do not co-administer	Elvitegravir and cobicistat levels decreased and rifabutin levels increased: Use not recommended; however, no alternative; reduce rifabutin to 150 mg three times weekly
Raltegravir	Raltegravir levels decreased: Increase raltegravir dosage to 800 mg twice daily Caution: C_{min} still reduced at increased dosage	Use standard doses

Table 42.9 Drug–drug interactions between antiretroviral therapy and rifampicin/rifabutin—cont'd

Antiretroviral	Rifampicin	Rifabutin
Maraviroc	Maraviroc levels decreased: Increase maraviroc dosage to 600 mg twice daily	Use standard doses
Enfuvirtide	Use standard doses	Use standard doses

TDM, Therapeutic drug monitoring.

In patients with a CD4 T-cell count less than 50 cells/microlitre, prophylaxis azithromycin 1250 mg once weekly should be considered. The addition of ART is considered essential to the management to restore a weakened immune function.

Viral infections

Herpes simplex and varicella zoster

The herpes viruses are a large family with three phases of infection: primary infection, latency and reactivation. Herpes simplex viruses 1 and 2 (HSV) and VZV are classified as α herpes viruses. VZV is usually transmitted via the respiratory route and causes both varicella (chickenpox) and zoster (shingles). HSV is transmitted via contact with infectious secretions and causes genital or orolabial ulcers. VZV cutaneous presents as localised, erythematous, maculopapular eruptions usually along a single dermatome, but may be multi-dermatomal. They then crust over a few days and typically last for 2–3 weeks. VZV eye disease causes visual loss, keratitis, anterior uveitis, severe post-herpetic neuralgia and necrotising retinopathy. Herpes zoster can disseminate and cause CNS disease and present with neurological disease.

Orolabial HSV is most commonly caused by HSV-1 and presents with sensory prodromal symptoms (usually a tingling), which typically precede development of vesicles that ulcerate and crust. Left untreated, they will usually resolve within 7–10 days. Genital HSV is caused by both HSV-1 and -2. Anogenital lesions develop and usually resolve untreated within 5–10 days; however, they may not resolve spontaneously and require treatment. Systemic HSV infection can result in pneumonia, hepatitis, oesophagitis and CNS disease.

VZV is usually diagnosed based on appearance of lesions, especially cutaneous disease. Swabs of infected lesions can also be checked for detection of expression viral antigens. CSF analysis can be performed; a positive result for VZV DNA supports the diagnosis of CNS disease. Swabs of infected lesions can be tested for identification of HSV-1 or -2, and in systemic disease appropriate samples should be obtained for analysis to identify HSV.

First-line treatment should be with aciclovir. Alternative treatment options which may be considered are valaciclovir and famciclovir. Oral aciclovir can be used for the treatment of local VZV (zoster), orolabial HSV and genital HSV if severe or recurrent disease. Systemic aciclovir is required for VZV (varicella), systemic VZV (zoster) and systemic HSV. Regular suppressive use of oral aciclovir at lower doses can be used in cases of recurrent disease (Nelson et al., 2011).

Cytomegalovirus

CMV is a member of the β -herpes viruses which infects greater than 50% of the human population. After infection the virus has the ability to establish lifelong, latent infection (Bronke et al., 2005). In individuals with advanced immunodeficiency, typically with a CD4 T-cell count less than 50 cells/microlitre, this can result in reactivation of the virus (viraemia) and clinical end-organ disease in a proportion of patients. Major sites of CMV disease are the retina (75%), gastro-intestinal tract, lung, liver and biliary tract, heart, adrenal glands and the nervous system (<1%) (Nelson et al., 2011).

Symptoms are dependent on the site of infection. Viral infection of the retina may be asymptomatic or present with floaters, scotomata, peripheral or central visual field defects and decreased visual acuity. In the gastro-intestinal tract symptoms are likely to be colitis, weight loss, anorexia, abdominal pain, diarrhoea, malaise and perforation. Oesophagitis presents with odynophagia, nausea and epigastric/retrosternal discomfort. Presentation in lung infection is similar to many other respiratory conditions: non-productive cough, exertional dyspnoea, fever and marked hypoxaemia. However, pneumonitis is uncommon. When the CNS is involved symptoms are dementia, ventriculoencephalitis, polyradiculomyelitis, lethargy, confusion and fever (Centers for Disease Control and Prevention, 2015).

CMV viraemia, as detected by polymerase chain reaction, may be positive in the absence of end-organ disease and, therefore, may be of negligible diagnostic use. If a positive result is obtained, evidence of end-organ disease should be considered depending on the patient's clinical symptoms.

For retina infections, diagnosis is usually based on clinical symptoms and visualisation of the retina. Endoscopy can reveal ulceration of the gut mucosa, and a biopsy can identify characteristic inclusions to aid diagnosis. Pneumonitis is hard to differentiate from CMV shedding in respiratory secretions. Therefore, BAL may reasonably exclude CMV pneumonia with a negative result; however, a positive result should be interpreted alongside clinical symptoms. Radiological imaging of the brain performed by MRI is a more sensitive test and, therefore, the preferred method over CT scanning. A lumbar puncture, if not contraindicated, can be performed for CSF examination to assess CNS infection.

Treatment of CMV is outlined in Table 42.10. For gastro-intestinal infection, treatment should be given with IV therapy because oral drugs may not be fully absorbed. Maintenance treatment is not recommended. However, for retinitis both induction and maintenance treatment should be given with either oral or IV therapy. A ganciclovir implant may be considered if systemic

Table 42.10 Treatment and maintenance of cytomegalovirus

Drug	Dosage: route, frequency, duration	Common or significant side effects	Significant interactions	Monitoring	Comments
Treatment					
Ganciclovir	5 mg/kg IV twice daily GI: 2–4 weeks Retinitis: 2–4 weeks Lung: 3 weeks	Sepsis, cellulitis, urinary tract infection, oral candidiasis, neutropenia, anaemia, thrombocytopenia, leucopenia, pancytopenia, appetite decreased, anorexia, depression, anxiety, confusion, abnormal thinking, headache, insomnia, dysgeusia, hypoaesthesia, paraesthesia, peripheral neuropathy, convulsions, dizziness, macular oedema, retinal detachment, vitreous floaters, eye pain, ear pain, dyspnoea, cough, diarrhoea, nausea, vomiting, abdominal pain, constipation, flatulence, dysphagia, dyspepsia, elevated LFTs, dermatitis, night sweats, pruritus, back pain, myalgia, arthralgia, muscle cramps, renal impairment, fatigue, pyrexia, rigors, pain, chest pain, malaise, asthenia, injection-site reactions, decreased weight	Imipenem-cilastin, probenecid, zidovudine, didanosine, mycophenolate, nephrotoxic drugs, bone marrow-suppressive agents	FBC, LFTs, renal function	Caution when handling; women of childbearing potential must be advised to use effective contraception during treatment; male patients should be advised to practise barrier contraception during and for at least 90 days following treatment
Valganciclovir	900 mg PO twice daily Retinitis: 2–4 weeks Lung: 3 weeks	See ganciclovir, similar potential side effects (except those associated with IV administration)	Imipenem-cilastin, probenecid, zidovudine, didanosine, mycophenolate, nephrotoxic drugs, bone marrow-suppressive agents	FBC, LFTs, renal function	Caution when handling; women of childbearing potential must be advised to use effective contraception during treatment; male patients should be advised to practise barrier contraception during and for at least 90 days following treatment
Foscarnet	90mg/kg IV twice daily GI: 2–4 weeks Lung: 3 weeks	Granulocytopenia, anaemia, leucopenia, thrombocytopenia, neutropenia, sepsis, decreased appetite, hypokalaemia, hypomagnesaemia, hypocalcaemia, hyperphosphataemia, hyponatraemia, hypophosphataemia, increased ALP, increased LDH, aggression, agitation, anxiety, confusional state, depression, nervousness, dizziness, headache, paraesthesia, abnormal coordination, convulsion, hypoaesthesia, involuntary muscle contractions, peripheral neuropathy, tremor, hypertension, hypotension, thrombophlebitis, diarrhoea, nausea, vomiting, abdominal pain, constipation, dyspepsia, pancreatitis, elevated LFTs, rash, pruritus, myalgia, renal impairment, genital discomfort and ulceration, asthenia, chills, fatigue, pyrexia, malaise, oedema	Nephrotoxic drugs, drugs that inhibit renal tubular secretion, IV pentamidine, ritonavir	Renal function, magnesium, bone profile, FBC, blood pressure, LFTs	Good hydration, prompt correction of electrolyte abnormalities and dose adjustment for renal function are vital Wash genital area after micturition to reduce risk of ulceration Reduce infusion rate if infusion-related side effects
Cidofovir	5 mg/kg IV once weekly Retinitis: 2 weeks Lung: 3 weeks	Renal impairment, neutropenia, ocular hypotony, iritis/uveitis, nausea, vomiting, alopecia, rash, asthenia, fever, chills, headache	Nephrotoxic drugs, drugs contraindicated with probenecid, tenofovir	Renal function (including urine protein), FBC	Must be co-administered with probenecid and IV fluids to minimise nephrotoxicity; caution with handling (potential carcinogen)

Maintenance					
Ganciclovir	5 mg/kg IV once daily for 5 days of the week GI: no maintenance recommended Retinitis: continue until CD4 T-cell count >100 cells/microlitre and suppressed HIV viral load	Sepsis, cellulitis, urinary tract infection, oral candidiasis, neutropenia, anaemia, thrombocytopenia, leucopenia, pancytopenia, appetite decreased, anorexia, depression, anxiety, confusion, abnormal thinking, headache, insomnia, dysgeusia, hypoaesthesia, paraesthesia, peripheral neuropathy, convulsions, dizziness, macular oedema, retinal detachment, vitreous floaters, eye pain, ear pain, dyspnoea, cough, diarrhoea, nausea, vomiting, abdominal pain, constipation, flatulence, dysphagia, dyspepsia, elevated LFTs, dermatitis, night sweats, pruritus, back pain, myalgia, arthralgia, muscle cramps, renal impairment, fatigue, pyrexia, rigors, pain, chest pain, malaise, asthenia, injection-site reactions, decreased weight	Imipenem-cilastin, probenecid, zidovudine, didanosine, mycophenolate, nephrotoxic drugs, bone marrow-suppressive agents	FBC, LFTs, renal function	Caution when handling; women of childbearing potential must be advised to use effective contraception during treatment; male patients should be advised to practise barrier contraception during and for at least 90 days following treatment
Valganciclovir	900 mg PO once daily GI: no maintenance recommended Retinitis: continue until CD4 T-cell count >100 cells/microlitre and suppressed HIV viral load	See ganciclovir, similar potential side effects (except those associated with IV administration)	Imipenem-cilastin, probenecid, zidovudine, didanosine, mycophenolate, nephrotoxic drugs, bone marrow-suppressive agents	FBC, LFTs, renal function	Caution when handling; women of childbearing potential must be advised to use effective contraception during treatment; male patients should be advised to practise barrier contraception during and for at least 90 days following treatment
Foscarnet	90 or 120 mg/kg IV once daily for 5 days of the week GI: no maintenance recommended Retinitis: continue until CD4 T-cell count >100 cells/microlitre and suppressed HIV viral load	Granulocytopenia, anaemia, leucopenia, thrombocytopenia, neutropenia, sepsis, decreased appetite, hypokalaemia, hypomagnesaemia, hypocalcaemia, hyperphosphataemia, hyponatraemia, hypophosphataemia, increased ALP, increased LDH, aggression, agitation, anxiety, confusional state, depression, nervousness, dizziness, headache, paraesthesia, abnormal coordination, convulsion, hypoaesthesia, involuntary muscle contractions, peripheral neuropathy, tremor, hypertension, hypotension, thrombophlebitis, diarrhoea, nausea, vomiting, abdominal pain, constipation, dyspepsia, pancreatitis, elevated LFTs, rash, pruritus, myalgia, renal impairment, genital discomfort and ulceration, asthenia, chills, fatigue, pyrexia, malaise, oedema	Nephrotoxic drugs, drugs that inhibit renal tubular secretion, IV pentamidine, ritonavir	Renal function, magnesium, bone profile, FBC, blood pressure, LFTs	Good hydration, prompt correction of electrolyte abnormalities and dose adjustment for renal function are vital Wash genital area after micturition to reduce risk of ulceration Reduce infusion rate if infusion-related side effects
Cidofovir	5 mg/kg IV every 2 weeks GI: no maintenance recommended Retinitis: continue until CD4 T-cell count >100 cells/microlitre and suppressed HIV viral load	Renal impairment, neutropenia, ocular hypotony, iritis/uveitis, nausea, vomiting, alopecia, rash, asthenia, fever, chills, headache	Nephrotoxic drugs, drugs contraindicated with probenecid, tenofovir	Renal function (including urine protein), FBC	Must be co-administered with probenecid and IV fluids to minimise nephrotoxicity Caution with handling (potential carcinogen)

ALP, Alkaline phosphatase; FBC, full blood count; GI, gastro-intestinal; IV, intravenous; LDH, lactate dehydrogenase; LFT, liver function test; PO, oral.

treatment is contraindicated. Evidence for treatment for CNS infection is limited; however, ganciclovir with or without addition of foscarnet may be considered. In the cases of CNS infection, correcting immunodeficiency with ART is critical.

Most individuals with a lung infection will not require treatment, and the decision to treat should be based on positive BAL results, as well as clinical symptoms with no alternative cause.

Impact of antiretroviral therapy and clinical infections

The widespread use of ART has had a dramatic effect on the incidence, prognosis and clinical aspects of opportunistic infections, with a major reduction in the vast majority of opportunistic infections. As a consequence, there has been a reduction in mortality rates and hospital admissions. ART, although vital in the overall management of opportunistic infections, can be associated with some complications, for example, overlapping toxicities, drug–drug interactions and occasionally a severe immune reconstitution inflammatory syndrome.

Cancers

HIV increases the risk of many malignancies but is associated with three AIDS-defining malignancies: KS, high-grade B-cell non-Hodgkin's lymphoma and invasive cervical cancer.

Kaposi's sarcoma

KS is the most common malignancy in people who are living with HIV and is caused by the KS herpes virus. Individuals present with cutaneous or mucosal lesions, and visceral disease is uncommon. Lesions appear as raised purple papules and may be single or multiple, and in severe cases may result in oedema, ulceration and infection. These lesions are often characteristic in appearance, but diagnosis should be confirmed by histology. Plasma level of KS herpes virus DNA can also be used as a surrogate marker of tumour burden. Local therapy can be used for troublesome or local disease; however, this is limited to treating only small areas. Radiotherapy, intralesional vinblastine and topical retinoids have all demonstrated some treatment success. In more widespread disease, systemic treatment is required.

Initiation of ART can result in an improvement and in some cases resolution of KS. However, in patients with advanced, symptomatic or rapidly progressive disease, administration of systemic cytotoxic chemotherapy is required, and liposomal anthracyclines and taxanes are the established standard treatment.

High-grade B-cell non-Hodgkin's lymphoma

High-grade B-cell non-Hodgkin's lymphoma is the second most common malignancy in people who are living with HIV, although incidence has declined since the introduction of ART. Diagnosis should be based on histological confirmation from a tissue

biopsy. Treatment should be according to conventional chemotherapy regimens; however, potential drug–drug interactions with ART should be considered because this can increase the toxicity of some chemotherapy combinations (e.g. PIs), increase the levels of some chemotherapy agents and increase the risk of neutropenia.

Invasive cervical cancer

Worldwide, cervical cancer is the second most common cancer in women overall and is associated with infection with human papillomavirus (HPV). Women who are living with HIV are more likely to have HPV infection, and therefore a higher prevalence of cervical cancer is seen in women living with HIV. Diagnosis is based on histopathological examination of cervical biopsies, and women with HIV should have an annual cervical cytology. Management should be the same as HIV-negative women according to national guidelines.

Neurological manifestations

Neurological symptoms may be caused by opportunistic infections, tumours or the primary neurological effects of the disease. HIV encephalopathy or HIV-associated cerebral disease is believed to result from direct infection of the CNS by HIV. This has dramatically declined with the effective use of ART; however, more subtle forms of brain disease, known as HIV-associated neurocognitive disorders, are reported. Initiation of ART should be immediate in individuals demonstrating any signs of neurocognitive disorders. Patients with any level of neurocognitive deficit should start standard ART; the level of CNS drug penetration should not influence therapeutic choice of ART because data of improvement in neurocognitive function are not conclusive (Churchill et al., 2015).

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy is associated with the presence of JC virus. Transmission of the virus is not well understood, but it is thought to spread via respiratory secretions and tonsillar tissue, probably in childhood (Nelson et al., 2011). The virus disseminates after primary transmission and becomes latent. Following immune suppression, the virus replicates and is transported to the brain via B lymphocytes, where it infects permissive oligodendrocytes via the serotonin receptor (Nelson et al., 2011). Patients present with severe immunodeficiency over a period of weeks to months. Focal neurology, motor deficit, altered mood or mental status, ataxia and cortical visual symptoms may be present. Seizures occur rarely. The presence of focal features helps to distinguish progressive multifocal leucoencephalopathy from HIV encephalopathy. Radiological brain imaging using MRI combined with JC virus detection in a CSF sample are sufficient to confirm a diagnosis, rather than having to consider a brain biopsy. In many cases, introduction of ART prevents progression of disease, but it is unlikely to reverse the functional deficit. Adjunctive cidofovir or cytarabine, although active in vitro against JC virus, has not been shown to provide any additional benefit over ART alone (Nelson et al., 2011).

Case studies

Case 42.1

Miss F is a 32-year-old legal secretary, originally from Zimbabwe, and has lived in the UK for 10 years. She was diagnosed with HIV-1 2 years ago during a routine sexual health screen. Her baseline CD4 count was 320 cells/mm³ and her viral load was 37,000 copies/mL. She had no baseline resistance and was hepatitis B immune and hepatitis C-negative. She was otherwise fit and well, taking only the combined oral contraceptive pill and had no allergies. She had a male partner who tested HIV-negative and they used condoms. She declines primary care doctor disclosure around her HIV status, as she is worried about confidentiality.

In view of her CD4 count less than 350 cells/mm³ she was offered treatment. She was keen on a single-tablet regimen and Eviplera (tenofovir disoproxil fumarate, emtricitabine and rilpivirine) was started as a 1-pill once-a-day combination. This was chosen because there are no significant interactions with the combined oral contraceptive pill and it suited her lifestyle. In addition her viral load was less than 100,000 copies/mL, above which rilpivirine is not recommended in people starting cART because of higher rates of virological failure. She tolerated this well and achieved an undetectable viral load after 3 months, her CD4 count increased to greater than 600 cell/mm³ and she remained stable.

She is recalled to clinic due to her viral load rising to 5697 copies/mL. A repeat sample confirms virological failure (viral load 7812 copies/mL), and a resistance test confirms an E138K mutation which confers resistance to rilpivirine.

Questions

1. What are the possible reasons for the rise in her viral load?
2. What ARV therapy change would you recommend?
3. What would you advise her to do regarding the combined oral contraceptive pill?

Answers

1. There are three main reasons for virological failure. Firstly, the patient has shown poor adherence to therapy, which should be explored in detail at this patient's appointment and support given around adherence if this has been the main issue. Secondly, rilpivirine has a significant food requirement of 390 calories to aid absorption and ensure adequate drug levels, so if she has been taking her Eviplera without food, this could put her at risk of virological failure. Thirdly, a full drug history needs to be taken. On discussion she reports that her primary care doctor prescribed her omeprazole 20 mg daily for the last 3 months due to new onset of dyspepsia. Omeprazole significantly decreases the rilpivirine plasma concentrations caused by an increase in gastric pH; therefore, co-administration is not recommended. This is the likely cause of virological failure in this patient. It is important that patients are supported to disclose to their primary care doctors/other clinicians and if they do not, that they seek advice from the specialist HIV pharmacy team if they are prescribed a new drug or buy over-the-counter medication.
2. She needs to switch her antiretroviral therapy because she is no longer receiving an effective combination. If she remains taking Eviplera, she is at risk of acquiring further drug resistance. The E138K mutation compromises rilpivirine and also has cross-class resistance, so the other NNRTIs are no longer an option. Tenofovir disoproxil fumarate and emtricitabine are still active; therefore, only the third agent needs

to be altered. The best option would be switching to a boosted PI. As a class, the PIs are much more robust and require multiple mutations to confer resistance; this strategy is recommended in the [BHIVA \(2015\)](#) guidelines. Atazanavir should be avoided because it also interacts with proton pump inhibitors. Therefore, ritonavir-boosted darunavir would be the third agent of choice, particularly if there were any adherence concerns. Other third agent choices would include an INI (raltegravir, elvitegravir or dolutegravir) or maraviroc if the patient was CCR5 tropic. These agents would not be recommended if there was any evidence of concurrent NRTI resistance.

3. Her contraception needs are important to consider because she is taking the combined oral contraceptive pill. Rilpivirine did not interact; however, darunavir/ritonavir will reduce its efficacy. Therefore, if she switches to this as a third agent, then she would have to be counselled and offered alternative contraception options. Medroxyprogesterone intramuscularly and the IUD/IUS are viable options, but the combined oestrogen/progesterone and other progesterone-based methods are less efficacious. If she switched to either raltegravir, dolutegravir or maraviroc, she could continue with the combined oral contraceptive pill because there are no significant drug-drug interactions.

Case 42.2

In 1997, Mr B, a 27-year-old man, presented with PCP. He had a CD4 count of 123 cells/mm³, and plasma HIV RNA was unknown because viral load testing was not routinely available in clinics at the time. He had a good response to treatment with high-dose cotrimoxazole and was subsequently commenced on triple-combination therapy with stavudine, didanosine and indinavir. He continued receiving this regimen for 2 years, until HIV RNA testing became available and he was found to have a suppressed viral load and CD4 count of 412 cells/mm³. His full antiretroviral therapy history, with reasons for switching, is detailed as follows ([Table 42.11](#)).

In April 2017 (now aged 47 years) his viral load remained <40 copies/mL, with CD4 count 670 cells/mm³. However, his creatinine clearance (calculated using Cockcroft–Gault equation) was 41 mL/min and urine protein/creatinine ratio (UPCR) was significantly raised, at 86 mg/mmol (normal <30 mg/mmol). Both were normal when last monitored 4 months previously. On questioning, he revealed that he had been taking regular ibuprofen (400 mg three times a day) for the past month, following a wrist fracture. His QRISK2 score was calculated at 3.5%, and he is HLA-B*5701-negative.

Two weeks after stopping the ibuprofen, Mr B's creatinine clearance is now 52 mL/min and he is restarted on Atripla 1 tablet daily. His repeat UPCR, 1 week after stopping ibuprofen was 42 mg/mmol (improving), with normal urine albumin/creatinine ratio. His serum phosphate was low and fractional excretion of phosphate was 35% (normal <25%). Although his renal function was improving, it was decided to recommend changing his antiretroviral therapy to Kivexa 1 tablet daily and efavirenz 600 mg daily.

Questions

1. What are the possible drug-related causes of Mr B's renal dysfunction and what alterations, if any, to his drug therapy would you recommend?
2. What information should Mr B be given about the proposed change of his regimen to Kivexa plus efavirenz?

Answers

1. Tenofovir disoproxil fumarate use has been associated with renal dysfunction; the first sign of which may be a raised UPCR, although there are other causes. Mr B has a raised UPCR and

Table 42.11 Mr B's antiretroviral therapy treatment history (Case 42.2)

Start date	Drug name, dose and frequency	Stop date	Viral load and CD4 at switch	Reason for changing
May 1997	Stavudine 40 mg twice a day Didanosine 200 mg twice a day Indinavir 800 mg three times a day	Apr 1999	Viral load <200 copies/mL (lower limit of detection at that time) CD4 count 412 cells/mm ³	Renal stones (indinavir)
Apr 1999	Stavudine 40 mg twice a day Didanosine 200 mg twice a day Efavirenz 600 mg once a day	Jan 2002	Viral load <50 copies/mL (lower limit of detection at that time) CD4 count 503 cells/mm ³	Lactic acidosis (stavudine and didanosine)
Jan 2002	Tenofovir disoproxil fumarate 300 mg once a day Lamivudine 300 mg once a day Efavirenz 600 mg once a day	Mar 2008	Viral load <40 copies/mL CD4 count 633 cells/mm ³	Simplification (reducing pill burden)
Mar 2008	Atripla 1 tablet once a day			

reduced creatinine clearance, suggesting moderate renal dysfunction, which may be tenofovir disoproxil fumarate related. However, regular concomitant non-steroidal anti-inflammatory drugs may increase the risk of renal dysfunction. It is possible that the addition of regular ibuprofen has precipitated the renal dysfunction. Therefore, he would be advised to change to an alternative analgesic, if one is still required, starting with regular paracetamol.

Tenofovir disoproxil fumarate has also been associated with hypophosphataemia, a decrease in bone mineral density and other bone abnormalities (infrequently contributing to fractures). With Mr B's recent fracture, this should be investigated via annual DEXA scanning. Atripla is not recommended for patients with creatinine clearance less than 50 mL/min, because the doses of emtricitabine and tenofovir disoproxil fumarate need to be adjusted. For creatinine clearance 30–49 mL/min, a dosage of 200 mg emtricitabine and 300 mg tenofovir disoproxil fumarate (245 mg tenofovir disoproxil) every 48 hours is required. The efavirenz dosage remains 600 mg daily. However, Mr B's renal function must be closely monitored, for example, twice a week, to ensure that the dosages are adjusted promptly to reflect any change. This is to avoid over-dosing or under-dosing, and the associated risks of toxicity and antiretroviral therapy failure. If the renal dysfunction continued or worsened, despite stopping the ibuprofen and dose-adjusting his antiretroviral therapy, then a change of antiretroviral therapy might be warranted.

2. Mr B is being switched from Atripla 1 tablet daily to Kivexa 1 tablet daily and efavirenz 600 mg daily. The efavirenz component of his new regimen is also contained in Atripla, and therefore is not new in terms of drug exposure, merely as form of drug delivery. However, Kivexa is new for this patient. Points to include when counselling Mr B on this new drug regimen are:
 - a. Why this change is being made: Mr B is demonstrating some toxicities of tenofovir disoproxil fumarate, and it has been decided to stop treatment with this drug to prevent any further renal deterioration. He also has a low phosphate level with a recent bone fracture which may have been contributed to by tenofovir disoproxil fumarate.
 - b. How to take this combination: It is best to take efavirenz at night to avoid any disturbance in daily activities if Mr B has any CNS effects after taking his dose. He is used to taking Atripla; therefore, both new drugs should be taken at the same time as he has been used to taking his medication.
 - c. Adverse effects: Mr B is HLA-B*5701-negative and is therefore very unlikely to develop a hypersensitivity reaction to abacavir (a component of Kivexa); however, he should still be aware of this reaction. Hypersensitivity reaction is characterised by fever and/or rash. Other symptoms associated may include

gastro-intestinal discomfort, respiratory symptoms, lethargy, malaise, headache, elevated liver function tests and myalgia. Symptoms usually appear within the first 6 weeks of initiation with abacavir, although they can occur anytime. General side effects such as nausea, vomiting, diarrhoea, fever, lethargy and rash are also present. Therefore, if Mr B has any of these symptoms he should be carefully evaluated for the presence of a hypersensitivity reaction. If Mr B experiences any worrying adverse effects, he should present for review.

- d. Monitoring and follow-up: Because Mr B is switching medication, he will need to return within 2 weeks to be monitored for tolerance to the new medication. This is in the form of a consultation, ideally with a pharmacist, to check whether he is experiencing any side effects. He will also have a safety blood test (usually liver function tests) at this stage to check for further potential adverse effects to new medication and subsequently (usually at 4 weeks) more safety bloods tests (usually liver and renal function tests) for viral suppression. At every review, patients should be made aware of the ongoing plan for their care and ensure they have enough medication to avoid any breaks in treatment.

Case 42.3

Mr C is a 58-year-old MSM who was recently diagnosed HIV through routine sexual health testing at his local genitourinary clinic. He is a smoker of 12 cigarettes a day and has hypertension which is under control (blood pressure 120/95 mmHg) on ramipril and bendroflumethiazide and is also taking pravastatin 40 mg once a day for high lipids. His fasting lipids were total cholesterol 5.9 mmol/L, low-density lipoprotein cholesterol 4.5 mmol/L, high-density lipoprotein 1.0 mmol/L, triglycerides 3.3 mmol/L. His height is 175 cm and his weight is 82 kg.

His CD4 count is 320 cells/mm³ and his viral load is 70,000 copies/mL. He has agreed to start ART, and baseline blood samples for renal function and liver function tests, HIV drug resistance and HLAB5701 status have been done. His calculated creatinine clearance (Cockcroft–Gault equation) was 73 mL/min. He has no drug resistance.

Questions

1. What assessments would you do to decide which NRTI backbone (Kivexa or Truvada) Mr C should be prescribed?
2. What are the limitations of using the QRISK2 calculator? Is the calculated risk likely to be an overestimate or underestimate?

- Mr C is concerned about the implications of his cardiovascular risk review. What information and advice should he be given?
- Having considered all the issues, which backbone would you recommend?
- What aspects need to be considered when determining the most suitable third agent to prescribe for Mr C?

Answers

- To determine the most appropriate medicine, Mr C's HIV viral load should first be reviewed. Because it is less than 100,000 copies/mL, both backbones would be appropriate. If it was more than 100,000 copies/mL, Kivexa would be excluded. This would be followed by a cardiovascular risk assessment using the QRISK2-2016 calculator (<http://qrisk.org>) to determine whether he would be suitable for Kivexa (abacavir, one of the drugs in Kivexa, may be associated with an increased risk of cardiovascular disease and would be best avoided if the cardiovascular risk is >20%). His HLAB*5701 status would be reviewed and Kivexa would only be considered if it was HLA-negative. Mr C would be assessed for any renal or osteoporosis risks to establish whether Truvada would be suitable. His renal function would be determined using the Cockcroft–Gault equation to ascertain whether the combination Truvada was appropriate. His drug resistance results would be reviewed to ascertain that whatever combination was prescribed would result in viral suppression.
- The main limitation of using the QRISK2 is that the population data underpinning the calculator come from individuals whose HIV status was not recorded. HIV infection itself is thought likely to increase the risk of cardiovascular disease, and therefore the cardiovascular risk may need to be increased by a factor of, for example, 1.6. Mr C's calculated 10-year risk rate is 25.3%, and this is likely to be an underestimate. Because abacavir may be associated with an increased risk of cardiovascular disease and is best avoided if the cardiovascular risk is greater than 20%, Kivexa may not be an appropriate choice.
- Mr C should be given general lifestyle advice, especially to give up smoking, follow a healthy, balanced diet and regular exercise. Specific lipid-lowering dietary advice could be given. It would be useful to establish whether Mr C has changed his lifestyle in the last 4–6 months, for example, change in adherence to lipid-lowering therapy and/or change in diet. He should be encouraged to see his primary care doctor for review of his lipid-lowering agent to optimise his lipids.
- Given Mr C's high cardiovascular risk, Kivexa would not be ideal, but Truvada could be considered as a backbone.
- Aspects to consider with respect to a third agent are Mr C's concerns about pill burden, how medicine taking would fit into his lifestyle, whether he would be able to take raltegravir because this needs to be taken twice a day. If efavirenz is being considered, then its potential to cause CNS side effects would need to be reviewed with respect to Mr C's work and whether this could compromise safety in the workplace. In addition, if Mr C has had any mood problems they should be explored because they can be exacerbated by efavirenz. Resistance to drugs like efavirenz occurs if doses are missed. Therefore, if there was any likelihood that Mr C is going to miss doses, which would result in drug resistance, it would be better if Mr C was changed to a more robust regimen, for example, a PI-containing regimen – darunavir/ritonavir or atazanavir/ritonavir. If Mr C was taking any other concomitant medicines (e.g. stomach ulcer medicines like proton pump inhibitors) then atazanavir/ritonavir would not be an appropriate choice because of the drug–drug interactions. Therefore, the patient's wishes, concerns, lifestyle, as well as additional information (e.g. drug interactions), would be considered when determining a suitable third agent in line with local policy for the most cost-effective ARV therapy.

Case 42.4

Ms D is a 50-year-old social worker who was referred to the hospital accident and emergency department by her primary care doctor following a 4-week history of worsening respiratory symptoms, despite empirical treatment with amoxicillin, followed by clarithromycin. She has lost 3 kg in the last 2 months, has had a non-productive cough for 6 weeks and gets breathless climbing the stairs at home. Pulse oximetry showed desaturation to 91% on exercise, and her arterial blood gas sample had a PaO₂ of 8.1 kPa. Chest radiograph showed bilateral interstitial infiltrates. Her medical history includes irritable bowel syndrome (diagnosed 5 years ago), recurrent vaginal candidiasis for the past 7 years and allergic rhinitis, for which she uses fluticasone nasal spray. She works in an inner-city area and has no history of foreign travel outside mainland Europe. The hospital has recently introduced routine (opt out) HIV testing for all acute medical admissions, as a result of which Ms D was found to be HIV-positive, with a CD4 count of 47 cells/mm³.

Questions

- What are the most likely HIV-related differential diagnoses for her respiratory symptoms?
- How should her respiratory symptoms be managed?
- When should she start antiretroviral therapy?
- What drug interactions would you need to consider when managing Ms D both in the first few weeks and also in the longer-term?

Answers

- The history, signs and symptoms (gradual onset, failure to respond to treatment for community-acquired pneumonia, weight loss, non-productive cough, breathlessness on exertion, oxygen desaturation, low PaO₂ and chest radiograph appearance) are all suggestive of PCP. However, some of these could also be consistent with TB which she may have been exposed to as a result of the nature of her job. TB would need to be excluded. Because Ms D has a significant degree of immunosuppression, the possibility of more than one pathogen/diagnosis must always be considered.
- Until TB has been excluded, Ms D should be nursed in a negative pressure room. A bronchoscopy should ideally be performed to assist diagnosis. She should be started on treatment for PCP immediately with high-dose co-trimoxazole and systemic corticosteroid (see text and [Table 42.4](#) for doses and administration details). Following induction treatment (usually 3 weeks in duration), she should receive secondary prophylaxis until her CD4 count on fully suppressive antiretroviral therapy is maintained above 200 cells/mm³ for 3–6 months. If she responds well to PCP treatment and bronchial washings are negative for acid-fast bacilli, then it would be reasonable for her to be managed expectantly with regard to the possibility of TB, that is, not kept in isolation and not started on TB treatment unless relevant symptoms persist or worsen, or new ones develop. If TB treatment were required, the standard four-drug (rifampicin, isoniazid, pyrazinamide, ethambutol) 2-month induction regimen, followed by 4 months of rifampicin and isoniazid plus pyridoxine would be recommended.
- With a CD4 count of 47 cells/mm³, treatment with antiretroviral therapy would be recommended as soon as possible. Depending on how well she tolerated and responded to the PCP treatment, and whether TB treatment was also needed, antiretroviral therapy would usually be started within 2–4 weeks of diagnosis. For more information, refer to BHIVA guidelines for management of opportunistic infections ([Nelson et al., 2011](#)) and TB/HIV co-infection ([Pozniak et al., 2011](#)).

4. If Ms D did require TB treatment, the hepatic enzyme induction effect of rifampicin would need to be considered and a thorough review of drug–drug interactions would be advised. The choice and dose of antiretroviral therapy would also be affected if treatment was started after the HIV genotypic resistance test result was known; if no resistance had been found, then efavirenz-containing antiretroviral therapy would be possible. If co-administered with rifampicin, the efavirenz dose should be increased to 800 mg once daily if her weight was greater than 60 kg; if less than 60 kg, standard dosage of 600 mg should be used. If she is experiencing side effects from efavirenz, TDM of efavirenz is recommended.

If PI-based antiretroviral therapy were initiated, either because of the presence of resistance mutations or whilst awaiting the HIV resistance test result, then TB therapy (if required) would need to be altered. Rifabutin (150 mg three times a week e.g. Monday, Wednesday and Friday) would be used instead of rifampicin. PIs also interact with intranasal and inhaled fluticasone and budesonide, resulting in increased levels of these steroids, due to inhibition of cytochrome 4503A4 in the gut wall and the liver and risk of increased steroid side effects and Cushing's syndrome. Beclometasone nasal spray would be a suitable alternative preparation for Ms D's allergic rhinitis and should be substituted.

43 Fungal Infections

Manjusha Narayanan

Key points

- Fluconazole, a triazole, is considered to be standard therapy for oropharyngeal, oesophageal and vaginal candidiasis.
- Itraconazole and terbinafine are efficacious, non-toxic alternatives to griseofulvin when systemic treatment of dermatophytosis is required.
- Fungi can cause overwhelming deep-seated or systemic infections in immunocompromised hosts that are refractory to antifungal treatment alone.
- Incidence of non-*Aspergillus* mould infections has increased in transplant recipients over the past decade, and these can be lethal.
- Most therapy for deep-seated fungal infection in the immunocompromised host is empirical due to the difficulties in reaching a rapid, accurate diagnosis of systemic fungal infection.
- Lipid-complexed formulations of amphotericin offer a less toxic alternative to conventional amphotericin in the treatment of systemic fungal infection.
- Voriconazole, a triazole, appears to be an effective alternative to amphotericin in the treatment of invasive aspergillosis.
- Caspofungin is an alternative agent to amphotericin for invasive aspergillosis and may have a role to play in the empirical treatment of febrile neutropenic patients.
- Anidulafungin is an alternative to fluconazole in treatment of invasive candidiasis in adult non-neutropenic patients.

Introduction

Fungi are ubiquitous micro-organisms that differ from bacteria in their cellular structure, and this makes them naturally resistant to antibacterial agents (Table 43.1). Fungi are broadly divided into yeasts and moulds. Yeasts are typically round or oval-shaped microscopically; grow flat, round colonies on culture plates; and reproduce by forming buds from their cells. Moulds (e.g. *Aspergillus*, *Mucor*) appear as a collection or mass (mycelium) of individual tubular structures called hyphae that grow by branching and longitudinal extension. They appear as a fuzzy growth on appropriate conducive medium (e.g. *Penicillium* colonies on stale bread or Sabouraud's agar). The most commonly seen yeast, *Candida*, occasionally produces pseudohyphae.

Hundreds of species of fungi are in the environment, but only the important human fungal pathogens and their treatment will be discussed in this chapter. The fungi of medical importance can be divided into four groups (Table 43.2).

Some fungi like *Histoplasma capsulatum*, *Coccidioides immitis* and *Blastomyces dermatitidis* are known as dimorphic fungi (see Table 43.2) because they are found in the infected host in yeast form at 35–37 °C temperature but grow as moulds, in vitro, at room temperatures (22 °C incubation).

Fungi mainly reproduce by forming spores through mitosis giving rise to two daughter cells. They are known by names given to this imperfect state (asexual reproduction), but the same fungus, for example, *Scedosporium apiospermum* (asexual form), is also known as *Pseudoallescheria boydii* (sexual form). However, for all practical purposes, only the oldest and best-established name for the fungi is used in diagnostic laboratories.

Fungal spore are spread by air, water and direct contact with infected source. Humans usually become infected by inhalation of airborne spores or by inoculation into traumatised skin and mucous membrane.

Laboratory diagnosis

Microscopical examination and culture of fungi is the mainstay of laboratory diagnosis. Appropriate staining of histological sections of affected tissue is helpful in making a diagnosis when culture growth may or may not be positive. Yeast colonies and moulds are characteristic in their appearance on culture plates and can be preliminarily identified by their shape, colour and temperatures at which they grow. For the genus and species identification of yeasts, microscopic examination and biochemical tests are necessary. Moulds are identified by their morphology and the nature of sporulation on agar medium.

Antifungal sensitivity testing for yeast is done by determining the minimum inhibitory concentration (MIC) of the antifungal agent in the E-test strip method, which has now replaced the measurement of 'inhibition zone' by disc testing. E-test strips are also available for determining sensitivity of antifungal agents against moulds. Molecular diagnosis utilising polymerase chain reaction is not available for use in routine practice, but it can be available as a send-away test to specialised laboratories. Serological diagnosis to look for antibodies in patient's blood is of use only in *Coccidioides* infection. Enzyme-linked immunosorbent assay methods to look for galactomannan antigen in deep *Aspergillus* infection are available but not fully evaluated. A positive test needs to be interpreted in conjunction with other findings. Antigen detection is useful in disseminated *Histoplasmosis* and *Cryptococcosis*.

Table 43.1 Important characteristics of a fungal cell

Fungi	Bacteria
Eukaryotes	Prokaryotes, eubacteria
Cell and cytoplasm	Cell and cytoplasm
Nucleus with multiple chromosomes enclosed in a nuclear membrane	No nucleus or nuclear membrane has single chromosome
Contains endoplasmic reticulum, Golgi apparatus, mitochondria and ribosomes	Other structures absent except ribosomes
Cytoplasmic membrane	Cytoplasmic membrane
Contains phospholipids and sterols	Contains phospholipids and no sterols
Cell wall	Cell wall
Contains chitins, mannans, +/- cellulose	Contains peptidoglycan, lipids and proteins

Fungal infection

It is important to distinguish harmless colonisation with fungi and significant clinical infection, because only the latter would benefit from antifungal treatment.

More often, fungi are a cause of superficial infections of the skin and mucous membranes.

In some susceptible hosts whose immune system is heavily compromised, deep-seated infections involving organs like lungs and brain can manifest as 'difficult to cure' infections, for example, pulmonary aspergillosis or cryptococcal meningitis.

Antifungal agents

Topical and systemic antifungal agents are available to treat mucocutaneous candidiasis, various forms of tinea (ringworm) and other dermatophytosis, onychomycosis and deep-seated systemic infections (e.g. candidaemia, mucor mycoses, fungal endocarditis, osteomyelitis). Some infective conditions and their treatment are dealt with in the sections that follow. The side effects of a range of antifungal agents are set out in [Table 43.3](#).

Table 43.2 Classification of fungi of medical importance

Group	Examples	Infections caused
Yeast	<i>Candida</i> spp. <i>Cryptococcus neoformans</i> <i>Saccharomyces cerevisiae</i> <i>Malassezia furfur</i>	Oral and vaginal thrush Deep seated: candidaemia, empyema Meningitis Rare systemic infection in immunocompromised host
Yeastlike	<i>Geotrichum candidum</i> <i>Trichosporon beigeli</i>	
Dimorphic fungi	<i>Blastomyces dermatitidis</i> <i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i> <i>Paracoccidioides brasiliensis</i> <i>Sporothrix schenckii</i>	For first three: deep systemic organ involvement, more commonly in the immunocompromised host Deep subcutaneous infection following trauma
Moulds		
1. Hyaline a. Zygomycoses	<i>Rhizopus</i> <i>Mucor</i> <i>Absidia</i>	Infections in patients with neutropenia and those with diabetic ketoacidosis
b. Hyalohyphomycosis	<i>Aspergillus fumigatus</i> and other <i>Aspergillus</i> spp. <i>Fusarium</i> <i>Scedosporium apiospermum</i>	Systemic infection: invasive pulmonary or central nervous system involvement Fusarium keratitis Deep infection in immunocompromised host, e.g. transplant patients
2. Dermatophytes	<i>Trichophyton</i> spp. <i>Microsporum</i> spp. <i>Epidermophyton</i>	For all three: various skin (ringworm), hair and nail infections
3. Dematiaceous	<i>Alternaria</i> spp. <i>Cladophialophora</i> spp.	Deep tissue infection with granulomas Chromomycosis, mycetomas

Table 43.3 Side effects of systemic antifungal agents

Drug	Side effects
Griseofulvin	Mild: headache, gastro-intestinal side effects; hypersensitivity reactions such as skin rashes, including photosensitivity Moderate: exacerbation of acute intermittent porphyria; rarely, precipitation of systemic lupus erythematosus Contraindicated in acute porphyria, systemic lupus erythematosus, pregnancy and severe liver disease
Terbinafine	Usually mild: nausea, abdominal pain; allergic skin reactions; loss and disturbance of sense of taste Not recommended in patients with liver disease
Amphotericin	Immediate reactions (during infusion) include headache, pyrexia, rigors, nausea, vomiting, hypotension; occasionally, there can be severe thrombophlebitis after the infusion Nephrotoxicity and hypokalaemia Anaemia due to reduced erythropoiesis Cardiac failure (exacerbated by peripheral neuropathy [rare] hypokalaemia due to nephrotoxicity) Immunomodulation (the drug can both enhance and inhibit some immunological functions)
Flucytosine	Mild: gastro-intestinal side effects (nausea, vomiting); occasional skin rashes Moderate: myelosuppression (dose related), hepatotoxicity
Fluconazole	Mild: nausea, vomiting and occasional skin rashes; occasionally, elevated liver enzymes (reversible) Moderate or severe: rarely, hepatotoxicity and severe cutaneous reactions, especially in patients with AIDS
Itraconazole	Mild: nausea and abdominal pain; occasional skin rashes Moderate or severe: rarely, hepatotoxicity
Voriconazole	Similar to fluconazole and itraconazole Mild: reversible visual disturbances occur in about 30% of patients
Caspofungin, anidulafungin	Mild: gastro-intestinal side effects; occasional skin rashes

AIDS, Acquired immune deficiency syndrome.

Superficial infection

Candida infections

Epidemiology

Candida is a normal commensal of the human gastro-intestinal tract and skin. Loss of skin and mucosal integrity or use of broad-spectrum antibiotics which alter normal bacterial flora allow overgrowth of endogenous *Candida*. There are more than 100 species of *Candida*, but only a few are important as common human pathogens.

Thrush is candidal infection of the mucous membrane. It can manifest as oral infection, for example, oral thrush in various patient groups, vulvovaginal thrush in females, balanitis in the uncircumcised man or intertrigo infection in moist skin surfaces in close proximity, for example, groin area. Patients with diabetes and corticosteroid users, whether inhaled or oral, are also prone to infections. Dysphagia due to candidal oesophagitis presents in patients with acquired immune deficiency syndrome (AIDS) and cancer.

Clinical presentation

Oral thrush typically presents as a sore mouth with white curd-like patches on the tongue or oral mucosa which can bleed on scraping. Females with vaginal thrush present with itching and a creamy vaginal discharge. Skin infection in babies can present as pustular body rash or nappy rash in the moist perianal area.

Candida folliculitis may present in unkempt, bearded men. Nail infection with *Candida* (onychomycosis) or subcutaneous tissue involvement under the nail (paronychia) is seen in people whose occupation involves prolonged hand immersion in water.

In severe oesophageal candidiasis, ulceration or formation of pseudomembranes and, rarely, perforation of the lower third of the oesophagus may occur.

Candida can be a cause of hospital-acquired infection in patients, because it is found in the hospital environment on inanimate objects or on skin of healthcare workers.

Treatment

Oral and vaginal candidiasis may be treated by either topical or systemic antifungal agents. The drugs currently available for topical use fall into two groups: the polyenes, of which only amphotericin and nystatin are used clinically; and the imidazoles, such as econazole, clotrimazole, miconazole and fenticonazole. These agents are essentially identical in their antifungal activity, and the only reasons to choose between them are price and differing preparations. The two first-line systemic agents are both triazoles (fluconazole and itraconazole) and can be given by mouth. Voriconazole, a triazole, should be considered as second-line treatment if the *Candida* is resistant to first-line triazoles. Skin infections may also be treated topically, but nail infections are unlikely to respond to

a topical antifungal agent alone and require systemic treatment. Oesophagitis will invariably require systemic treatment.

Topical treatment. The polyenes are broad-spectrum antifungal agents that are virtually insoluble in water and which are not absorbed from the gastro-intestinal tract or from skin or mucous membranes. Both nystatin and amphotericin (but particularly nystatin) are available in a wide range of formulations including pessaries, creams, gels, tablets, pastilles, etc. The choice of formulation clearly depends on the site of infection and patient preference.

Systemic treatment. Three triazole agents – fluconazole, itraconazole and voriconazole – are available for systemic treatment of oral and vulvovaginal candidiasis. A good source of advice on treatment is that from the Infectious Diseases Society of America (Pappas et al., 2009)

Vulvovaginal candidiasis.

- Several topical antifungal agents provide effective therapy; no agent is clearly superior.
- A single 150 mg dose of fluconazole is recommended for the treatment of uncomplicated cases.
- Complicated vulvovaginal candidiasis requires topical therapy for 7 days or multiple doses of fluconazole (150 mg every 72 hours for 3 doses). Recurrent infections with non-albicans *Candida*, for example, *C. glabrata*, may be more difficult to treat.

Candida balanitis.

- *Candida* balanitis can be treated with topical polyenes or imidazoles, or with systemic fluconazole at the same dose as for vaginal infection (e.g. fluconazole 150 mg for 1 dose).

It is sometimes stated that when treating a woman with vaginal candidiasis, the male partner should be treated simultaneously to prevent reinfection. Although there is no evidence to support this approach, it may be considered in women who suffer from repeated vaginal candidiasis.

Guidance on the treatment of topical and systemic therapy (Pappas et al., 2009) is also available for treatment of mild, moderate and severe oropharyngeal and oesophageal candidiasis and suppressive therapy for patients with human immunodeficiency virus (HIV) infection.

Dermatophytosis

Epidemiology

Dermatophytosis, or tinea, is a condition caused by three genera of dermatophyte fungi: *Trichophyton*, *Epidermophyton* and *Microsporum*. Unlike *Candida*, these are moulds which have a predilection for keratinised tissue such as skin, nail and hair. These fungi are very widely distributed throughout the world and may be acquired from the soil (anthrophilic, e.g. *Trichophyton rubrum*), from animals (zoophilic) or from humans (geophilic) infected with the fungus.

Some species are prevalent throughout the world, for example, *Microsporum canis*, whereas some are area specific, for example, *Trichophyton mentagrophytes* in Europe and New Zealand.

Clinical presentation

The classical clinical presentation of dermatophyte infection of the skin is ringworm (tinea), a circular, inflamed lesion with a raised

edge and associated skin scaling. However, presentation is influenced by the site of infection, for example, tinea pedis (athlete's foot) between the toes or tinea cruris on the body, and by the actual species of fungus causing the infection. In general, less severe lesions are produced by human fungal strains, whereas those acquired from animals can produce quite intense inflammatory reactions.

Dermatophytosis of the nail results in thickened, discoloured nails, whereas in the scalp, infection presents with itching, skin scaling and inflammation, and patchy hair loss (alopecia).

Rarely, deep dermatophytosis may be seen in immunocompromised patients with involvement of subcutaneous tissue (granuloma).

Diagnosis

The diagnosis of dermatophyte infection is confirmed by collecting appropriate specimens such as material from infected nails and skin. The fungi can be seen microscopically and specimens may also be cultured, but antifungal susceptibility testing is not required.

Treatment

Small or medium areas of skin infection can be treated with topical therapy, but nail, hair and widespread skin infection should be systemically treated with oral antifungal agents.

The most commonly used topical agents are the imidazoles, of which a wide variety is available, including clotrimazole, econazole, miconazole and tioconazole. There is little to choose between these agents, all of which are usually applied two or three times daily, continuing for up to 2 weeks after the lesions have healed. Side effects are uncommon and usually consist of mild skin irritation. Other topical agents include amorolfine, terbinafine and tolnaftate.

The main oral antifungals used for dermatophytosis are terbinafine, itraconazole and fluconazole. Griseofulvin is an alternative treatment for tinea capitis.

Terbinafine. Terbinafine was the first member of a new class of antifungal agents, the allylamines, which became available for systemic use. These agents act by inhibition of the fungal enzyme squalene epoxidase, an enzyme involved in the synthesis of ergosterol, an essential component of the fungal cytoplasmic membrane. Although terbinafine has a very broad antifungal spectrum in the laboratory, its in vivo efficacy does not correspond to its in vitro activity, and it is used only for the treatment of dermatophyte infection.

About 70% of an oral dose of terbinafine is absorbed, and the drug appears in high concentrations in the skin. The half-life is about 16–17 hours; therefore, the drug can be given once per day. Terbinafine is metabolised in the liver and the metabolites are excreted in the urine so that hepatic or renal dysfunction will prolong the elimination half-life.

Terbinafine is the treatment of choice for tinea infections at 250 mg/day for 2–6 weeks, depending upon the infection. However, for nail infections a longer course of terbinafine is required (e.g. fingernails infections may be for ≥ 6 weeks at 250 mg/day and for toenail infections it may need to be continued for 12 weeks).

Itraconazole is the second preferred agent at 200 mg twice a day for 1 week and longer with repeated courses for finger and toenail involvement.

Griseofulvin. The first orally administered treatment for dermatophytosis was griseofulvin, which has been available since the late 1950s. Griseofulvin is active only against dermatophyte fungi, and it is inactive against all other fungi and bacteria. To exert its antifungal effect, it must be incorporated into keratinous tissue, where levels are much greater than serum levels; therefore, it has no effect if used topically.

Griseofulvin is well absorbed and absorption is enhanced if taken with a high-fat meal. In children, it may be given with milk. A 1000 mg dose produces a peak serum level of about 1–2 mg/L after 4 hours, with a half-life of at least 9 hours. An ultra-fine preparation of griseofulvin exists which is almost totally absorbed and permits the use of lower dosages (typically 330–660 mg daily). This preparation is not available in the UK. Elimination is mainly through the liver, and inactive metabolites are excreted in the urine. Less than 1% of a dose is excreted in urine in the active form, but some active drug is excreted in the faeces.

The usual adult dosage is 500 mg daily or 1 g for severe infections. The duration of treatment will depend upon the infection; it may require 6 weeks for treatment of larger lesions in tinea corporis.

The duration of treatment with griseofulvin is dependent entirely on clinical response. Skin or hair infection usually requires 4–12 weeks of therapy, but nail infections respond much more slowly; 6 months of treatment is often required for fingernails and a year or longer for toenail infections. Unfortunately, the rate of treatment failure or relapse in nail infection is high and may reach up to 60%; hence terbinafine and itraconazole may be preferred agents.

Pityriasis versicolor

Pityriasis versicolor is a common superficial skin infection caused by a yeastlike fungus, *Malassezia furfur*. The organism is a member of the normal skin flora and lives only on the skin because it has a growth requirement for medium-chain fatty acids present in sebum.

Clinical presentation

Pityriasis versicolor usually appears as patches scattered over the trunk, neck and shoulders. These patches produce scales and may be pigmented in light-skinned individuals, appearing light brown in colour. In dark-skinned patients, the lesions may lose pigment and appear lighter than normal skin.

In some patients, *Malassezia* yeast is also associated with dandruff and seborrhoeic dermatitis, although the exact role of the yeast in causing this condition remains uncertain. In patients with AIDS, seborrhoeic dermatitis may be quite extensive and sudden in onset. *Malassezia* folliculitis can appear as greasy papules or pustules on the trunk or face of an HIV-infected individual.

Diagnosis

The diagnosis of pityriasis versicolor is made by microscopy of scrapings from the lesion. The specimen is examined for the presence of yeast cells and short hyphae. Culture is not usually required for diagnosis and, because it requires special culture media, is not routinely attempted.

Treatment

Pityriasis versicolor is treated with topical terbinafine cream or a topical imidazole cream such as clotrimazole, econazole or miconazole. Cheaper topical alternatives are 2% selenium sulphide lotion or 20% sodium thiosulphate applied daily for 10–14 days. Relapses are common, and treatment may need to be repeated. In severe cases, oral itraconazole (200 mg once daily for 7 days) may be given. Treatment of seborrhoeic dermatitis and folliculitis is undertaken with topical azole creams and 1% hydrocortisone. This condition can also often relapse.

Ear infection

Fungi sometimes infect the external auditory canal, causing otitis externa, with the most common causative organisms being various species of *Aspergillus* (such as *A. niger* and *A. fumigatus*) and *C. albicans* and other *Candida* species. A variety of other fungi found in the environment can also cause this condition. The use of topical antibacterial agents in the ear may predispose to local fungal infection.

Clinical presentation

Fungal infection of the ear usually presents as pain and itching in the auditory canal, sometimes with a reduction in hearing caused by blockage of the canal. There may be an associated discharge from the ear. Clinical examination shows a swollen red canal, and the fungal mycelium is sometimes visible as an amorphous white or grey mass.

Diagnosis

The diagnosis of a fungal infection of the external canal can be made by microscopy and culture of material obtained from the ear.

Treatment

Aural toilet with removal of obstructing debris is very important in the management of fungal infections of the external auditory canal. A topical antifungal agent such as nystatin or amphotericin, or an imidazole can also be applied.

Infections with saprophytic fungi

Most mouldy fungi are saprophytes; they obtain their nutrition from dead organic matter. Some saprophytic fungi can cause significant human infections. An example of such an infection in a host with a normal immune system is fusarium keratitis in contact lens wearers. *Penicillium marneffeii* can cause skin infection and disseminated fatal infection in HIV-infected patients in South East Asia. *Scedosporium* pulmonary infections are seen in lung transplant recipients. A large trial of retrospective data from the USA revealed that the three most common non-*Aspergillus* saprophytic moulds that cause invasive fungal infection among patients receiving haemopoietic stem cell transplants (HSCT) were *Fusarium*, *Scedosporium* and *Zygomycetes* (Marr et al., 2002).

Table 43.4 Conditions predisposing to systemic or deep-seated fungal infection

Infection	Predisposing conditions
Systemic candidiasis	Neutropenia from any cause (disease or treatment) Use of broad-spectrum antibiotics which eliminate the normal body flora Indwelling intravenous cannulae, especially when used for total parenteral nutrition Haematological malignancy and hematopoietic stem cell transplantation Solid organ transplantation AIDS (particularly associated with severe mucocutaneous infection) Intravenous drug abuse Cardiac surgery and heart valve replacement, leading to <i>Candida</i> endocarditis Gastro-intestinal tract surgery Oesophagectomy leak leading to pleural space infection (empyema)
Aspergillosis	Neutropenia from any cause, especially if severe and prolonged Acute leukaemia Solid organ transplantation (mainly lungs) Chronic granulomatous disease of childhood (defect in neutrophil function) Pre-existing lung disease (usually leads to aspergillomas; fungus balls form in the lung rather than invasive or disseminated infection)
Cryptococcosis	AIDS Systemic therapy with corticosteroids Renal transplantation Hodgkin's disease and other lymphomas Sarcoidosis Collagen vascular diseases
Zygomycosis	Diabetic hyperglycaemic ketoacidosis (leading to rhinocerebral infection) Severe, prolonged neutropenia Burns (leading to cutaneous infection)

AIDS, Acquired immune deficiency syndrome.

Deep-seated fungal infections

Most deep-seated or systemic fungal infections seen in the UK are the result of some breakdown in the normal body defences, which may be due to disease or medical treatment. Fungi that cause superficial infections can also cause deep-seated infection in immunocompromised patients with leukaemia and lymphoma, and those in the post-transplant period of immunosuppression. There are, however, a group of fungi, often referred to rather misleadingly as the pathogenic fungi, which are able to cause systemic infection in a previously healthy person. These infections, which are usually due to dimorphic fungi, include diseases such as histoplasmosis, blastomycosis and coccidioidomycosis. They are rare in the UK but rather more common in the USA and other parts of the world.

Fungal infections in the compromised host

Common mycoses

Epidemiology and predisposing factors

A large number of conditions may predispose the individual to systemic or deep-seated fungal infection. These are

summarised in [Table 43.4](#). A breach in the body's mechanical barriers may predispose to fungal infection. For example, fungal infection of the urinary tract occurs most commonly in catheterised patients who have received broad-spectrum antibiotics, whereas total parenteral nutrition (TPN) is strongly associated with fungaemia, sometimes with unusual fungi such as *Malassezia furfur*. This is due to the use of TPN infusions containing lipids, which are a growth requirement of this organism. Most cases of systemic fungal infection, however, are associated with a defect in the patient's immune system, and the nature of the organisms encountered is often related to the nature of the immunosuppression. Neutropenia, for example, is usually associated with *Candida* species, *Aspergillus* and mucormycosis, whereas defects of cell-mediated immunity, for example, HIV infection, are strongly associated with infection by *Cryptococcus neoformans*. Prolonged diabetic ketoacidosis is a risk factor for development of rhinocerebral zygomycosis, where mortality rates can be as high as 100% if there is significant underlying disease.

Many different fungi have been described as causing systemic fungal infection, but the most common organisms encountered and the conditions they cause are listed in [Table 43.5](#). Of these, *Candida* and *Aspergillus* are by far the most common in the UK.

Table 43.5 Common causes of systemic and deep-seated fungal infection in the UK

Condition/organism	Common clinical presentations
Candidiasis (<i>Candida albicans</i> , <i>C. glabrata</i> , <i>C. krusei</i> , <i>C. tropicalis</i> other <i>Candida</i> species)	Fungaemia Colonisation of intravenous cannulae Pneumonia Meningitis Bone and joint infections Endocarditis Endophthalmitis Peritonitis in chronic ambulatory peritoneal dialysis
Aspergillosis (<i>Aspergillus fumigatus</i> , <i>A. flavus</i> , other <i>Aspergillus</i> species)	Invasive pulmonary aspergillosis Disseminated aspergillosis Aspergilloma Endocarditis
Cryptococcosis (<i>Cryptococcus neoformans</i>)	Meningitis Pneumonia Cutaneous infection
Zygomycosis (various species of the genera <i>Rhizopus</i> , <i>Mucor</i> , <i>Absidia</i>)	Rhinocerebral infection Pulmonary mucormycosis Surgical wound and burns infection
<i>Malassezia furfur</i>	Cutaneous infection (especially in burn patients) Fungaemia associated with total parenteral nutrition

Clinical presentation

Symptoms can be non-specific, such as low-grade fever, night sweats, weight loss, cough, chest pain and septic shock in extreme cases (Table 43.6).

Diagnosis

Organ-specific radiological findings backed by laboratory tests, as discussed earlier in this chapter, are the mainstay of diagnosis.

Treatment

Compared with the vast array of antibacterial agents available to treat bacterial infections, very few systemic antifungal agents are available and these comprise four major categories: the polyenes (conventional and lipid formulations of amphotericin B), the triazoles (fluconazole, itraconazole, voriconazole and posaconazole), the echinocandins (caspofungin, anidulafungin and micafungin) and flucytosine. To provide optimal therapy to the patient, it is necessary to understand the profile, properties and toxicity of these agents. Table 43.7 details the antifungal spectrum of activity against common fungi.

Antifungal prophylaxis is commonly used to prevent invasive fungal infections in the 'at-risk' group of patients.

Polyenes

Amphotericin B. Amphotericin, a member of the polyene group, is obtained from various species of *Streptomyces*. Chemically, it is a large carbon ring of 37 carbon atoms closed by a lactone bond. One side of the molecule contains seven

Table 43.6 Clinical presentation of systemic fungal infection

Condition	Clinical presentation
Fungaemia (the presence of fungi in the bloodstream), usually due to <i>Candida</i> species	Fever, low blood pressure and sometimes other features of septic shock, especially in patients with neutropenia Relatively low-grade fungaemias such as those associated with colonised intravenous cannulae often present only with fever Disseminated infection to multiple organ systems is quite common with <i>Candida</i> species, leading to central nervous system disease, endocarditis, endophthalmitis, skin infections, renal disease, and bone and joint infection
Pneumonia, most frequently due to <i>Aspergillus</i> species	Fever, chest pain and cough which may be non-productive; may progress rapidly, especially with <i>Aspergillus</i> infection, to severe respiratory distress, necrosis of the lung and pulmonary haemorrhage Formation of fungal balls in pre-existing lung cavities with or without invasion
Meningitis and other central nervous system infection	<i>Candida</i> infection may present as a typical meningitis, although it is often more insidious Aspergillosis is associated with headache, confusion and focal neurological signs due to the presence of brain infarcts Cryptococcosis most frequently presents as a chronic, insidious meningitis with headache and alteration in mental state
Mucormycosis	Angioinvasive; the most common presentation of mucormycosis is rhinocerebral infection Initially an infection of the sinuses, it then spreads locally to the palate, orbit and eventually into the brain, leading to encephalitis Pulmonary disease can present as fungal balls radiologically with symptoms of haemoptysis

Table 43.7 Antifungal spectrum of activity against common fungi

Plus signs (+) indicate that the antifungal agent has activity against the organism specified. Minus signs (–) indicate that the antifungal agent does not have activity against the organism specified. Plus/minus signs (±) indicate the agent has variable activity against the organism specified.

^aIncludes lipid formulations.

^bIn vitro data show that the echinocandins (specifically, micafungin) may have variable activity against the dimorphic fungi, depending on whether they are in the mycelial or yeastlike form.

AmB, Amphotericin B; Flu, fluconazole; Itr, itraconazole; Pos, posaconazole; Vor, voriconazole.

Adapted from [Dodds Ashley et al. \(2006\)](#).

carbon-to-carbon double bonds (polyene), and the other side contains seven hydroxyl groups. It dissolves in organic polar solvents but forms a colloidal suspension of micelles in water which is rendered stable by the addition of the surfactant sodium deoxycholate.

Amphotericin B binds to the ergosterol in fungal cytoplasmic membrane affecting its integrity by forming pores and, therefore, cell death. Nystatin, the other polyene, is only used topically because of toxicity associated with its systemic use.

Amphotericin is active against a vast majority of fungi, and this is the same for all formulations. Development of resistance is uncommon, although primary resistance has been identified for

Aspergillus terreus, *Scedosporium* spp., *Trichosporon* spp. and *Candida lusitaniae*.

Pharmacodynamically, the ratio of the peak serum concentration to the MIC is important for its efficacy.

Amphotericin B deoxycholate. Released in 1950, colloidal in nature, amphotericin B deoxycholate is highly protein bound (99%) and insoluble in water. It penetrates poorly into cerebrospinal fluid (CSF). Initial elimination of the drug occurs with a half-life of 24–48 hours, but this is followed by very slow elimination (half-life about 14 days). As a consequence, it may take 10 weeks for the drug to disappear from the circulation.

Amphotericin B deoxycholate is given by slow intravenous (IV) infusion (manufacturer recommends between 2 and 6 hours) in 5% dextrose with a dose range of 0.25–1 mg/kg increased to 1.5 mg/kg for serious invasive infections. The duration of treatment can vary from 1 to 2 weeks to longer, depending on the severity of the infection and the organ system involved.

The most serious side effect of amphotericin is nephrotoxicity. Renal failure should be monitored regularly at least every other day, and if the serum creatinine exceeds 250 mmol/L, the drug should be discontinued until the creatinine level is below this limit. Hypokalaemia is also a problem and may be severe, necessitating replacement therapy.

Azotaemia may be seen in patients after the first few infusions of amphotericin B deoxycholate. Chills, fever and tachypnoea may occur but can be avoided by prescribing hydrocortisone 25–50 mg.

The manufacturer recommends that before commencing treatment, a 1 mg test dose should be given in 50 mL of 5% dextrose over a 20- to 30-minute period and the patient monitored for fever, rigors and hypotension. True allergic reactions are rare.

Amphotericin B lipid formulations. The advantage of delivering amphotericin encapsulated in liposomes or as a complex with lipid molecules is that a higher unit dose can be given and there is reduction in toxic effects. Three such preparations are currently available: liposomal amphotericin B (AmBisome), amphotericin B lipid complex (Abelcet) and amphotericin B colloidal dispersion (Amphocil).

Liposomal amphotericin B. In liposomal amphotericin B (AmBisome), the drug is contained in small vesicles, each consisting of a phospholipid bilayer enclosing an aqueous environment. This permits the delivery of higher doses (3 mg/kg once daily is recommended, but doses up to 10 mg/kg have been used in some centres) compared with conventional amphotericin, with very little of the immediate toxicity which is such a problem with the conventional formulation. Higher peak serum concentrations are obtained with the liposomal formulation compared with equivalent doses of the conventional drug, although it is not certain whether this is clinically relevant. Liposomal amphotericin is concentrated mainly in the liver and spleen, where it is taken up by cells of the reticuloendothelial system. Concentrations in the lung and kidneys are much lower, which may or may not be clinically important.

There is reduced nephrotoxicity with this formulation, and some of the renal dysfunction which has been described in clinical trials of liposomal amphotericin may have been due to concomitant drugs. Comparative clinical trials of liposomal amphotericin versus conventional amphotericin B have shown reduced toxicity because of the liposomal preparation (Cagnoni, 2002; Hamill, 2013; Walsh et al., 1999). It is this comparative lack of toxicity which accounts for much of the popularity of this agent, despite its expense. This agent performs as well as the conventional preparation in patients with febrile neutropenia (Cagnoni, 2002).

Amphotericin B lipid complex and amphotericin B colloidal dispersion. Amphotericin B lipid complex (Abelcet) is not a liposomal formulation, but consists of large sheets of amphotericin combined with phospholipids. This formulation gives lower peak serum levels compared with the conventional drug because it is rapidly taken up by tissue macrophages, whereas concentrations in the lungs and the liver are much higher. Patients seem

to experience more immediate side effects than with liposomal amphotericin. There is less clinical trial evidence for the use of this agent compared with the liposomal preparation. Amphotericin B colloidal dispersion (Amphocil) is a formulation consisting of tiny discs of amphotericin and cholesteryl sulphate. Like the lipid complex, it too produces low peak serum levels but high liver concentrations compared with the conventional drug. There is less clinical experience with this preparation than with the liposomal preparation, and it appears to have a higher incidence of certain adverse reactions than conventional amphotericin.

Choosing a lipid preparation. At present, the greatest clinical experience is with liposomal amphotericin B, and by reason of this and the reduced incidence of side effects it is the preferred agent of the three in many UK centres. Ideally all patients who require amphotericin would receive the conventional preparation initially, being changed to a lipid formulation only if they do not respond to or cannot tolerate the side effects of the conventional form. However, the incidence of side effects and the difficulty in administration of conventional amphotericin have in practice led to its replacement in most centres with a lipid formulation.

Other Antifungal Agent

Flucytosine. Amphotericin B and griseofulvin were the only systemic antifungal agents available until the early 1970s, when flucytosine became available for patient use.

Flucytosine (5-fluorocytosine) is a synthetic fluorinated nucleotide analogue. The mode of action is twofold. Following uptake by the cell, which is dependent on the presence of cytosine permease, flucytosine is deaminated to 5-fluorouracil by cytosine deaminase. This in turn is incorporated into fungal RNA in place of uracil, leading to impairment of protein synthesis. Further metabolism of 5-fluorouracil leads to a metabolite that inhibits the enzyme thymidylate synthetase, leading to inhibition of DNA synthesis. Mammalian cells have absent or weak cytosine deaminase activity which accounts for the selective toxicity of flucytosine.

For all practical purposes, flucytosine is only active against yeasts and yeastlike fungi. Inherent resistance occurs in approximately 10% of clinical isolates of *Candida* species, and acquired resistance develops rapidly if the drug is used alone. There are several resistance mechanisms, some of which result from a single-step mutation giving a high frequency of acquired resistance in organisms exposed to the drug. For this reason, flucytosine should always be given in combination with another agent such as amphotericin, with which it is synergistic.

Flucytosine is highly soluble in water, and more than 90% of an oral dose is absorbed from the gastro-intestinal tract. Virtually all of the absorbed dose is excreted unchanged in the urine by glomerular filtration. The elimination half-life is about 4 hours, but this is greatly prolonged in renal failure, and dosage modification is required in patients with renal dysfunction. The degree of protein binding is very low and flucytosine penetrates well into all tissues, including the aqueous humour of the eye, where about 10% of the serum level is achieved, and the cerebral spinal fluid, where about 80% of the serum level is achieved.

Flucytosine is given orally or by short IV infusion. The dosage administered by either route in patients with normal renal function is 100–200 mg/kg per day in four divided doses. This must be reduced in renal failure, but the degree of reduction depends

on the degree of renal impairment, and it is obligatory to monitor the serum levels of flucytosine. Unfortunately, because the flucytosine assay is now rarely carried out routinely in UK laboratories, the sample is sent to a specialist laboratory. Monitoring is usually only carried out if there is a concern about the patient's renal function. Flucytosine is usually given in conjunction with amphotericin, which will probably cause some degree of renal dysfunction, therefore requiring modification of the flucytosine dose. Blood levels should be taken as per local guidelines to avoid dose-related marrow toxicity.

Some of the side effects of flucytosine are given in Table 43.3. The most important toxic effect is a dose-related myelosuppression with neutropenia and thrombocytopenia. This is usually reversible and can be avoided by monitoring serum levels of flucytosine and adjusting the dose accordingly. Hepatotoxicity is also probably a result of high serum levels, and liver function tests should be performed regularly. The drug is teratogenic in

some animals and is not recommended in pregnant women for relatively trivial infections such as a fungal urinary tract infection. In cases of a life-threatening fungal infection, which is rare in pregnancy, the potential benefits of flucytosine must be weighed against the possible risks.

Azoles

Systemic azoles: Triazoles. Four triazoles are licensed in the UK: fluconazole, itraconazole, voriconazole and posaconazole. They differ substantially from one another in their pharmacokinetic and antifungal activity (Table 43.8). Their main side effects are listed in Table 43.3.

The basic chemical structure of the triazoles is the azole ring, a five-membered ring containing three nitrogen atoms. Their principal mode of action involves one of the nitrogen atoms of the azole ring binding to fungal cytochrome P450 enzymes. This inhibits the demethylation of lanosterol and leads to a reduced concentration of ergosterol necessary for a normal fungal cytoplasmic membrane.

Adapted from Dodds Ashley et al. (2006).

The propensity, in humans, to also inhibit the metabolism of drugs by cytochrome P450 results in a considerable number of drug interactions.

Fluconazole. Fluconazole is available both orally and parenterally and is used only in the treatment and prophylaxis of infections due to yeasts and yeastlike fungi. It is not used for the treatment of infections caused by moulds. It is highly effective in the treatment of *Cryptococcus* infection, but the first-line treatment of cryptococcosis of the central nervous system (CNS) is the combination of amphotericin B plus flucytosine for CNS infection caused by this organism. This may be followed by fluconazole, which in HIV-infected patients will be required lifelong as suppressive treatment to prevent relapse. In immunocompetent hosts, fluconazole may be used as the primary treatment for disease not involving the CNS, such as pulmonary infection.

In patients with candidaemia due to colonised IV cannulae, the most important treatment is removal of the infected cannula, but it is common practice to give a short course of fluconazole (until *Candida* speciation and susceptibility results are available) to prevent disseminated infection elsewhere. Although not proven in randomised clinical trials, changing potentially infected central-line catheters in patients with candidaemia is probably the most important part of therapy.

In non-neutropenic patients, studies have shown fluconazole and caspofungin to be as efficacious as and less toxic than conventional amphotericin B. In such patients, where the infecting organism and its susceptibility to fluconazole are known, it would be reasonable to commence treatment with fluconazole; caspofungin is a potential alternative. In patients with neutropenia and in patients infected with fluconazole-resistant organisms, amphotericin continues to be the treatment of choice. Fluconazole has also been successfully used as prophylaxis against *Candida* infections in patients with neutropenia and patients with AIDS, but this in turn has been associated with an increasing incidence of systemic infections with fluconazole-resistant strains.

Some units that use fluconazole extensively have noted an increase in the isolation of yeasts resistant to the drug, with the prevalence of resistance related to the extent of use of fluconazole. Resistance in *Candida* species is mainly seen in patients who are given long-term prophylactic fluconazole. This selects out those *Candida* species such as *C. krusei* and *C. glabrata* that are inherently less susceptible to fluconazole. Resistance in *C. albicans*, the most common species infecting humans, is seen mainly in patients with AIDS, partly because of the extensive use of fluconazole in treating severe oral and pharyngeal candidiasis in such patients and partly because of the very large numbers of yeasts in the oropharynx of patients with AIDS with candidiasis, which increases the chance of resistance due to spontaneous mutation.

Depending on the type of deep infection and the organ involved, fluconazole is used between the range of 200 and 800 mg/day. It is available for oral and IV use. Oral fluconazole has very good bioavailability (nearly 90%) and with a long half-life of about 34 hours, it is given once a day. It has good penetration in most tissues and all body fluids including the CSF. Because there is good correlation between clinical outcome and fluconazole's

pharmacokinetic/pharmacodynamics parameters, therapeutic drug monitoring is not required. Fluconazole is a substrate for inhibition of CYP450 isoenzymes, including CYP3A4, CYP2C9, and CYP2C19; therefore, medications should be reviewed for potential drug interactions. Amongst antibiotics, rifampicin is the single CYP450 inducer that has been shown to markedly reduce fluconazole serum concentrations.

Itraconazole. Itraconazole is available for both oral and IV use (IV formulation may not always be available). The drug is available as capsules and as a liquid; however, the liquid formulation gives better absorption and pharmacokinetic profile than the capsule preparation, leading to significantly greater bioavailability and higher serum levels. Systemic bioavailability of itraconazole oral solution is around 55% optimised under fasting conditions. Itraconazole is extensively metabolised by the liver, predominantly by the CYP 3A4 isoenzyme system, and is known to undergo enterohepatic circulation. This is a broad-spectrum antifungal which is effective against yeasts, dermatophytes, the 'pathogenic' fungi and some filamentous fungi, such as *Aspergillus*.

In deep-seated infection, itraconazole is used to treat infections caused by the 'pathogenic' fungi, but there is less published evidence of its use in the treatment of systemic candidiasis, and it cannot be recommended for this purpose (Maertens and Boogaerts, 2005). However, although not a first-line agent for systemic candidiasis, it may be useful in patients who are infected with strains resistant to fluconazole, some of which may remain sensitive to itraconazole, and in patients who are for some reason unable to tolerate fluconazole. It has also been used to treat cryptococcosis, despite its poor penetration of CSF, and in that condition it is an alternative to fluconazole for patients who cannot take the latter drug.

There is now considerable evidence to support the use of itraconazole as a prophylactic agent in immunocompromised patients. It has been shown to be effective in reducing the incidence of systemic fungal infection compared with placebo and to be more effective than fluconazole, although this is due to a greater reduction in infections caused by filamentous fungi, including *Aspergillus*.

A loading dose of itraconazole 200 mg three times a day for 3 days is administered to achieve steady-state serum concentration, followed by 200 mg daily or twice a day. Therapeutic drug monitoring is essential to optimise clinical efficacy for prophylaxis or for treatment of invasive fungal infection.

Voriconazole. Voriconazole is available for both oral and IV administration. It has advantages over itraconazole in that its absorption from the gastro-intestinal tract is significantly better and is not affected by reductions in gastric acidity due to disease or concomitant medication. Its spectrum of activity is similar to that of itraconazole, but it is more active against *Fusarium* species, a mould which causes superficial infection of the nails and cornea, and occasionally systemic infection in immunocompromised patients.

Voriconazole given orally is rapidly and almost fully absorbed (oral bioavailability >90%), with a maximum serum concentration being achieved in about 2 hours after administration under fasting conditions. It is extensively distributed into tissue and penetrates well into the CSF and into vitreous and aqueous humour.

It is cleared by hepatic cytochrome P450 metabolism and is involved in many clinically relevant drug–drug interactions. Therapeutic drug monitoring may be indicated in some clinical settings.

The main clinical indication for the use of voriconazole is aspergillosis (Karthaus, 2011). Studies have shown improved efficacy compared with conventional amphotericin B in systemic *Aspergillus* infection. The largest randomised control trial demonstrates that voriconazole is superior to amphotericin B deoxycholate as primary therapy of aspergillosis (Walsh et al., 2008). One particular indication is cerebral aspergillosis. Although rare, this carries a high mortality rate ($\geq 90\%$), and one study has shown this to be reduced by voriconazole, presumably because of its better penetration into the CNS (Schwartz et al., 2005). In addition to aspergillosis, voriconazole is also licensed for the treatment of *Fusarium* infection and for the management of patients infected with strains of *Candida* resistant to fluconazole. It has been shown to be as efficacious as amphotericin B followed by fluconazole in the treatment of candidaemia in patients who were not neutropenic, but it is not licensed for this indication.

For invasive pulmonary aspergillosis, a loading dose of 6 mg/kg IV every 12 hours for 2 doses was given followed by 4 mg/kg every 12 hours and converted to oral therapy 200 mg every 12 hours depending on clinical review to decide duration of treatment.

Voriconazole has a side-effect profile similar to that of other triazoles. Two adverse effects associated with voriconazole are visual disturbance (appearance of bright lights, colour changes or wavy lines) in 45% of patients and cutaneous phototoxicity (rash) in 8% patients. Both side effects are reversible after discontinuation of therapy.

Posaconazole. Posaconazole is the latest triazole to be made available for clinical use. It has activity against a wide range of yeasts (including *Cryptococcus* and many species of *Candida*) and a variety of moulds. Like itraconazole, it is absorbed slowly, is highly protein bound ($>98\%$) and reaches a steady state after a period of 7–10 days. In contrast with voriconazole, optimal absorption is achieved when taken with a high-fat meal. It is available for oral use only in the form of tablets and oral suspension. Posaconazole penetrates very well in most tissues and fluid including CSF and the eye.

In adults it is indicated for treatment of invasive aspergillosis and fusariosis refractory to amphotericin, chromoblastomycosis and mycetoma refractory to itraconazole, and for prophylaxis of invasive fungal infections in patients with HSCT with graft-versus-host disease and haematological malignancies with prolonged neutropenia.

Posaconazole oral suspension is used 200 mg four times daily or 400 mg twice daily, and tablets are used 300 mg twice daily on first day followed by 300 mg daily.

Echinocandins. The echinocandin group of antifungal agents acts by inhibiting synthesis of fungal cell wall glucan.

Caspofungin. Caspofungin was the first of the echinocandins to become available for routine use; others, such as micafungin and anidulafungin, are now available. These agents interfere with the production of the fungal cell wall by inhibiting the synthesis of an important component, 1,3- β -D-glucan. This is a

target which does not exist in mammalian cells, providing selective toxicity against fungi. Caspofungin has a significant advantage over the triazoles in that it does not inhibit the cytochrome P450 system and, therefore, is not associated with such a wide range of drug interactions.

The drug has a rather unusual spectrum of activity. It is active against most species of *Candida*, although some are less susceptible than others, but *Cryptococcus* is resistant. The commonly encountered species of *Aspergillus* are susceptible, but the drug is inactive against the dermatophytes, and activity against other fungi is variable.

Caspofungin is available only for administration via the IV route and does not penetrate into the CSF. Due to its spectrum of activity, caspofungin is indicated only for empirical treatment (in patients with neutropenia) and targeted treatment of candidiasis and aspergillosis. A comparative study showed caspofungin to be as efficacious as conventional amphotericin B in invasive candidiasis (Mora-Duarte et al., 2002). It has been shown to be effective in patients with aspergillosis who did not respond to or could not tolerate other antifungal agents. Finally, caspofungin was also shown to be as effective as liposomal amphotericin B in the empirical treatment of fungal infection in patients with neutropenia, and it had a lower incidence of unwanted effects (Walsh et al., 2004). The dosage for adults is 70 mg on the first day, then 50 mg once daily (70 mg once daily if body weight is more than 80 kg).

Anidulafungin. Anidulafungin is only available for administration via the IV route and is used in the treatment of invasive candidiasis in adult non-neutropenic patients (Reboli et al., 2007). Like caspofungin, it does not penetrate into the CSF. It is given as a single 200 mg loading dose by IV infusion on day 1, followed by 100 mg daily thereafter. No dose adjustment is required for renal or hepatic impairment.

Micafungin. Micafungin is very similar to caspofungin and anidulafungin. It is used for treatment of candidaemia, invasive candidiasis in adults and children if other antifungals are not appropriate. It is also used for treatment of oesophageal candidiasis if IV therapy is required and for prophylaxis of *Candida* infections in immunocompromised patients following HSCT. It is used between 1 and 3 mg/kg per day in patients ≤ 40 kg body weight and between 50 and 100 mg/day in greater than 40 kg body weight. No dose adjustment is necessary for renal or mild-to-moderate hepatic failure.

Choice of treatment

A recent development has been the use of combinations of antifungal agents to improve on the results of single agents. Currently, there is little firm evidence to support the use of such combinations. Amphotericin B plus flucytosine in the treatment of cryptococcosis is the only combination where evidence exists of increased efficacy over either agent alone. However, faced with a seriously ill patient who is not responding to single agents, it is not surprising that many clinicians attempt the use of a combination of antifungals, even though the evidence is that the results are no better than monotherapy.

Practice points regarding the drug toxicity in systemic antifungal agents are detailed in Table 43.9.

Table 43.9 Practice points

Drug toxicity in systemic antifungal agents	
Infusion-related side effects	<ul style="list-style-type: none"> • Particularly with conventional amphotericin B • Lipid-based preparations also show these, but to a lesser extent
Nephrotoxicity	<ul style="list-style-type: none"> • Particularly with conventional amphotericin B • Results in renal dysfunction • Cessation of treatment may be required • Drug-level monitoring is not helpful in prevention • Potassium loss and hypokalaemia are a serious complication • Renal toxicity may be potentiated by concomitant nephrotoxic agents
Hepatotoxicity	<ul style="list-style-type: none"> • Associated with the azole antifungals • Was particularly severe with ketoconazole • The newer triazoles may also cause serious liver damage
Bone marrow suppression	<ul style="list-style-type: none"> • Associated with flucytosine • Dose-related problem, so drug-level monitoring may help prevent it • Tends to preclude the use of flucytosine in patients whose marrow is already damaged (e.g. in haematological malignancy or following bone marrow transplant)
Drug interactions	<ul style="list-style-type: none"> • Associated particularly with the azoles • Due to their mode of action in inhibiting the cytochrome P450 system • A wide range of drugs may be affected, some with serious interactions
Difficulties in drug administration	
Drug precipitation	<ul style="list-style-type: none"> • Amphotericin B will precipitate out if given in electrolyte-containing infusions • This may also happen in 5% dextrose due to acidity resulting from the manufacturing process
Need for a test dose	<ul style="list-style-type: none"> • Required for all amphotericin B preparations
Long infusion times and/or large infusion volumes	<ul style="list-style-type: none"> • A particular problem with conventional amphotericin • Long infusion times mean reduced access to intravenous cannulae for other purposes • Large infusion volumes may be undesirable in patients with renal or cardiac dysfunction
Variable absorption when taken by mouth	<ul style="list-style-type: none"> • A known problem with itraconazole • Absorption is reduced in the presence of raised gastric pH (e.g. following the use of antacids or drugs such as omeprazole) • Absorption is increased in the presence of food or if taken with a cola drink • Subtherapeutic levels may occur because of poor absorption • Therapeutic drug monitoring is recommended to avoid low levels
Resistance to antifungal agents	
Amphotericin B	<ul style="list-style-type: none"> • Usually seen as a very broad-spectrum antifungal, but inherent resistance is seen in several clinically significant species: <i>Aspergillus terreus</i> <i>Candida lusitanae</i> <i>Scedosporium apiospermum</i> • Acquired resistance developing during treatment is very uncommon • Lipid preparations have identical in vitro antifungal activity to the conventional form

Table 43.9 Practice points—cont'd

Flucytosine	<ul style="list-style-type: none"> • Acquired resistance during treatment is very common in <i>Candida</i> species • Monotherapy promotes the rapid development of resistance • Combination therapy with amphotericin will reduce the possibility of acquired resistance developing during treatment
Fluconazole	<ul style="list-style-type: none"> • Some species of <i>Candida</i> are inherently resistant or less susceptible to fluconazole: <i>C. krusei</i> <i>C. glabrata</i> • Long-term use of fluconazole may result in increased infections with these more resistant strains • Long-term use may also result in reduced susceptibility in strains of <i>C. albicans</i>

Case studies

Case 43.1

Ms TH, a 66-year-old woman with carcinoma of the oesophagus, undergoes sub-total oesophagectomy. She spends the early post-operative period on surgical intensive therapy unit (ITU) and is sent to the surgical ward for further management. On day 6 post-operation, she begins to show signs of sepsis, for which antibiotics are commenced. However, 48 hours later she has difficulty in breathing, takes a turn for the worse and is transferred to ITU. Chest imaging revealed a leak from the oesophagectomy site and fluid collection in the pleural space. Gram stain of aspirated pleu-

ral fluid reveals budding yeast cells, and mucopurulent sputum culture grows *Candida albicans*.

Question

How should Ms TH's infection be managed?

Answer

The immediate management of this patient would involve drainage of pleural fluid through an intercostal drain and commencement of systemic antifungal therapy. The source is very likely to be oral thrush. Fluconazole at 800 mg once a day, normally for 14–21 days, should be commenced awaiting antifungal sensitivity result. Urgent patient review is indicated to discuss surgical intervention to close the leak. Re-collection of yeasts in inadequately treated spaces can be a problem. It may be useful to consider the addition of a second antifungal agent to fluconazole.

Case 43.2

Mrs DM, a 38-year-old woman with diabetes, sustained severe trauma to the right leg requiring total knee replacement and insertion of metal rod into the right femur. She had an uneventful post-operative course. Four months later, she had to undergo washout and debridement of her prosthetic joint, thigh tissues and removal of the metal rod. Ten deep specimens grew *Candida tropicalis*.

Question

How should Mrs DM's infection be managed?

Answer

Fungal infections of prosthesis and deep subcutaneous tissues are difficult to treat. Mrs DM will need a two- or three-stage procedure. The prosthetic joint will need removal, and antifungal treatment (depending on sensitivity results) will be required for an 8- to 12-week period. Complete debridement of infected tissues, temporary stabilisation of the femur and thorough washout of the joint will be required. In some instances, the antifungal agent in orthopaedic cement can be used to pack the joint space along with systemic antifungal treatment. A new total knee replacement can be planned for a minimum of 3 months (or longer if antifungal treatment is prolonged beyond 3 months for satisfactory clearance of the infection).

Case 43.3

Ms KR, a 27-year-old woman, visits her primary care doctor reporting that her toenails have become distorted and discoloured. It looks unattractive, so she would like it corrected before her summer beach holiday. The primary care doctor makes the clinical diagnosis of tinea unguium (dermatophytosis of the nail), which is confirmed by laboratory culture of nail scrapings. The doctor knows that this condition is unlikely to respond to topical treatment and therefore consults the British National Formulary for a systemic agent. He finds that griseofulvin, terbinafine and itraconazole are all available for this condition. However, the situation is complicated by the fact that his patient tells him that she is trying to become pregnant and does not want to take anything which might harm a baby. At this point, the doctor seeks specialist advice.

Question

What is the most appropriate and safe treatment for Ms KR?

Answer

This is a complex decision. Griseofulvin is contraindicated in pregnancy because of its known teratogenicity in animals; therefore, it is not an appropriate choice for Ms KR. Itraconazole should only be used in life-threatening situations where the potential benefits to the mother outweigh the potential harm to the foetus (Actavis, 2016a). Therefore, it would be difficult to recommend itraconazole to Ms KR.

Terbinafine could be used if the potential benefit outweighs the risk (Actavis, 2016b); foetal toxicity and fertility studies in animals suggest no adverse effects. However, because this is not a serious condition, treating Ms KR with terbinafine would be difficult to justify.

After some discussion, Ms KR decided that she wanted the condition treated more than she wanted to become pregnant and returned to using her oral contraception. Griseofulvin decreases the effectiveness of oral contraceptives, and there are reports of contraceptive failure with imidazoles and oestrogens. Therefore, following this discussion Ms KR decided to take a course of terbinafine.

Case 43.4

Mr DF, an 18-year-old boy with acute myeloblastic leukaemia, sustained 20% accidental burns injury on face, upper body and right arm at a family barbecue. (He had only just recently left hospital after successful antibiotic treatment for a febrile neutropenic episode post-chemotherapy.)

Two weeks after admission to ITU for management of burns, Mr DF underwent a septic episode with septic shock. A blood culture was taken through a central line which showed Gram-negative bacilli. He was commenced on broad-spectrum antibiotics. His peripheral blood count was $3 \times 10^9/L$, and he had a markedly raised C-reactive protein level. Mr DF suffered a moderate degree of renal failure. Two days later another blood culture was taken through an arterial line and showed yeast cells on Gram stain. IV fluconazole was added to his treatment. Culture growth from the central line blood culture revealed *Pseudomonas aeruginosa* and *C. albicans*. The arterial blood culture grew *Candida krusei*. Antifungal sensitivities have been requested.

Question

How should Mr DF be managed?

Answer

Treatment of infections in burn patients can be challenging because the loss in skin integrity increases the risk of being colonised with various endogenous and hospital-acquired bacteria and fungi. Patients with haematological malignancies and chemotherapy treatment are more vulnerable to opportunistic infections. Ideally antibiotics should be avoided in a patient who has an invasive fungal infection because it is believed that killing the bacterial flora helps fungi thrive in the absence of commensal competition. In this case, Mr DF has concomitant Gram-negative sepsis and lacks a strong bodily defence system because of his underlying disease condition.

Candida krusei is known to be resistant to fluconazole. It is difficult to treat IV catheter and other line infections with systemic antibiotics and antifungals alone. It is imperative that these lines are removed and treatment given through temporary peripheral lines for at least 48 hours before a new central line is inserted. New lines are very likely to become colonised with the same micro-organisms if inserted too early. Both *C. albicans* and *C. krusei* can be treated with a lipid formulation of amphotericin. The use of non-lipid conventional formulations of amphotericin should be avoided because Mr DF has a moderate degree of renal failure. The duration of treatment should be decided by reviewing the patient daily; this would include imaging and echocardiograms for up to 2 weeks to look for seeding of *Candida* in other organs. Choice of antifungals can be reviewed after antifungal sensitivity is available, and amphotericin can be switched to caspofungin if necessary.

Case 43.5

Mr TH, a 78-year-old male gardener, sustained an eye injury while cleaning out old dried plants from his client's garden. He sustained a laceration to the cornea and presented to eye casualty 48 hours after the incident. He was started on topical and systemic antibiotics. A corneal scrape revealed no organisms on Gram stain but grew *Fusarium* species on culture plates 4 days later.

Question

How will Mr TH be managed, and what are the further associated risks to his eye?

Answer

If there is no bacterial growth, the antibiotics can be stopped. Topical antifungal agents in the form of eye drops like natamycin or amphotericin B (if available) should be commenced and administered frequently.

The associated risk is from the spread of infection to the back of the eye with development of endophthalmitis. Urgent surgical vitrectomy and washout, with instillation of intravitreal antifungal agent (amphotericin B 5 micrograms) would be indicated, along with systemic antifungal therapy with amphotericin B 1.5 mg/kg or voriconazole 4 mg/kg every 12 hours and converted to oral therapy 200 mg every 12 hours.

44 Thyroid and Parathyroid Disorders

Atul Kalhan and Mike D. Page

Key points

- Thyroid dysfunction is extremely common in clinical practice, with estimated prevalence rate of primary hypothyroidism and hyperthyroidism stated to be 1–2% and 0.4–2% of the population, respectively, based on epidemiological studies.
- Iodine deficiency remains the commonest cause of thyroid dysfunction worldwide, leading to enlarged and underactive thyroid gland while autoimmune thyroid disorders are more common in iodine-replete areas.
- The treatment of hypothyroidism requires lifelong levothyroxine therapy and monitoring. Commonly used medications such as antacids, iron, calcium tablets, and proton pump inhibitors may interfere with absorption of levothyroxine therapy.
- Thyroxine replacement therapy should be introduced with caution in the elderly, particularly those with cardiac disease.
- Thyroxine replacement therapy can be given weekly in patients who forget their daily doses or who are unable to self-medicate.
- Thyrotoxicosis can be treated with thionamide therapy, radioiodine, or surgery. The choice will largely be determined by the age of the patient, the cause of the thyrotoxicosis, the severity of the condition, comorbidity and patient preference.
- Patients treated with thionamide therapy require careful counselling about the symptoms and management of agranulocytosis and should be given written guidance.
- Elective parathyroidectomy is indicated in a select group of patients with primary hyperparathyroidism based on the age of the patient and/or evidence of end organ damage (osteoporosis, renal stones, renal impairment, etc.).
- Hypoparathyroidism can occur after thyroid surgery. It is managed with vitamin D analogues and requires lifelong monitoring.

Thyroid physiology

The thyroid gland consists of two lobes and is situated in the lower neck. The gland synthesises, stores and releases two major metabolically active hormones: tetra-iodothyronine (thyroxine [T_4]) and tri-iodothyronine (T_3). Regulation of hormone synthesis is by variable secretion of the glycoprotein hormone thyroid-stimulating hormone (TSH) from the anterior pituitary. In turn TSH is regulated by hypothalamic secretion of the tripeptide

thyrotrophin-releasing hormone (TRH) (Fig. 44.1). Low circulating levels of thyroid hormones initiate the release of TSH and probably also TRH. Rising levels of TSH promote increased iodide trapping by the gland and a subsequent increase in thyroid hormone synthesis. The increase in circulating hormone levels feeds back on the pituitary and hypothalamus, shutting off TRH, TSH and further hormone synthesis.

Both T_4 and T_3 are produced within the follicular cells in the thyroid. The stages in synthesis are shown in Fig. 44.2. In summary:

- Thyroglobulin and thyroid peroxidase are synthesised by follicular cells.
- Hydrogen peroxide (H_2O_2) is synthesised at the luminal membrane.
- Dietary inorganic iodide is trapped from the circulation and transported to the follicular lumen, where it is oxidised by H_2O_2 .

Fig. 44.1 Control of thyroid hormone secretion. TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone.

Fig. 44.2 Synthesis of thyroid hormones. DIT, Diiodotyrosine; MIT, monoiodotyrosine; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone; Tyr, tyrosine.

- Iodine is then transferred onto the tyrosine residues in thyroglobulin by iodinase enzymes forming mono-iodotyrosine (MIT) and di-iodotyrosine (DIT).
- Subsequently the formation of T₄ occurs as a result of the coupling of two DIT residues and of T₃ by coupling a DIT and an MIT residue. The hormones are then stored within the gland until their release into the circulation.
- Finally, thyroglobulin is resorbed into the follicular cell, hydrolysed, and its amino acids and remaining iodine re-used.

The T₄:T₃ ratio secreted by the thyroid gland is approximately 10:1. Consequently the gland secretes approximately 80–100 micrograms of T₄ and 10 micrograms of T₃ per day. However, only 10% of circulating T₃ is derived from direct thyroidal secretion, the remaining 90% being produced by peripheral conversion from T₄. T₄ can therefore be considered a prohormone that is converted in the peripheral tissues (liver, kidney and brain) either to the active hormone T₃ or to the biologically

Table 44.1 Plasma protein binding of thyroid hormones

Carrier protein	Plasma concentration	Proportion of T ₄ and T ₃ bound (%)
Thyroid-binding globulin	15 mg/L	75
Transthyretin (formerly thyroid-binding prealbumin)	250 mg/L	10
Albumin	40 g/L	15

inactive reverse T₃ (rT₃). In the circulation the hormones exist in both the active free and inactive protein-bound forms. T₄ is 99.98% bound, with only 0.02% circulating free. T₃ is slightly less protein bound (99.8%), resulting in a considerably higher circulating free fraction (0.2%). Details of protein binding are listed in [Table 44.1](#).

The hormones are metabolised in the periphery (kidney, liver and heart) by deiodination. T_4 and T_3 are also eliminated by biliary secretion of their glucuronide and sulphate conjugates (15–20%). The half-life of T_4 in plasma is about 6–7 days and that of T_3 is 24–36 hours in euthyroid adults. The apparent volume of distribution for T_4 is about 10 L and for T_3 about 40 L.

Hypothyroidism

Hypothyroidism is the clinical state resulting from decreased production of thyroid hormones or rarely from tissue resistance.

Epidemiology

Accurate assessment of the prevalence and incidence of hypothyroidism is difficult due to variation in definitions and population samples. The prevalence rate of spontaneous primary hypothyroidism is estimated to be around 1–2% of the total population, with a female preponderance (10:1 female/male ratio). The prevalence of hypothyroidism is higher in the elderly population. A significant proportion of the adult population may show raised TSH levels in the presence of normal thyroid hormone levels (free T_4 and T_3). This biochemical abnormality may or may not be associated with hypothyroidism-related symptoms and is termed as subclinical hypothyroidism. According to the Whickham survey (Vanderpump et al., 1995), 8% of women and 3% of men in the study population had subclinical hypothyroidism. Despite a relatively high incidence and prevalence of hypothyroidism, mass population screening for autoimmune hypothyroidism is not considered to be cost-effective.

Aetiology

Iodine deficiency is the commonest cause of hypothyroidism globally and is especially common in Himalayan mountainous region in South East Asia, Central Africa and Latin America. In iodine-replete regions autoimmune disease is the common cause of primary hypothyroidism (Vanderpump, 2011) and accounts for more than 95% of adult cases. It is usually due to a failure of the thyroid gland itself as a result of autoimmune destruction, or the effects of treatment of thyrotoxicosis. Hypothyroidism may be drug induced. Amiodarone and lithium cause hypothyroidism in around 10% of patients treated (see later). Secondary disease is due to hypopituitarism, and tertiary disease is due to failure of the hypothalamus. Peripheral hypothyroidism is due to tissue insensitivity to the action of thyroid hormones. A more extensive classification is shown in Box 44.1.

Iodides may produce hypothyroidism in patients who are particularly sensitive to their ability to block the active transport pump of the thyroid gland. Iodine absorption from topical iodine-containing antiseptics has been shown to cause hypothyroidism in neonates. This is potentially very dangerous at a critical time of neurological development in the newborn infant. Transient hypothyroidism may be seen in 25% of iodine-exposed infants.

Clinical manifestations

Hypothyroidism can affect multiple body systems, but symptoms are mainly non-specific and gradual in onset (Box 44.2). Symptoms

Box 44.1 Classification of hypothyroidism

Primary hypothyroidism

Congenital hypothyroidism
 Agenesis
 Inherited enzyme defects
 Immune
 Hashimoto's thyroiditis
 Spontaneous hypothyroidism in Graves' disease
 Postpartum hypothyroidism
 Iatrogenic
 Postoperative hypothyroidism
 Hypothyroidism after radioactive iodine
 External neck irradiation
 Drugs: antithyroid thionamides, amiodarone, lithium, elemental iodide
 Iodine deficiency
 Subacute (viral)

Secondary/tertiary hypothyroidism

Hypopituitarism: any cause
 Hypothalamic disease

Peripheral hypothyroidism

Insensitivity to thyroid hormones

Box 44.2 Signs and symptoms of hypothyroidism

Skin and appendages

Dry, cool, flaking, thickened skin
 Reduced sweating
 Yellowish complexion
 Puffy facies and eyes
 Sparse, coarse, dry hair
 Brittle nails

Neuromuscular system

Slow speech
 Poor memory and reduced cognitive function
 Somnolence
 Carpal tunnel syndrome
 Psychiatric disturbance
 Hearing loss
 Depression
 Muscle pain and weakness
 Delayed deep tendon reflexes

Metabolic abnormalities

Raised total and low-density lipoprotein cholesterol
 Macrocytic anaemia

Gastro-intestinal

Weight gain with decreased appetite
 Abdominal distension and ascites
 Constipation

Cardiovascular

Reduced cardiac output
 Bradycardia
 Cardiac enlargement

are frequently vague, especially in the early stages. It is common for symptoms to be incorrectly attributed by patients and their relatives to increasing age. The reverse is also common in that patients who have read about or have friends/family with hypothyroidism will assume that it is responsible for symptoms of fatigue and

weight gain. Thus, hypothyroidism is often confused with simple obesity and depression. Mercifully, simple thyroid function tests (TFTs) give accurate diagnosis in all cases (see later).

The most useful clinical signs are myotonic (slow relaxing) tendon reflexes, bradycardia, hair loss and cool, dry skin. Effusions may occur into pericardial, pleural, peritoneal or joint spaces. Mild anaemia of a macrocytic type is quite common and responds to thyroxine replacement. Pernicious anaemia is a frequent concomitant finding in hypothyroidism. Other, organ-specific autoimmune diseases such as Addison’s disease may be associated.

Myxoedema coma

Myxoedema coma is a rare but potentially fatal complication of severe, untreated hypothyroidism. Coma can be precipitated by hypothermia, stress, infection, trauma and certain drugs, notably β-blockers and respiratory depressants, including anaesthetic agents, narcotics, phenothiazines and hypnotics. The condition is a medical emergency and should be treated rapidly and aggressively.

The term ‘myxoedema’ used to be synonymous with hypothyroidism. It is now reserved for advanced disease in which there is swelling of the skin and subcutaneous tissues.

Investigations

The laboratory investigation of hypothyroidism is extremely simple. Usually clinical assessment, combined with a single estimation of thyroid hormones and TSH, is sufficient to make the diagnosis. In primary disease, the levels of free T₄ and T₃ are low, and the TSH level rises markedly. Some laboratories offer only TSH as a first-line test of thyroid function, although this can result in delayed diagnosis of secondary or tertiary hypothyroidism, which should be suspected on the basis of a low free T₄ along with low TSH levels.

Elevation of the TSH level occurs early in the course of thyroid failure and may be present before overt clinical manifestations appear. It is important to appreciate that hypothyroidism is not one disease but a spectrum. Early hypothyroidism may be asymptomatic or the symptoms less obvious and non-specific, but a normal TSH with normal free T₄ effectively excludes the diagnosis.

A chest radiograph may detect the presence of effusions, and an electrocardiogram is useful, especially in patients with angina or coronary heart disease, in whom replacement therapy needs to be introduced gradually.

Testing thyroid function: Pitfalls for the unwary

As indicated earlier (and in the section, Hyperthyroidism/thyrotoxicosis), a clinical assessment and measurement of free T₄ and TSH are usually all that is necessary to arrive at an accurate diagnosis of thyroid state. All modern TSH assays now use double antibody immunometric techniques, which are robust and highly reliable. Moreover, these assays are now so sensitive that they are able to identify thyrotoxic patients with TSH levels below the normal euthyroid range. Commercial free T₄ and free T₃ assays, however, are all indirect methods and are subject to interference from drugs and other disease states. As such, both T₃ and T₄ can be decreased as a non-specific consequence of systemic illness (the euthyroid

Table 44.2 Drug effects on thyroid function

Clinical/Biochemical effects	
Decrease TSH secretion	
Dopamine Glucocorticoids Octreotide	Hypothyroidism (rarely clinically important)
Alter thyroid hormone secretion	
Iodide (amiodarone, contrast agents)	Both hyperthyroidism and hypothyroidism
Lithium	Hypothyroidism
Decrease T₄ absorption	
Cholestyramine/colestipol Aluminium hydroxide Ferrous sulphate Calcium carbonate Multivitamins Sevelamer Proton pump inhibitors Sucralfate	Increased levothyroxine dose requirement
Alter T₄ and T₃ metabolism	
Increased hepatic metabolism Phenobarbital Phenytoin Rifampicin Carbamazepine	Low T ₄ and T ₃ levels Normal or increased TSH
Reduce conversion of T₄ to T₃	
β-Blockers Propylthiouracil Amiodarone Glucocorticoids	Lower T ₃ levels Normal or increased TSH
Reduce T₄ and T₃ binding	
Furosemide Salicylates and non-steroidal anti-inflammatory drugs Heparin	Increased measured free T ₄ in some assays
Increase thyroglobulin levels	
Oestrogen and tamoxifen Opiates and methadone	Increased total T ₄
Others	
Cytokines: interferon and interleukin-2	Thyroiditis; can produce hypothyroidism and thyrotoxicosis
T ₃ , tri-iodothyronine; T ₄ , thyroxine; TSH, thyroid-stimulating hormone.	

sick syndrome) and depression, along with a host of drugs (Surks and Sievert, 1995) that can interfere with thyroid hormone metabolism and free hormone assays (Table 44.2). Such patients require specialist assessment and collaboration with the local laboratory to rule out confounding disease and pituitary failure.

Treatment

The aims of treatment with levothyroxine are to ensure that patients receive a dose that will restore well-being and which usually returns the TSH level to the normal range. All patients with symptomatic hypothyroidism require replacement therapy.

T₄ is usually the treatment of choice except in myxoedema coma, where T₃ may be used in the first instance. Before commencing T₄ replacement the diagnosis of glucocorticoid deficiency must be excluded to prevent precipitation of a hypoadrenal crisis. If in doubt, hydrocortisone replacement should be given concomitantly until cortisol deficiency is excluded.

The initial dose of T₄ will depend on the patient's age, severity and duration of disease, and the coexistence of cardiac disease. In young, healthy patients with disease of short duration, T₄ may be commenced in a dosage of 50–100 micrograms of levothyroxine daily. Because the drug has a long half-life it should be given once daily. The most convenient time is usually in the morning. After 6–8 weeks on the same dose (not a shorter interval because TSH takes this time to stabilise after a dose change) TFTs should be checked. The TSH concentration is the best indicator of the thyroid state, and this should be used for further dosage adjustment. A raised TSH concentration indicates either inadequate treatment, poor adherence or both. Commonly used medications such as antacids, iron, calcium tablets and proton pump inhibitors (PPIs) may also interfere with absorption of levothyroxine therapy, and it is useful to advise the patients to take levothyroxine tablets separately from these medications (Zamfirescu and Carlson, 2011). The majority of patients will be controlled with dosages of 100–200 micrograms of levothyroxine daily, with few patients requiring more than 200 micrograms daily. In adults the median dose required to suppress TSH to normal is 125 micrograms daily. In the majority of patients once the appropriate dosage has been established it remains constant. During pregnancy, an increase in the dose of levothyroxine by 25–50% is needed to maintain TSH levels in a trimester-specific reference range.

Exacerbation of myocardial ischaemia, infarction and sudden death are all well-recognised complications of T₄ replacement therapy. Patients with coronary heart disease may be unable to tolerate full replacement doses because of palpitations, angina or heart failure. Elderly patients may have undiagnosed ischaemic heart disease (IHD). In these two groups of patients, treatment should therefore be started with 25 micrograms of levothyroxine daily and increased slowly by 25 micrograms every 4–6 weeks. During this time the patient's clinical progress should be carefully monitored. There is insufficient evidence supporting use of combination of T₄ and T₃ therapy over T₄ monotherapy in patients with primary hypothyroidism (Okosieme et al., 2016).

It is important to avoid both under-treatment and over-treatment. Hypothyroidism is rarely life-threatening, but adverse effects may result from prolonged over-treatment. This is indicated by a TSH level suppressed below the normal range. Although T₄ exerts an effect on many organs and tissues, it is the effect on bone and the heart that give the greatest cause for concern. There is evidence that bone density is reduced in patients who are taking excessive T₄ replacement therapy (Faber and Galloe, 1994; Uzzan et al., 1996), and that atrial fibrillation is more common if TSH is suppressed (Sawin et al., 1994). To minimise the risk of development of these complications, the dose should be carefully tailored to the needs of each individual patient. A proportion of patients may remain persistently symptomatic in spite of receiving an optimum dose of thyroxine replacement therapy despite the TSH levels being in

the normal range. In these patients alternate aetiologies such as anaemia, renal and liver impairment, vitamin D/B₁₂/folate deficiency, adrenal insufficiency and depression, among others, should be considered. There is no convincing evidence supporting further increasing levothyroxine dose or use of thyroid extracts, T₃ (monotherapy or in combination with T₄) or over-the-counter dietary supplements in this subgroup of patients.

Patient care

The treatment of hypothyroidism requires lifelong treatment with T₄. Patients receiving long-term drug therapy are recognised to have a low adherence with their medication regimen. Treatment with T₄ is often terminated because patients feel well and think that treatment is no longer required. Patients should be educated to understand the effects of drug holidays on their health and TFTs, and should know that a normal TSH indicates adequate dosage. Written advice should be provided and monitoring of dosage should continue annually. A series of excellent patient information leaflets is available on the British Thyroid Association website (<http://www.british-thyroid-association.org>).

An official website of the Society of Endocrinology (<http://www.yourhormones.info>) also provides useful and relevant information for patients and caregivers.

Despite adequate counselling, some patients persistently forget to reliably take their tablets, leading to variable thyroid state and wildly fluctuating test results. Other patients lack the capacity to reliably self-medicate. There is evidence to show that weekly dosing with T₄ is a safe and acceptable way to manage this type of patient, for whom family members or community staff can supervise treatment (Grebe et al., 1997; Rangan et al., 2007). No guidelines have yet been published, although a weekly dose of levothyroxine which is sevenfold higher than the usual daily dose is considered a safe and efficacious way of bringing clinical and biochemical improvement in this sub-group of patients. Dosage changes are made in exactly the same way by assessing TSH levels after 6–8 weeks of stable dosing.

Rarely, patients are seen in whom TSH levels fluctuate or remain elevated despite high doses of levothyroxine and in whom adherence seems to be very good. There are a number of possible causes for this including malabsorption of levothyroxine, which can be due to coeliac or inflammatory bowel disease, or a number of commonly prescribed drugs (see Table 44.2). Such patients will need a careful sequential assessment by an endocrine service (Morris, 2009).

Prevention

Currently, nothing can be done to prevent autoimmune thyroid failure from developing; however, much can be done to ensure early detection and treatment. Careful follow-up of patients who have undergone radioiodine treatment, subtotal thyroidectomy, or completed a course of treatment for thyrotoxicosis is essential, along with monitoring of those prescribed amiodarone and lithium. An increase in TSH with normal concentrations of T₃ and T₄ will indicate the onset of hypothyroidism before the patient becomes symptomatic. Box 44.3 shows the prevalence of hypothyroidism after treatment for thyrotoxicosis.

Hyperthyroidism/thyrotoxicosis

Hyperthyroidism is defined as the production by the thyroid gland of excessive amounts of thyroid hormones. Thyrotoxicosis refers to the clinical syndrome associated with prolonged exposure to elevated levels of thyroid hormone. This distinction is important when evaluating TFTs (Table 44.3).

Box 44.3 Prevalence of thyroid disturbance after treatment for thyrotoxicosis

Thyroidectomy

6–75% hypothyroidism over their lifetime, dependent on the amount of remnant tissue.
Risk highest during first year after surgery

Antithyroid drugs (>6-month course)

43% relapse with thyrotoxicosis in the first year
13–21% relapse with thyrotoxicosis in the next 4 years

¹³¹I therapy

24–90% develop hypothyroidism over their lifetime, depending on dose given

Epidemiology

Hyperthyroidism is a common condition. The Wickham survey identified 4.7/1000 women with active disease (Tunbridge et al., 1977). When previously treated cases were included, the population prevalence rose to 20/1000 women. As for hypothyroidism, it is much less common in men, who have a lifetime prevalence of around 2/1000.

Aetiology

Hyperthyroidism is a disorder of various aetiologies. In clinical terms, thyrotoxicosis is the result of persistently elevated levels of thyroid hormones.

Graves' disease

Graves' disease is the commonest cause of thyrotoxicosis. It is an autoimmune condition and results from production of an abnormal immunoglobulin G (IgG) that is able to occupy the TSH receptor on the thyroid follicular cell. Here it mimics the effect of TSH, causing cell division and stimulating thyroid hormone secretion. These stimulatory immunoglobulins

Table 44.3 Aetiology of hyperthyroidism

Condition	Frequency	Clinical features	¹³¹ I uptake
Thyrotoxicosis (increased hormone synthesis)			
Graves' disease	70%	Antibody mediated (TRABs) 90% are young women Diffuse goitre Ophthalmopathy (30%) Pretibial myxoedema Acropachy Transmissible to neonate	Increased
Multinodular goitre	20%	Benign autonomous nodules Often secrete T ₃ Older women Always relapse after withdrawal of thionamides	Increased
Toxic single adenoma	5%		Increased
Iodine induced	<1%	Increased urine iodine	Variable
HCG induced	Rare	Molar pregnancy or choriocarcinoma	Increased
TSH dependent	Rare	Pituitary tumour	Increased
Thyroiditis (thyroid destruction and leakage of stored thyroid hormones)			
Acute	2%	Probably viral Neck pain: often severe	Absent
Silent	2%	Viral Autoimmune	Absent
Amiodarone induced	<1%	Increased urine iodine	Absent

HCG, human chorionic gonadotropin; T₃, triiodothyronine; TRAB, thyroid receptor antibody; TSH, thyroid-stimulating hormone.

are known as thyroid receptor antibodies (TRABs). Rarely are the TRABs inhibitory to the TSH receptor, resulting in hypothyroidism.

Ninety percent of patients with Graves' disease are young women often with a family history of the condition. In addition to the effects of thyrotoxicosis, around 30% of patients experience additional features including a congestive ophthalmopathy which is thought to result from antibody-mediated inflammation of orbital contents. Pretibial myxoedema, gynaecomastia and thyroid acropachy are rare manifestations.

In pregnancy the maternal TRABs can pass across the placenta to the foetus, resulting in transient neonatal thyrotoxicosis.

Nodular disease

Toxic multinodular goitre is also common but more often affects older women in whom an euthyroid nodular goitre may have been present for many years. Individual nodules become autonomous, producing T₃ and/or T₄. Clinically the thyrotoxicosis is generally less severe and more gradual in onset. Often only T₃ levels are elevated, although the TSH will be suppressed in all cases. Thyrotoxicosis may also be caused by single autonomous thyroid adenomas. These are benign, well-differentiated tumours that secrete excessive amounts of thyroid hormones.

Thyroiditis

If the thyroid is inflamed by viral or rapid autoimmune attack, the resulting follicular cell death will result in the release of pre-formed thyroid hormones. This usually presents as a painful mildly enlarged and tender thyroid. There is a brief period of hyperthyroidism before thyroid hormone levels fall to subnormal. Most often this period of hyperthyroidism does not lead to clinically apparent thyrotoxicosis and in any event is brief, but it is common for these patients to be prescribed thionamides which compound the ensuing hypothyroidism. It is therefore necessary to be aware of these conditions. Neck pain with disturbed TFTs should prompt referral for specialist assessment which will usually include a request for an iodine uptake scan. Iodine uptake is absent in hyperthyroidism associated with thyroiditis.

Clinical manifestations

Thyrotoxicosis is characterised by increases in metabolic rate and activity of many systems due to excessive circulating quantities of thyroid hormones. There is a wide spectrum of clinical disturbance. The signs and symptoms reflect increased adrenergic activity, especially in the cardiovascular and neurological systems (Box 44.4). Not all manifestations will be seen in every patient. Additional clinical features will depend on the underlying cause of the thyrotoxicosis (see Table 44.3).

The clinical features of thyrotoxicosis in the elderly may not be so obvious. Signs and symptoms of cardiovascular disturbance tend to predominate, atrial fibrillation is frequent and the patient may experience congestive heart failure. Unexplained heart failure after middle age should always arouse suspicion of thyrotoxicosis.

The extrathyroidal manifestations of Graves' disease deserve separate mention. Most frequent is ophthalmopathy due to inflammation and expansion of the contents of the orbit. The eye is pushed forward (proptosis) such that white sclera appears between the iris and the lower lid. Congestive changes develop including peri-orbital oedema, conjunctival swelling and redness. The extraocular muscles are swollen and become tethered, leading to failure of movement of the globe of the eye and thus diplopia. Severe disease causes pressure in the orbit, which can compress the optic nerve leading to blindness. The cutaneous features of Graves' disease include thickening of the pretibial skin (myxoedema), onycholysis (separation of the nail from the nail bed) and acropachy (similar to finger clubbing).

Investigations

In those with suspected thyrotoxicosis it is good practice to document the diagnosis with two sets of TFTs. If the diagnosis is in doubt, treatment should be withheld because unless severe, thyrotoxicosis can usually be safely observed whilst awaiting the results of investigations. Plasma free T₄ (and/or T₃) levels are elevated. The TSH level is suppressed to subnormal levels in all causes of thyrotoxicosis, except the exceptionally rare cases of TSH-secreting pituitary adenomas.

In the overwhelming majority of patients, the combination of the clinical findings and simple investigations is sufficient to make a firm diagnosis. Radioactive iodine uptake scans will differentiate those patients with thyroiditis. Measurement of TRABs

Box 44.4 Signs and symptoms of thyrotoxicosis

Skin and appendages

Warm, moist skin
Thinning or loss of hair
Increased sweating
Heat intolerance

Nervous system

Weight loss despite increased appetite
Thirst
Diarrhoea

Cardiovascular

Palpitations, tachycardia
Shortness of breath on exertion
Atrial fibrillation
Congestive heart failure
Worsening angina

will identify patients with Graves’ disease. If the diagnosis is still equivocal, the clinical findings should be reassessed and particular attention paid to the patient’s drug history. A number of drugs, such as amiodarone, lithium, corticosteroids, interferons and levodopa, may modify the clinical features or interfere with the tests.

Treatment

A number of factors need to be considered when choosing the most appropriate form of therapy for an individual patient (Table 44.4). Usually a number of therapeutic options are available, and the patient should be involved in the decision on what treatment to have. The decision may also be influenced by physician preference, which in turn can depend on the facilities available. Three forms of therapy are available, including antithyroid drugs, surgery and radioactive iodine. There is no general agreement as to the specific indications for each form of therapy, and none of them is ideal, because all are associated with both short- and long-term sequelae. Neither surgery nor radioactive iodine should be given until the patient has been rendered euthyroid because of the risk of inducing a thyroid crisis (see later).

In children, surgery may be difficult and the complication rate is higher. Also radioiodine has been avoided because of concern about the potential development of thyroid malignancy, although there are no data which suggest this to be a problem. In pregnancy, radioiodine is not used because of the likelihood of the neonate having hypothyroidism. Thyroid surgery during pregnancy should be deferred until the second trimester if possible, and most patients’ symptoms can be controlled with drugs. Thionamide doses should be kept as low as possible, especially in the last 2 months of pregnancy, because excessive treatment may produce goitre in the foetus. Aplasia cutis is said to occur after carbimazole therapy, so propylthiouracil is usually preferred over the former during the first trimester of pregnancy. Pregnant patients with thyrotoxicosis should be under the care of a specialist endocrine unit.

Immediate treatment of thyrotoxicosis

Patients need to have their symptoms addressed and their thyrotoxicosis controlled. Non-selective β-blockers in standard

antihypertensive doses are effective within a matter of hours and should be offered to all non-asthmatics with severe thyrotoxicosis. These agents help to alleviate symptoms such as tremors, palpitations and anxiety which are generally associated with sympathetic over-activity. Carbimazole (40 mg once a day) or propylthiouracil (150 mg twice a day) will render most patients euthyroid within 6 weeks. Adjunctive treatment of cardiac disease and anxiety/sleeplessness may be required.

Graves’ disease

A proportion (40–50%) of patients with Graves’ disease will achieve a long-lasting remission after a period of euthyroidism while receiving thionamides. The optimal duration of antithyroid treatment is unknown and remains a controversial issue (Maugendre et al., 1999), but in most units the length of the treatment course has fallen to between 6 and 12 months. It is not appropriate to discuss complex treatment decisions with a thyrotoxic patient, so most are well into this period when discussions of their options occur. Remission of Graves’ disease is much less likely in those with very large goiters, those who require high-dose thionamide treatment to maintain euthyroidism, those with high TRAB titres and patients who have relapsed once after a course of drug treatment. Such patients should therefore be rendered euthyroid and then have a discussion about either surgical or radioiodine thyroid ablation.

Nodular thyroid disease

As the nodules function autonomously and thyrotoxicosis will always recur when thionamides are stopped, there is no value in attempting to achieve a remission of nodular thyroid disease using prolonged medical treatment. Patients should be rendered euthyroid with drugs and then have a discussion about radioiodine ablative (RIA) therapy.

Antithyroid drugs

The thionamides, propylthiouracil, thiamazole (methimazole) and its precursor carbimazole, are equally effective

	Adverse effects (%)	Contraindications	Cautions
Thionamides Carbimazole Propylthiouracil	Rash/arthropathy (5%) Agranulocytosis (0.3%) Hepatitis (rare)	Previous severe allergy Cross-reactivity in 10%	Pregnancy: propylthiouracil is preferred Do not use block/replace regimens
Radioiodine	Hypothyroidism requiring lifelong T ₄	Pregnancy	Ensure euthyroid first Ophthalmopathy may deteriorate
Surgery	Hospital stay Neck scar Surgical/anaesthetic risk 10–75% requires T ₄		Ensure euthyroid first Ophthalmopathy may deteriorate

T₄, thyroxine.

Table 44.5 Adverse effects of thionamides

	Adverse effect	Comments
Skin	Pruritic, maculopapular rash	Most common in first 6 weeks May disappear spontaneously with continued treatment Can be treated with an antihistamine Change to alternative agent Occurs in 5% of patients
	Urticarial rash with systemic symptoms, i.e. fever, arthralgia	Discontinue drug Alternative treatment required
Haematological	Agranulocytosis	Most common in first 6 weeks Incidence increases with age Discontinue drug Reversible Consider alternative treatment Occurs in 0.3% of patients
	Leucopenia	Transient Continue treatment Does not predispose to agranulocytosis
Other	Hepatitis	Rare
	Vasculitis	Discontinue drug
	Hypoprothrombinaemia	
	Aplastic anaemia	
	Thrombocytopenia	

pharmacological therapies for thyrotoxicosis. In the UK carbimazole is usually used. These drugs prevent thyroid hormone synthesis by inhibiting the oxidative binding of iodide and its coupling to tyrosine residues. Propylthiouracil, but not carbimazole, inhibits the peripheral deiodination of T_4 to T_3 . Thionamides may also have an immunosuppressive action.

Adverse effects. The most common adverse effect of antithyroid treatment is rash and arthropathy (5%) and less commonly agranulocytosis, hepatitis, aplastic anaemia and lupus-like syndromes (Table 44.5). Overall, serious effects such as these occur in approximately 0.3% of patients treated. These side effects usually occur during the first 6 weeks of treatment, but this is not invariable. Cross-sensitivity between carbimazole and propylthiouracil is around 10%, and the patient can often be safely changed to the alternative agent if an adverse event occurs.

Regular monitoring of white cell counts has been advocated, but is not warranted. Agranulocytosis is a rare event and even if it does occur, it happens rapidly such that routine monitoring of white cell counts may miss it. At the time of prescription, all

patients should be counselled about the possible implication of sore throat, mouth ulcers and pyrexia, and instructed to seek an urgent (within hours) full blood count. This verbal information should be backed up by written advice which should specify where the patient should go for the blood test. An abnormal white cell count should prompt urgent admission under a specialist endocrine team.

The regimen

Carbimazole is usually given initially at a dosage up to 40–60 mg daily, depending on the severity of the condition. It can be given as a single daily dose in multiples of 20 mg tablets to aid adherence. Although the plasma half-life is short (4–6 hours), the biological effect lasts longer (up to 40 hours). T_4 concentrations are checked at 6-week intervals until the patient is clinically euthyroid and the T_4 and T_3 levels are normalised. (TSH remains suppressed for at least 4 weeks after resolution of significant thyrotoxicosis, so TSH levels are unhelpful in the early stages of treatment.)

At this point a decision is made about ongoing treatment. It is simplest to continue a high dose of carbimazole to suppress endogenous thyroid hormone production and to give a standard replacement dose of levothyroxine to maintain euthyroidism, the “block and replacement” regimen. This combination results in a steadier thyroid state, reduces the need for blood monitoring and requires fewer hospital attendances. Because adverse drug effects are allergic and not dose related, it is no riskier than tailored dose regimens.

Pregnancy is a specific situation, however, in which tailored-dose propylthiouracil is preferred over carbimazole during the first trimester. Both the immunoglobulins, which cause Graves’ disease, and thionamide drugs cross the placenta and will affect the fetal thyroid, but maternal levothyroxine is not able to reach the foetus. Thus, the lowest possible dose of propylthiouracil or carbimazole in pregnancy should be used and the foetus closely monitored for heart rate and growth. Breastfeeding is considered to be safe when mothers are taking thionamides.

Patient counselling

Box 44.5 outlines counselling points for patients receiving anti-thyroid drugs. Patients should be advised of the importance of regular clinic attendance. This is necessary to monitor both therapeutic outcome and the development of adverse effects. As indicated earlier, the development of skin rashes, mouth ulcers or a sore throat should be immediately investigated and a full blood count performed. It may be dangerous to treat these symptoms with over-the-counter medication before carrying out further investigations.

It is important for the patient to understand the difference between specific antithyroid therapy and symptomatic treatment. The patient should also be advised about the timing of doses to aid adherence. Following completion of a course of treatment, the patient should understand that relapse may occur, and medical help should be sought if the initial symptoms recur.

Box 44.5 Counselling points for patients who are receiving antithyroid drugs

1. Carbimazole can be given as a single daily dose.
2. Identify anticipated duration of treatment.
3. Explain block and replacement regimens.
4. Explain use of adjuvant therapy, e.g. β -blockers.
5. Encourage reporting of skin rashes, sore throat or mouth ulcers. Provide written guidance.
6. Ensure the patient understands the need for regular review.
7. Outline management of relapse.

Thyroid ablative therapy

Thyroid ablation is required for all patients with toxic multinodular goiters, those who have relapsed or are likely to relapse after drug therapy for Graves' disease, and those who are allergic to thionamides. Thyroid ablation can be achieved by radioiodine or surgery.

Radioactive iodine. Radioiodine therapy is extremely easy to administer by mouth and is very effective for a large majority of patients. It is contraindicated in pregnancy and breastfeeding, and is usually avoided in children. It is known to make ophthalmopathy worse in some patients with Graves' disease, but giving prednisolone 0.5 mg/kg for 3 weeks and commencing thyroxine replacement early (3 weeks after radioiodine) can mitigate this. Despite public concern in relation to radioactivity, accumulated experience over more than 60 years has not demonstrated any discernible risk of genetic, leukaemic or lymphoma risk (Vanderpump et al., 1996).

The commonest complication is the development of hypothyroidism. Doses sufficient to cause thyrotoxicosis to remit will result in virtually 100% of patients given radioiodine for Graves' disease becoming hypothyroid and around 50% of those treated for multinodular disease. Patients should be counselled to expect to require lifelong levothyroxine treatment after radioiodine therapy.

Antithyroid drugs must be withdrawn 1 week prior to radioiodine is given and should not be restarted for at least 3 days afterwards (otherwise the isotope will not be trapped by the thyroid). Because the ablative effect of radioiodine usually commences within 2–3 months, many patients with mild or moderate disease will not need to restart their drug treatments, although close patient monitoring is required. Patients with severe thyrotoxicosis should restart their antithyroid drugs on day 3. Treatment is then withdrawn periodically to assess the effects of the radioiodine.

The patient who is receiving radioiodine treatment is effectively radioactive for 6 weeks without ill effect. Because the patients are not at risk from this radioactivity, it seems inherently unlikely that the public faces any risk at all to health. Nevertheless, there are regulations governing exposure to radiation, which must be followed. After a standard 555 MBq dose a patient must for 14 days avoid close continuous contact (2 m) with other persons for periods of more than 1 hour, undertake to be careful in disposing of urine and must not work. For 24 days they must avoid close contact with children and pregnant women. In practice it is these regulations and the

concerns they engender in the patient that result in a proportion of patients preferring a surgical approach.

Surgery. Surgery is required for those patients with very large goiters, patients who cannot be persuaded of the safety of radioiodine and those who have reacted adversely to both thionamides in pregnancy. The patient with hyperthyroidism to be treated surgically should first be rendered biochemically euthyroid whenever possible, but occasionally surgery needs to be performed as a semi-urgent procedure. This may require urgent patient preparation with a combination of antithyroid drugs and β -blockers, and iodide given as Lugol's solution. Iodide exerts a (usually) transient inhibitory effect on the ability of the gland to trap iodide, and it may also reduce the vascularity of the gland. In doses of 800–1200 mg/day, lithium is an effective antithyroid drug for patients who have reacted to thionamides. Lithium levels should be monitored to minimise toxicity. β -Blockers should be introduced and the dose titrated to reduce the pulse rate to less than 80 beats/min. They are usually continued for 1 week postoperatively. It is imperative that treatment is given right up to the time of operation, and the operation deferred if the pulse rate is not adequately controlled. Inadequate pretreatment can result in the occurrence of a thyroid crisis.

Complications of surgery include the generic ones of anaesthetic risk, bleeding, thromboembolic disease and infection. Specific risks of thyroid surgery include damage to recurrent laryngeal nerves (which may be particularly important to actors, singers and teachers) and hypoparathyroidism as a result of interference of the blood supply to the parathyroids or their inadvertent removal during surgery. If this occurs, tetany will begin within 48 hours of the operation, and treatment should be initiated with intravenous calcium gluconate. All patients who have undergone partial thyroidectomy should have serum calcium estimation 3 months after the operation because the development of hypoparathyroidism can be delayed. Later complications of thyroidectomy include hypothyroidism and recurrent thyrotoxicosis.

Treatment of complications

Ophthalmopathy

In most patients with Graves' disease, no specific treatment is required for the eyes. The commonest complaint is of 'grittiness', which can be treated with hypromellose eye drops or gel. If lid retraction is severe, inadequate lid closure can result in early-morning soreness. This can be alleviated by the short-term use of 5% guanethidine eye drops instilled each night and morning. The eyes should be monitored for any signs of infection and treated appropriately.

Fortunately, severe eye involvement occurs in less than 2% of patients with Graves' disease. Progressive ophthalmopathy-producing severe complications from proptosis, diplopia or visual failure should be treated with high-dose corticosteroid therapy (prednisolone 60 mg daily) until symptoms resolve. Failure to respond is an indication for orbital irradiation or surgical decompression, but such patients should be under the care of a highly specialised ophthalmic surgeon.

Treatment of localised myxoedema

Myxoedema is usually localised to small areas and is asymptomatic. More extensive disease causes difficulty in walking and considerable discomfort. Probably the most effective therapy is the nightly topical application of corticosteroid creams, such as betamethasone, under occlusive polythene dressings.

Thyroid Crisis

Thyroid crisis can develop in any patient with significant untreated thyrotoxicosis, but it is most common in those with severe Graves' disease. It is precipitated in such patients by infection, injury, trauma, anaesthetics, surgery and radioiodine. There is rapidly progressive tachycardia, muscle weakness (including cardiomyopathy), hyperthermia, sweating and vomiting compounded by hypotension with ensuing circulatory collapse. In addition, patients are extremely anxious and often psychotic. It should be managed as a medical emergency in a high care area. In addition to supportive measures, specific antithyroid therapy is required along with drugs, which inhibit deiodination of T_4 to T_3 . Propylthiouracil (inhibits deiodinase) is given orally (or via nasogastric tube) in high dose along with Lugol's iodine. Glucocorticoids should be given intravenously because they also inhibit deiodinase. Effective β -blockade is required by an intravenous infusion (propranolol is preferred because it also inhibits deiodinase).

Drugs and the thyroid

From the previous pages it will be evident that many commonly used drugs can affect the thyroid. This section draws together the most frequently encountered problems. In clinical practice drug effects and interactions produce thyrotoxicosis or hypothyroidism or disturb TFTs. It is worth specifically noting amiodarone, which contains large quantities of iodide which is released into the circulation during drug metabolism. Amiodarone's effects on the thyroid are extensive and complex.

Drugs and thyrotoxicosis

Table 44.2 indicates drug treatments associated with thyrotoxicosis. Amiodarone-induced thyrotoxicosis (AIT) is caused by two entirely different mechanisms. Type 1 AIT is similar to iodide-induced thyrotoxicosis and results from activation of nodular disease or of latent Graves' disease in patients with thyroid autoimmunity. In this condition the thyroid is actively synthesising hormone and treatment is with thionamides. Type 2 AIT has features similar to thyroiditis with leakage of pre-formed thyroid hormone, low uptake of radiolabel on scanning and is treated with glucocorticoids. AIT is an extremely challenging condition to manage for multiple reasons. These include difficulty in discrimination between type 1 and 2 diseases, each of which have different treatments, and the fact that most patients are taking amiodarone for serious cardiac dysrhythmias and amiodarone

has a very long tissue half-life. These patients should be under the care of a specialist endocrinology team.

A recent observation has been increased frequency of Graves' disease in patients who are undergoing bone marrow transplantation, after administration of alemtuzumab (a monoclonal antibody to CD52 cells) or α -interferon for multiple sclerosis and during highly active anti-retroviral treatment of HIV infection. It is thought that these cases all have immunological reconstitution as an underlying factor in aetiology (Weetman, 2009).

Drugs and hypothyroidism

Amiodarone is frequently associated with the development of hypothyroidism, particularly in those patients with positive thyroperoxidase (TPO) antibodies, indicative of latent Hashimoto's disease. Such patients seem particularly sensitive to the high levels of iodine liberated by drug metabolism, and it is thought that hypothyroidism occurs because of a failure of the patient's thyroid to escape from the suppressive effect of iodine on thyroxine synthesis (the Wolff-Chaikoff effect). If amiodarone can be withdrawn, hypothyroidism will resolve over a period of months. More often, however, amiodarone is continued and levothyroxine treatment is required.

Lithium inhibits T_4 and T_3 release from the thyroid (making it a useful adjunctive treatment for thyrotoxicosis in patients who react to thionamides) and causes a goitre in 40% of patients and hypothyroidism in 20%; again, this is more common in those with positive TPO antibodies. Like amiodarone, lithium is usually continued and these patients are treated with levothyroxine.

Drug-related interference with absorption of levothyroxine is one of the causes of hypothyroidism in patients treated with levothyroxine. Table 44.2 indicates the agents which may be implicated.

Calcium and parathyroid hormone Physiology

Calcium ion plays a key role in multiple physiological functions in the human body including skeletal and cardiac muscle contraction, synaptic transmission, coagulation apart from acting as a second messenger intracellularly to regulate cell division, motility and signal transduction essential for homeostasis. Around 99% of total body calcium is stored in the bones, with only 1% of the rest of extracellular calcium being available for essential metabolic functions. Half of the calcium in extracellular fluid is bound to albumin, and it is the remaining ionised calcium that is biologically active.

The calcium levels in the body are dependent upon its absorption from the gastro-intestinal tract, turnover from the bones and excretion from the kidneys. Parathyroid hormone (PTH), vitamin D and magnesium levels play a role in controlling the calcium levels in the body. PTH is an 84-amino acid polypeptide which acts on hormone-specific receptors on target tissue cells and is secreted from parathyroid glands. Most individuals possess four parathyroid glands situated posterior to the upper and lower lobes of the thyroid with an extra fifth gland being present in around

10% of the population. PTH acts on the renal tubular transport of calcium and phosphate, and also stimulates the renal synthesis of 1,25-dihydroxycholecalciferol. Low levels of ionised (unbound) calcium stimulate PTH secretion, whereas high levels suppress its secretion.

PTH increases distal tubular reabsorption of calcium and decreases proximal and distal tubular reabsorption of phosphate. The effects of PTH on bone are complex. The two major cell types in bone are osteoblasts and osteoclasts. Osteoblasts are responsible for the synthesis of extracellular bone matrix and priming of its subsequent mineralisation. Osteoclasts decalcify and digest the protein matrix of bone, liberating calcium. PTH stimulates osteoclast-mediated bone resorption, but in addition has an anabolic effect on bone, with an increase in osteoblast number and function.

Vitamin D (calciferol) can either be derived from plant sources (vitamin D₂ or ergocalciferol) or animal sources (vitamin D₃ or cholecalciferol), or produced in epidermis of skin from cholesterol precursors. Vitamin D₃ needs hydroxylation in liver and kidney to get converted into the biologically active form 1,25-dihydroxycholecalciferol. Vitamin D increases calcium as well as phosphate absorption from the gastro-intestinal tract and influences PTH-mediated reabsorption of calcium from renal tubules.

Hypoparathyroidism/hypocalcaemia

Hypoparathyroidism is the clinical state which may arise either from failure of the parathyroid glands to secrete PTH, or from failure of its action at the tissue level.

Aetiology

Hypoparathyroidism most commonly occurs as a result of surgery for thyroid disease or after neck exploration and resection of adenoma-causing hyperparathyroidism. In experienced hands, the incidence of permanent hypoparathyroidism is less than 1% for all thyroid and parathyroid surgery. Other causes include autoimmune parathyroid destruction either as an isolated idiopathic disorder or as part of a multiple endocrine deficiency characterised by hyposecretion of several endocrine glands. Transient hypoparathyroidism with symptomatic hypocalcaemia can occur in neonates. The condition pseudohypoparathyroidism occurs in patients with defects of the PTH receptor such that although PTH levels are normal (or raised), calcium is low. Increasingly reports are identifying acute symptomatic hypocalcaemia and hypomagnesaemia complicating the use of omeprazole and other PPIs. These patients are severely magnesium depleted and have an acquired hypoparathyroidism which is reversible on stopping the offending drug (Cundy and Dissanayake, 2008).

Clinical manifestations

Most of the clinical features of hypoparathyroidism are due to hypocalcaemia. The decrease in ionised plasma calcium levels leads to increased neuromuscular excitability. The major signs and symptoms are shown in [Box 44.6](#).

Box 44.6 Signs and symptoms of hypocalcaemia

Numbness and tingling in the extremities and around the mouth
Muscle spasm (tetany)
Epilepsy
Irritability
Cataracts (prolonged hypocalcaemia)
Chvostek's sign (facial spasm on tapping the seventh cranial nerve)
Trousseau's sign (spasm of hand when blood pressure cuff inflated above systolic pressure)

Box 44.7 Causes of hypocalcaemia

- Hypoparathyroidism
- Pseudohypoparathyroidism
- Vitamin D deficiency/malabsorption/insensitivity
- Acute and chronic renal failure
- Chronic alcoholism
- Hypomagnesaemia
- Drug induced (proton pump inhibitors)
- Acute pancreatitis

Investigations

Hypocalcaemia associated with undetectable or low plasma PTH levels is consistent with hypoparathyroidism. Total plasma calcium levels should always be corrected for any abnormality in the plasma albumin concentration using the following equation:

$$\text{corrected calcium} = \text{measured calcium} + (0.02 \times [40 - \text{plasma albumin}])$$

Hyperphosphataemia is often present. It should be noted that there are many other causes of hypocalcaemia ([Box 44.7](#)). Pseudohypoparathyroidism is easily distinguished because it is associated with excessive PTH secretion and reduced target organ responsiveness. Drugs that may produce hypocalcaemia include calcitonin, phosphate, bisphosphonates, phenytoin, phenobarbital, cholestyramine, cisplatin, 5-fluorouracil and high-dose intravenous citrate or lactate.

Treatment

Severe, acute hypocalcaemia with tetany should be treated with intravenous calcium gluconate. Initially, 10 mL of 10% calcium gluconate is given by slow intravenous injection, preferably with electrocardiographic monitoring. If the patient can swallow, oral therapy should then be commenced. If further parenteral therapy is required, 20 mL of 10% injection should be added to each 500 mL of intravenous fluid and given over 6 hours. The plasma magnesium level should always be measured in patients with hypocalcaemia and if low, magnesium therapy instituted.

For chronic treatment, PTH therapy is not currently a practical option because the hormone (recombinant human PTH) has to be administered parenterally, and the current high cost is prohibitive. Maintenance treatment for hypoparathyroidism is easily achieved with a vitamin D preparation to increase intestinal calcium absorption,

often in conjunction with calcium supplementation. Many preparations, in a variety of formulations, are available including tablets, capsules, oral drops and injections. Ergocalciferol (vitamin D₂) is difficult to use and is not recommended. It has a long pharmacological and biological half-life, takes 4–8 weeks to restore normocalcaemia and its effects can persist for up to 4 months following withdrawal. In contrast, calcitriol and its synthetic analogue alfacalcidol are much easier to use. Alfacalcidol restores normocalcaemia within 1 week and its effects persist for only 1 week following withdrawal, permitting greater flexibility in dosage manipulation. The usual daily dose is 0.5–1 micrograms. Patients need close monitoring initially until stable normocalcaemia is achieved and thereafter at a minimum of 6-monthly intervals indefinitely.

Hyperparathyroidism

Hyperparathyroidism occurs when there is increased production of PTH by the parathyroid gland. Primary hyperparathyroidism causes hypercalcaemia. Secondary hyperparathyroidism reflects a physiological response to hypocalcaemia or hyperphosphataemia.

Epidemiology

Recent studies in the USA and Europe indicate an incidence rate for primary hyperparathyroidism of 25 cases per 100,000 of the population per year. The incidence is two to three times higher in women than in men, and the disease most commonly presents between the third and fifth decades of life.

Aetiology

Primary hyperparathyroidism is due to the development of either single parathyroid adenomas or rarely (<5%) hyperplasia of all four glands. It may occur as part of the dominantly inherited multiple endocrine neoplasia syndromes.

Several conditions are associated with secondary hyperparathyroidism, including chronic renal failure and vitamin D deficiency. Chronic renal failure is the commonest cause. In the early stages of the disease a rise in the plasma phosphate concentration causes stimulation of PTH release, and in more advanced renal impairment reduced 1 α -hydroxylation of vitamin D results in reduced intestinal calcium absorption, hypocalcaemia and further stimulation of the parathyroid glands. Tertiary hyperparathyroidism occurs in a minority of patients with end-stage renal disease, when hyperplastic parathyroid glands become autonomous and secrete PTH in levels that raise calcium levels above normal.

Clinical manifestations

The clinical features of primary hyperparathyroidism are shown in [Box 44.8](#). These are related to the effects of hypercalcaemia itself, plus the effects of mobilisation of calcium from the skeleton and excretion in the urine. With increasingly early recognition of the biochemical abnormalities of primary hyperparathyroidism largely due to automated measurement of plasma calcium, most patients are identified at an early stage with mild or asymptomatic disease. The classical presenting features of bone disease and renal stones are now relatively uncommon. Although radiological evidence of

Box 44.8 Signs and symptoms in hyperparathyroidism

- Anorexia, weight loss
- Polydipsia, polyuria
- Mental changes: poor concentration and memory
- Fatigue
- Nausea, dyspepsia and vomiting
- Constipation
- Hypertension
- Renal stones
- Conjunctival and corneal deposits
- Bone pain and deformity
- Pathological fractures

bone disease is now rare in these patients, measurement of bone mineral content by densitometry (dual-energy X-ray absorptiometry) scanning usually indicates that bone loss is accelerated, and the risk of osteoporotic fractures later in life is increased.

Investigations

Hypercalcaemia is the primary biochemical abnormality in primary hyperparathyroidism. Phosphate levels are often decreased and PTH levels are either inappropriately normal in the face of hypercalcaemia or elevated. In a patient with borderline elevation of calcium and a normal or only marginally elevated PTH, the benign condition familial hypocalcaemic hypercalcaemia must be excluded. Urine calcium excretion is increased in primary hyperparathyroidism and low in familial hypocalcaemic hypercalcaemia.

There are many other causes of hypercalcaemia, including malignancy (including myeloma), drugs (thiazides, excess vitamin D), thyrotoxicosis, immobilisation and sarcoidosis. In all these situations PTH levels are undetectable because the normal parathyroid glands appropriately switch off production of PTH in the face of hypercalcaemia. The most common cause of symptomatic hypercalcaemia in clinical practice is that associated with malignancy, and this diagnosis must always be excluded.

Localisation of parathyroid tumours is required only in those listed for neck exploration. Most parathyroid surgeons request a neck ultrasound prior to performing a neck exploration. Isotope scanning (technetium-99m sestamibi scan), computed tomography, magnetic resonance imaging and selective venous sampling are reserved for those patients (around 1% in experienced hands) in whom the adenoma cannot be located at the first operation.

Treatment

Surgical removal of the adenoma or removal of all hyperplastic tissue is the only curative treatment for primary hyperparathyroidism; however, the natural history of hyperparathyroidism is not fully documented. Some studies have indicated that more than 50% of untreated patients with primary hyperparathyroidism show no deterioration over 5 years, but the longer-term effects on renal function and bone mass remain unknown. In practice many patients are observed and their specific problems separately addressed. [Tables 44.6 and 44.7](#) list current recommendations for initial evaluation and monitoring of patients with primary asymptomatic hyperparathyroidism, respectively. 25-Hydroxyvitamin

Table 44.6 Initial evaluation of patients with primary hyperparathyroidism

Investigation	Parameter
Blood test	Corrected calcium Phosphate Alkaline phosphatase Creatinine and urea 25 hydroxyvitamin D PTH
Urine test	urinary calcium/creatinine excretion or 24 h urinary calcium
Bone mineral density	DXA scan
Radiology	Abdominal X-ray or ultrasound renal tract

PTH, parathyroid hormone; DXA, dual energy X-ray absorptiometry.

Table 44.7 Monitoring of patients with primary hyperparathyroidism managed medically

Measurement	Recommendation
Bone mineral density	DXA scan every 1-2 years
Serum calcium	Annually
Renal function	eGFR and serum creatinine annually

DXA, dual energy X-ray absorptiometry; eGFR, estimated glomerular filtration rate.

D replacement therapy is recommended in patients with primary hyperparathyroidism having co-existent vitamin D deficiency to maintain levels greater than 50 nmol/L. Bisphosphonate therapy (weekly alendronic acid or monthly zoledronic acid) should be prescribed in patients with primary hyperparathyroidism deemed unsuitable for elective parathyroidectomy who have evidence of osteoporosis on dual-energy X-ray absorptiometry scan (Bilezikian et al., 2014).

The main indications for surgical treatment are persistent hypercalcaemia greater than 2.85 mmol/L, symptomatic hypercalcaemia, renal impairment, renal stones and progression of osteoporosis (Table 44.8). Postoperatively temporary hypocalcaemia (“hungry bones”) is common. In patients with bone disease, treatment with alfacalcidol and calcium supplements should be started on the day before the operation. Approximately 10% of surgically treated patients experience permanent hyperparathyroidism.

Treatment of hypercalcaemia

Severe hypercalcaemia is a common medical emergency. It must be corrected whilst investigation continues to identify

Table 44.8 Guidelines for surgery in patients with primary hyperparathyroidism

Measurement	Recommended cutoff for surgery
Age	<65 years
Bone mineral density	1. T score <−2.5 at lumbar spine, total hip, femoral neck and distal one-third radius 2. Radiological evidence of vertebral fracture
Renal function	1. Creatinine clearance <60 mL/min 2. 24 h urinary Ca >400 mg 3. Radiological evidence of nephrocalcinosis or nephrolithiasis
Serum calcium	>2.85 mmol/L
Dialysis	

Table 44.9 Treatment of hypercalcaemia

Mechanism	Treatment
Increase urinary calcium excretion	Normal saline plus loop diuretic
Reduce bone resorption	Bisphosphonates Calcitonin Gallium, mithramycin
Reduce gastro-intestinal absorption	Glucocorticoids if calcitriol dependent (vitamin D excess, sarcoid and some lymphoma patients)
Chelation Dialysis	Intravenous ethylenediaminetetraacetic acid or phosphate

the cause. Table 44.9 lists the available treatments. In practice rehydration and parenteral bisphosphonates (e.g. pamidronate 60–90 mg in 250 mL of normal saline over 60–90 minutes) will normalise calcium over 72 hours in most patients.

Case studies

Case 44.1

Mrs AD, a 38-year-old woman with known primary hypothyroidism, was reviewed in the endocrine clinic because of persistently elevated TSH levels of 24.5 mIU/L (0.4–4.5 mIU/L) despite being prescribed a high dosage of levothyroxine (350 micrograms/day) therapy. She was diagnosed to have primary autoimmune hypothyroidism around 3 years ago, although TSH levels were never well controlled despite gradual increase in her levothyroxine dose. She had not noticed any alteration in bowel habits and reported having normal appetite. Mrs AD denied poor adherence with levothyroxine tablets and was not taking any other medications.

On examination, she had a pulse rate of 58 beats/min, dry skin and non-pitting oedema at ankles. Her routine blood tests including full blood count, renal and liver function, and bone profile were within normal range.

Questions

1. What is the most likely cause of Mrs AD's persistently elevated TSH levels?
2. How would you investigate and manage her further?

Answers

1. Poor adherence with prescribed levothyroxine therapy remains the most common cause of persistently elevated TSH levels in a patient with primary hypothyroidism in clinical practice. The mean dosage of oral levothyroxine therapy most patients require is 1.6–1.8 micrograms/kg/day. Most patients respond well to this dose. Apart from poor adherence, one needs to consider malabsorption and drug-related interference with levothyroxine absorption if TSH levels remain persistently elevated despite optimum levothyroxine dose.
2. A careful history should focus on intake of over-the-counter medications such as antacids, calcium supplements, iron tablets and herbal remedies which can potentially interfere with absorption of levothyroxine therapy. Patient should be evaluated for malabsorption-related syndromes such as coeliac disease, and anti-tissue transglutaminase antibodies should be measured if indicated. Because poor adherence remains one of the most common causes of persistently elevated TSH levels in patients with hypothyroidism, once-weekly supervised levothyroxine therapy remains a useful strategy to treat such patients. Levothyroxine has an elimination half-life of around 7 days with a single dose up to 3 mg being well tolerated. The weekly supervised levothyroxine therapy is an efficacious, as well as safe, way to treat patients with non-adherence with therapy in primary care.

Stepwise approach to manage patients with hypothyroidism with persistently elevated TSH

Step 1: Confirm the diagnosis.

Repeat the blood test; exclude assay interference due to presence of heterophile antibodies. If free T_4 and free T_3 levels are normal in the presence of elevated TSH, consider TSH-secreting tumour or thyroid hormone resistance, although these are quite rare.

Step 2: Take medication history.

Check the patient's prescription and enquire about over-the-counter medication intake.

Step 3: Perform clinical evaluation.

Assess clinically for malabsorption syndromes such as coeliac disease and short bowel syndromes, and investigate accordingly.

Step 4: Assess adherence.

Evaluate adherence with the prescribed levothyroxine tablets because this remains the most common reason for persistently elevated TSH levels in clinical practice. Box 44.9 shows the possible causes of persistently elevated TSH levels in patients with hypothyroidism despite thyroxine therapy.

Case 44.2

Mrs NR, a 43-year-old school teacher, presented to her primary care doctor with ongoing symptoms of lethargy and gradual weight gain. On examination she had a body mass index of 30 kg/m². Her pulse rate was 68 beats/min; general physical, as well

Box 44.9 Causes of persistently elevated thyroidstimulating hormone (TSH) levels in patients with hypothyroidism

Impaired absorption

- Malabsorption syndromes
- Proton pump inhibitors
- Iron and/or calcium tablets
- Antacids
- Herbal remedies

Increased metabolism

- Barbiturates
- Carbamazepine
- Phenytoin
- Rifampicin
- Tyrosine kinase inhibitors, e.g. sunitinib

Increased demand

- Weight gain
- Pregnancy

Other causes

- Poor adherence (commonest cause)
- Nephrotic syndrome (rare)

as systemic, examination was unremarkable. Her investigations showed a free T_4 of 11.8 pmol/L (10–25 pmol/L) and TSH of 5.9 mIU/L (0.4–4.5 mIU/L).

Questions

1. What is the likely diagnosis?
2. How would you like to investigate and manage Mrs NR further?

Answers

1. Mrs NR has primary subclinical hypothyroidism which is estimated to have a prevalence rate of 3–8% in the general population. The hypothalamic-pituitary-thyroid axis is extremely sensitive to even minor changes in thyroid hormone with a twofold change in free T_4 levels associated with 100-fold change in TSH levels. Gender, ethnic origin and body mass index also influence TSH values. The TSH levels also show an increase with age with values of 6–7 mIU/L considered normal at age of 70 years.
2. The first step is to confirm the diagnosis and exclude possibility of assay interference, silent thyroiditis and recovery from non-thyroidal illness by repeating the TFTs in 6–12 weeks. Measurement of anti-TPO antibodies can help predict development of overt hypothyroidism in the near future (estimated 4.3% risk of development of overt hypothyroidism if TPO antibodies are positive). Subclinical hypothyroidism is further subdivided into two categories based on TSH levels: (1) TSH >10 mIU/L and (2) TSH of 4.5–10 mIU/L. A therapeutic trial of levothyroxine can be considered in patients with TSH > 10 mIU/L (Pearce et al., 2013), although if the TSH levels are 4.5–10 mIU/L, levothyroxine therapy should be considered in the following cases:
 - history of infertility or miscarriages,
 - younger patients with increased risk of development of cardiovascular disease,
 - presence of goitre,
 - history of bipolar disease,
 - patient preference as a therapeutic trial.

Case 44.3

Mr RK, a 71-year-old man, was incidentally detected to have TSH <0.01 mIU/L (0.4–4.5 mIU/L) and FT₄ of 14.4 pmol/L (10–25 pmol/L) on routine blood tests done on an annual follow-up. He had a background history of type 2 diabetes mellitus and hypertension. He had no family history of thyroid dysfunction. On examination his pulse rate was 76 beats/min with regular rhythm. His general physical and systemic examination was unremarkable with no visible or palpable goitre.

Questions

1. What is the most likely diagnosis?
2. How would you like to investigate and manage Mr RK further?

Answers

1. Mr RK has subclinical hyperthyroidism (SHyper) which is estimated to have a prevalence rate of 0.6–16% of population based on age, TSH assay used and iodine intake. Solitary toxic adenoma, multinodular goitre and Graves' disease remain the commonest aetiologies leading to SHyper, with the first two being relatively more common in the elderly population as compared with Graves' disease which predominantly is seen in younger patients (more common in women as compared with men).

2. The management approach for a patient with suspected SHyper should include the following steps:

Step 1: Confirm the diagnosis.

Repeat the TFTs after 1–3 months in asymptomatic patients with no risk factors for ischaemic heart disease (IHD) or atrial fibrillation. In patients with symptoms (palpitations, weight loss, tremors, increased sweating, etc.) and/or presence of risk factors for IHD, the TFTs should be repeated within 2 weeks.

Step 2: Evaluate the severity.

Biochemically: SHyper can be subdivided into two categories, grade 1 (TSH 0.1–0.4 mIU/L) and grade 2 (TSH <0.1 mIU/L).

Clinically: Patients with SHyper are considered to be high risk if:

- aged >65 years;
- presence of hyperthyroidism related symptoms;
- presence of comorbidities such as arrhythmias, heart disease and osteoporosis.

Step 3: Establish the aetiology.

Toxic solitary thyroid adenoma, multinodular goitre, viral thyroiditis and Graves' disease are the commonest aetiologies leading to SHyper. Iatrogenic hyperthyroidism can be seen in patients receiving levothyroxine, amiodarone, lithium, corticosteroids, alemtuzumab (used in the treatment of multiple sclerosis) and interferon therapy.

Step 4: Assess for complications.

Atrial tachycardia, atrial fibrillation, heart failure and osteoporosis are associated with untreated severe SHyper.

Step 5: Initiate appropriate treatment.

Treatment is indicated in high-risk patients with SHyper who have persistent grade 2 disease (TSH <0.1 mIU/L), with RIA therapy being the modality of choice (Biondi et al., 2015). Patients who are deemed unsuitable or refuse RIA therapy can be managed with low-dose thionamide therapy (preferably carbimazole because of better tolerability and fewer side effects as compared with propylthiouracil).

In contrast, the treatment of subclinical hypothyroidism in patients with TSH 4.5–10 mIU/L has limited benefits.

Case 44.4

Mrs. GE, a 78-year-old woman, was incidentally detected to have elevated calcium levels of 2.82 mmol/L (2.2–2.6 mmol/L) on routine blood tests. She has a background history of hypertension, osteoarthritis and chronic obstructive pulmonary disease. She was receiving amlodipine, ramipril and long-acting β -agonist inhaler therapy. Her mobility is limited because of breathing difficulties, and she mostly is confined indoors. Her subsequent investigations showed:

PTH	7.8 pmol/L (1.5–6.5 pmol/L)
Estimated glomerular filtration rate	65 mL/min per 1.73 m ²
25-Hydroxyvitamin D	14 nmol/L (>50 nmol/L)
Bone mineral density scan	Severe osteoporosis

Questions

1. What is Mrs GE's likely diagnosis?
2. What is the definitive treatment for Mrs GE's underlying condition, and when should it be considered?
3. What other treatment options are available?

Answers

1. Mrs GE has elevated calcium and PTH levels suggestive of underlying primary hyperparathyroidism. It is a relatively common condition with prevalence of around 4/1000 women older than 60 years. The majority of patients with primary hyperparathyroidism may be asymptomatic, although it can lead to increased bone resorption leading to osteoporosis. Increased calcium may predispose to renal stone formation (mostly calcium oxalate stones) and contribute to gradual decline in renal function.

2. The definitive therapy for primary hyperparathyroidism includes an elective removal of the parathyroid gland after localising the gland using radiological investigations such as sestimibi scan. The 2014 consensus guidelines for elective parathyroidectomy include the presence of one or more of the following (Marcocci et al., 2014):

- calcium >2.85 mg/dL,
- decline in estimated glomerular filtration rate <60 mL/min,
- age <50 years,
- osteoporosis,
- calcium excretion over 24 hours >400 mg.

Elective parathyroidectomy is also recommended in patients with primary hyperparathyroidism who are deemed unsuitable for medical surveillance or who wish to opt for surgical treatment (in the absence of any medical contraindication for surgery).

3. Mrs GE is frail and elderly with multiple comorbidities; as a result, elective parathyroidectomy may not be a feasible option in her case. She can be managed conservatively by giving her bisphosphonates for osteoporosis and vitamin D supplements for her co-existent vitamin D deficiency. Her calcium levels can be lowered by using calcimimetic agents such as cinacalcet. Cinacalcet is a calcimimetic agent which acts as an allosteric modulator of calcium-sensing receptors which reduces the PTH secretion resulting in lowering of serum calcium levels. The calcium-sensing receptors are trans-membrane G-protein-coupled receptors present in parathyroid gland, bone, intestine, kidneys and vascular endothelium. These play a key role in regulation of serum calcium concentration. Cinacalcet use was approved by the European Medicine Agency in June 2008 for treatment of patients with primary hypercalcaemia who are deemed unsuitable for surgery. Cinacalcet tablet is usually initiated orally at a

dosage of 30 mg twice a day with the titration of the dose (every 2–4 weeks) based on serum calcium levels (maximum dose 90 mg four times a day). It is contraindicated in patients younger than 18 years, during pregnancy and in patients with hypocalcaemia; cautious use is suggested in epilepsy, heart and liver failure. Cinacalcet has been shown to be an efficacious agent in reducing serum calcium concentration, although it has modest impact on lowering PTH levels (Khan et al., 2015). It has also been shown to have no significant effect on bone density.

Cinacalcet along with low-dose vitamin D has been shown to attenuate vascular and cardiac valve calcification in patients with secondary hyperparathyroidism with chronic kidney disease stage 5 who were undergoing haemodialysis (Raggi et al., 2011). Cinacalcet use in patients with secondary hyperparathyroidism due to renal failure who were undergoing haemodialysis was not associated with reduced risk of cardiovascular death or non-fatal myocardial infarction. Although after adjustment to baseline characteristics were made in intention-to-treat analysis, a 12% reduction in risk of cardiovascular death or non-fatal myocardial infarction in patients receiving cinacalcet therapy was noticed. There was also a 50% reduction in need for elective parathyroidectomy in the group of patients receiving cinacalcet therapy (Chertow et al., 2012).

Case 44.5

Mr ML, a 38-year-old man, was admitted to a medical assessment unit at the hospital with weakness and cramps in the hands. He had a background history of gastro-oesophageal reflux disease and had been taking omeprazole (40 mg once a day) intermittently for the last 3 years.

On examination he had evidence of carpedal spasm and paraesthesia on face.

Investigations showed serum calcium level of 1.92 mmol/L (2.2–2.6 mmol/L) and serum magnesium level of 0.35 mmol/L (0.7–1.2 mmol/L).

Questions

1. What is the likely diagnosis?
2. How should Mr ML be managed?

Answers

1. The most likely diagnosis in this patient is PPI-induced hypomagnesaemia and hypocalcaemia. This was first reported by Epstein et al. (2006), who described two patients receiving PPI therapy presenting with symptomatic hypocalcaemia and hypomagnesaemia that resolved on stopping PPI therapy. Since then multiple case reports and observational studies have been published suggestive of chronic PPI use predisposing to low magnesium and associated symptoms which may include arrhythmias, tetany and seizures. The exact mechanism leading to PPI-induced hypomagnesaemia is yet to be established, although it is believed to be linked to reduced absorption of magnesium from the gastrointestinal tract.
2. The PPI therapy needs to be stopped and substituted with a H₂ receptor antagonist such as ranitidine. The patient needs to be given a magnesium replacement (oral or intravenous depending upon symptoms and severity of hypomagnesaemia). Hypomagnesaemia needs to be corrected before hypocalcaemia because low magnesium levels render hypocalcaemia refractory

to calcium replacement. Because there is widespread use of PPIs, apart from non-specific signs and symptoms associated with hypomagnesaemia, as well as hypocalcaemia, a high index of suspicion is required to diagnose these potentially life-threatening electrolyte abnormalities in patients receiving long-term PPI therapy.

Case 44.6

Mr. GD, a 55-year-old man of South East Asian origin, presented to his primary care doctor with generalised aches and pains. He had background history of dyslipidaemia and was receiving atorvastatin therapy. His subsequent blood tests showed:

25-Hydroxyvitamin D	15 nmol/L (<50 nmol/L)
Calcium	2.25 mmol/L (2.2–2.6 mmol/L)
Renal function	Normal
PTH	10.3 pmol/L (1.5–6.5 pmol/L)

Questions

1. What is the likely diagnosis?
2. What further treatment should Mr GD receive?

Answers

1. Mr GD has secondary hyperparathyroidism caused by vitamin D deficiency. Vitamin D deficiency is believed to have a prevalence rate varying from 15% to 25% of the population and is more common in elderly people living in nursing or residential homes, pregnant or breastfeeding women and individuals with low or no exposure to the sun. Vitamin D deficiency is also common in individuals of Afro-Caribbean and South East Asian ethnic origin because pigmented skin hampers sunlight-mediated conversion of cholesterol precursors to vitamin D in deeper layers of the epidermis. Vitamin D deficiency has been associated with increased risk of falls and osteoporosis in the elderly population. It has been linked with conditions such as multiple sclerosis, tuberculosis, bronchial asthma and diabetes, although the evidence linking it with these disorders is inconclusive.
2. According to National Osteoporosis Society guidelines (Francis et al., 2013), patients with serum 25-hydroxy vitamin D levels less than 30 nmol/L are considered to be vitamin D deficient, whereas levels of 30–50 nmol/L may be inadequate in some individuals. Oral vitamin D3 remains the treatment of choice in vitamin D deficiency. In patients with symptomatic disease, a loading regimen comprising 300,000 IU vitamin D (given as parenteral weekly or oral daily doses) is recommended. Subsequently, patients can be switched to maintenance dose comprising 800–2000 IU/day vitamin D. The maintenance doses are often continued lifelong. Serum calcium levels should be assessed 1 month after initiation of loading regimen or after initiation of maintenance therapy. Once a patient is receiving vitamin D replacement therapy, repeat routine monitoring of PTH levels is not indicated. Vitamin D toxicity is seen only occasionally in patients who are erroneously taking much higher than the recommended dose (>50,000 IU/day taken for several weeks to months), and doses less than 10,000 IU/day are generally considered to be safe.

45 Diabetes Mellitus

Sallianne Kavanagh and Jackie Elliott

Key points

- Diabetes is one of the most common chronic diseases in the UK, with an estimated 3.2 million individuals diagnosed in the UK, equivalent to more than 4% of the population.
- Up to 15–20% of hospital in-patients will have diabetes.
- The number of people with diabetes increased by 53% between 2006 and 2013.
- The life expectancy of a person with diabetes is shortened by approximately 15 years.
- Macrovascular complications are the cause of 75% of diabetes-related deaths.
- The cost of treating diabetes and its related complications is around £9 billion, equating to 10% of the total National Health Service (NHS) budget.
- Effective control of diabetes (glycaemic levels, blood pressure, dyslipidaemia) reduces the risk of developing long-term complications and saves both lives and money.
- Extreme hyperglycaemia and hypoglycaemia may lead to diabetic emergencies, both of which carry risks for morbidity and mortality.
- Dietary modifications and oral medicines may maintain adequate glycaemic control in type 2 diabetes, but in time, many patients will eventually require insulin.
- There is a wide variety of insulins and other medication classes, allowing regimens to be tailored to individual need.

Diabetes is one of the largest global health emergencies of the 21st century. Each year, more and more people are living with the condition, which leads to significant morbidity and mortality. Worldwide estimates are that 415 million adults have diabetes, with a further 318 million with impaired glucose tolerance and thus at high risk of developing the disease in the future ([International Diabetes Federation, 2015](#)).

Introduction

Diabetes mellitus is the most common of the endocrine disorders. It is a chronic metabolic condition, characterised by hyperglycaemia due to impaired insulin production and secretion with or without insulin resistance. Diabetes mellitus may be classified according to aetiology, by far the most common types being type 1 and type 2 diabetes ([Box 45.1](#)). In 2013, more than 3.2 million

adults in the UK had a diagnosis of diabetes, with a prevalence of 6% and 6.7% in England and Wales, respectively. In 2014 the global prevalence of diabetes in adults was estimated to be 9%, and it is estimated that by 2030, diabetes will be the seventh leading cause of death ([Mathers and Loncar, 2006](#)).

Type 1 diabetes is a disease characterised by the destruction of the insulin-producing pancreatic β -cells. In more than 90% of cases, β -cell destruction is associated with autoimmune disease. Type 1 diabetes usually develops in children or young adults, although it can develop at any age and is associated with a faster onset of symptoms, leading to dependency on extrinsic insulin for survival.

Type 2 diabetes is more common and traditionally occurs in adults older than 40 years, with a peak onset between 60 and 70 years of age in developed countries. Regrettably, it is being increasingly seen in younger people, including adolescents and children. The prevalence of type 2 diabetes varies widely in different populations, being six times more common in those of South Asian origin compared with those of Northern European origin. It is caused by a relative insulin deficiency and the body's inability to effectively use insulin. The pancreas is able to produce some insulin; however, as insulin resistance increases, the effectiveness of circulating insulin decreases, and the amount produced is not sufficient to meet the body's requirements. Symptoms are generally slower in onset and less marked than those of type 1. Type 2 diabetes may be undiagnosed for many years, and during this period, the excessive glucose levels may lead to complications such as cardiovascular disease. Type 2 disease often progresses to the extent that extrinsic insulin is required to maintain blood glucose levels. The differences between type 1 and type 2 diabetes are highlighted in [Table 45.1](#). Sometimes the type of diabetes is not clear, and additional tests are required to try to establish the correct diagnosis. However, there may be uncertainty even after further testing, so it is predominantly the degree of metabolic abnormality that is the key determinant of the form of treatment.

In high-income countries, one in seven births is affected by gestational diabetes. Gestational diabetes is hyperglycaemia that is first detected during pregnancy. Overt symptoms of hyperglycaemia are difficult to distinguish from normal symptoms of pregnancy; consequently, screening is performed in high-risk individuals. The risk of gestational diabetes should be assessed during early pregnancy for women with a body mass index (BMI) greater than 30 kg/m², a previous macrosomic baby weighing 4.5 kg or greater, previous gestational diabetes, family

Box 45.1 Aetiological classification of diabetes mellitus

Type 1

- β -Cell destruction, usually leading to absolute insulin deficiency
- Autoimmune
- Idiopathic

Type 2

- Ranges from mild to significant secretion of insulin deficiency, with or without insulin resistance

Other specific types

- Gestational diabetes
- Maturity onset diabetes of the young
- Genetic defects in β -cell function or insulin action
- Diseases of the exocrine pancreas (e.g. neoplasia, hereditary haemochromatosis, cystic fibrosis)
- Endocrinopathies (e.g. acromegaly, Cushing's)
- Drug or chemical induced (e.g. alcohol, glucocorticoid steroids, high-dose thiazides)

Table 45.1 Differences between type 1 and type 2 diabetes

Type 1 diabetes	Type 2 diabetes
Autoimmune-mediated β -cell destruction	No autoimmune-mediated β -cell destruction
Islet cell antibodies present	No islet cell antibodies present
Genetic link	Very strong genetic link
Age of onset usually younger than 30 years	Age of onset usually older than 40 years
Faster onset of symptoms	Slower onset of symptoms
Insulin must be administered	Diet control and oral hypoglycaemic agents often sufficient control
Patients usually not overweight	Patients usually overweight
Extreme hyperglycaemia causes diabetic ketoacidosis	Extreme hyperglycaemia causes hyperosmolar hyperglycaemic state

history of diabetes or minority ethnic family origin with a high prevalence of diabetes. Testing for gestational diabetes should be offered to women with any of these risk factors ([National Institute for Health and Care Excellence \[NICE\], 2015a](#)). Hyperglycaemia in pregnancy is associated with adverse outcomes, including hypertension and foetal macrosomia. Women with gestational diabetes may respond to changes in diet and exercise; however, the majority of women will need oral blood glucose lowering agents or insulin therapy. Usually, gestational diabetes resolves after birth, but these women are at greater risk of developing gestational diabetes in subsequent pregnancies and type 2 diabetes in later years. Babies born to mothers with gestational diabetes have a higher risk of developing type 2

diabetes in adolescence and early adulthood. To minimise the potential adverse outcomes for the woman and baby, the targets for blood glucose control during pregnancy are tighter than for non-pregnant women.

Two other varieties of nontypical diabetes that may be seen are latent autoimmune diabetes in adults (LADA) and maturity-onset diabetes of the young (MODY). LADA occurs in younger, leaner individuals who appear to have type 2 diabetes because they do not become ketotic, and they may manage without insulin for a time. Antigliutamic acid decarboxylase (GAD) antibodies may be present, and the individual usually progresses to insulin more rapidly than those with other varieties of type 2 diabetes. MODY was noted more than 30 years ago and described a subset of type 2 diabetes of young onset, often with a positive family history. Genetic studies have now identified this to be a monogenic autosomal-dominant form of diabetes. MODY related to a mutation in the glucokinase gene typically causes a resetting of the glucose level with a 'mild' nonprogressive hyperglycaemia in which diet treatment is usually sufficient. Other types of MODY are related to mutations in the hepatocyte nuclear factor genes and usually develop during adolescence or the third decade of life. Pharmacological treatment is required, but sulfonylureas are often extremely effective, and the need for insulin can usually be avoided.

Secondary diabetes arises due to complications of other diseases, such as diseases of the pancreas or hormone disturbances such as in Cushing's disease and acromegaly.

Epidemiology

The incidence of type 1 diabetes, whilst less common, is increasing by around 3% every year worldwide. The causality is unknown, although it is speculated that environmental changes may be causing modification to the diabetes-associated alleles. Also, since the introduction of insulin in the 1920s, an increasing number of people with type 1 diabetes have had children.

More than half a million children are estimated to be living with type 1 diabetes worldwide; however, there are major ethnic and geographical differences in the incidence. In Northern Europe, the prevalence is approximately 0.3% in those younger than 30 years; the UK is ranked fifth in rates of prevalence. Figures are highest in Caucasians, especially Scandinavians, whereas the disorder is rare in Japan and the Pacific area ([International Diabetes Federation, 2015](#)).

Type 1 diabetes may present at any age, but there is a sharp increase around the time of puberty and a decline thereafter. Approximately 50–60% of patients with type 1 will present before 20 years of age. Type 2 diabetes is much more common than type 1, accounting for approximately 90% of people with diabetes. Currently it is estimated that worldwide, 1 in 11 adults has diabetes, with an anticipated increase to 1 in 10 by 2040 ([International Diabetes Federation, 2015](#)). Estimates in the UK suggest that type 2 diabetes currently affects approximately 3.2 million adults with a confirmed diagnosis, and a further 500,000 are thought to be undiagnosed ([Diabetes UK, 2016](#)). The incidence of type 2 rises with age, increasing obesity and physical inactivity, and it is associated with hypertension and disturbed lipid profiles. As with type 1, there are major ethnic

and geographical variations. Type 2 diabetes is more common in people of African, African-Caribbean and South Asian family origin. The highest prevalence (1 in 8 adults) per capita is found in the North American and Caribbean region ([International Diabetes Federation, 2015](#)), increasing to values as high as 50% in the Pima Indians of Arizona ([Bogardus, 1993](#)). Diabetes is five times more common among Asian immigrants in the UK than in the indigenous population ([Montesi et al., 2016](#)). World studies indicate that type 2 diabetes is increasing in response to increased urbanisation and social changes; this is evident when considering the rapid economic growth and Westernisation observed in Asia, which is now emerging as an epicentre for diabetes prevalence ([Chan et al., 2009](#); [Gavin et al., 2002](#)).

Aetiology

Both genetic and environmental factors are relevant in the development of type 1 diabetes, but the exact relationship between the two is still unknown. There is a strong immunological component to type 1 and a clear association with many organ-specific autoimmune diseases. Circulating islet cell antibodies (ICAs) are present in 70–90% of those with type 1 at the time of diagnosis. Family studies have shown that the appearance of ICAs often precedes the onset of clinical diabetes by several years. However, most patients diagnosed with type 1 diabetes do not have a positive family history. Type 1 diabetes is a disease of clinically rapid onset, but the physiological development is related to slowly progressive immunological damage. However, it is not currently possible to use screening methods to reliably identify patients who will develop diabetes in the future. The final event that precipitates clinical diabetes may be caused by sudden stress, such as an infection when the mass of β -cells in the pancreas falls to less than 5–10%, but more usually is unknown.

Studies have been carried out in which patients with newly diagnosed type 1 were treated with immunosuppressive therapies such as ciclosporin, azathioprine, prednisolone and anti-thymocyte globulin. When started soon after diagnosis, these therapies showed transient improvements in clinical measures and increased the rate of remissions in which insulin was not required. However, their use is limited in an otherwise healthy and young population due to potential toxicity and the risks associated with immune suppression. Studies of potentially less toxic immunosuppressives are ongoing ([Chatenoud et al., 2012](#)).

Studies have investigated the use of anti-CD3 monoclonal antibodies. When newly diagnosed type 1 patients are treated with short courses of anti-CD3 monoclonal antibodies, smaller insulin doses are required. This relates to better preservation of β -cell function ([Herold and Taylor, 2003](#)).

Type 2 diabetes has a stronger genetic predisposition. Identical twins have a concordance rate approaching 100%, suggesting the relative importance of inheritance over environment. If a parent has type 2, the risk of a child eventually developing type 2 is 15%, increasing to 50% if both parents, compared with 2–6% for type 1 ([American Diabetes Association, 2013](#)). Type 2 diabetes occurs because of the progressive development of insulin resistance and β -cell dysfunction, the latter leading to an inability of the pancreas to produce enough insulin to overcome the insulin

resistance. About 80% of people with type 2 diabetes are obese. This highlights the clear association between type 2 and obesity, with obesity causing insulin resistance. In particular, central obesity, where adipose tissue is deposited intra-abdominally rather than subcutaneously, is associated with the highest risk. Body mass index (BMI) has been used as an indicator for predicting type 2 risk; however, it does not take fat distribution into account, so waist circumference measurements are more reliable and are now being increasingly used.

Pathophysiology

The islets of Langerhans form the endocrine component of the pancreas, constituting 1–2% of the total pancreatic mass. Insulin is synthesised in the pancreatic β -cells, initially as a polypeptide precursor, proinsulin. The latter is rapidly converted in the pancreas to proinsulin. This forms equal amounts of insulin and C-peptide through the removal of four amino acid residues. Insulin consists of 51 amino acids in two chains (the A chain contains 21 amino acids; the B chain contains 30), connected by two disulphide bridges. In the islets, insulin and C-peptide (and some proinsulin) are packaged into granules. Insulin associates spontaneously into a hexamer containing two zinc ions and one calcium ion.

Glucose is the major stimulant to insulin release. The response is triggered both by the intake of nutrients and the release of gastro-intestinal peptide hormones. After an intravenous injection of glucose, there is a biphasic insulin response. There is an initial rapid response in the first 2 minutes, followed after 5–10 minutes by a second response which is smaller but sustained over 1 hour. The initial response represents the release of stored insulin, and the second phase reflects discharge of newly synthesised insulin. Glucose is unique; other agents, including sulfonylureas, do not result in insulin biosynthesis, only release. Once released from the pancreas, insulin enters the portal circulation. The liver rapidly degrades it, and only 50% reaches the peripheral circulation. In the basal state, insulin secretion is at a rate of approximately 1 unit/h. The intake of food results in a prompt 5- to 10-fold increase in insulin release. Total daily secretion of insulin into the circulation in healthy individuals ranges from 30 to 50 units.

Insulin circulates free as a monomer, has a half-life of 3–5 minutes and is primarily metabolised by the liver and kidneys. In the kidneys, insulin is filtered by the glomeruli and reabsorbed by the tubules and degraded. In both renal and hepatic disease, there is a decrease in the rate of insulin clearance, which may necessitate dosage reduction for those using exogenous insulin. Peripheral tissues such as muscle and fat also degrade insulin, but this is of minor quantitative significance.

The interaction of insulin with the receptor on the cell surface sets off a chain of messengers within the cell. This opens up transport processes for glucose, amino acids and electrolytes.

In type 1 diabetes, there is an acute deficiency of insulin that leads to unrestrained hepatic glycogenolysis and gluconeogenesis with a consequent increase in hepatic glucose output. Also, glucose uptake is decreased in insulin-sensitive tissues such as adipose tissue and muscle; hence, hyperglycaemia ensues. Either as a result of the metabolic disturbance itself or secondary to

Fig. 45.1 Insulin–glucose relationship detailing the actions of insulin.

infection or other acute illness, there is increased secretion of the counter-regulatory hormones glucagon, cortisol, catecholamines and growth hormone. All of these will further increase hepatic glucose production (Fig. 45.1)

In type 2 diabetes, the process is usually less acute because relative insulin deficiency decreases over a sustained period of time. The initial response to hyperglycaemia is increased insulin production enabling euglycaemia. This hyperinsulinemia is able to maintain glucose levels for a period of time, but as insulin resistance increases, eventually not enough insulin can be produced, and β -cell function deteriorates, leading to a relative deficiency in insulin, and hyperglycaemia ensues. If this cycle is not interrupted, type 2 diabetes develops. Impaired glucose tolerance (IGT), impaired fasting glucose or hyperinsulinemia may be detected before overt diabetes develops, and if so, a strict diet and exercise regimen leading to weight loss and improved insulin sensitivity may delay or even prevent the onset of diabetes. At the time of diagnosis, those with type 2 diabetes may have already lost about 50% of their β -cell function. Irrespective of treatment, β -cell function continues to decline with time, often leading to the need for exogenous insulin therapy.

Type 2 diabetes is also associated with metabolic syndrome, although the relevance of this ‘syndrome’ continues to be debated in the literature (Khan et al., 2005). Metabolic syndrome is a group of risk factors commonly found in those with type 2 diabetes, including insulin resistance, glucose intolerance (type 2 diabetes or IGT), hyperinsulinemia, hypertension, dyslipidaemia, central obesity, atherosclerosis and increased levels of procoagulant factors, for example, plasminogen activator inhibitor-1 and fibrinogen.

Pathophysiology of insulin resistance

Abdominal fat is metabolically different from subcutaneous fat due to excess lipids in non-adipose tissue, which leads to cell dysfunction and death and subsequently lipotoxicity. Abdominal

fat is resistant to the antilipolytic effects of insulin, resulting in the release of excessive amounts of free fatty acids, which in turn leads to insulin resistance in the liver and muscle. The effect is an increase in gluconeogenesis in the liver and an inhibition of insulin-mediated glucose uptake in the muscle. Both of these result in increased levels of circulating glucose. Further, excess fat itself may contribute to insulin resistance because when adipocytes become too large, they are unable to store additional fat, resulting in fat storage in the muscles, liver and pancreas, causing insulin resistance in these organs.

Additionally, the excess intra-cavity adipose tissue causes the oversecretion of some cytokines (adipokines or adipocytokines) associated with inflammation, endothelial dysfunction and thrombosis. Examples of such adipokines include plasminogen activator inhibitor-1 (prothrombotic), tumour necrosis factor- α and interleukin-6 (proinflammatory) and resistin (causes insulin resistance). The atherosclerosis associated with insulin resistance is considered to be due to hypercoagulability, impaired fibrinolysis and the toxic combination of endothelial damage, caused by chronic, subclinical inflammation, oxidative stress and hyperglycaemia. Excess adipose tissue is also thought to cause undersecretion of a beneficial adipokine called adiponectin. Adiponectin suppresses the attachment of monocytes to endothelial cells, thereby protecting against vascular damage. People with type 2 diabetes have lower levels of adiponectin than those without diabetes, and weight reduction increases adiponectin levels.

Clinical manifestations

The symptoms of both type 1 and type 2 diabetes are similar, but they usually vary in intensity. Those associated with type 1 diabetes are more severe and faster in onset. The symptoms are related to the osmotic effects of glucose and the abnormalities of energy partitioning. Common symptoms include polyuria and polydipsia, accompanied by fatigue due to an inability to utilise

glucose and marked weight loss because of dehydration, and the breakdown of body protein and fat as an alternative energy source to glucose. Blurred vision caused by a change in lens refraction often occurs, and patients should be advised that as glucose levels are normalised, vision normally improves, and new spectacles should be avoided for the first 3 months until effective hyperglycaemia treatment is established. Patients may also experience higher infection rates, especially *Candida*, skin and urinary tract infections.

Type 1 diabetes

The metabolic abnormalities at presentation of an individual with type 1 diabetes are often profound. The symptoms mentioned earlier are usually extreme and of recent (days or weeks) onset. In a significant proportion, the presenting symptoms are those of diabetic ketoacidosis (DKA): nausea, vomiting, abdominal pain, dehydration, and shortness of breath (secondary to an attempt by the respiratory system to compensate for the metabolic acidosis caused by ketones) and, in extreme cases, coma. Without prompt treatment, DKA can be fatal.

Type 2 diabetes

Many patients with type 2 diabetes have an insidious onset of hyperglycaemia, with few or no classic symptoms. This is particularly true in obese individuals, whose diabetes may be detected only after glycosuria or hyperglycaemia is found during routine investigations or when they seek medical help for a problem they were unaware is a recognised complication of diabetes. Some patients are unaware of the disease even with marked classic symptoms because they begin so gradually and over such a long period of time. Recurring infections (e.g. urinary tract, chest, soft tissue) are common because sustained hyperglycaemia can result in severe impairment of phagocyte function, and raised glucose levels provide a growth medium for bacteria.

Generalised pruritus and symptoms of vaginitis, which may be due to candidal infection, are frequently the initial complaints of women with type 2 diabetes. Patients often present when the complications of sustained hyperglycaemia have already developed, for example, cardiovascular disease or renal disease. Retinopathy may be detected on routine ophthalmological examination. Alternatively, a combination of neuropathy, peripheral vascular disease (PVD) and infection may manifest as foot ulceration or gangrene. In some cases, patients present with hyperosmolar hyperglycaemic state (HHS), where glucose levels in excess of 35 mmol/L are found and excessive dehydration has occurred. Occasionally, patients with type 2 diabetes present with diabetic ketoacidosis, especially in severe infection or in those of African/Caribbean descent.

Diagnosis

In 2006 the World Health Organization (WHO, 2006) recommended that a glycated haemoglobin (HbA_{1c}) threshold of 48 mmol/mol (6.5%) may be used to diagnose diabetes. The

current criteria have been accepted because they distinguish a group with significantly increased risk of premature mortality and increased risk of microvascular and cardiovascular complications. The UK has adopted the WHO criteria, which are based on a number of assumptions, including that normoglycaemia is a term for blood glucose levels associated with low risk of developing diabetes or cardiovascular disease, generally accepted to be blood glucose less than 6.1 mmol/L.

The use of glycated haemoglobin is not appropriate for all patient groups, including those, for example, who are suspected to have type 1 diabetes, gestational diabetes, haemoglobinopathies, anaemia, acute illnesses or with renal disease. As such, current recommendations are that the diagnosis is confirmed by a glucose measurement performed in an accredited laboratory on a venous serum sample. A diagnosis should never be made on the basis of glycosuria or a capillary reading of a finger-prick blood glucose alone, although such tests are commonly used for screening purposes. Diagnosis of type 1 diabetes is usually on clinical grounds, presence of hyperglycaemia, ketosis, rapid weight loss, younger age of onset, BMI less than 25 kg/m² and personal and/or family history of autoimmune disease. Do not discount the possible diagnosis of type 1 diabetes in patients who are older or have a raised BMI; it can occur at any age, with any BMI. A person is normally thought to have type 2 diabetes if he or she does not have type 1 diabetes, but as mentioned earlier, there are several other causes which ought to be considered (Table 45.2).

Diabetic emergencies

Hypoglycaemia and extreme hyperglycaemia, causing diabetic ketoacidosis or hyperosmolar hyperglycaemic state, constitute the three acute emergencies associated with diabetes.

Hypoglycaemia

Hypoglycaemia is the commonest side effect in the treatment of diabetes, resulting from the imbalance between glucose supply and insulin levels. It can occur both with insulin treatment and some oral agents, especially the longer-acting sulfonylureas (Table 45.3). Definitions of hypoglycaemia vary, but it is generally defined as being mild when blood glucose levels decrease and the person self-treats and as severe if intervention from a third party is required. Biochemical hypoglycaemia for hospital in-patients is specifically defined as a blood glucose less than 4.0 mmol/L. Physiologically, the defence to hypoglycaemia is the release of counter-regulatory hormones adrenaline (epinephrine), noradrenaline (norepinephrine) and glucagon. This tends to occur when the venous serum glucose drops to less than 3.5 mmol/L in healthy individuals. The symptoms people experience are non-specific and categorised as autonomic (adrenergic) symptoms and are the result of activation of the sympatho-adrenal system, whereas the neuroglycopenic symptoms are due to cerebral glucose deprivation (Table 45.4). These are a normal physiological response to hypoglycaemia and should alert the person to consume carbohydrates.

Table 45.2 Diagnostic criteria for the type 1, type 2 and gestational diabetes

Type 2 diabetes		Gestational	Type 1
Symptomatic	Asymptomatic		
A single fasting plasma glucose ≥ 7 mmol/L OR A single random plasma glucose ≥ 11.1 mmol/L	Positive results for two of the following on 2 different days: <ul style="list-style-type: none"> • A fasting glucose ≥ 7 mmol/L • A random plasma glucose ≥ 11.1 mmol/L • HbA_{1c} ≥ 48 mmol/mol OR A single random plasma glucose ≥ 11.1 mmol/L OR A fasting glucose ≥ 7 mmol/L + HbA _{1c} ≥ 48 mmol/mol	Fasting plasma glucose level of 5.6 mmol/L or greater OR A 2-h plasma glucose level of 7.8 mmol/L or greater	Based on clinical grounds Hyperglycaemia plus two out of three of: <ul style="list-style-type: none"> • Short history of symptoms • Ketones • Rapid weight loss

Table 45.3 Pharmacokinetic properties of non-insulin hypoglycaemic agents

Drug	Main elimination route	Elimination half-life (h)	Duration of action	Daily dose range	Doses per day
Sulfonylureas					
Tolbutamide	Hepatic	4–24	6–10	0.5–2 g	1–3
Chlorpropamide	Hepatic (80%) Renal (20%)	24–48	24–72	100–500 mg	1

Liraglutide	No main organ identified	13	Data not available	0.6–1.8 mg	1
Lixisenatide	Renal	3	Data not available	10–20 micrograms	1
Dulaglutide	No main organ	Depot	Depot	0.75–1.5 mg	Once weekly

GLP-1, Glucagon-like peptide 1 receptor agonist.

Table 45.4 Symptoms of hypoglycaemia

Adrenergic effects/autonomic (early symptoms) ^a	Neuroglycopenic effects (late symptoms)
Sweating	Confusion
Tachycardia	Slurred speech
Palpitations	Drowsiness
Pallor	Numbness of nose, lips or fingers
Hunger	Abnormal behaviour (anxiety, agitation, aggression)
Restlessness	Visual disturbances
Trembling	Loss of consciousness, seizures, coma and death

^aThese effects may be suppressed in people taking non-cardioselective β -blockers.

Hypoglycaemia unawareness is the term for when individuals do not counter-regulate to hypoglycaemia as effectively as normal. The reasons for the development of unawareness are multifactorial but are predominately due to a smaller counter-regulatory response with longer duration of diabetes and to

previous recurrent episodes of hypoglycaemia suppressing the counter-regulatory response. These are exacerbated by a poor understanding of hypoglycaemia and the importance of effective treatment and, indeed, the rationale for preventing hypoglycaemia. If the serum glucose falls to approximately 2.8–3.2 mmol/L, there are acute changes in cerebral function which lead initially to cognitive dysfunction and which may present as confusion. As glucose levels fall further, the person is at risk of seizures, coma and even death. In patients who can detect hypoglycaemia, the autonomic symptoms of sweating, shaking and so forth occur above the level of cerebral dysfunction, and so they are able to self-treat. However, in patients with impaired awareness of hypoglycaemia, the autonomic symptoms occur below the level of neuroglycopenic symptoms, and so patients may be very confused before any adrenergic symptoms occur, and therefore they are less likely to be able to self-treat. Thus, hypoglycaemia unawareness is associated with a much higher rate of severe hypoglycaemic episodes.

The ability to respond to the symptoms of hypoglycaemia are masked by alcohol intoxication, autonomic neuropathy and medications that suppress the autonomic nervous system. There is evidence that the symptoms can be regained if, for a period of a few weeks/months, the serum glucose level can be maintained out of the hypoglycaemic range; this can be achieved without worsening glycaemic control (De Zoysa et al., 2014).

It is imperative, therefore, that people with diabetes who are prescribed medication which is known to cause hypoglycaemia

Table 45.5 Causes of hypoglycaemia

	Lifestyle factors		Medical factors
Diet	Reduced carbohydrate intake not matched with medication adjustment, e.g. due to missed or delayed meals and snacks	Insulin-/glucose-lowering drugs	Inappropriate use of one-off and when-required insulin doses Incorrect insulin or oral secretagogue prescribed Intravenous insulin infusion prescribed without concomitant glucose Incorrect timing of medication
Age	More likely in older people and those with longer duration of disease (decreased counter-regulatory response) Signs and symptoms may be misinterpreted because of age of patient (e.g. confusion)	Problems with blood glucose monitoring	Lack of education about how to interpret and use the results Monitoring not offered
Exercise/physiotherapy	Increase levels of exercise not matched with medication or dietary adjustment Mobilisation after illness Symptoms of hypoglycaemia may be misinterpreted as symptoms of exercise (e.g. sweating, tachycardia)	Changes in health status	Recovery from acute illness or stress, often related to changes in eating habits and reduced carbohydrate intake Bariatric surgery, leading to reduced carbohydrate consumption
History of severe hypoglycaemia	Inadequate treatment of previous event	Medication interactions	Discontinuation of long-term steroids Medication may need altering/stopping, discuss with the multidisciplinary healthcare team responsible for the patient
Hypoglycaemia unawareness	Recurrent hypoglycaemia not adequately addressed in patients on insulin or a sulfonylurea	Renal impairment/hepatic impairment	Dialysis Acute kidney injury (AKI) Medication may need stopping or the dose reducing – this will depend on the level of impairment and the product licence
Periods of fasting (e.g. Ramadan)	Reduced dietary intake and changes of meal-time need to be considered in conjunction with medication timing and doses		

should be educated about the autonomic symptoms so that they may take action to avoid further decline of serum glucose and are taught how to prevent future episodes.

Causes of hypoglycaemia

Hypoglycaemia occurs when insulin levels are higher than physiologically required to maintain a normal glucose (euglycaemia). Aside from changes in medication, the most common causes of hypoglycaemia are either a decrease in carbohydrate consumption or excess glucose utilisation from unexpected physical activity (Table 45.5).

If individuals have good control of their diabetes (as measured by HbA_{1c}), it would not be surprising that they may have one or two daytime mild episodes of hypoglycaemia each week. If hypoglycaemia is occurring more often than that, then possible contributory factors need to be reviewed: inappropriate insulin regimen; too high a dose of a sulfonylurea; meal and activity patterns, including alcohol; injection techniques and skills (including insulin resuspension); injection site problems; organic causes such as gastroparesis; changes to insulin sensitivity (drugs

affecting the renin–angiotensin system, weight loss, renal impairment); and psychological problems.

Nocturnal hypoglycaemia

Sometimes, hypoglycaemia occurs during the night, which may or may not wake the person with diabetes. Not unsurprisingly, blood glucose levels are often lower than detected during daytime hypoglycaemia, as the counter-regulatory response is less marked, and a more pronounced counter-regulatory response is required to wake the individual from sleep. Symptoms may include restlessness, although this may not be identified unless observed by another person. When nocturnal hypoglycaemia occurs, the person often wakes feeling unrested, unwell or with a headache. If nocturnal hypoglycaemia is suspected, then blood glucose should be measured at night, for example, 2.00–3.00 a.m. If confirmed, the patient should either have a snack before bedtime, reduce the evening/night-time dose of insulin or alter the timing of administration of the evening dose of intermediate or long-acting insulin to delay the peak of bioavailability or change the intermediate-acting insulin to a peakless analogue as

appropriate. Nocturnal hypoglycaemia not only makes patients with diabetes feel unwell the next day but also predisposes them to further episodes of hypoglycaemia during the day; hypoglycaemia begets hypoglycaemia. If nocturnal hypoglycaemia is severe enough, there is a risk of death ('dead in bed' syndrome), but thankfully, this is rare.

Treatment of hypoglycaemia

The key to the management of hypoglycaemia is the provision of pure sources of glucose to return the blood glucose to normal. Episodes of mild hypoglycaemia can be managed by the individuals themselves; however, severe hypoglycaemia requires assistance from a third party. When treating severe hypoglycaemia, it is essential to determine the patient's level of consciousness, including whether the patient has a gag reflex and can take treatment orally. If the patient is able to swallow safely without the risk of aspiration, then glucose should be taken orally, as 15–20 g of fast-acting (absorbed) carbohydrate (5 glucose tablets, glass of Lucozade). However, if the patient is unable to swallow or if there is a risk of aspiration because of a decreased level of consciousness, parenteral treatment should be given, either as intravenous glucose or intramuscular glucagon.

In an emergency, hot drinks should be avoided because they might burn, and drinks containing milk are not suitable because the fat in milk slows down glucose absorption. Blood glucose levels should be measured about 10–15 minutes after treating hypoglycaemia. If they are less than 4 mmol/L, more glucose should be consumed.

Should parenteral treatment be required, administer approximately 25 g of intravenous glucose (10% or 20% glucose solution) or 1 mg of intramuscular glucagon. Glucagon takes approximately 10 minutes to work and may be less effective or ineffective in patients under the influence of alcohol, those taking sulfonylureas and those chronically malnourished or in a prolonged period of starvation. Only one dose is required to mobilise glycogen stores, and further doses will be ineffective until a large carbohydrate snack or meal is consumed to enable glycogen stores to be replenished.

After acute hypoglycaemia treatment, consideration should be given to the provision of a longer-acting carbohydrate snack or meal, especially if there is a likelihood of the hypoglycaemia event being prolonged (especially if long-acting insulin or sulfonylurea implicated) and investigating the underlying cause of the hypoglycaemic event. Acarbose is rarely prescribed in the UK; however, if it is administered, then monosaccharide carbohydrates must be given because disaccharides and polysaccharides will not be absorbed due to inhibition of the enzymes cleaving carbohydrate into absorbable monosaccharide units.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is a complex disordered metabolic state with three characteristic features: hyperglycaemia, metabolic acidosis and ketonaemia. Although preventable, it is associated with mortality; thankfully, the rates have fallen from 8% to 0.7% in the last 20 years (Lin et al., 2005; Wang et al., 2006). It is most often seen in patients with type 1 diabetes, as a consequence of severe

insulin deficiency, an increase in counter-regulatory hormones and the normal restraining effect of insulin on lipolysis being removed. Non-esterified fatty acids are released into the circulation and taken up by the liver, which produces acetyl coenzyme A (acetyl CoA). The capacity of the tricarboxylic acid cycle to metabolise acetyl CoA is rapidly exceeded. Ketone bodies, acetone, acetoacetate and hydroxybutyrate are formed and released into the circulation. Further, osmotic diuresis, caused by hyperglycaemia, lowers serum volume, causing hypotension and weakness, which is exacerbated by urinary excretion of potassium. Vomiting is attributable to stimulation of the vomiting centre by ketones and catabolism of muscle protein, producing further dehydration and electrolyte disturbances. As serum osmolality rises, impaired consciousness ensues, with coma developing in approximately 10% of cases. Metabolic acidosis causes stimulation of the medullary respiratory centre, giving rise to Kussmaul respiration (deep and rapid breathing) in a futile attempt to correct the acidosis. The patient's breath may have the fruity odour of acetone (ketones) commonly described as smelling like pear drops or nail varnish remover.

Precipitating factors for diabetic ketoacidosis in type 1 disease are usually omission of insulin dose, acute infection, trauma, a new diagnosis or myocardial infarction. Although diabetic ketoacidosis is normally associated with type 1 diabetes, it may rarely occur in people with type 2.

Diagnosis of diabetic ketoacidosis

Diagnosis requires demonstration of hyperglycaemia, metabolic acidosis and the presence of ketones. The biochemical diagnosis of ketoacidosis is usually made when a blood glucose level of more than 11 mmol/L, capillary ketones greater than 3 mmol/L or urinary ketones ++ or more and venous pH less than 7.3 and/or bicarbonate less than 15 mmol/L. Two potentially misleading laboratory results are the white blood cell count and serum sodium. The former will often be raised but correlates with the ketone body level and is not, therefore, a guide to infection. The serum sodium level will often be low due to the osmotic effect of glucose draining water from cells and diluting sodium. The sodium concentration will also be spuriously low if there is marked dyslipidaemia.

Treatment of diabetic ketoacidosis

The treatment goals are prompt fluid and electrolyte resuscitation, insulin replacement, correction of ketosis and reduction of serum glucose. The most appropriate first intervention is fluid replacement, initially with 0.9% sodium chloride, because this aids restoration of the circulatory volume, clearance of ketones and correction of electrolyte imbalances. The next step is commencing insulin therapy, usually as a fixed-rate intravenous infusion calculated for individual patient weight (0.1 units/kg/h) (Joint British Societies Inpatient Care Group, 2010). This suppresses ketoneogenesis, reduces blood glucose and corrects electrolyte imbalances. Careful attention to serum potassium levels is required because patients may present with hyperkalaemia, but initial treatment with saline and insulin will lower levels (because total body stores of potassium are usually low). Cardiac arrhythmias can be fatal due to either hyper- or hypokalaemia. Venous

thromboembolism prophylaxis should also be given, where indicated.

Continuing care should include assessment of the severity of dehydration, patient age, comorbidities, pregnancy and renal impairment. To prevent further episodes, patients need education about ‘sick-day rules’, including monitoring of blood glucose and ketones. Attendance at structured education has been shown to reduce rates of DKA and severe hypoglycaemia (Elliott et al., 2014).

Hyperosmolar hyperglycaemic state

Hyperosmolar hyperglycaemic state (HHS) is a serious and distinct condition associated with type 2 disease and is associated with a significant mortality rate (15–20%), secondary to serious consequences, including myocardial infarction, stroke, or peripheral thrombosis, seizures, cerebral oedema and central pontine myelinolysis (CPM). HHS usually occurs in older people, about 25% of whom have previously undiagnosed type 2 diabetes.

In HHS, there is no significant ketone production and therefore no severe acidosis. Hyperglycaemia occurs gradually over a sustained period of time, the osmotic diuresis which ensues leads to severe dehydration and subsequently hyperosmolality. Hyperosmolality may increase blood viscosity and the risk of thromboembolism. Factors precipitating HHS are infection, myocardial infarction, poor adherence to medication regimens or medicines which cause diuresis or impair glucose tolerance (e.g. glucocorticoids).

Diagnosis of hyperosmolar hyperglycaemic state

The diagnostic features of HHS are hyperglycaemia (often in the region of 55 mmol/L), severe dehydration (fluid deficit 100–220 mL/kg) and hyperosmolality. There may be a mild metabolic acidosis but without marked ketone production. Consciousness levels on presentation range from slight confusion to coma.

Treatment of hyperosmolar hyperglycaemic state

Treatment requires fluid replacement to stabilise blood pressure and improve circulation and urine output. Sodium chloride 0.9% is required initially, only switching to 0.45% if serum sodium increases to greater than 150 mmol/L despite appropriate fluid resuscitation (Joint British Societies Inpatient Care Group, 2012). Potassium may be added if required. A fixed-rate insulin infusion (0.05 units/kg/h) is started if blood glucose fails to reduce adequately despite good fluid replacement. Aggressive insulin administration is not required because fluid replacement also lowers serum glucose levels. Prophylaxis or treatment for thromboembolism is also required.

Long-term diabetes complications

People with diabetes are at a greater risk of developing disabling and life-threatening health problems than people without diabetes. Diabetic complications can be limited and prevented

altogether through early identification and good management of the modifiable risk factors of blood glucose, blood pressure and cholesterol from an early stage.

Diabetes and its long-term complications have a substantial economic impact on countries and national health systems, with the majority of countries spending between 5% and 20% of the total health expenditure on diabetes (International Diabetes Federation, 2015). The UK spends approximately 10% of the total NHS budget (£173 million/week [Diabetes UK, 2014]). This is related to direct drug cost but to a greater extent to the increased use of health services, loss of productivity, and long-term support required to overcome diabetes-related complications such as blindness, renal failure, limb loss and cardiac disease.

Although all long-term complications may occur in each type of diabetes, the spectrum of incidence is different. Many patients with type 2 diabetes have had their disease for a long time before the diagnosis, by which time many have developed diabetic complications (Fig. 45.2).

Diabetic complications are frequently divided into macrovascular and microvascular complications. The general aetiology of macro- and microvascular complications is the same and results from atherosclerosis of blood vessels, which may lead to occlusion. The main aims of treatment are to prevent the immediate symptoms associated with diabetes and to prevent or reduce the development of the long-term disease-related complications.

Macrovascular disease

The risk of macrovascular complications, including cardiovascular disease (coronary heart disease and stroke) and peripheral vascular disease (PVD), is two to four times higher for people with diabetes.

Cardiovascular disease

The most common cause of death in people with type 2 diabetes is cardiovascular disease (angina, myocardial infarction, stroke, peripheral artery disease and heart failure). The risk of cardiovascular disease is increased further if nephropathy is present. Other cardiovascular risk factors are enhanced in the presence of diabetes; smokers are encouraged to stop, and individuals with hypertension and lipid disorders are actively reviewed and treated. Silent myocardial infarction (infarction with no symptoms) is more common in those with diabetes and may be due to cardiac autonomic neuropathy. Cerebrovascular disease is also more commonly associated with diabetes, and patients have greater mortality and morbidity compared with the general population (Ergul et al., 2012).

Management of cardiovascular risk is an essential component of diabetes care, taking into account an individual's preferences and need. The NICE (2015b) guidance for cardiovascular disease (CVD) recommends that a statin should be considered for all adults with type 1 diabetes and offered if the person is older than 40 years, has had diabetes for more than 10 years or has other CVD risk factors or established nephropathy. People with type 2 diabetes should be offered a statin (atorvastatin 20 mg) if they have a 10% or greater 10-year risk of developing CVD.

Fig. 45.2 Complications of diabetes. ECG, Electrocardiogram.

Hypertension

Hypertension is twice as common amongst the diabetic population compared with the general population, occurring in more than 80% of those with type 2 diabetes. Hypertension is associated with the development of macro- and microvascular complications; hence, the treatment target ranges for people with diabetes are generally lower than those for people without diabetes. For people with type 2 diabetes, hypertension is a feature of metabolic syndrome and is associated with insulin resistance. For those with type 1 disease, it is closely associated with renal disease. First-line antihypertensive drug treatment should be once-daily angiotensin-converting enzyme (ACE) inhibitors; exceptions to this are patients of African or Caribbean family origin and women who may become pregnant. Patients of African and Caribbean family origin should be offered an ACE plus diuretic or calcium channel blocker; women seeking to become pregnant should be offered a calcium channel blocker (NICE, 2015d).

Peripheral vascular disease

PVD affects more than 30% of people with diabetes who are older than 50 years. PVD particularly affects the arteries of the legs and may give rise to intermittent claudication, a cramping pain experienced on walking that is due to reversible muscle ischaemia secondary to atherosclerosis. The iliac vessels can be affected, causing buttock pain and erectile dysfunction. If PVD is present, the risk of cardiovascular disease increases, with approximately 20% of people suffering from a fatal

myocardial infarction within 2 years of symptom onset. PVD is also responsible for much of the morbidity associated with diabetic foot problems.

Microvascular disease

Microvascular complications include retinopathy, nephropathy and neuropathy.

Retinopathy

Diabetic retinopathy is one of the leading causes of blindness in the UK and is the most common cause of blindness among people of working age in industrialised countries. Persistently high levels of blood glucose damage the network of blood vessels that supply the retina. The resulting retinopathy is initially symptomless in the early stages and may be advanced before it affects vision; therefore, screening is essential for early detection and subsequent treatment. Twenty years from the onset of diabetes, more than 90% of people with type 1 and more than 60% of people with type 2 will have diabetic retinopathy. Tight glycaemic control has been shown to prevent and delay the progression of retinopathy in patients with type 1 disease (Diabetes Control and Complications Trial Research Group [DCCT], 1993). Likewise, for patients with type 2 diabetes, both tight glycaemic control and tight blood pressure control reduce the risk of developing retinopathy (Kohner et al., 1998). When retinopathy is detected early, sight may be saved by laser photocoagulation. In advanced cases, surgery may be required.

Pregnancy may worsen moderate to severe retinopathy, particularly if there is poor or sudden improvement in glycaemic control. However, tight glycaemic control during pregnancy reduces the risk of foetal abnormalities.

Nephropathy

In diabetic renal disease, the kidneys become enlarged, and the glomerular filtration rate (GFR) initially increases. However, as nephropathy progresses, the GFR starts to decline. The GFR can be estimated (eGFR), but serum creatinine used alone to estimate renal function has limitations. The most popular method is the modified Modification of Diet in Renal Disease (MDRD) formula, which requires serum creatinine, age, sex and ethnicity. Creatinine clearance is often used for medication review and dose optimisation and may be calculated using the Cockcroft and Gault formula:

$$\text{CrCl (mL/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)}}{\text{serum creatinine (mmol/L)}} \begin{matrix} (\times 1.23 \text{ if male,} \\ 1.04 \text{ if female)} \end{matrix}$$

The presence of nephropathy is indicated by the detection of microalbuminuria (small amounts of albumin present in urine). If higher amounts of albumin are detected, this is termed proteinuria or macroalbuminuria and signifies more severe renal damage. Microalbuminuria is defined as an albumin/creatinine ratio (ACR) greater than or equal to 3 mg/mmol. Proteinuria may be defined as an ACR greater than 30 mg/mmol or albumin concentration greater than 200 mg/L. Proteinuria may progress to end-stage renal disease and require dialysis. Albumin in the urine increases the risk of cardiovascular disease, with microalbuminuria associated with two to four times the risk, proteinuria with nine times the risk and end-stage renal disease increasing risk by 50 times.

Tight control of both glycaemic levels and blood pressure reduces the risk of developing nephropathy. ACE inhibitors or angiotensin receptor blockers (ARBs) are the treatments of choice because both have been proven to delay the progression to proteinuria in patients with macroalbuminuria, a renal protective outcome additional to their antihypertensive effects. Although not proven for all individual drugs in these classes, it is considered to be a class effect. These drugs should be used with care if there is a risk of renovascular disease.

Peripheral neuropathy

Peripheral neuropathy is the progressive loss of functional peripheral nerve fibres. Diabetic neuropathies can lead to a wide variety of sensory, motor and autonomic symptoms. The most common is the symmetrical distal sensory type, which is particularly evident in the feet and may slowly progress to a complete loss of feeling. Distal motor neuropathy can lead to symptoms of impaired fine coordination of the hands and/or foot slapping. Painful diabetic neuropathy is another manifestation of sensory neuropathy; it can be extremely disabling and may cause considerable morbidity. Guidance on the treatment of painful neuropathy is available (NICE, 2013). Diabetic proximal motor neuropathy is a relatively rare condition which is rapid in onset and involves weakness and wasting, principally

of the thigh muscles. Muscle pain is common and may require multiple analgesic agents.

Autonomic neuropathy may affect any part of the sympathetic or parasympathetic nervous systems. The most common manifestation is erectile dysfunction. Bladder dysfunction usually manifests as loss of bladder tone with a large increase in volume. Diabetic diarrhoea is uncommon, but can be troublesome as it tends to occur at night. Gastroparesis may cause vomiting and delayed gastro-intestinal transit and variable food absorption, causing difficulty in the insulin-treated patient. There is no strong evidence that available antiemetic therapy is effective, although some people may benefit from domperidone, erythromycin or metoclopramide. Domperidone has the strongest evidence; however, the safety profile and cardiac risks must be considered. Postural hypotension due to autonomic neuropathy is uncommon but can be severe and disabling. Disorders of the efferent and afferent nerves controlling cardiac and respiratory function are more common but are rarely symptomatic. Autonomic neuropathy may also cause dry skin and lack of sweating, both of which may contribute to diabetic foot problems.

Macro- and microvascular disease combined

Diabetic foot problems

It is estimated that 10% of people with diabetes will develop a foot ulcer during their lifetime. Infected diabetic foot ulcers account for the largest number of diabetes-related hospital bed-days and are the most common non-trauma cause of amputations. Diabetic foot ulcers precede more than 80% of amputations in people with diabetes and are associated with poor morbidity and mortality, with approximately 50% of patients dying within 5 years. The rate of lower-limb amputation in people with diabetes is nearly 25 times higher than in the general population (NICE, 2015e). Diabetic foot ulcers impose immense medical and financial burdens on health care, as well as tremendous impact on the patient well-being and quality of life. Foot problems often develop as a result of a combination of sensory and autonomic neuropathy, PVD, poor foot care and hyperglycaemia. Development of foot ulcers may be partly preventable by patient education. People with diabetes need to learn that their feet are particularly vulnerable, and if problems arise, they must seek immediate professional advice.

There are three main types of foot ulcers: neuropathic, ischaemic and neuroischaemic. Neuropathic ulcers occur when peripheral neuropathy causes loss of pain sensation. The ulcers can be deep but are usually painless and are caused by trauma to the foot which is not noticed until after significant damage has occurred. Ischaemic ulcers result from PVD and poor blood supply causing a reduction in available nutrients and oxygen required for healing. Ischaemic ulcers may be painful and usually occur on the distal ends of the toes or the sides of the feet. Most ulcers have elements of both neuropathy and ischaemia and are termed neuroischaemic.

Diabetic foot ulcers are prone to infection, with the most common pathogens being staphylococci and streptococci. Wounds with an ischaemic component are commonly infected with anaerobic organisms. Resistant organisms are becoming common, and

Table 45.6 Glycaemic targets for patients with diabetes

	Fasting	Pre-meal	1 h post-meal	2 h post-meal	HbA _{1c}
Type 1 (NICE, 2015c)	5–7 mmol/L on waking	4–7 mmol/L		5–9 mmol/L (at least 90 min after eating)	48 mmol/mol
Type 2 (NICE, 2015d)		4–7 mmol/L		<8.5 mmol/L	48 mmol/mol (monotherapy) OR 58 mmol/mol (dual + therapy)
Gestational diabetes (NICE, 2015a)	<5.3 mmol/L		<7.8 mmol/L	<6.6 mmol/L	<48 mmol/mol

as such, antibiotic stewardship in the management of diabetic foot care is becoming increasingly important.

Charcot arthropathy. Charcot arthropathy is an uncommon foot complication caused by severe neuropathy, usually in a person with palpable foot pulses. It results in chronic, progressive destruction of joints with marked inflammation. Disorganised bone remodelling leads to fractures, altered foot shape and gross deformity. Because of the deformity which occurs, excess pressure over malpositioned bone frequently leads to ulceration unless footwear is extensively modified.

Treatment of diabetes

Treatment for people with diabetes includes advice on nutrition, physical activity, weight loss and smoking cessation. Drug therapy is prescribed where necessary, and a patient-centred approach should be undertaken, based on consideration of the individual needs, treatment aims and comorbidities.

The aim of treatment for most people is to achieve blood glucose as close to normal as possible. The current treatment target for people with type 2 diabetes is to achieve an HbA_{1c} of 48 mmol/mol (6.5%), unless on multiple treatments or prescribed a drug associated with hypoglycaemia, in which case the aim is 53 mmol/mol (7.0%) (Table 45.6). Treatment targets may be further moderated for patients unlikely to achieve long-term risk reduction due to reduced life expectancy or significant comorbidities, where tight control poses a risk of significant hypoglycaemia, impaired hypoglycaemia awareness, or the person drives or operates machinery.

Structured education programmes

Diabetes is a chronic condition that is predominately managed by the person with diabetes. Accordingly, understanding of diabetes and successful self-management are imperative in achieving optimal outcomes. Evidence-based structured education that empowers patients to manage their own diabetes is now considered standard care. Group education is often utilised because it offers economic advantages over one-to-one education, as well as peer support. Examples of such programmes include Dose Adjustment for Normal Eating (DAFNE) in type 1 diabetes and Diabetes Education for Self-Management in the Ongoing and Newly Diagnosed (DESMOND) in type 2 diabetes (Box 45.2).

Diet

Dietary control is the mainstay of treatment for type 2 diabetes, and carbohydrate counting plays an integral part in the management of type 1. Dietary recommendations have undergone extensive review in recent years, and considerable changes have been made. Healthy eating advice for people with diabetes is the same as for the general population, and dietary interventions should be part of a personalised plan that addresses the individual's nutritional needs, personal choice, cultural preferences and willingness to change (Box 45.3).

Carbohydrates and sweeteners

The blood glucose level is closely affected by carbohydrate intake. Current guidance for carbohydrate consumption emphasises the importance of total carbohydrate intake, with a focus on selecting carbohydrates with a lower glycaemic index. Low-glycaemic-index carbohydrates give sustained release of glucose over time; examples include beans, pulses and starchy foods like whole-meal pasta and whole-grain bread. High-glycaemic-index carbohydrates that give high peaks in blood glucose concentration are best avoided or eaten in small quantities. Total carbohydrate consumption should not exceed 45–60% of energy intake, with monounsaturated fat and carbohydrate combined making up 60–70% of energy intake.

Sucrose or 'sugar' may be included in the diet but should account for no more than 10% of total energy and should be spaced throughout the day, rather than being consumed all in one go. Sugar alcohols, for example, sorbitol, maltitol and xylitol, are often used as sugar substitutes in diabetic foods and may cause diarrhoea. They are therefore considered to confer little advantage over sucrose. Non-nutritive or intense sweeteners such as aspartame, saccharin, acesulphame K, cyclamate and sucralose may be useful, especially for those who are overweight.

Alcohol

Alcohol contains carbohydrates and, if consumed in excess, may cause hyperglycaemia. However, more dangerously, it is also associated with later-onset (up to 16 hours post-alcohol) hypoglycaemia and hypoglycaemia unawareness. Alcohol should be restricted to the same maximum weekly quantities as for the general population (14 units/week).

Box 45.2 Essential topics to be included in patient diabetes education programmes

The disease Signs and symptoms
Hyperglycaemia Signs and symptoms <ul style="list-style-type: none"> • Frequent urination • Extreme thirst • Fatigue
Hypoglycaemia Signs and symptoms <ul style="list-style-type: none"> • Hungry • Palpitations/fast heartbeat • Sweating/clammy skin Treatment choices <ul style="list-style-type: none"> • Small carton of full sugar juice • 5 Jellybeans or similar sweets • Glucose tablets or gel
Exercise <ul style="list-style-type: none"> • Benefits and effect on blood glucose control
Diet <ul style="list-style-type: none"> • Carbohydrate awareness • Benefits of a well-balanced diet
Insulin therapy <ul style="list-style-type: none"> • Injection technique • Types of insulin • Onset and peak actions • Storage • Stability
Urine testing <ul style="list-style-type: none"> • Glucose • Ketones
Home blood glucose and ketone testing <ul style="list-style-type: none"> • Technique • Interpretation
Oral hypoglycaemic agents <ul style="list-style-type: none"> • Mode of action • Dosing • Need for multiple therapies
Foot care <ul style="list-style-type: none"> • Checking feet daily for cuts, sores, redness or infection • Daily washing of feet • Keeping the skin smooth and soft
Management during illness <ul style="list-style-type: none"> • Sick-day rules • Importance of maintaining hydration
Cardiovascular risk factors <ul style="list-style-type: none"> • Smoking • Hypertension • Obesity • Hyperlipidaemia
Eye care <ul style="list-style-type: none"> • Regular medical and ophthalmological examinations

Box 45.3 General dietary advice for people with diabetes

- Eat regular meals based on starchy foods such as bread, pasta, potatoes, rice and cereals. Whenever possible, choose high-fibre varieties of these foods, e.g. whole-meal bread and whole-meal cereals, which have a lower glycaemic index.
- Try to cut down on fat, particularly saturated (animal) fats. Monounsaturated fats such as olive oil are preferred. Use less butter, margarine and cheese and eat fewer fatty meals. Choose low-fat dairy foods, e.g. skimmed milk and low-fat yoghurt. Grill, steam or oven bake instead of frying or cooking with oil or other fats.
- Try to eat at least five portions of fruit and vegetables every day. This provides vitamins and fibre and helps balance the overall diet.
- Cut down on sugar and sugary foods. Sugar can still be used as an ingredient in foods and baking as part of a healthy diet. Use sugar-free, low-sugar or diet squashes and fizzy drinks because sugary drinks cause blood glucose levels to rise quickly.
- Use less salt because high intake can raise blood pressure. Food can be flavoured with herbs and spices instead of salt.
- Drink alcohol in moderation. Two units/day for women and men. A small glass of wine or half a pint of normal-strength beer is one unit. Never drink on an empty stomach. Excess alcohol can cause hypoglycaemia.

Fats

Because obesity is a major factor in type 2 diabetes and fats contain more than twice the energy content per unit mass than either carbohydrate or protein, consumption of fats should be limited. Intake of fat should be less than 35% of total energy consumption, with saturated and trans-unsaturated fats accounting for less than 10% of energy intake. Saturated fats are chiefly of animal origin; however, some are found in plants, such as cocoa butter, coconut oil and palm oil. Trans-unsaturated fats are found in hydrogenated vegetable oils and hard margarines.

Protein

For adults without nephropathy, protein intake is recommended as less than 1 g/kg of body weight, equivalent to about 10–20% of total energy intake. For those with nephropathy, protein intake may need to be further restricted, but this requires expert dietetic advice and supervision.

Fibre

Dietary fibre has useful properties in that it is physically bulky, and it delays the digestion and absorption of complex carbohydrates, thereby minimising hyperglycaemia. For the average person with type 2 diabetes, 15 g of soluble fibre from fruit, vegetables or pulses is likely to produce a 10% improvement in fasting blood glucose, glycated haemoglobin and low-density lipoprotein cholesterol (LDL-C). Insoluble fibre from cereals, whole-meal bread, rice and pasta has no direct effect on glycaemia or dyslipidaemia, but it has an overall benefit on gastro-intestinal health and may help in weight loss by promoting satiety.

Salt

Evidence shows that a modest reduction in salt consumption can significantly reduce both systolic and diastolic blood pressure in both hypertensive and normotensive individuals. Reducing salt intake from 9–12 to 5–6 g/day has a major effect on blood pressure, with the evidence supporting that a larger reduction in salt has the greatest impact on blood pressure reduction (He et al., 2013).

Obesity management in type 2 diabetes

Obesity management is an important issue in type 2 diabetes because of the insulin resistance which occurs as a consequence of excess adipose tissue. Weight loss in those who are overweight or obese is associated with an improvement in dyslipidaemia, hypertension and glycaemic control. Bariatric surgery can lead to profound improvements, with studies showing that laparoscopic banding can induce remission of type 2 diabetes in 48% of individuals and that Roux-en-y bypass procedures can induce remission in 84% (Vetter et al., 2009). More importantly, bariatric surgery is associated with a 92% relative risk reduction in diabetes-specific mortality and consequently should be offered to those with diabetes who have a BMI of 35 kg/m² or higher (NICE, 2014). For those with a BMI of 28 kg/m² or greater, it is recommended that the pancreatic and gastric lipase inhibitor orlistat be considered because the modest weight reduction which can be achieved with this agent yields benefits in diabetes control.

Insulin therapy in type 1 diabetes

Insulin replacement is the mainstay of treatment for all patients with type 1 diabetes. Exogenous insulin is used to mimic the normal physiological pattern of insulin secretion as closely as possible for each individual patient. However, a balance is required between tight glycaemic control and hypoglycaemia risk. If the risk of hypoglycaemia is high, then it may be necessary to aim for less tight glycaemic control. There is a wide variety of insulin preparations available which differ in species of origin, onset of action, time to peak effect and duration of action (Table 45.7).

Adults with type 1 diabetes should be supported to achieve a target HbA_{1c} of 48 mmol/mol (6.5%) to minimise the risk of long-term vascular complications. Ideally this should be achieved through a flexible insulin regimen of self-injecting multiple daily doses of insulin, adjusted based on physical activity, food intake and current blood glucose. Blood glucose may be tested up to 10 times a day, with target blood glucose levels of 5–7 mmol/L on waking and 4–7 mmol/L before meals at other times of the day. Bedtime targets should be individually set. Adults who wish to test post-meals should aim for a plasma glucose 5–9 mmol/L at least 90 minutes after eating (see Table 45.6). Adults with type 1 diabetes who are unable to obtain good control of their diabetes or who have significant problems with hypoglycaemia may benefit from insulin pump therapy (NICE, 2008a). If, despite insulin pump therapy, adults with type 1 diabetes have recurrent severe hypoglycaemic episodes unresponsive to treatment, islet cell or pancreas transplantation may be considered. This option

Table 45.7 Common insulin nomenclature

Type of insulin	Description	Additional Information
Endogenous insulin	The natural insulin produced by the pancreas	
Human insulin	Laboratory synthesised insulin – equivalent to endogenous insulin	Available as two forms: <ul style="list-style-type: none"> • Short-acting soluble • Intermediate acting
Short-acting soluble insulin	A human insulin with a moderately fast onset and short duration of action	Often given with meals (prandial)
Intermediate-acting neutral protamine Hagedorn (NPH) Isophane	A suspension of human insulin with a more sustained duration of action	Given as background (basal) insulin
Premixed insulin	A mixture of the short- or rapid-acting insulin with the intermediate-acting insulin in predetermined concentrations	Human biphasic Analogue biphasic
Analogue insulin	Laboratory synthesised and modified insulin to alter how quickly or slowly it acts	Available as two forms: <ul style="list-style-type: none"> • Rapid acting • Long acting
Rapid-acting analogue	Modified synthetic insulin with rapid onset and short duration of action	Given with meals (prandial)
Long-acting analogue	Modified synthetic insulin with slow onset of action and sustained duration of action	Given as background (basal) insulin

is more widely offered if the patient has already received a renal transplant and is therefore currently taking immunosuppressive therapy.

Insulin species of origin

Until the 1980s, insulin was obtained and purified from the pancreas of pigs and cows. Many of the animal-derived products have been withdrawn, but some continue to be available. Porcine insulin only differs from human insulin in one amino acid at the end of the B chain (position B30). Human sequence insulins have subsequently been developed using recombinant DNA technology and are now the most common insulins in use. Human insulin may be produced semi-synthetically by enzymatic modification of porcine insulin (emp) or using genetic engineering and recombinant DNA technology. This is done by inserting either synthetic

genes for the insulin A chain and B chain, or the proinsulin gene, or a proinsulin-like precursor into *Escherichia coli* (crb, prb) or yeast cells (pyr). The cells are fermented, resulting in large amounts of the recombinant protein, which is then converted into insulin and purified. More recently, human insulin analogues have been developed through genetic and protein engineering, producing insulin molecules with differing pharmacokinetic properties. In recent years, biosimilar insulin products have also been introduced; this is a biological copy of an existing insulin, but it cannot be said to be identical.

It is now standard practice to commence all patients requiring insulin on human insulin. Historically, in those who have been changed from animal to human insulin, there was a concern regarding an increased risk of hypoglycaemia and hypoglycaemic unawareness, although this was much less likely if the dose was reduced appropriately. Human insulin may be more potent dose for dose than animal insulin due to the formation of antibodies; hence, doses need to be reduced by 25% or more when changing from animal to either human or analogue insulin.

Insulin preparations

The onset of action, peak effect and duration of action are determined by the insulin type and by the physical and chemical form of the insulin, as detailed in [Table 45.8](#).

Fast-acting insulins. Conventional fast-acting insulins are soluble insulins (also known as neutral insulins). After subcutaneous injection, soluble insulin starts to appear in the circulation within 10 minutes. The concentration rises to a peak after about 2 hours and then declines over a further 4–8 hours. This absorption curve can be contrasted with the physiological insulin concentration curve, where peak concentrations are reached 30–40 minutes after a meal and decline rapidly to 10–20% of peak levels after about 2 hours.

The fast-acting recombinant insulin analogues (insulin lispro, insulin aspart and insulin glulisine) offer greater convenience and flexibility, due to a more rapid absorption and shorter duration of action. They can be given immediately before a meal rather than the 30 minutes before recommended for human soluble insulin. The pharmacokinetic differences arise because the short-acting analogues remain as monomers (single units), unlike regular soluble human insulins, which self-associate into a hexameric (6-unit) form. Hexamers need to dissociate into dimers and monomers to be readily absorbed from subcutaneous tissue, which causes delayed absorption. However, in those people aiming for very tight glycaemic control (e.g. during pregnancy), there is benefit in injecting these short-acting insulin analogues 15–30 minutes pre-meals.

Intermediate-acting insulins. Conventional intermediate-acting insulins are insoluble, cloudy suspensions of insulin complexed with either protamine (also known as isophane or NPH insulin) or zinc (lente insulin). Over time, insulin dissociates from the complex, which gives the preparation its extended activity. The onset of action is usually 1–2 hours, with the peak effect being seen at 4–8 hours. There is considerable inter-patient variation in the duration of action, but it usually requires twice-daily administration to adequately cover a 24-hour period. Protamine

insulin and soluble insulin do not interact when mixed together. Therefore, ready-mixed (biphasic) preparations are available that contain both isophane and soluble insulin.

Long-acting insulins. More recently, long-acting insulin analogues, such as insulin glargine (Lantus), detemir (Levemir) and degludec (Tresiba), have been developed using recombinant DNA technology. They have a sustained duration of action, with more predictable, flat profiles of action with no pronounced peaks and less inter- and intra-subject dosing variability.

Insulin glargine differs from human insulin because two arginine molecules have been added to the B chain at the C-terminal end. This alters the isoelectric point from pH 5.4 to 6.7. Also, the neutral amino acid glycine replaces the asparagine residue at position A21. The changes mean that insulin glargine remains soluble at a slightly acidic pH. The product is buffered at a pH of 4. Once it is injected into subcutaneous tissue, it forms a micro-precipitate in the more neutral surrounding pH. This allows slow absorption from the injection site. The recent introduction of glargine 300 units/mL (Toujeo), which forms a more compact micro-precipitate, has a longer duration of action and less variable release profile.

Insulin detemir is formulated at neutral pH. It differs from human insulin by omission of the amino acid threonine at position B30 and the attachment of a fatty acid chain (myristic acid) to lysine at position B29. The modification allows the insulin molecule to reversibly bind to albumin, via the fatty acid chain, after absorption from subcutaneous injection. This reduces the amount of free, active insulin detemir because bound insulin is inactive. The long duration of action is produced by dissociation of the insulin molecule from albumin.

Insulin degludec forms soluble multihexamers upon subcutaneous injection, resulting in a depot that is continuously, slowly and evenly absorbed, with a duration of action beyond 42 hours. The sustained duration of action offers flexibility in dosing time, which may, for example, be particularly helpful for shift workers. In addition, due to its long half-life, it has been shown to reduce episodes of ketosis ([Thalange et al., 2015](#)).

Historically, insulin has been available in the UK as standard 100 units/mL. In recent years there have been increasing numbers of high-strength insulins developed. It is important to understand the insulin strength and how to use insulin correctly to minimise medication errors.

Combination products. Combined formulations of basal insulin and glucagon- (GLP-1-like peptide 1) receptor agonist are now commercially available. These offer the advantage of a single injection.

Insulin delivery

All the currently licensed insulin products are available only by injection. The subcutaneous route is routinely used for patients to self-administer their maintenance therapy and can be injected into the outer aspect of the thigh, abdominal wall, buttocks or upper arm. However, injecting into the arm safely over a long period of time is difficult and is therefore not usually a site of choice. Subcutaneous administration cannot be regarded as physiological because it delivers insulin to the systemic rather than portal circulation.

Table 45.8 Insulin preparations

Preparation	Origin	Onset (h)	Peak (h)	Duration (h)	Comments
Soluble insulin					
Actrapid (pyr)	H	0.5	2–5	8	Given at meal times (three times a day), usually with once-daily or twice-daily Humulin I Insulatard Levemir Lantus Tresiba Toujeo
Humulin S	H	0.5	1–3	5–7	
Insuman Rapid (crb)	H	0.5	1–3	7–9	
Hypurin Bovine Neutral	B	0.5–1	2–5	6–8	
Hypurin Porcine Neutral	P	0.5–1	2–5	6–8	
Apidra (glulisine)	H A	0.25	1	3–4	
Humalog (lispro)	H A	0.25	1–1.5	2–5	
NovoRapid (aspart)	H A	0.25	1–3	3–5	
Isophane insulin					
Hypurin Porcine Isophane	P	2	6–12	24	Once daily or twice daily Usually at bedtime and/or breakfast Occasionally pre-tea Used as monotherapy or with pre-meal quick-acting insulin
Insuman basal (crb)	H	1	3–4	12–20	
Insulatard (pyr)	H	2	4–12	24	
Humulin I	H	0.5	2–8	18–20	
Hypurin Bovine Isophane	B	2	6–12	24	
Long-acting analogues					
Levemir (detemir)	H A	2–4	6–14	16–20	Once daily or twice daily Usually at bedtime and/or breakfast Occasionally pre-tea Used as monotherapy or with pre-meal quick-acting insulin
Lantus (glargine 100 units/mL)	H A	2–4	6–12	20–24	
Toujeo (glargine 300 units/mL)	H A	2–4	No peak	24–26	
Tresiba (degludec)	H A	1	No peak	24–42	
Premixed insulin					
Humulin M3 (prb)	H	0.5	1–8.5	14–15	Usually twice daily Usually pre-breakfast and tea Rarely once a day NEVER at bedtime
Novomix 30	H A	0.25	1–4	Up to 24 h	
Humalog Mix 25	H A	0.25	1–2	22	
Humalog Mix 50	H A	0.25	1–2	22	
Hypurin Porcine 30/70	P	0.5	4–12	24	
Insuman Comb 15 (prb)	H	0.5	2–4	12–20	
Insuman Comb 25 (prb)	H	0.5	2–4	12–19	
Insuman Comb 50 (prb)	H	0.5	1–4	12–16	

Insulin preparation are classified as being human (H), beef (B), or pork (P) in origin. Analogue (A) denotes modified to alter onset and duration of action. crb, chain recombinant bacteria; prb, proinsulin recombinant bacteria; pyr, precursor yeast recombinant.

Insulin is available in a number of administration devices, including vials with syringes, cartridges for reusable pens and disposable pens.

Intravenous insulin delivery should be used in the management of ketoacidosis and hyperosmolar states. The intravenous route is also preferable for people with diabetes due to have major surgery and who may be 'nil by mouth' after surgery. The short half-life of insulin (3–5 minutes) means that changes in infusion rate have a rapid effect on insulin action and glycaemic control. Intravenous insulin is commonly delivered as a variable-rate insulin infusion (VRII), referred to as a 'sliding-scale' insulin regimen, in which the rate of infusion is adjusted according to frequent blood glucose readings, usually hourly. It is administered with a co-infusion of glucose (with potassium, unless patient is hyperkalaemic). Intravenous insulin regimens are not routinely recommended for patients who are eating and drinking.

Insulin regimens

Standard insulin regimens for managing type 1 disease vary between two and five injections daily. They must be tailored to the individual patient and will depend on lifestyle, willingness to achieve the best control and ability to cope with both injecting insulin and monitoring of blood glucose. The chosen insulin regimen is negotiated between patient and healthcare professional and may change throughout life according to priorities and patient preference. Starting doses of insulin and the ratio of short- to intermediate-acting insulin are very variable. In patients who are very active, such as manual workers and those who exercise regularly, lower doses are usually required.

Mealtime plus basal regimens. The best control for type 1 diabetes may be attained using a mealtime bolus plus basal regimen, also referred to as a basal-bolus regimen. This mimics normal physiological insulin release more closely than other regimens. A mealtime bolus plus basal regimen requires mealtime injections of insulin with a fast-acting preparation, preferably with an analogue, plus one or two injections of a basal (intermediate- or long-acting) insulin. This may require up to five injections a day. As a general rule, with this regimen, the soluble insulin injections given before each meal usually comprise 40–60% of the total daily dosage.

Current UK guidance is that newly diagnosed adults with type 1 diabetes should be offered multiple daily injections (basal bolus), including a rapid-acting analogue at mealtimes and twice-daily detemir, unless well managed on an alternative product, or twice-daily basal injections is not acceptable to the person (NICE, 2015c). Some individuals may benefit from delivery of fast-acting analogue insulin via a continuous subcutaneous insulin infusion administered via a pump worn on their person. The pump can be programmed to give a different basal rate of infusion at different times of day, and boluses are then provided by the pump at mealtimes. There are specific indications for pump therapy (NICE, 2008b).

These regimens offer the most flexibility of dosing and eating habits, and they often result in better blood glucose control. Individuals are taught to count mealtime carbohydrates and

calculate their own insulin dose on the basis of the preprandial blood glucose concentration, which allows greater scope for 'normal eating'. An example is the DAFNE programme (DAFNE Study Group, 2002), in which patients are required to attend structured group education for 5 days.

The disadvantage of mealtime plus basal regimens is that they require multiple injections, unless a pump is in situ, and require regular blood glucose monitoring and the ability of the patient to match insulin doses according to carbohydrate intake, exercise levels and prevailing glucose levels. For some people, this is either too difficult or unsuitable.

Twice-daily regimens. The basal-bolus regimen may be too demanding for some to manage; as such, a twice-daily regimen may be more suitable. The simplest and most effective twice-daily regimens use premixed insulin, comprising a short- or rapid-acting plus an intermediate-acting insulin. Regular human insulin mixes and analogue mixes are available. The regular human insulin mixes should be given 30 minutes before breakfast and 30 minutes before the evening meal, whereas analogue mixes may be given immediately before these meals. The longer-acting component of the insulin mix given at breakfast time spans the lunchtime meal, and the evening dose bridges the night time. Twice-daily regimens using intermediate- or long-acting insulins alone are not usually sufficient for optimal control of type 1 diabetes.

Insulin dose adjustment. The information on which insulin dosage adjustment is based should be derived from blood glucose self-monitoring and the incidence and timing of hypoglycaemia. The frequency of monitoring usually mirrors the frequency of insulin injections, so the glucose concentration can be taken as a measure of the appropriateness of the previous insulin dose.

Adjustments to a dose of insulin should depend on the degree of insulin resistance present. To determine a suitable adjustment dose, the effect of other dosage adjustments in the same patient should be taken into consideration, as should the total insulin dose. For example, a 2-unit dose increase in someone taking 6 units of insulin would be a 33% dosage increase; however, a 2-unit dose increase in someone taking 60 units of insulin would be proportionately much less and make less impact. If monitoring shows persistent hyperglycaemia, then dose increases of 10–20% are usually required.

Storage of insulin

Insulin formulations are stable if kept out of light and not subject to freezing or extremes of heat. Loss of potency of 5–10% occurs in vials kept at high ambient room temperatures for 2–3 months. Insulin should therefore be stored in a domestic refrigerator except for the vial, cartridge or pen in current use, which, depending on the individual preparation, may be stable for 4–6 weeks (see manufacturers' recommendations). When pen injector devices are in use, they should never be stored in a refrigerator because there have been reports of devices 'seizing up' when stored in the cold. Also, the injecting of cold or refrigerated insulin is undesirable because it is more painful and the insulin absorption profile is altered.

Adverse effects of insulin

Hypoglycaemia is a common physiological complication of insulin therapy and is often a source of great anxiety to patients and carers. The symptoms may occur at different blood glucose levels in different individuals.

Thickening of subcutaneous tissues can occur at injection sites because of recurrent injection in the same area, known as lipohypertrophy. As well as looking unsightly, it can result in impaired and erratic insulin absorption, leading to poor glycaemic control. Good injection-site rotation reduces the incidence and impact. Bruising is usually a sign of superficial injections. Localised skin reactions occasionally occur but resolve even with continued use of the same insulin preparation.

Systemic allergic reactions rarely occur with the current highly purified insulins. Although reactions are not usually species specific, it is worthwhile to try insulin of a different species if allergy occurs. Also, some patients may experience allergy to the excipients within the insulin product or to the needle used for administration. If this is suspected, it is helpful to seek the advice of an immunologist and try an insulin product with different excipients.

Management of type 2 diabetes

About 85% of patients with type 2 diabetes are overweight at diagnosis, and this is known to cause insulin resistance; obese individuals also require higher doses of medication to control blood glucose levels. Education about healthy eating and weight loss through increased physical exercise and calorie restriction is required. Targets for weight should be to maintain a normal BMI of between 20 and 25 kg/m² or a waist circumference of less than 88 cm in women and 102 cm in men, which lowers the risk of developing insulin resistance. In those who are already overweight or obese, however, an achievable target of 10–15% body weight loss should be discussed because, if achieved, this will have significant benefits in overall diabetes control.

Some people are able to normalise their glycaemic control by weight loss and attention to diet (diet controlled). Nevertheless, such individuals still invariably have diabetes and are at risk of developing diabetic complications. Hyperglycaemia may still occur, especially in times of stress or if dietary control is lost, and consequently, they should be monitored regularly.

For more than 75% of people with type 2 diabetes, dietary measures and exercise alone do not produce adequate glycaemic control, and oral hypoglycaemic therapy is required. In the UK, there are seven classes of oral agents currently available: a biguanide (metformin), sulfonylureas (glibenclamide, gliclazide, glimepiride, glipizide, tolbutamide), meglitinides (repaglinide and nateglinide), a thiazolidinedione (pioglitazone), an α -glucosidase inhibitor (acarbose), the dipeptidyl peptidase-4 inhibitors (saxagliptin, sitagliptin, linagliptin, alogliptin and vildagliptin) and most recently the sodium-glucose co-transporter-2 inhibitors (canagliflozin, dapagliflozin and empagliflozin).

When choosing and optimising the medication, it is important to adopt an individualised approach, not only considering the evidence base for the medication but also the individual circumstances. Factors to consider include degree of hyperglycaemia, weight, renal function, personal preference, comorbidities, risks

from polypharmacy, ability to benefit from long-term interventions because of reduced life expectancy and also consideration of any disabilities such as visual impairment.

Metformin remains the foundation of oral treatment for type 2 diabetes (NICE, 2015d). The sulfonylureas and meglitinides are known as insulin secretagogues because they both enhance secretion of insulin from the pancreatic β -cells. The relatively recent introduction of the dipeptidyl peptidase inhibitors (DPP-4 inhibitors) and sodium-glucose co-transporter-2 inhibitors (SGLT-2s) has been welcomed; these are useful classes of drugs, particularly for those in whom weight is a problem because they do not cause weight gain. Likewise, the injectable incretin mimetics (exenatide, liraglutide, lixisenatide and dulaglutide) are often helpful for the obese population because they are associated with weight reduction (Table 45.9).

In type 2 diabetes, the progressive decline in β -cell function with time and increasing insulin resistance means people with this disease show a progressive loss of glycaemic control and usually require two or three drugs with different modes of action to maintain control before ultimately requiring insulin (Fig. 45.3).

Biguanides

Mode of action. Metformin is the only biguanide available in the UK. The full mechanism of action of biguanides is still not completely understood. However, the principal mode of action is via potentiation of insulin action at an unknown intracellular locus, resulting in decreased hepatic glucose production by both gluconeogenesis and glycogenolysis. Metformin also stimulates tissue uptake of glucose, particularly in muscle, and is thought to reduce gastro-intestinal absorption of carbohydrate. The action of metformin does not involve stimulation of pancreatic insulin secretion, and therefore it is still a beneficial agent when β -cell function has declined. Metformin also offers the advantage that it does not cause hypoglycaemia and is not associated with weight gain. Metformin has a short duration of action, with a half-life of between 1.3 and 4.5 hours, and does not bind to serum proteins. It is not metabolised and is totally renally eliminated.

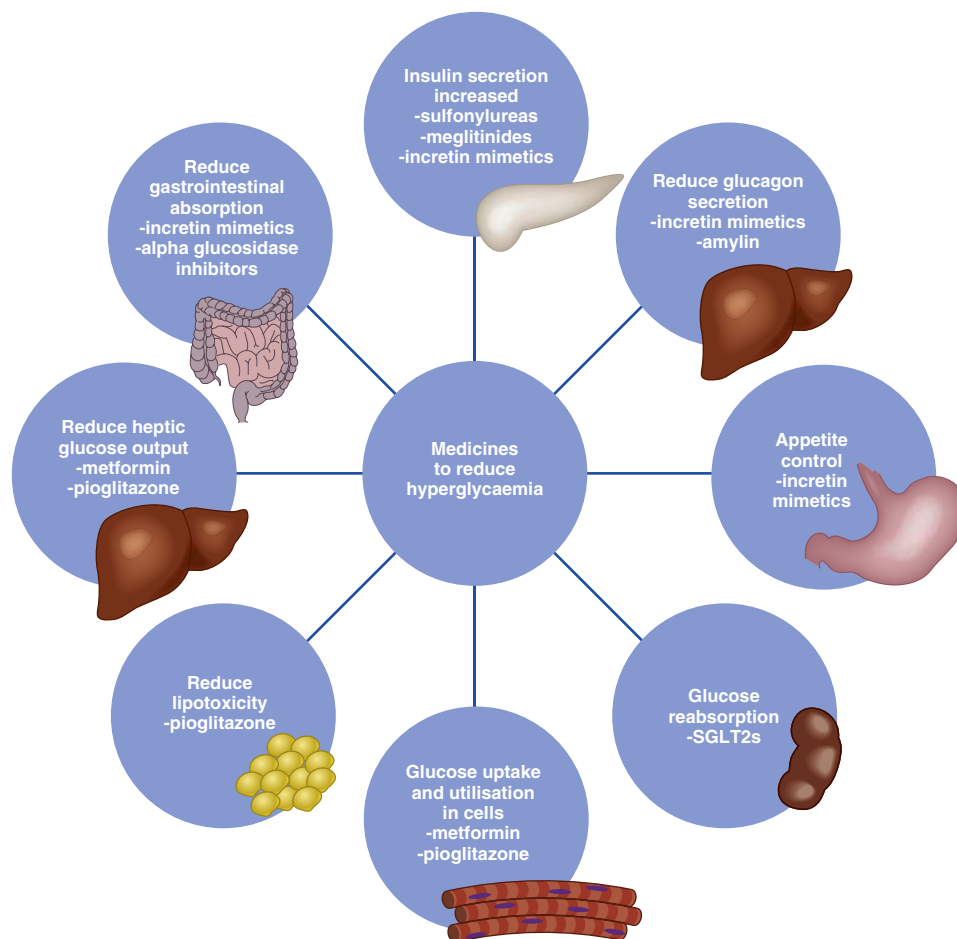

It has been shown that diabetes-related death was reduced by 42% in overweight subjects who took metformin for 10 years compared with those who took conventional therapies such as a sulfonylurea or insulin. Myocardial infarction was also reduced by 39% over the 10-year follow-up period. Consequently, metformin has become the first-line therapy for glycaemic control when oral agents are indicated, especially in overweight and obese patients (UK Prospective Diabetes Study Group [UKPDS], 1998a).

Adverse effects. The most common adverse effects of metformin, affecting about a third of patients, result from gastro-intestinal disturbances including anorexia, nausea, abdominal discomfort and diarrhoea. In some patients, diarrhoea can be extreme and can preclude metformin use. However, the gastro-intestinal side effects are usually transient and can be minimised by starting with a low dose, increasing the dose slowly and administering the drug with or after food. A suggested regimen is to start with 500 mg daily for 1 week, then 500 mg twice daily for 1 week, increasing the dosage at weekly intervals until the desired glycaemic response is achieved or intolerance occurs. The

Table 45.9 Factors to consider for dual therapy with metformin + additional agent (NICE, 2015d)

	Sulfonylurea	Thiazolidinedione	DPP-4 inhibitor	SGLT-2 inhibitor	GLP-1 agonist ^a	Insulin (basal)
Efficacy	High	High	Intermediate	Intermediate	High	High
Hypoglycaemia risk	Moderate	Low	Low	Low	Low	Moderate to high
Weight	Gain	Gain	Neutral	Loss	Loss	Gain
Side effects	Hypoglycaemia Rash Urticaria Liver enzyme disturbances	Oedema Heart failure, Fractures Bladder cancer, Respiratory tract infections Hypoesthesia	Hypoglycaemia Pancreatitis Headaches	Urinary tract Infections Dehydration Hypotension DKA	Gastrointestinal disturbances Pancreatitis Nausea and vomiting	Hypoglycaemia Injection site reactions Lipohypertrophy, rarely lipodystrophy
Relative cost	Low	Low	High	High	High	Variable

^aNICE does not specifically recommend this combination at first intensification. Specialised and European practice does recognise this place in therapy
DKA, Diabetic ketoacidosis; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide 1; SGLT-2, sodium-glucose co-transporter-2.

**Fig. 45.3** Mode and place of action of the oral hypoglycaemic agents.

maximum licensed dose is 3 g/day, but doses of more than 2 g/day often cause intolerance and are not generally recommended.

Modified-release metformin preparations are now available and permit once-daily dosing. Clinical evidence suggests that these formulations cause fewer problems with gastro-intestinal side effects. The maximum licensed dose of the modified-release preparations (2 g daily) differs from the standard preparation.

The two previously available biguanides, phenformin and buformin, were withdrawn due to deaths associated with lactic acidosis. Lactic acidosis is a rare but potentially life-threatening complication with metformin, with an estimated incidence of five cases per 100,000 patient-years. Patients at most risk are those with renal insufficiency in whom the drug accumulates, individuals with co-existing conditions where lactate accumulates, and those who are unable to metabolise lactate. In practice, metformin should be used with caution for patients who have renal impairment (eGFR <45 mL/min/1.73 m²) and should be stopped in anyone with an eGFR less than 30 mL/min/1.73 m². Metformin should also be stopped in severe liver disease, uncontrolled cardiac failure or severe pulmonary insufficiency. It should be withdrawn in patients with severe intercurrent illness, for example, acute myocardial infarction or septicaemia, or those undergoing major surgery or requiring investigation using radiographic contrast media and should only be restarted once renal function has been evaluated and determined as within acceptable limits.

Role of metformin. Metformin is recommended as the first-line drug for people with type 2 diabetes and is particularly useful in obese patients because it is weight neutral. Because it has a different mode of action than the other oral agents, it can be valuable when prescribed in combination.

Current NICE (2015c) guidance for type 1 diabetes states to consider metformin as an adjunct to insulin therapy if an adult has a BMI greater than or equal to 25 kg/m² (23 kg/m² in South Asian or related ethnic group).

Sulfonylureas

Mode of action. The major action of this class of drug relies on the ability of the pancreas to secrete insulin and hence requires functioning β -cells to exert a beneficial effect. Sulfonylureas lower blood sugar by increasing pancreatic β -cell sensitivity to glucose, allowing more insulin to be released from storage granules for a given glucose load. Sulfonylurea therapy is also associated with increased tissue sensitivity to insulin, resulting in improved insulin action. Studies also suggest that sulfonylureas may promote an increased systemic bioavailability of insulin due to reduced hepatic extraction of insulin secreted from the pancreas.

Pharmacokinetics. The pharmacokinetic parameters of oral hypoglycaemic agents are shown in Table 45.3. Chlorpropamide is the slowest and longest-acting agent, but it is now very rarely used. Although glibenclamide has been shown to have a short elimination half-life, it has a prolonged biological effect. All sulfonylureas are metabolised by the liver to some degree, and some may have active metabolites.

Choice of drug. There are few well-controlled long-term clinical comparisons between sulfonylureas; it would appear that when dosage is individualised and governed by the effect on fasting blood glucose, there is little or no difference in clinical efficacy

between different agents. Therefore, choice is governed by the drug profile, the patient and the prescriber's clinical experience. In general, if a patient is not well controlled on the maximum dosage of one sulfonylurea, it is not worthwhile to change to another one.

Adverse effects. The frequency of adverse effects from sulfonylureas is low. They are usually mild and reversible on drug withdrawal. The most common adverse effects are weight gain and hypoglycaemia. Hypoglycaemia may be profound and long lasting and is often misdiagnosed, particularly in the elderly. The major risk factors for the development of hypoglycaemia include the use of a long-acting agent, increasing age, renal or hepatic dysfunction and inadequate carbohydrate intake.

Sulfonylurea dosage. The dosage should be individualised for each patient. The lowest possible dose required to attain the desired levels of blood glucose, without producing hypoglycaemia, should be used. Treatment should start with a low dose and be increased if necessary approximately every 2 weeks. For many agents, the maximum effect is seen if the dose is taken half an hour before a meal, rather than with or after food. The number of daily doses required will depend on the agent used and the total daily dose.

A modified-release preparation of gliclazide is available. A dose of 30 mg of the modified-release product is equivalent to 80 mg of the standard-release preparation.

Drug interactions. Several drugs can interfere with the efficacy of sulfonylureas by influencing either their pharmacokinetics or pharmacodynamics, or both. Despite much literature about displacement interactions with sulfonylureas, the clinical significance is doubtful. Many reported cases involve first-generation agents, which have a different protein-binding site from the second-generation agents, which bind in a non-ionic fashion and are not readily displaced. Ingestion of alcohol can cause hypoglycaemia in itself and can also prolong the hypoglycaemic effect of sulfonylureas.

Meglitinides

The meglitinides are insulin-releasing agents (insulin secretagogues), also called 'post-prandial glucose regulators'. They are characterised by a more rapid onset and shorter duration of action than sulfonylureas. Their site of action is pharmacologically distinct from that of the sulfonylureas. Repaglinide, a benzoic acid derivative, is licensed for use as a single agent when diet control, weight reduction and exercise have failed to regulate glucose levels, or in combination with metformin. Nateglinide is a derivative of the amino acid D-phenylalanine, licensed for combination therapy with metformin when metformin alone is inadequate.

Mode of action. Like the sulfonylureas, the meglitinides stimulate first-phase insulin secretion by inhibiting adenosine triphosphate (ATP)-sensitive potassium channels in the membrane of the pancreatic β -cells. This causes depolarisation and gating of the calcium channels (which are voltage sensitive), increasing the intracellular concentration of calcium and stimulating insulin release. The release of insulin only occurs in the presence of glucose. As glucose levels drop, less insulin is secreted. Conversely, if carbohydrates are consumed and glucose levels rise, insulin secretion is enhanced.

Pharmacokinetics. The pharmacokinetic properties of meglitinides confer a rapid onset and a short duration of action (see Table 45.3). Meglitinides are extensively metabolised in the liver, repaglinide by oxidative biotransformation and direct conjugation

with glucuronic acid. The cytochrome P450 enzymes CYP2C8 and CYP3A4 have been shown *in vitro* to be involved in its metabolism. Nateglinide is metabolised predominantly by cytochrome P450 enzyme CYP2C9 and to a lesser extent by CYP3A4. Repaglinide has no active metabolites, but nateglinide has partially active metabolites, one-third to one-sixth the potency of the parent compound. Meglitinides should be taken immediately before main meals, although the time can vary up to 30 minutes before a meal. The pharmacokinetic profile of meglitinides offers some advantages in patients with poor renal function or irregular eating habits.

Adverse effects. Meglitinides may cause a range of side effects, most commonly hypoglycaemia, weight gain, visual disturbances, abdominal pain, diarrhoea, constipation, nausea and vomiting. More rarely, hypersensitivity reactions and elevation of liver enzymes can occur.

Dosage. The recommended starting dose for repaglinide is 500 micrograms before or with each meal, increasing as necessary (depending on blood glucose measurements) every 1–2 weeks to a maximum single dose of 4 mg and a maximum daily dose of 16 mg. When patients are transferred from other therapies, the recommended starting dose is 1 mg preprandially. The recommended starting dose of nateglinide is 60 mg three times a day before meals, which may be subsequently increased to 120 mg three times a day. The maximum single dose is 180 mg, which may be given with the three main meals of the day.

Drug interactions. Drugs which induce or inhibit the cytochrome P450 enzymes CYP2C8 and CYP3A4 interact with repaglinide. Examples of drugs which enhance or prolong the hypoglycaemic effect include gemfibrozil, clarithromycin, ketoconazole, itraconazole, trimethoprim, other hypoglycaemic drugs, monoamine oxidase inhibitors, non-selective β -blockers, ACE inhibitors, salicylates, NSAIDs, octreotide, alcohol and anabolic steroids. Drugs which induce cytochrome P450 enzymes may also interact, for example, rifampicin and phenytoin, and may decrease repaglinide serum levels. Drugs that inhibit CYP2C9 may interact with nateglinide. Drugs that may enhance or prolong the hypoglycaemic effect include ACE inhibitors, gemfibrozil and fluconazole. The hypoglycaemic effects of nateglinide may be reduced by diuretics, corticosteroids and β -blockers.

Role of meglitinides. Meglitinides are an effective hypoglycaemic therapy in type 2 diabetes. They may be most beneficial in patients who experience problems with post-prandial glucose elevation and as single therapy in patients who eat at unpredictable times or have a tendency to miss meals.

Thiazolidinediones

Research into the action of the thiazolidinediones, also known as glitazones, has led to greater understanding of the development of type 2 diabetes. Pioglitazone has been shown to have a significant benefit on macrovascular morbidity and mortality, demonstrating the benefit of a glucose-lowering agent on macrovascular disease (Dormandy *et al.*, 2005).

Mode of action. Glitazones act as agonists of the nuclear peroxisome proliferator-activated receptor- γ (PPAR- γ). PPAR- γ is mostly expressed in adipose tissue but is also found in pancreatic β -cells, vascular endothelium and macrophages. It is

also expressed weakly in those tissues that express predominantly PPAR- α , for example, skeletal muscle, liver and heart. Thiazolidinediones lower fasting and post-prandial glucose levels in addition to lowering free fatty acid and insulin concentrations. They enhance insulin sensitivity and promote glucose uptake and utilisation in peripheral tissues. They also suppress gluconeogenesis in the liver and, by increasing insulin sensitivity in adipose tissue, suppress free fatty acid concentrations. The indirect effects of glitazones on adipose tissue are due to alterations in the regulation of gene expression. Various adipokines (adiponectin, tumour necrosis factor- α , resistin and 11 β -hydroxysteroid dehydrogenase 1) are regulated by PPAR- γ agonists in animal studies.

Pharmacokinetics. Pioglitazone is metabolised extensively in the liver to both active and inactive metabolites.

Adverse effects. Congestive cardiac failure is an adverse effect. Therefore, because of the potential worsening of heart failure, pioglitazone should not be used in patients with a history of or pre-existing heart failure. Combination therapy with insulin and thiazolidinediones has been found to result in a higher incidence of oedema. There is also an increased risk of bone fracture with pioglitazone, and it should be used with caution in post-menopausal women. Approximately 1% of patients show a small decrease in the haemoglobin concentration during the first 4–12 weeks of therapy, possibly due to dilutional effects caused by an increase in serum volume. Pioglitazone caused weight gain of around 3.6 kg during clinical trials (Cheng and Kashyap, 2011). Some patients also experience headache, abdominal pain, myalgia and upper respiratory infection. Pioglitazone may also elevate liver transaminases. Studies have identified that there is a potential increase in the risk of bladder cancer. Pioglitazone should not be used in individuals with a history of bladder cancer, and the risk factors for bladder cancer should be assessed before initiating pioglitazone treatment (risks include age, smoking history, exposure to some occupational or chemotherapy agents, e.g. cyclophosphamide or prior radiation treatment in the pelvic region). Any macroscopic haematuria should be investigated before starting pioglitazone therapy, and patients should be advised to seek the attention of their doctor if haematuria or symptoms such as dysuria or urinary urgency develop during treatment.

Dosage. Pioglitazone is started at a dose of 15 or 30 mg and may be increased to 45 mg once daily. In combination with metformin or a sulfonylurea, the current dose can be continued. Dosage adjustment is not necessary in patients with mild or moderate renal impairment or in the elderly. Discontinue treatment in patients with severe renal impairment or in those with hepatic impairment.

Drug interactions. Pioglitazone is metabolised by cytochrome P450 CYP3A4. Therefore, ketoconazole, itraconazole, erythromycin and fluconazole increase serum concentrations, whereas rifampicin and phenytoin decrease serum levels of pioglitazone.

Role of thiazolidinediones. Thiazolidinediones improve glycaemic control in patients, especially in those with insulin resistance, by reducing HbA_{1c} levels up to 1.5% compared with a sulfonylurea or metformin alone.

Glitazones may be used after lifestyle modification and the use of metformin monotherapy. Treatment should only be continued

if, after 6 months of treatment, the HbA_{1c} has reduced by 0.5% of its starting value.

Monotherapy with a thiazolidinedione may be a valuable treatment option for patients who are known to be insulin resistant. Triple therapy can be an alternative to transferring a patient to insulin, but the modest reduction in HbA_{1c} usually means that many patients will eventually require insulin. It is important to be aware that because of their mode of action, which involves changes in gene transcription, thiazolidinediones take up to 3 months to have their maximum effect on glycaemic control.

Sodium-glucose co-transporter-2 inhibitors

The SGLT-2s are a new class of oral medications for the treatment of type 2 diabetes. They are commonly referred to as the 'gliflozins'. They work by lowering the renal threshold to glucose, which leads to its urinary excretion. There are currently three licensed products: canagliflozin, dapagliflozin and empagliflozin.

Mode of action. Orally active, they selectively and reversibly inhibit the sodium-glucose co-transporter 2 (SGLT-2), which is selectively expressed in the proximal renal tubules of the kidney. SGLT-2 is the predominant transporter responsible for reabsorption of glucose from the glomerular filtrate back into the circulation. By inhibiting SGLT-2 the reabsorption of glucose is reduced. The amount of glucose excreted is dependent on blood glucose concentration and GFR. The reduction of renal reabsorption leading to urinary increased excretion of glucose improves both fasting and post-prandial glucose levels. Urinary glucose excretion is associated with calorific loss and reduction in weight, max 280 kcal/day and max 70 g/day, respectively.

Pharmacokinetics. The efficacy of SGLT-2s is dependent on renal function, and efficacy is reduced in renal impairment; dapagliflozin is not recommended if eGFR is less than 60 mL/min/m². Canagliflozin and empagliflozin require dose reduction in impaired renal function (eGFR less than 60 mL/min/m²) and should be discontinued if eGFR is less than 45 mL/min/m². No dose adjustment is required in mild to moderate hepatic impairment; severe impairment requires discontinuation. They are not licensed in adults older than 75 years or children younger than 18 years of age.

Dapagliflozin and canagliflozin are metabolised via glucuronide conjugation mediated by UDP glucuronosyltransferase 1A9 (UGT1A9). Canagliflozin is also metabolised by UGT2BA and transported by P-glycoprotein and breast cancer resistance protein (BCRP).

In studies dapagliflozin neither inhibited cytochrome P450 (CYP) 1A2, CYP2A6, CYP2BB, CYP2C8, CYP2C9, CYP2C19, CYP2D6 CYP3A4 nor induced CYP1A2, CYP2BB or CYP3A4. Therefore, it is not expected to alter the metabolic clearance of co-administered medicinal products.

Empagliflozin is primarily metabolised by glucuronidation by uridine 5 diphosphoglucuronosyltransferases UGT1A3, UGT1A8, UGT1A9 and UGT2B7. It is a substrate of P-glycoprotein and breast cancer resistance protein (BRP), but medicinal interactions are not considered significant.

Adverse effects. Serious and life-threatening cases of DKA have been reported in people taking SGLT-2 inhibitors; the exact mechanism remains unclear. This atypical presentation in people

with type 2 diabetes and near-normal blood glucose may delay diagnosis and treatment. As such, blood ketone tests should be undertaken in patients with acidosis symptoms, even if plasma glucose levels are near normal.

The most commonly reported side effects are infections and infestations, especially urinary tract infections, vulvovaginitis, balanitis and related genital infections. There may be a decrease in creatinine clearance, especially if taking other medication known to increase the risk of renal impairment, and it can lead to osmotic diuresis and volume-depletion reactions in elderly patients and those on diuretics. Caution should be applied if used with pioglitazone due to potential increases in the incidence of bladder cancer.

Drug interactions. Co-administration with diuretics may lead to dehydration and hypotension. Canagliflozin clearance is increased by enzyme inducers such as St John's wort, rifampicin, barbiturates, phenytoin, carbamazepine, ritonavir and efavirenz. If it is to be co-administered, the dose of canagliflozin may need to be increased, and glycaemic control monitored. Canagliflozin has been noted to inhibit P-glycoprotein (P-gp); therefore, patients taking digoxin and other cardiac glycosides should be monitored closely. The impact of the inhibition of the breast cancer resistance protein (BCRP) cannot be excluded, and therefore caution should be exerted when administering other medicinal products transported by BCRP such as rosuvastatin and anti-cancer medicinal products.

Role. The SGLT-2s are licensed for use in monotherapy or in combination with other glucose-lowering medicinal products, including insulin. Because they offer an alternative mechanism of action that is not insulin related, they are useful for patients with significant β -cell decline. They are also of particular benefit in patients where calorific reduction and weight loss would be valuable. It has also been identified that patients at high risk of cardiovascular events taking empagliflozin have a lower rate of cardiovascular outcomes and death compared with those receiving standard care (Zinman et al., 2015).

Dipeptidyl peptidase-4 inhibitors

The dipeptidyl peptidase-4 (DPP-4) inhibitors are a class of drugs that work on the incretin system. They are also commonly referred to as the 'gliptins' – sitagliptin, vildagliptin, saxagliptin, alogliptin and linagliptin.

Mode of action. DPP-4 inhibitors block the normal enzymatic inactivation of incretins, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP). Incretins play a role in increasing endogenous insulin in response to a high glucose load post-prandially. They also reduce the amount of glucose produced by the liver when glucose levels are sufficiently high. By blocking DPP-4, these drugs prolong incretin activity and inhibit glucagon release. This in turn causes a decrease in blood glucose and an increase in insulin secretion.

Pharmacokinetics. DPP-4 inhibitors are predominantly renally excreted. However, there is also a degree of hepatic metabolism involved in the elimination process, which varies with each drug. Sitagliptin is mainly excreted as unchanged drug in the urine, with a small metabolic contribution from the liver via the cytochrome P450 system. The kidney is thought to be mainly

responsible for metabolic hydrolysis of vildagliptin to an inactive compound. Although saxagliptin is mainly eliminated renally, some hepatic biotransformation does occur via the cytochrome P450 system (CYP3A4/5), which results in a metabolite with half the potency of the parent compound. The dose guidance and pharmacokinetic parameters of the DPP-4 inhibitors are detailed in Table 45.3. In people with renal impairment, the significance of renal clearance for each of the DPP-4 inhibitors should be considered. The choice of agent and dose must be adjusted in accordance with the manufacturers' guidance.

Adverse effects. All DPP-4 inhibitors have been linked to gastro-intestinal side effects and upper respiratory tract infection. DPP-4 inhibitors do not cause hypoglycaemia, but they have the potential to cause hypoglycaemia when prescribed with other agents that can produce this effect. Vildagliptin has been associated with rare reports of liver dysfunction. Therefore, it is recommended that liver function tests are performed before starting treatment, at 3-month intervals for the first year and then periodically thereafter.

Drug interactions. DPP-4 inhibitors have a low potential for interaction with other medicines. However, because both sitagliptin and saxagliptin are metabolised by cytochrome P450 3A4/5 (and CYP2C8 for sitagliptin), they have the potential to interact with potent inducers or inhibitors of these enzyme. In practice, few drugs have been formally assessed. Therefore, general advice is to monitor blood glucose levels carefully if one of these drugs is co-prescribed with sitagliptin or saxagliptin.

Role of dipeptidyl peptidase-4 inhibitors. DPP-4 inhibitors are useful for those who still do not have adequate control or cannot tolerate treatment with metformin. DPP-4 inhibitors are also useful if further weight gain is likely or there is concern about the risk of hypoglycaemia. However, if insulin resistance is a key factor, then treating with a thiazolidinedione may be a better choice. The choice of agent will need to consider the degree of renal impairment, some agents require dose adjustment as renal function deteriorates.

Incretin mimetics

The incretin mimetics, as the name suggests, mimic the effects of incretins. The currently licensed products in the UK, exenatide, liraglutide, dulaglutide and lixisenatide are only available as subcutaneously injectable products. Incretin mimetics have been demonstrated to cause weight loss, which is a particularly beneficial effect in many patients with type 2 diabetes.

Mode of action. The incretin mimetics bind to and activate the glucagon-like peptide-1 (GLP-1) receptor, hence increasing insulin secretion, suppressing glucagon secretion, increasing satiety and slowing gastric emptying. All of these effects help lower blood glucose levels.

Pharmacokinetics. Incretin mimetics have a longer duration of action than endogenous GLP-1. Exenatide is eliminated primarily by renal clearance. However, the specific organ responsible for liraglutide elimination has not been identified.

Adverse effects. All incretin mimetics have been associated with nausea and other gastro-intestinal disturbances. However, once therapy has been established, the incidence of these side effects decreases. Acute pancreatitis has also been rarely reported.

For this reason, both patients and their carers should be advised of the signs and symptoms of this complication and advised to stop taking the drug and seek medical attention immediately if they occur. Because the incretin mimetics cause glucose-dependent insulin release, hypoglycaemia is uncommon and in most cases can be attributed to other agents taken concurrently.

Drug interactions. The potential for drug interactions with the incretin mimetics is low. However, because they can cause a delay in gastric emptying, they may influence the absorption of other medicines administered at the same time. For this reason, it is advised that any narrow-therapeutic-index drugs taken concomitantly are monitored carefully.

Role of incretin mimetics. It is recommended that GLP-1 mimetics be added as third-line therapy for patients who have a BMI of ≥ 35 kg/m², are of European descent (adjustments to this threshold may be made for other ethnic groups at greater risk of cardiac disease) and have other medical problems associated with increased body weight. Alternatively, they may be used in patients with a BMI less than 35 kg/m² who are not able to take insulin, for example, for occupational reasons, or who have other conditions that would benefit from weight loss. Treatment should only be continued if there has been an HbA_{1c} reduction of at least 1% and a weight loss of at least 3% from starting treatment over a 6-month period (NICE, 2015d).

Insulin therapy in type 2 diabetes

The younger age of onset of type 2 diabetes and tighter glycaemic targets mean that the majority of patients with type 2 diabetes progress to insulin therapy because evidence confirms that long-term glycaemic improvement reduces the risk of both microvascular (Holman et al., 2008) and macrovascular (Turnbull et al., 2009) complications.

It is currently common practice to introduce insulin to an oral medication schedule, although the oral medications may be reduced or stopped. A number of different insulin regimens for use in patients with type 2 diabetes are available, the most common of which include once-daily basal insulin, twice-daily biphasic (premixed) insulin, or prandial insulin, using a rapid/short-acting insulin with meals. Studies suggest that patients who have basal insulin or prandial insulin added to their oral therapy have better HbA_{1c} control than those who receive biphasic insulin. In addition, the basal insulin regimen is associated with fewer hypoglycaemic episodes and less weight gain than the other two regimens (Holman et al., 2009). Basal insulin should be titrated to achieve normal fasting glucose levels, and the patient may be taught this self-titration protocol (Davies et al., 2005).

In a lean patient (BMI <25 kg/m²), significant insulin deficiency is more likely, and therefore insulin treatment with either a basal-bolus or twice-daily regimen may be preferred from the outset.

A-glucosidase inhibitors

Acarbose reduces carbohydrate digestion by interfering with gastro-intestinal glucosidase activity, reducing the post-prandial hyperglycaemic peaks. Acarbose is minimally absorbed in unchanged form from the gastro-intestinal tract.

Adverse effects. The most common adverse effect is abdominal discomfort associated with flatulence and diarrhoea. These symptoms usually improve with continued treatment but can be minimised by starting with a low dose and titrating slowly.

Systemic adverse effects are rare, but high doses have been associated with idiosyncratic elevations of serum hepatic transaminase levels; therefore, patients titrated to the maximum should be closely monitored, preferably at monthly intervals for the first 6 months. If elevated transaminase levels are observed, reduction in dose or withdrawal of therapy should be considered.

Role of acarbose. Acarbose is a therapeutic option in type 2 patients inadequately controlled by diet alone or by diet and other oral hypoglycaemic agents. However, the gastro-intestinal side effects do limit the use of acarbose in clinical practice.

Treating hypertension

The co-existence of hypertension and diabetes dramatically increases the risk of microvascular and macrovascular complications. Most important is the increased risk of cardiovascular disease. Tight control of blood pressure may be a more effective method of preventing complications in patients with type 2 diabetes than tight glycaemic control (UKPDS, 1998b). It is recommended that for patients with type 2 diabetes, the target blood pressure should be less than 140/80 mmHg; for those with pre-existing kidney, eye or cerebrovascular damage, the target should be reduced to less than 130/80 mmHg (NICE, 2015d). First-line blood-pressure-lowering therapy should be a once-daily, generically prescribed ACE inhibitor. Exceptions to this are people of African-Caribbean descent, in whom first-line therapy should be an ACE inhibitor plus either a diuretic or a calcium-channel blocker.

In patients with type 1 diabetes, the blood pressure target is less than 135/85 mmHg. However, if there is abnormal albumin excretion (renal disease), then the blood pressure target should be lowered to 130/80 mmHg with maximal doses of either an ACE inhibitor or ARB as first-line therapy (NICE, 2015c).

Patient care

Annual review

People with diabetes should attend their hospital clinic or primary care practice (if this service is offered locally) for an annual review to screen for diabetic complications. Monitoring and optimising of glycaemic control are also undertaken, although these should be done on a more regular basis, as should review of patients with known complications. In the UK the annual review is increasingly taking place in primary care, with referral to secondary care if required. The typical assessments undertaken at an annual review are described in Box 45.4.

Glycaemic management

The theoretical ideal for all patients with diabetes is to achieve normoglycaemia. Because this is not always possible, the aim is to achieve the best possible control compatible with an acceptable lifestyle for the patient. In some patients, this may mean

Box 45.4 Annual review for diabetes

Routine assessment

- Capillary blood glucose level
- Weight, body mass index and waist circumference
- Blood pressure
- Urinalysis for glucose, protein and ketones
- Foot assessment

Laboratory investigations

- Lipid profile
- HbA_{1c}
- U&E, creatinine
- Liver function tests
- Urine specimen for albumin/creatinine ratio

Referral, if appropriate

- Retinopathy screening (should be done annually)
- Dietician
- Podiatry
- Exercise programme
- Smoking cessation programme

HbA_{1c}, glycated haemoglobin, a definition that identifies the average plasma glucose concentration; U&E, urea and electrolytes (blood test used to assess a patient's fluid status, renal function and electrolyte balance).

only symptomatic control; in others this may be tight control. In making this decision, the following factors should be considered: the patient's age, motivation, understanding, likely adherence, co-existing diseases, and ability to recognise hypoglycaemia; the duration of their diabetes; and the presence/absence/severity of diabetic complications.

Targets for pre-meal blood glucose of between 4 and 7 mmol/L and post-meal values of less than 8.5 mmol/L may be set for most patients, provided there is no significant hypoglycaemia risk. An optimal HbA_{1c} target of 48 mmol/mol for most of those with type 2 diabetes has been suggested; however, for patients not adequately controlled on a single agent, polypharmacy puts the individual at risk of hypoglycaemia, so a target of 53 mmol/mol should be encouraged (NICE, 2015d). However, it is recommended that targets should be individualised and that for some, a higher target would be more appropriate, especially if there is a risk of hypoglycaemia at the lower target. For those with type 1 diabetes, the recommended target is less than 48 mmol/mol, but again, this does need to be individualised (NICE, 2015c) (see Table 45.6).

The diabetes treatment goals in older people may be different and more conservative than in younger adults. For example, some elderly patients may have poor vision and limited manual dexterity, which may or may not be linked to a degree of cognitive impairment. Others may have multiple pathology and take a number of other medications. Therefore, the goals of therapy need to be both individual and realistic. In some people, they will involve only the optimisation of body weight, control of symptoms and avoidance of hypoglycaemia, which has an increased risk of brain damage and may occur without the usual warning signs in the elderly. In others, reasonably tight control may be appropriate. There is, therefore, a difficult balance between the use of aggressive treatment with its associated risk of hypoglycaemia and the benefits of reducing complications to maintain an acceptable quality of life.

Monitoring glycaemic control

Clinic monitoring

There are several ways in which glycaemic control can be monitored in primary and secondary care. Estimates of average control are often useful. Glycation of minor haemoglobin components occurs in the blood, with the extent depending on both the amount of glucose present and the duration of exposure of the haemoglobin to glucose. Estimates of glycated haemoglobin (HbA_{1c}) provide an index of average diabetes control over the preceding 2–3 months, that is, the lifespan of a red blood cell. HbA_{1c} can be measured at any time, the patient does not need to be fasted and levels are not normally affected by acute changes in therapy, diet or exercise. However, they may be lower in those with reduced red cell lifespan, for example, in pregnancy, advanced renal failure or sepsis. Serum fructosamine represents the glycation of all serum proteins and gives information about control over the preceding 3 weeks. Because albumin is the major serum protein, hypoalbuminaemia may affect fructosamine levels. However, HbA_{1c} is the preferred marker for average glycaemic control.

Home monitoring

Type 1 diabetes. All patients treated with insulin should be offered home blood glucose monitoring. Capillary blood is applied to a reagent strip which has been impregnated with enzymes, for example, glucose oxidase. Home blood glucose monitoring enables patients and carers to make a direct assessment of the effect of changes in medicines, dietary habits, exercise and patterns of illness. It has the additional benefit that it can detect hypoglycaemia.

Patients with type 1, who are by definition ketosis prone, should also know how and when to test for blood ketones. This test need not be carried out as part of routine monitoring but is essential at times of intercurrent illness, especially when the blood glucose is ≥ 17 mmol/L.

Type 2 diabetes. NICE (2015d) guidance is that routine blood glucose monitoring is not offered to patients with type 2 unless they are on insulin, there is evidence of hypoglycaemia episodes, they are on an oral agent that may increase risk of hypoglycaemia whilst driving or they are pregnant or planning to become pregnant. Further information about blood glucose monitoring and a person's fitness to drive is provided by the Driver and Vehicle Licencing Agency (DVLA, 2016).

NICE (2015d) guidance suggests considering short-term monitoring for adults when starting treatment with steroids or to confirm suspected hypoglycaemia. Before continuing self-monitoring, it is important to assess (annually) the person's self-monitoring skills, quality and frequency of testing, interpretation of the results, impact on quality of life and continued benefit. Many people with type 2 diabetes are treated with diet alone or with oral hypoglycaemic agents, and unless they have problems with hypoglycaemia, urine glucose monitoring should be adequate. This is a simple, noninvasive test that can detect hyperglycaemia but not hypoglycaemia. Home blood glucose monitoring is used by some patients with type 2,

particularly if control is poor, if they are undergoing medication dose titration, if they are being treated with insulin or if they are prone to hypoglycaemia. It is also recommended that blood glucose monitoring be undertaken before driving and at times of intercurrent illness, when blood glucose levels may be particularly erratic.

Regardless of whether individuals with type 1 or type 2 diabetes are using home blood glucose monitoring or urine testing, it is important they are educated about what to do with the results; otherwise, there is little point in testing.

Case studies

Case 45.1

Mrs SG is a 32-year-old woman who has type 1 diabetes. She is hoping to become pregnant and wishes to talk to you about pre-conception care and diabetes. During the consultation, you discover that she is taking folic acid 400 micrograms daily and has been for the previous 6 months but, until now she has not received any pre-conception diabetes care. Her most recent HbA_{1c} was 57 mmol/mol (7.3%). Her regular medications are ramipril 10 mg daily, simvastatin 40 mg daily, insulin glargine at night and insulin aspart three times daily with meals.

Questions

1. Why should women of childbearing age be offered advice about pregnancy?
2. What blood glucose targets should Mrs SG be advised to aim for before and after conceiving?
3. Is Mrs SG taking appropriate dietary supplements before conception?
4. What advice should she be given with respect to her regular medication?

Answers

1. Mrs SG should be offered preconception advice before becoming pregnant because glucose control needs to be optimal to reduce the risk of miscarriage, congenital malformation, stillbirth and neonatal death. Preconception advice should also include information for the patient on how diabetes affects pregnancy and how pregnancy affects diabetes, what dietary supplements to take and advice on diabetes-related medicines that are unsafe to take during pregnancy.
2. Mrs SG should aim for an HbA_{1c} target of less than 48 mmol/mol (6.5%) before conceiving and throughout the pregnancy, whilst aiming to avoid significant hypoglycaemia. Her capillary blood glucose targets should be the same as for all people with type 1 diabetes, fasting glucose level 5–7 mmol/L on waking and 4–7 mmol/L before meals at other times of the day. During pregnancy, she should aim for fasting blood glucose levels of 5.3 mmol/L and less than 7.8 mmol/L 1-hour post-prandial levels.
3. Mrs SG is taking the appropriate dietary supplement; however, the recommended dose of folic acid for women with diabetes is 5 mg daily, rather than 400 micrograms daily. The 5 mg strength tablets are available by prescription. This should be taken before pregnancy and until 12 weeks of gestation to reduce the risk of having a baby with neural tube defects.

- Mrs SG should be advised to stop her ramipril and simvastatin because both have been associated with an increased risk of birth defects. She will need to be assessed for hypertension because if ramipril is being used for its antihypertensive effects in addition to renal protection, then consideration will need to be given to alternative antihypertensive medications.

Case 45.2

Mr RK is a 57-year-old man with type 2 diabetes. He has recently had basal insulin (insulin isophane) added to his other diabetes medicines: metformin 1 g twice a day and gliclazide 160 mg twice a day. Mr RK complains of waking with a headache and feeling 'groggy' and unrested in the morning. His recent blood glucose readings have generally been very good, and his recent HbA_{1c} is much improved since the addition of insulin. Mr RK is worried because he is feeling worse since he started insulin, even though his blood glucose levels are much improved. He has completed a hypoglycaemia awareness questionnaire at his community pharmacy and is concerned that nocturnal hypoglycaemia may be causing his recent symptoms. Mr RK wishes to know more about hypoglycaemia and how he can manage the risk whilst maintaining his recent improved blood glucose control.

Questions

- What is nocturnal hypoglycaemia?
- How can the diagnosis of nocturnal hypoglycaemia be confirmed?
- How should it be managed?

Answers

- Nocturnal hypoglycaemia is a low blood glucose reading that occurs during the night. Definitions vary, but it is generally accepted that a reading of less than 3.5 mmol/L is 'hypoglycaemia'. Night-time blood glucose levels may be even lower than those detected during the daytime because a more pronounced counter-regulatory hormone is required to wake the person with diabetes. The normal symptoms of hypoglycaemia may be missed if the patient does not wake. However, signs noticed (often by partners) might include restlessness, sweating and nightmares. Symptoms experienced by the patient in the mornings commonly include headache and lethargy.
- Commonly, nocturnal hypoglycaemia can be confirmed by undertaking a blood glucose reading in the early hours of the morning, that is, between 2 and 3 a.m. This may require the patient to set an alarm to be woken at this time.
