Preface

In both primary and secondary health care, the use of medicines is the most common intervention. However, the use of medicines is not without risk. Selecting and prescribing drugs is increasingly complex and demanding, and it is undertaken as part of a multi-disciplinary process that involves pharmacists, some of whom are now prescribers in their own right, along with doctors, nurses and other members of the healthcare team. All must strive to promote safe, appropriate and cost-effective prescribing that respects patient choice and promotes adherence. This book was written to help the reader understand and address many of these issues. It is unashamedly written from a pharmacy perspective, although we do hope those from other disciplines will also find it of use.

We have made considerable effort to update each chapter and ensure the content is relevant to current practice. Selected website addresses have been included to assist those who want to obtain further information, and many references are now available electronically. However, knowledge in therapeutics progresses rapidly, changes to dose regimens and licensed indications are frequent, safety issues emerge with established drugs and new medicines appear at regular intervals. Yesterday another landmark study may have been published that added to, or perhaps

altered, the evidence base for a specific treatment. Together with the ongoing publication of national and international guidelines and frameworks, the face of therapeutics is ever changing. It is therefore inevitable that some sections of this book will date more quickly than others.

In practice, many licensed drugs are used ‘off label’ or ‘near label’ when prescribed for a certain indication or used in a specific patient group, such as children. To omit reference to these agents in the relevant chapter would leave an apparent gap in therapeutic management. As a consequence, we have encouraged our authors to present details of all key drugs used, along with details of the prescribed regimens, even if not licensed for that specific indication. There is, however, a downside to this approach. The reader must always use this text critically and with caution. If this is done, the book will serve as a valuable learning resource and help the reader understand some of the principles of therapeutics. We hope that, in some small way, this will also assist in achieving positive patient outcomes.

Cate Whittlesea
Karen Hodson

Acknowledgements

The first edition of this book was published in 1994 by Roger Walker and Clive Edwards. We very much hope that this edition lives up to the high standards of both past editors. We acknowledge the enormous contribution Roger Walker made to all previous editions and very much hope he will look in pride at this, our first edition, without him at the helm. Like Roger, undergraduate and postgraduate students have sustained our enthusiasm and commitment while continuing to be the inspiration and the *raison d'être* for this book. To all those who have provided feedback in the past, thank you. For those who would like to comment on this edition, we welcome your feedback; please contact us at c.whittlesea@ucl.ac.uk or hodsonkl@cardiff.ac.uk.

We remain indebted to all authors who, through their hard work, patience and tolerance, have contributed to the sixth edition of this book. We are particularly grateful to those who have again contributed to another edition of this textbook and who strive, along with us, to produce an ever-better book. To our first-time authors, we are very grateful for your contribution, that you accepted our cryptic editorial comments in good faith and still managed to submit on time. We hope that you will continue to work with us on future editions.

A textbook of this size cannot, of course, be produced without the invaluable help, support and occasional comments of numerous colleagues, particularly from the Department of Pharmacy, Durham University, UCL School of Pharmacy and the Associate Course Directors of the MSc in Clinical Pharmacy within the School of Pharmacy and Pharmaceutical Sciences, Cardiff University. It would be invidious to name individuals who have helped us, in part for fear of offending anyone we might miss. We do, however, continue to make one exception to this rule. The administrative support from Dean Routledge has been invaluable.

Finally, and on a personal note, we would like to thank our close families for their support and tolerance with our indulgence in editing this text. At times it may have appeared that everything in our lives took second place to 'the book'. We are eternally grateful for their understanding, particularly when we got our priorities in life wrong. Without the unfailing support of Rob and Phil, Maddy and Logan, this book would never have materialised.

Cate Whittlesea
Karen Hodson

List of Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Tamara Ahmed Ali
Directorate Lead Pharmacist-Ophthalmology, City
Hospitals Sunderland NHS Trust, Sunderland, UK
56. Glaucoma

Sotiris Antoniou
Consultant Pharmacist, Cardiovascular Medicine, Barts
Health NHS Trust, St Bartholomew's Hospital, London, UK
22. Arrhythmias

Kelly Atack
Advanced Clinical Pharmacist, Medicines Management
and Pharmacy, St James's University Hospital, Leeds
Teaching Hospital NHS Trust, Leeds, UK
25. Asthma

Deborah Baidoo
Chief Pharmacist (Interim), West London Trust,
St Bernard's Hospital, Middlesex, London, UK
27. Insomnia

David S. Baldwin
Professor of Psychiatry, Clinical and Experimental
Sciences Academic Unit, Faculty of Medicine, University
of Southampton, Southampton, UK
28. Anxiety disorders

Catrin Barker
Chief Pharmacist, Pharmacy Department, Alder Hey
Children's NHS Foundation Trust, Liverpool, UK
10. Paediatrics

Roger Barker
Professor of Clinical Neuroscience, Honorary
Consultant in Neurology, University of Cambridge and
Addenbrooke's Hospital, Cambridge, UK
32. Parkinson's disease

Lee Beale
Anaesthetic Registrar ST7, University Hospital of Wales,
Cardiff, UK
6. Laboratory data

Jonathan Berry
Academic Clinical Educator, School of Pharmacy, Keele
University, Staffordshire, UK
14. Constipation and diarrhoea

Stephen Bleakley
Chief Pharmacist, Salisbury NHS Foundation Trust,
Salisbury, UK
28. Anxiety disorders

Gonçalo Caçao
UCL Institute of Neurology, London, UK
31. Epilepsy

Anthony Cadogan
Macmillan Advanced Pharmacist, Haematology and
Oncology, Prince Charles Hospital (Merthyr Tydfil)
and Royal Glamorgan Hospital (Llantrisant), Cwm Taf
University Health Board, Wales, UK
50. Anaemia

Laura Cameron
Principal Pharmacist - Cancer Services Operational Lead,
Guy's and St Thomas' NHS Foundation Trust, London, UK
52. Lymphomas

Toby Capstick
Lead Respiratory Pharmacist, Pharmacy Department,
Leeds Teaching Hospitals NHS Trust, Leeds, UK
41. Tuberculosis

Neil J. B. Carbarns
Consultant Medical Microbiologist, Aneurin Bevan
University Health Board, Abergavenny,
Monmouthshire, UK
37. Urinary tract infections

Sheena Castelino
Principal Pharmacist, HIV and Sexual Health, Guy's
and St Thomas' NHS Foundation Trust, Pharmacy
Department, St Thomas' Hospital, London, UK
42. HIV infection

Ben Challocombe
 Consultant Urologist, Guy's and St Thomas' NHS
 Foundation Trust, London, UK
 49. *Prostate disease*

Ian Clifton
 Consultant Respiratory Physician and Honorary Senior
 Lecturer, Department of Respiratory Medicine,
 St James's University Hospital, Leeds Teaching Hospital
 NHS Trust, Leeds, UK
 25. *Asthma*

Paul Cockwell
 Consultant Nephrologist, University Hospital
 Birmingham and Professor of Nephrology, University of
 Birmingham, Birmingham, UK
 17. *Acute kidney injury*
 18. *Chronic kidney disease and end-stage renal disease*

Katie Conway
 Consultant Physician in GU/HIV Medicine, Guy's and
 St Thomas' NHS Foundation Trust, Pharmacy
 Department, St Thomas' Hospital, London, UK
 42. *HIV infection*

Jonathan Cooke
 Honorary Professor, Manchester Pharmacy School,
 Faculty of Biology, Medicine and Health, University
 of Manchester, Manchester; Visiting Professor in the
 Infectious Diseases and Immunity Section, Division of
 Infectious Diseases, Department of Medicine, Imperial
 College London, London, UK
 8. *Pharmacoeconomics*

Alan G. Cosslett
 Lecturer, School of Pharmacy and Pharmaceutical
 Sciences, Cardiff University, Cardiff, UK
 7. *Parenteral nutrition*

Anthony R. Cox
 Senior Lecturer in Clinical Pharmacy and Drug Safety,
 School of Pharmacy, University of Birmingham,
 Birmingham, UK
 5. *Adverse drug reactions*

Netty (Annette) Cracknell
 Specialist Oncology Pharmacist, Netty Cracknell
 Consultancy; Pharmacy Manager, Springfield Hospital,
 Chelmsford, UK; Executive Committee Member, British
 Oncology Pharmacy Association (BOPA), UK
 53. *Solid tumours*

 Professor of Clinical Pharmacy and Therapeutics, King's
 College London, London, UK
 1. *Clinical pharmacy practice*

Nemesha Desai
 Consultant Dermatologist, St John's Institute of
 Dermatology, Guy's and St Thomas' NHS Foundation
 Trust, London, UK
 58. *Eczema and psoriasis*

Mark D. Doherty
 Consultant Ophthalmologist, Sunderland Eye Infirmary,
 Sunderland, UK
 56. *Glaucoma*

Tobias Dreischulte
 Research Pharmacist, NHS Tayside, Community Health
 Sciences Division, Dundee, UK
 21. *Chronic heart failure*

Jackie Elliott
 Senior Clinical Lecturer in Diabetes and Honorary
 Consultant, Diabetes and Endocrine Centre, Northern
 General Hospital, Sheffield, UK
 45. *Diabetes mellitus*

Sarah Fenner
 Director, West Midlands Medicines Information Service
 and UK Drugs in Lactation Advisory Service, Good Hope
 Hospital, Sutton Coldfield, UK
 48. *Drugs in pregnancy and lactation*

Ray W. Fitzpatrick
 Clinical Director of Pharmacy, New Cross Hospital,
 Wolverhampton, UK
 3. *Practical pharmacokinetics*

- Peter Golightly
Senior Medicines Information Pharmacist, West Midlands and Trent Regional Medicines Information Services and UK Drugs in Lactation Advisory Service, Good Hope Hospital NHS Trust, Sutton Coldfield, UK
48. Drugs in pregnancy and lactation
- Alison Grant
Highly Specialist Pharmacist in HIV and Sexual Health, Guy's and St Thomas' NHS Foundation Trust, St Thomas' Hospital, London, UK
42. HIV infection
- Jim Gray
Consultant Microbiologist, Department of Microbiology, Birmingham Women's and Children's NHS Foundation Trust, Birmingham Children's Hospital, Birmingham, UK
38. Gastro-intestinal infections
39. Infective meningitis
- Dan Greer
Pharmacist Lecturer/Practitioner, Programme Manager, Postgraduate Programme in Pharmacy Practice, University of Leeds, Leeds, UK
12. Dyspepsia, peptic ulcer disease and gastro-oesophageal reflux disease
- Imran Hafiz
Principal Cardiovascular Pharmacist, Guy's and St Thomas' NHS Foundation Trust; Clinical Lecturer, King's College London, UK
20. Coronary heart disease
- Keith Harding
Dean of Clinical Innovation, Professor of Wound Healing Research, Clinical Innovation Cardiff (CLIC), College of Biomedical and Life Sciences, Cardiff University School of Medicine, Cardiff, UK
59. Wounds
- Susanna J. Harwood
Pharmacist, Aseptic Services, University Hospital of Wales, Cardiff, UK
7. Parenteral nutrition
- Tina Hawkins
Retired Specialist Pharmacist in Rheumatology, Leeds, UK
54. Rheumatoid arthritis and osteoarthritis
55. Gout and hyperuricaemia
- Gregory J. Hobbs
Consultant in Pain Medicine, Primary Integrated Community Solutions, Nottingham, UK
34. Pain
- Samantha Holloway
Senior Lecturer/Programme Director, Centre for Medical Education, School of Medicine, Cardiff University, Cardiff, UK
59. Wounds
- Philip Howard
NHS-Improvement AMR Project Lead, Leeds Teaching Hospitals, Leeds, UK
40. Surgical site infection and antimicrobial prophylaxis
- Gail Jones
Consultant Haematologist, Northern Centre for Cancer Care, Freeman Hospital, Newcastle upon Tyne, UK
51. Leukaemia
- Atul Kalhan
Endocrinology, Department of Diabetes and Endocrinology, Royal Glamorgan Hospital, Ynysmaerdy, Llantrisant, UK
44. Thyroid and parathyroid disorders

34. Pain
- Apostolos Koffas
ST4 in Gastroenterology and Hepatology, University Hospital of Larisa, Larisa, Greece
16. Liver disease
- Janet Krska
Professor of Clinical and Professional Practice, Medway School of Pharmacy, Chatham, Kent, UK
5. Adverse drug reactions
- Alan Lamont
Clinical Oncologist (Retired), Colchester Hospital University Foundation Trust, Colchester, UK; Chair, Cambridge East Research Ethics Committee, Health Research Authority, London, UK
53. Solid tumours

Emma Lane

Senior Lecturer in Pharmacology, School of Pharmacy and Pharmaceutical Sciences, Cardiff University, Cardiff, UK

32. *Parkinson's disease*

Michelle Lannon

Post CCT Fellow, Haematology, Northern Centre for Cancer Care, Freeman Hospital, Newcastle Upon Tyne, UK

51. *Leukaemia*

Catherine Loughran

Lead Pharmacist, Haematology, Pharmacy Department, Leicester Royal Infirmary, Leicester, UK

52. *Lymphomas*

Katie Maddock

Director of Master of Pharmacy Learning and Teaching, School of Pharmacy, Keele University, Keele, UK

3. *Practical pharmacokinetics*

Helen Marlow

Lead Pharmacist, Surrey Down CCG, Leatherhead, UK

2. *Prescribing*

John Marriott

School of Clinical and Experimental Medicine, College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK

17. *Acute kidney injury*

18. *Chronic kidney disease and end-stage renal disease*

Kay Marshall

Head of the School of Health Sciences, University of Manchester, Manchester, UK

46. *Menstrual cycle disorders*

47. *Menopause*

Emma Mason

Department of Acute Medicine, Royal Gwent Hospital, Newport, Wales, UK

35. *Nausea and vomiting*

John McAnaw

Head of Pharmacy, NHS 24, South Queensferry, UK

21. *Chronic heart failure*

Niamh McGarry

Lead Pharmacist for Care of the Elderly/Older People Services, Belfast Health and Social Care Trust, Belfast City Hospital, Belfast, UK

50. *Anaemia*

Duncan McRobbie

Associate Chief Pharmacist – Clinical Services, Guy's and St Thomas' NHS Foundation Trust; Clinical Reader, Kings College London; Visiting Professor UCL School of Pharmacy, Pharmacy Department, St. Thomas' Hospital, London, UK

1. *Clinical pharmacy practice*

20. *Coronary heart disease*

Helen Meynell

Consultant Pharmacist/Clinical Governance Lead, Doncaster and Bassetlaw Teaching Hospitals NHS Foundation Trust, Doncaster, UK

26. *Chronic obstructive pulmonary disease*

Catherine Molyneux

Consultant Microbiologist, County Durham and Darlington NHS Foundation Trust, Durham, UK

36. *Respiratory infections*

Manjusha Narayanan

Consultant Microbiologist, Department of Microbiology, Royal Victoria Infirmary, Newcastle upon Tyne, UK

43. *Fungal infections*

Mike D. Page

Consultant Diabetes and Endocrinology (Retired), Royal Glamorgan Hospital, Ynysmaerdy, Llantrisant, UK

44. *Thyroid and parathyroid disorders*

Caroline Parker

Consultant Pharmacist Adult Mental Health, St Charles' Hospital for Central and North West London NHS Foundation Trust, London, UK

30. *Schizophrenia*

Alan Pollard

Independent Mental Health Pharmacy Consultant, Associate Lecturer Worcester University, Worcester, UK

29. *Affective disorders*

Sophie Rintoul-Hoad

Specialist Registrar in Urology, Guy's and St. Thomas' hospital, London, UK

49. *Prostate disease*

Ali Robb

Consultant Microbiologist, Royal Victoria Infirmary, Newcastle upon Tyne, UK

36. *Respiratory infections*

Trevor Rogers

Consultant Respiratory Physician and Director of R&D, Chest Clinic, Doncaster Royal Infirmary, Doncaster, UK

26. *Chronic obstructive pulmonary disease*

Linda Ross

SECTION 1

GENERAL

1

Clinical Pharmacy Practice

Duncan McRobbie, David Webb and J. Graham Davies

Key points

- Clinical pharmacy comprises a set of skills that promote the optimal use of medicines for individual patients. Optimising the use of medicines requires a patient-centred approach that is grounded in principles of safety, evidence-based and consistent practice, and an understanding of the patient's experience.
- Clinical pharmacy has enabled pharmacists to shift from a product-oriented role towards direct engagement with patients and the value they derive from, or the problems they encounter with, their medicines.
- Achieving specific and positive patient outcomes from the optimal use of medicines is a characteristic of the pharmaceutical care process. The practice of clinical pharmacy is an essential component of pharmaceutical care.
- The three main elements of the care process are assessing the patient, determining the care plan and evaluating the outcome.
- An ability to consult with patients is a key step in the delivery of pharmaceutical care and the optimal use of medicines. Consultation skills require regular review and practice, regardless of the practitioner's experience.

Clinical pharmacy encourages pharmacists and pharmacy support staff to shift their focus from product orientation to more direct engagement with patients, to maximise the benefits that individuals obtain from the medicines they take. Since the late 1980s the practice of clinical pharmacy has grown from a collection of patient-related functions to a process in which all actions are undertaken with the intention of achieving explicit outcomes for the patient. In doing so clinical pharmacy has moved forward to embrace the philosophy of pharmaceutical care (Hepler and Strand, 1990) and, more recently, the principles of medicines optimisation (Royal Pharmaceutical Society, 2013).

The aim of this chapter is to provide a practical framework within which knowledge of therapeutics and an understanding of clinical practice can best be utilised. This chapter describes a pragmatic approach to applying aspects of the pharmaceutical care process and the specific skills of clinical pharmacy to support the optimal use of medicines in a manner that does not depend on the setting of the practitioner or patient.

Development of clinical practice in pharmacy

The emergence of clinical pharmacy as a form of professional practice has been attributed to the poor medicines control systems that existed in hospitals during the early 1960s (Cousins and Luscombe, 1995). Although provoked by similar hospital-associated problems, the nature of the professional response differed between the USA and the UK.

In the USA the approach was to adopt unit dose dispensing and pursue decentralisation of pharmacy services. In the UK the unification of the prescription and the administration record meant this document needed to remain on the hospital ward and required the pharmacist to visit the ward to order medicines. Clinical pharmacy developed from the presence of pharmacists in these patient areas and their interest in promoting safer medicines use. This was initially termed 'ward pharmacy', but participation in medical ward rounds in the late 1970s signalled the transition to clinical pharmacy.

Medication safety may have been the spur, but clinical pharmacy in the 1980s grew because of its ability to promote the cost-effective use of medicines in hospitals. This role was recognised by the government, which in 1988 endorsed the implementation of clinical pharmacy services to secure value for money from medicines. Awareness that support depended to an extent on the quantification of actions and cost savings led several groups to develop ways of measuring pharmacists' clinical interventions. Coding systems were necessary to aggregate large amounts of data in a reliable manner, and many of these drew upon the eight steps (Table 1.1) of the drug use process (DUP) indicators (Hutchinson et al., 1986).

Data collected from these early studies revealed that interventions had very high physician acceptance rates, were made most commonly at the 'select regimen' and 'need for drug' stages of the DUP, and were influenced by hospital ward type (intensive care and paediatrics having the highest rates), pharmacist seniority (rates increasing with seniority) and time spent on wards (Barber et al., 1997).

Despite the level of activity that intervention monitoring revealed, coupled with evidence of cost containment and a broadly supportive healthcare system, frustrations began to

Table 1.1 Drug use process indicators

DUP stage	Action
Establish need for a drug	Ensure there is an appropriate indication for each medicine and that all medical problems are addressed therapeutically. Consider deprescribing medicines that are no longer appropriate.
Select drug	Select and recommend the most appropriate medicine based upon the ability to reach therapeutic goals, with consideration of patient variables, formulary status and cost of therapy.
Select regimen	Select the most appropriate medicines for accomplishing the desired therapeutic goals at the least cost without diminishing effectiveness or causing toxicity.
Provide drug	Facilitate the dispensing and supply process so that medicines are accurately prepared, dispensed in ready-to-administer form and delivered to the patient on a timely basis.
Administer drug	Ensure that appropriate devices and techniques are used for medicines administration.
Monitor drug therapy	Monitor medicines for effectiveness or adverse effects to determine whether to maintain, modify or discontinue.
Counsel patient	Counsel and educate the patient or caregiver about the patient's therapy to ensure proper use of medicines.
Evaluate effectiveness	Evaluate the effectiveness of the patient's medicines by reviewing all the previous steps of the DUP and taking appropriate steps to ensure that the therapeutic goals are achieved.

DUP, Drug use process.

appear. These in part stemmed from a lack of certainty about the fundamental purpose of clinical pharmacy and also from tensions between the desire for clinical specialisation and organisational goals of improving services more generally in hospitals and other care settings.

Pharmaceutical care

A need to focus on outcomes of medicines use, as opposed to the functions of clinical pharmacy, became apparent (Hepler and Strand, 1990). The launch of pharmaceutical care as the 'responsible provision of drug therapy for the purpose of achieving definite outcomes that improve a patient's quality of life' (Hepler and Strand, 1990, p. 539) was a landmark in the topography of pharmacy practice. In reality, this was a step forward rather than a revolutionary leap, as expansion of the traditional dispensing role and the acquisition of new responsibilities, in particular

Table 1.2 Definitions of clinical pharmacy, pharmaceutical care and medicines optimisation

Term	Definition
Clinical pharmacy	Clinical pharmacy comprises a set of functions that promote the safe, effective and economic use of medicines for individual patients. Clinical pharmacy process requires the application of specific knowledge of pharmacology, pharmacokinetics, pharmaceuticals and therapeutics to patient care.
Pharmaceutical care	Pharmaceutical care is a cooperative, patient-centred system for achieving specific and positive patient outcomes from the responsible provision of medicines. The practice of clinical pharmacy is an essential component in the delivery of pharmaceutical care.
Medicines optimisation	Medicines optimisation aims to ensure that the right patients get the right choice of medicine at the right time. The purpose is to help patients take their medicines appropriately and, by doing so, avoid unnecessary treatment, improve safety and outcomes, and reduce wastage. Ultimately it can support patients to take greater ownership of their treatment.

the ability to be able to handle the interpersonal relationships required at the interface of the pharmacy system and the patient, had been debated for some time (Brodie, 1981).

The delivery of pharmaceutical care is dependent on the practice of clinical pharmacy, but the key feature of care is that the practitioner takes responsibility for a patient's medicines-related needs and is held accountable for that commitment. None of the definitions of pharmaceutical care is limited by reference to a specific professional group. Although pharmacists and pharmacy support staff would expect to play a central role in pharmaceutical care, it is essentially a cooperative system that embraces the contribution of other professionals and patients (Table 1.2). The philosophy of pharmaceutical care anticipated healthcare policy in which certain functions, such as the prescribing of medicines, have extended beyond their traditional professional origins to be undertaken by those trained and identified to be competent to do so.

Medication-related problems

When the outcome of medicines use is not optimal, the underlying medication-related problem (MRP) can be classified according to the criteria set out in Box 1.1 (Hepler and Strand, 1990). Some MRPs are associated with significant morbidity and mortality. Preventable medication-related hospital admissions in the UK and USA have been estimated to have a prevalence rate of 4% to 5%, indicating that gains in public health from improving prescribing, monitoring and adherence to medicines would be sizeable (Howard et al., 2003; Winterstein et al., 2002).

In prospective studies, up to 28% of accident and emergency department visits have been identified as medication related, of

Box 1.1 Categories of medication-related problems

- Untreated indication
- Treatment without indication
- Improper drug selection
- Too little drug
- Too much drug
- Non-adherence
- Adverse drug reaction
- Drug interaction

which 70% were deemed preventable (Zed, 2005). Again the most frequently cited causes were non-adherence and inappropriate prescribing and monitoring. In England adverse drug reactions (ADRs) have been identified as the cause of 6.5% of hospital admissions for patients older than 16 years. The median bed stay for patients admitted with an ADR was 8 days, representing 4% of bed capacity. The projected annual cost to the National Health Service (NHS) was £466 million, the equivalent of seven 800-bed hospitals occupied by patients admitted with an ADR. More than 70% of the ADRs were determined to have been avoidable (Pirmohamed et al., 2004).

Between 2005 and 2010 more than half a million medication incidents were reported to the National Patient Safety Agency, and 16% of these reports involved actual patient harm (Cousins et al., 2012). In 2004 the direct cost of medication errors in NHS hospitals, defined as preventable events that may cause or lead to inappropriate medicines use or harm, was estimated to lie between £200 and £400 million per year. To this should be added the costs arising from litigation (Department of Health, 2004). In care homes, one study found that more than two-thirds of residents were exposed to one or more medication errors (Barber et al., 2009), whilst in hospitals a prescribing error rate of almost 9% has been identified (Doran et al., 2010). In addition nearly a third of patients are non-adherent 10 days after starting a new medicine for a chronic condition, of whom 45% are intentionally non-adherent (Barber et al., 2004), a significant contributor to the £150 million per annum estimated avoidable medicines waste in primary care (York Health Economics Consortium and School of Pharmacy, 2010). The scale of the misadventure that these findings reveal, coupled with increasing concerns about the costs of drug therapy, creates an opportunity for a renaissance in clinical pharmacy practice, providing that it realigns strongly with the principles of medicines optimisation. Pharmacists and their teams are uniquely placed to help reduce the level of medication-related morbidity in primary care by virtue of their skills and accessibility, and by building on relationships with general practice.

Medicines optimisation

The aim of medicines optimisation is to help patients take their medicines appropriately and, by doing so, improve safety and outcomes, avoid unnecessary treatment and reduce wastage. Ultimately it supports patients in taking greater ownership of

their treatment (Royal Pharmaceutical Society, 2013). At its heart are four guiding principles:

- communicating with the patient and/or his or her carer about the patient's choice and experience of using medicines to manage his or her condition;
- supporting the most appropriate choice of clinically and cost-effective medicines (informed by the best available evidence base);
- ensuring that medicines use is as safe as possible, including safe processes and systems, effective communication between professionals and the minimising likelihood of unwanted effects and interactions;
- making medicines optimisation part of routine practice by routinely discussing with patient, carers and other health professionals how to achieve the best outcomes from medicines.

By locating clinical pharmacy skills within a pharmaceutical care philosophy, medicines optimisation seeks to be the step change that will better realise the benefits of treatment with medicines and reduce both suboptimal use and MRPs. It is a patient-centred endeavour based firmly on professionalism and partnership.

Evidence supporting the unique clinical contribution of pharmacists has been building since the launch of pharmaceutical care in the 1990s. In the USA, for example, pharmacists' participation in physician ward rounds was shown to reduce adverse drug events by 78% and 66% in general medical (Kucukarslan et al., 2003) and intensive care settings (Leape et al., 1999), respectively. A study covering 1029 US hospitals was the first to indicate that both centrally based and patient-specific clinical pharmacy services are associated with reduced mortality rates (Bond et al., 1999). The services involved were medicines information, clinical research performed by pharmacists, active pharmacist participation in resuscitation teams and pharmacists undertaking admission medication histories.

In the UK the focus also has been on prevention and management of MRPs. Recognition that many patients either fail to benefit or experience unwanted effects from their medicines has elicited two types of response from the pharmacy profession. Firstly, to put in place, and make use of, a range of post-graduate initiatives and programmes to meet the developmental needs of pharmacists working in clinical settings; secondly, the re-engineering of pharmaceutical services to introduce schemes for medicines optimisation at an organisational level. These have ranged from specific initiatives to target identified areas of medication risk, such as pharmacist involvement in anticoagulation services, to more general approaches where the intention is to ensure consistency of medicines use, particularly across care interfaces. Medicines reconciliation on hospital admission ensures that medicines prescribed to in-patients correspond to those that the patient was taking prior to admission. Guidance recommends that medicines reconciliation should be part of standard care and that pharmacists should be involved as soon as possible after the patient has been admitted (National Institute for Health and Care Excellence [NICE], 2015). The process requires the name, dosage, frequency and route of administration to be established for all medicines taken prior to admission. The information collected as part of medicines reconciliation is a prerequisite for medication review that the NICE guideline defines as a

structured, critical examination of a person's medicines with the objective of reaching an agreement about treatment, optimising the impact of medicines, minimising the number of MRPs and reducing waste (NICE, 2015).

Pharmaceutical consultation

Structured postgraduate education has served to improve the knowledge of clinical pharmacists, but fully achieving the goals of pharmaceutical care has proved more challenging. Part of the difficulty has been the requirement to place the patient at the heart of the system, rather than being a relatively passive recipient of drug therapy and associated information. To deliver pharmaceutical care requires more than scientific expertise. It mandates a system that describes first the role and responsibilities of the pharmacist and provides the necessary infrastructure to support them in this role, and secondly a clear process by which the pharmacist can deliver his or her contribution to patient care.

Pharmaceutical care is predicated on a patient-centred approach to identifying, preventing or resolving medicine-related problems. Central to this aim is the need to establish a therapeutic relationship. This relationship must be a partnership in which the pharmacist works with the patient to resolve medication-related issues in line with the patient's wishes, expectations and priorities. Table 1.3 summarises the three key elements of the care process (Cipolle et al., 1998). Research in chronic diseases has shown that self-management is promoted when patients more fully participate in the goal-setting and planning aspects of their care (Sevick et al., 2007). These are important aspects to consider when pharmacists consult with patients. In community pharmacy in the UK, approaches to help patients use their medicines more effectively are the medicines use review (MUR) and the new medicines service (NMS). The MUR uses the skills of pharmacists to help patients understand how their medicines should be used, why they take them and to identify any problems patients have in relation to their medicines, providing feedback to the prescriber if necessary. Two goals of MUR are to improve the adherence of patients to prescribed medicines and to reduce medicines wastage. The NMS has been introduced to allow pharmacists to support patients with long-term conditions who have been recently started on a medicine to target medicines adherence

Table 1.3 Key elements of the care process

Element	Purpose
Assessment	The main goal of assessment is to establish a full medication history and highlight actual and potential medication-related problems.
Care plan	The care plan should clearly state the goals to optimise care and the responsibilities of both the pharmacist and the patient in attaining the stated goals.
Evaluation	The evaluation reviews progress against the stated patient outcomes.

early. Currently the service targets four key conditions/therapies: asthma and chronic obstructive pulmonary disease, type 2 diabetes, hypertension and antiplatelet or anticoagulant therapy (Pharmaceutical Services Negotiating Committee, 2013). Clinical guidance on medicines adherence emphasises the importance of patient involvement in decisions about medicines (NICE, 2009).

Recommendations include that healthcare professionals should:

- Adapt their consultation style to the needs of individual patients.
- Consider any factors that may affect patients' involvement in the consultation.
- Establish the most effective way of communicating with each patient.
- Encourage patients to ask about their condition and treatment.
- Be aware that consultation skills can be improved to enhance patient involvement.

Medicines-taking behaviour

The need for a care process that ensures that the patient is involved at all stages has become clearer as the extent of non-adherence to medicines has been revealed. Significant proportions (between 30% and 50%) of patients with chronic conditions do not take their prescribed medicines as directed. Many factors are thought to influence a patient's decision to adhere to a prescribed regimen. These include the characteristics of the disease and the treatment used to manage it, the patient's beliefs about his or her illness and medicines, as well as the quality of the interaction between the patient and healthcare practitioners. Non-adherence can be categorised broadly into two types: intentional and unintentional. Unintentional non-adherence may be associated with physical or sensory barriers to taking medicines, for example, not being able to swallow or unable to read the labels, forgetfulness or poor comprehension. Traditionally pharmacists have played a key role in helping patients overcome these types of problems, but they have been less active in identifying and resolving intentional non-adherence.

Intentional (or deliberate) non-adherence may be because of a number of factors. Recent work in health psychology has shaped our understanding of how patients perceive health and illness, and why they often decide not to take their medicines. When people receive information about illness and its treatment, it is processed in accordance with their own belief systems. Often patients' perceptions are not in tune with the medical reality and when this occurs, taking medicines may not make sense to the individual. For example, a patient diagnosed with hypertension may view the condition as one that is caused by stress and, during periods of lower stress, may not take their prescribed medicines (Baumann and Leventhal, 1985). Consequently, a patient holding this view of hypertension may be at increased risk of experiencing an adverse outcome such as a stroke.

Research has shown that patient beliefs about the necessity of the prescribed medication and concerns about the potential long-term effects have a strong influence on medicines-taking behaviour (Home et al., 2013). However, a patient's beliefs about the benefits and risks of medicines are rarely explored during consultation, despite evidence of an association between non-adherence

and the patient's satisfaction with the consultation process adopted by practitioners (Ley, 1988). Classifying patients as intentional or unintentional non-adherers does not fully explain the reasons for such behaviour. A recently proposed psychological framework takes into account a wider range of factors. Known as the COM-B framework (Michie et al., 2011), it proposes that for people to engage in a behaviour, they must have the capability (C), opportunity (O) and motivation (M) to do so. For example, a complex treatment regimen may be beyond the planning ability of a patient (capability barrier), especially if the patient fears disclosure about a health condition that is incorrectly perceived to have a detrimental effect on his or her ability to do his or her job (opportunity barrier). Over time non-adherence may have no discernible effect on the patient's health status, so he or she makes the decision to stop treatment completely (motivation barrier). Interventions designed to support behaviour change need to address any barriers within all three key components. Jackson et al. (2014) provide more examples of the COM-B framework applied to medicines adherence.

Consultation process

There are several comprehensive accounts of the functions required to satisfy each stage of the DUP, but few go on to explore how the pharmacist can create a therapeutic relationship with his or her patient. The ability of a pharmacist to consult effectively is fundamental to pharmaceutical care, and this includes establishing a platform for achieving adherence/concordance. Nurturing a relationship with the patient is essential to understanding the patient's medication-related needs.

Descriptions of pharmaceutical consultation have been confined largely to the use of mnemonics such as WWHAM, AS METHOD and ENCORE (Box 1.2). These approaches provide the pharmacist with a rigid structure to use when questioning patients about their symptoms, but, although useful, serve to make the symptom or disease the focus of the consultation rather than the patient. A common misconception is that healthcare professionals who possess good communication skills are also able to consult effectively with patients; this relationship will not hold if there is a failure to grasp the essential components of the consultation technique. Research into patients' perceptions of their illness and treatment has demonstrated that they are more likely to adhere to their medication regimen, and be more satisfied with the consultation, if their views about illness and treatment have been taken into account and the risks and benefits of treatment discussed (Martin et al., 2005). The mnemonic approach to consultation does not adequately address the complex interaction that may take place between a patient and a healthcare practitioner.

Undertaking a pharmaceutical consultation can be considered as a series of four interlinked phases, each with a goal and set of competencies (Table 1.4). These phases follow a problem-solving pattern, embrace relevant aspects of adherence research and attempt to involve the patient at each stage in the process. This approach forms the basis of the medication-related consultation framework, a tool shown to improve the capability of pharmacists to consult (Abdel-Tawab et al., 2011). For effective consultation the practitioner also needs to draw upon a range of communication behaviours (Box 1.3). By integrating the agendas

Box 1.2 Mnemonics used in the pharmacy consultation process

WWHAM

Who is it for?
What are the symptoms?
How long has it been going on?
Action taken?
Medicines taken?

AS METHOD

Age of the patient?
Self or for someone else?
Medicines being taken?
Exactly what do you mean (by the symptom)?
Time and duration of the symptom?
Taken any action (medicine or seen a healthcare practitioner)?
History of any disease?
Other symptoms?
Doing anything to alleviate or worsen the symptom?

ENCORE

Evaluate the symptom, its onset, recurrence and duration.
No medication is always an option.
Care when dealing with specific patient groups, notably the elderly, the young, nursing mothers, pregnant women, those receiving specific medication such as methotrexate and anticoagulants, and those with a particular disease, for example, renal impairment.
Observe the patient for signs of systemic disturbance and ask about presence of fever, loss of weight and any accompanying physiological disturbance.
Refer when in doubt.
Explain any course of action recommended.

of both patient and pharmacist, the approach outlined earlier provides the vehicle for agreeing on the issues to be addressed and the responsibilities accepted by each party in achieving the desired outcomes.

The ability to consult with patients is a key process in the delivery of pharmaceutical care and consequently requires regular review and development, regardless of experience. To ensure these core skills are developed, individuals should use trigger questions to prompt reflection on their approach to consulting (Box 1.4).

Clinical pharmacy functions and knowledge

The following practical steps in the delivery of pharmaceutical care are based largely on the DUP. The 'select regimen' and 'drug administration' indicators have been amalgamated at step 3.

Step 1. Establishing the need for drug therapy

For independent prescribers this step includes establishing a diagnosis and then balancing the risks and benefits of treatment against the risks posed by the disease. Current practice for most pharmacists means that another professional, most frequently a

Table 1.4 Pharmaceutical consultation process

Element	Goal	Examples of associated competencies
Introduction	Building a therapeutic relationship	Invites patient to discuss medication or health-related issue Discusses structure and purpose of consultation Negotiates shared agenda
Data collection and problem identification	Identifying the patient's medication-related needs	Takes a full medication history Establishes patient's understanding of his or her illness Establishes patient's understanding of the prescribed treatment Identifies and prioritises patient's pharmaceutical problems
Actions and solutions	Establishing an acceptable management plan with the patient	Involves patient in designing management plan Tailors information to address patient's perception of illness and treatment Checks patient's understanding Refers appropriately
Closure	Negotiating safety netting strategies with the patient	Provides information to guide action when patient experiences problems with management plan Provides further appointment or contact point

Box 1.3 Consultation behaviours

- Apply active listening.
- Appropriately use open and closed questions.
- Respect patient.
- Avoid jargon.
- Demonstrate empathy.
- Deal sensitively with potentially embarrassing or sensitive issues.

Box 1.4 Key postconsultation questions

- Do I know more now about the patient?
- Was I curious?
- Did I really listen?
- Did I find out what really mattered to the patient?
- Did I explore the patient's beliefs and expectations?
- Did I identify the patient's main medication-related problems?
- Did I use the patient's thoughts when I started explaining?
- Did I share the treatment options with the patient?
- Did I help my patient to reach a decision?
- Did I check that my patient understood what I said?
- Did we agree?
- Was I friendly?

doctor, will have diagnosed the patient's presenting condition and any co-existing disease. The pharmacist's role, therefore, is often one of providing information to the independent prescriber on the expected benefits and risks of drug therapy by evaluating both the evidence base and individual patient factors. Pharmacists also draw on these concepts as they become more involved in prescribing and adjusting therapy for patients under their care.

The evidence for one specific mode of therapy may not be conclusive. In this circumstance the pharmacist will need to call on his or her understanding of the principles of pharmaceutical science and on clinical experience to provide the best advice possible.

Step 1.1. Relevant patient details

Without background information on the patient's health and social circumstances (Table 1.5) it is difficult to establish the existence of, or potential for, MRPs. When this information is lacking, a review solely of prescribed medicines will probably be of limited value and incurs the risk of making a flawed judgement on the appropriateness of therapy for that individual.

Current and co-existing conditions with which the patient presents can be established from various sources. In medical notes the current diagnosis (Δ) or differential diagnoses ($\Delta\Delta$) will be documented, as well as any medical history. Other opportunities to gather information come from discussion with the patient and participation in medical rounds. In primary care, primary care clinicians' computer systems carry information on the patient's diagnosis.

Once the diagnosis and past medical history (PMH) are established, it is then possible to identify the medicines that would be expected to be prescribed for each indication, based on contemporary evidence. This list of medicines may be compiled from appropriate national or international guidelines, local formularies and knowledge of current practice.

Step 1.2. Medication history

A medication history is the part of a pharmaceutical consultation that identifies and documents allergies or other serious adverse medication events, as well as information about how medicines are taken currently and have been taken in the past. It is the starting point for medicines reconciliation and medication review.

Obtaining accurate and complete medication histories has been shown to have a positive effect on patient care, and pharmacists have demonstrated that they can compile such histories with a high degree of precision and reliability as part of medicines reconciliation. The benefit to the patient is that prescribing errors of omission or transcription are identified and corrected early, reducing the risk of harm and improving care.

Discrepancies between the history recorded by the medical team and that which the pharmacist elicits fall into two categories: intentional (where the medical team has made a decision to alter the regimen) or unintentional (where a complete record was not obtained). Discrepancies should be clarified with the prescriber or referred to a more senior pharmacist. Box 1.5 lists the key components of a medication history.

Table 1.5 Relevant patient details

Factor	Implications
Age	The very young and the very old are most at risk of medication-related problems. A patient's age may indicate his or her likely ability to metabolise and excrete medicines, and has implications for step 2 of the drug use process.
Gender	This may alter the choice of the therapy for certain indications. It may also prompt consideration of the potential for pregnancy or breastfeeding.
Ethnic or religious background	Racially determined predispositions to intolerance or ineffectiveness should be considered with certain classes of medicines, for example, angiotensin-converting enzyme inhibitors in Afro-Caribbean people. Formulations may be problematic for other groups, for example, those based on blood products for Jehovah's Witnesses or porcine-derived products for Jewish patients.
Social history	This may impact on ability to manage medicines and influence pharmaceutical care needs, for example, living alone or in a care home, or availability of nursing, social or informal carers
Presenting complaint	The presenting complaint includes symptoms the patient describes and the signs identified by the doctor on examination. Pharmacists should consider whether these might be attributable to the adverse effects of prescribed or purchased medicines.
Working diagnosis	This should enable the pharmacist to identify the classes of medicines that would be anticipated on the prescription based on current evidence.
Medical history	Understanding the patient's other medical conditions and his or her history helps ensure that management of the current problem does not compromise a prior condition and guides the selection of appropriate therapy by identifying potential contraindications.
Laboratory or physical findings	The focus should be on findings that may affect therapy, such as: <ul style="list-style-type: none"> • renal function • liver function • full blood count • blood pressure • cardiac rhythm Results may convey a need for dosage adjustment or presence of an adverse reaction.

Step 1.3. Deprescribing

Given that many problems associated with medicines use often occur as a result of problematic polypharmacy, sometimes because of a lack of ongoing review, a new concept, namely that of deprescribing, has emerged. This has been defined by [Reeve et al. \(2015\)](#) as 'the process of withdrawal of an inappropriate medication, supervised by a healthcare professional with the goal

Box 1.5 Key components of a medication history

1. Introduce yourself to the patient and explain the purpose of the consultation.
2. Identify any allergies or serious adverse reactions and record these on the prescription chart, care notes or patient medication record.
3. Ascertain information about prescribed and non-prescribed treatments from:
 - the patient's recall
 - medicines in the patient's possession
 - referral letter (usually from the patient's primary care doctor)
 - copy of prescriptions issued or a repeat prescription list
 - medical notes
 - contact with the appropriate community pharmacist or primary care doctor
4. Ensure the following are recorded:
 - generic name of medicine (unless specific brand is required)
 - dose
 - frequency
 - duration of therapy
5. Ensure items such as inhalers, eye drops, topical medicines, and herbal and homeopathic remedies are included because patients often do not consider these as medicines.
6. Ascertain the patient's medication-taking behaviour.
7. Consider practical issues such as swallowing difficulties, ability to read labels and written information, container preferences, and ordering or supply problems.
8. Document the history in an appropriate format.
9. Note any discrepancies between this history and that recorded by other healthcare professionals.
10. Ascertain whether these discrepancies are intentional (from patient, nursing staff, medical staff or medical notes).
11. Communicate non-intentional discrepancies to the prescriber.
12. Document any other important medication-related information in an appropriate manner, for example, implications of chronic renal failure, dialysis and long-term steroid treatment.

of managing polypharmacy and improving outcomes' (p. 1264). This should now be seen as an important aspect of establishing the need for drug therapy to limit the adverse effects seen by the continued prescribing of inappropriate medicines.

Step 2. Selecting the medicine

The issues to be tackled at this stage include clinical and cost-effective selection of a medicine in the context of individual patient care. The list of expected treatments generated at step 1 is now scrutinised for its appropriateness for the patient. This requires three separate types of interaction to be identified: drug–patient, drug–disease and drug–drug. The interactions should be prioritised in terms of likelihood of occurrence and the potential severity of outcome should they occur.

Step 2.1. Identify drug–patient interactions

Many medicines have contraindications or cautions to their use that relate to age groups or gender. Potential drug–patient interactions should be identified that may arise with any of

the medicines that could be used to treat the current and pre-existing conditions. Types of drug–patient interactions may include allergy or previous ADR, the impact of abnormal renal or hepatic function or chronic heart failure on the systemic availability of some medicines, and patients’ preferences for certain treatment options, formulations or routes of administration.

Step 2.2. Identify drug–disease interactions

A drug–disease interaction may occur when a medicine has the potential to make a pre-existing condition worse. Older people are particularly vulnerable due to the co-existence of several chronic diseases and exposure to polypharmacy. Prevention of drug–disease interactions requires an understanding of the pharmacodynamic properties of medicines and an appreciation of their contraindications.

Step 2.3. Drug–drug interactions

Medicines may affect the action of other medicines in a number of ways. Those with similar mechanisms of action may show an enhanced effect if used together, whilst those with opposing actions may reduce each other’s effectiveness. Metabolism of one medicine can be affected by a second that acts as an inducer or inhibitor of the cytochrome P450 enzyme system.

The practitioner should be able to identify common drug interactions and recognise those medicines with increased risk of potential interaction, such as those with narrow therapeutic indices or involving hepatic P450 metabolic pathways. It is important to assess the clinical significance of drug interactions and consider the options for effective management.

The list of potential evidence-based treatments should be reviewed for possible drug–patient, drug–disease and drug–drug interactions. The refined list can then be compared with the medicines that have been prescribed for the patient. The practitioner should explore any discrepancies to ensure the patient does not experience an MRP. This may necessitate consultation with medical staff or other healthcare professionals, or referral to a more senior pharmacist.

Step 3. Administering the medicine

Many factors influence the effect that a medicine has at its locus of action. These include the rate and extent of absorption, degree of plasma protein binding and volume of distribution, and the routes of metabolism or excretion. Factors that affect bioavailability may include the extent of absorption of the drug from the gastro-intestinal tract in relation to food and other medicines, or the amount adsorbed onto intravenous infusion bags and giving sets when used to administer medicines parenterally.

The liver has extensive capacity for drug metabolism, even when damaged. Nevertheless, the degree of hepatic impairment should be assessed from liver function tests and related to potential changes in drug metabolism. This is particularly important for medicines that require activation by the liver (prodrugs) or those whose main route of elimination is transformation into water-soluble metabolites.

Table 1.6 Pharmaceutical considerations in the administration of medicines

Dose	Is the dose appropriate, including adjustments for particular routes or formulations? Examples: differences in dose between intravenous and oral metronidazole, intramuscular and oral chlorpromazine, and digoxin tablets compared with the elixir
Route	Is the prescribed route available (is the patient nil by mouth?) and appropriate for the patient? Examples: unnecessary prescription of an intravenous medicine when the patient can swallow, or the use of a solid dosage form when the patient has dysphagia
Dosage form	Is the medicine available in a suitable form for administration via the prescribed route?
Documentation	Is documentation complete? Do nurses or carers require specific information to safely administer the medicine? Examples: appropriateness of crushing tablets for administration via nasogastric tubes, dilution requirements for medicines given parenterally, rates of administration and compatibilities in parenteral solutions (including syringe drivers)
Devices	Are devices required, such as spacers for inhalers?

Table 1.6 summarises the main pharmaceutical considerations for step 3. At this point the practitioner needs to ensure the following tasks have been completed accurately.

Step 3.1. Calculating the appropriate dose

Where doses of oral medicines require calculation, this is usually a straightforward process based on the weight of the patient. However, medicines to be administered parenterally may require more complex calculations, including knowledge of displacement values (particularly for paediatric doses) and determination of appropriate concentrations in compatible fluids and rates of infusion.

Step 3.2. Selecting an appropriate regimen

Giving medicines via the oral route is the preferred method of administration. Parenteral routes carry significantly more risks, including infection associated with vascular access. This route, however, may be necessary when no oral formulation exists or when the oral access is either impossible or inappropriate because of the patient’s condition.

Although simple regimens (once- or twice-daily administration) may facilitate adherence, some medicines possess short half-lives and may need to be given more frequently. The practitioner should be familiar with the duration of action of regularly encountered medicines to ensure dosage regimens are optimally designed.

Step 4. Providing the medicine

Ensuring that a prescription is legal, legible, accurate and unambiguous contributes in large measures to the right patient receiving the right medicine at the right time. For the majority of pharmacists this involves screening prescriptions written by other professionals, but those acting as supplementary and independent prescribers need to be cognisant of guidance on prescribing, such as that contained within the British National Formulary, when generating their prescriptions.

In providing a medicine for an individual, due account must be taken of the factors that influence the continued availability and supply of the medicine within the hospital or community setting, for example, formulary and drug tariff status, primary/secondary shared care arrangements and whether the prescribed indication is within the product licence. This is particularly important with unlicensed or non-formulary medicines when information and agreement on continuation of prescribing, recommended monitoring and availability of supply are transferred from a hospital to a primary care setting.

Risks in the dispensing process are reduced by attention to products with similar names or packaging, patients with similar names, and when supplying several family members at the same time. Medicines should be labelled accurately, with clear dosage instructions and advisory labels, and presented appropriately for patients with specific needs, for example, the visually impaired, those unable to read English or those with limited dexterity.

Step 5. Monitoring therapy

Monitoring criteria for the effectiveness of treatment and its potential adverse effects can be drawn from the characteristics of the prescribed medicines used or related to specific patient needs. Close monitoring is required for medicines with narrow therapeutic indices and for the subset of drugs where therapeutic drug monitoring may be beneficial, for example, digoxin, phenytoin, theophylline and aminoglycosides. Anticoagulant therapy, including warfarin and unfractionated heparin, is associated with much preventable medication-related morbidity and always warrants close scrutiny.

Throughout this textbook, details are presented on the monitoring criteria that may be used for a wide range of medicines. Patients with renal or hepatic impairment or an unstable clinical condition need particular attention because of the likely requirement for dosage adjustment or change in therapy.

Step 6. Patient advice and education

A vast quantity of information on drug therapy is available to patients. The practitioner's contribution in this context is to provide accurate and reliable information in a manner that the patient can understand. This may require the pharmacist to convey the benefits and risks of therapy, as well as the consequences of not taking medicines.

Information about medicines is best provided at the time of, or as soon as possible after, the prescribing decision. In the

hospital setting this means enabling patients to access information throughout their stay, rather than waiting until discharge. With many pharmacy departments providing medicines in patient packs, the patient can be alerted to the presence of information leaflets, encouraged to read them and ask any questions they may have. This approach enables patients to identify their own information needs and ensures that pharmacists do not create a mismatch between their own agenda and that of the patient. However, there will be a need to clearly explain the limitations of leaflets, particularly when medicines are prescribed for unlicensed indications.

Although the research on adherence indicates the primacy of information that has been tailored to the individual's needs, resources produced by national organisations, such as Diabetes UK (<https://www.diabetes.org.uk>) and British Heart Foundation (<https://www.bhf.org.uk>), may also be of help to patients and their family or carers. In addition, patients often require specific information to support their daily routine of taking medicines. All written information, including medicines reminder charts, should be dated and include contact details of the pharmacist to encourage patients to raise further queries or seek clarification.

Step 7. Evaluating effectiveness

The provision of drug therapy for the purpose of achieving definite outcomes is a fundamental objective of pharmaceutical care. These outcomes need to be identified at the outset and form the basis for evaluating the response to treatment. Practitioners delivering pharmaceutical care have a responsibility to evaluate the effectiveness of therapy by reviewing the earlier steps 1–6 and taking appropriate action to ensure the desired outcomes are achieved. Depending on the duration of direct engagement with a patient's care, this may be a responsibility the pharmacist can discharge in person, or it may necessitate transfer of care to a colleague in a different setting where outcomes can be assessed more appropriately.

Case study

The following case is provided to illustrate the application of several steps in the delivery of pharmaceutical care. It is not intended to be a yardstick against which patient care should be judged.

Case 1.1

Mr JB, a 67-year-old retired plumber, has recently moved to your area and has come to the pharmacy to collect his first prescription. He has a PMH of coronary heart disease and has recently had an elective admission where a drug-eluting coronary artery stent was inserted. He has a long history of asthma, which is well controlled with inhaled medicines.

Step 1. Establishing the need for drug therapy

What classes of medicines would you expect to be prescribed for these indications? (Answer is listed in Table 1.7.)

Table 1.7 The case of Mr JB: Potential drug interactions with the patient, the disease or other drugs

	Drug–patient interactions	Drug–disease interactions	Drug–drug interactions
Medicines that should be prescribed for coronary heart disease			
Aspirin	Previous history of dyspepsia	Aspirin should be used with caution in asthma	Combination of antiplatelet agents increases risk of bleeding
Clopidogrel	Previous history of dyspepsia		Combination of antiplatelet agents increases risk of bleeding
Statins			
β -Blockers		β -Blockers should be used with caution in asthma; if peak flows worsen, an alternative rate-controlling agent should be considered	Combination of different agents to control angina may lead to hypotension
Nitrates (glyceryl trinitrate spray)	Previous history of side effects (e.g., headache, flushing) may result in patient not using spray when required		
Medicines that may be prescribed for asthma			
β_2 -Agonist inhalers	Patient's ability to use inhaler devices effectively	β_2 -Agonists can cause tachycardia	
Corticosteroid inhaler			

Mr JB gives a complete medication history that indicates he takes his medicines as prescribed, he has no medication-related allergies, but he does suffer from dyspepsia associated with acute use of non-steroidal anti-inflammatory agents. He has a summary of his stent procedure from the hospital that indicates normal blood chemistry and liver function tests.

Step 2. Selecting the medicine

What drug–patient, drug–disease and drug–drug interactions can be anticipated? (See [Table 1.7.](#))

Steps 3 and 4. Administering and providing the medicines

What regimen and individualised doses would you recommend for Mr JB? (Answer is listed in [Table 1.8.](#))

This predicted regimen can be compared with the prescribed therapy and any discrepancies resolved with the prescriber. Step 4 (provision) in Mr JB's case would be relatively straightforward.

Steps 5, 6 and 7. Monitoring therapy, patient education and evaluation

What criteria would you select to monitor Mr JB's therapy, and what information would you share with the patient? What indicators would convey effective management of his condition? (Answer is listed in [Table 1.9.](#))

Quality assurance of clinical practice

Quality assurance of clinical pharmacy has tended to focus on the review of performance indicators, such as intervention rates, or rely upon experienced pharmacists to observe and comment on the practice of others using local measures. The lack of generally agreed or national criteria raises questions about the consistency of these assessments, where they take place and the overall standard of care provided to patients. Following the [Bristol Royal Infirmary Inquiry \(2001\)](#) into paediatric cardiac surgery, there has been much greater emphasis on the need for regulation to maintain the competence of healthcare professionals, the importance of periodic performance appraisal coupled with continuing professional development and the introduction of revalidation.

The challenges for pharmacists are twofold: firstly, to demonstrate their capabilities in a range of clinical pharmacy functions and, secondly, to engage with continuing professional development in a meaningful way to satisfy the expectations of pharmaceutical care and maintain registration with, for example, the General Pharmaceutical Council in the UK. The pragmatic approach to practice and the clinical pharmacy process outlined throughout this chapter has been incorporated into a professional development framework, called the Foundation Pharmacy Framework ([Royal Pharmaceutical Society, 2014](#)), that can be used to develop skills, knowledge and other attributes irrespective of the setting of the pharmacist and their patients.

Table 1.8 The case of Mr JB: Possible therapeutic regimen

Recommendation		Rationale
Medicines that should be prescribed for CHD		
Aspirin	75 mg daily orally after food	Benefit outweighs risk if used with PPI
Clopidogrel	75 mg daily orally after food	Benefit outweighs risk if used with PPI Length of course should be established in relation to previous stent
Lansoprazole	15 mg daily orally	Decreases risk of GI bleeds with combination antiplatelets Concerns about some PPIs reducing the effectiveness of clopidogrel makes selection of specific PPI important
Atorvastatin	40 mg daily orally	Higher doses are recommended if patient suffers an acute coronary event
Nitrates	2 puffs sprayed under the tongue when required for chest pain	
Bisoprolol	5 mg daily orally	Used for rate control to reduce anginal episodes; dose can be titrated against pulse and blood pressure
Ramipril	10 mg daily orally	To reduce the progression of CHD and heart failure
Medicines that may have been prescribed		
Salbutamol inhaler	2 puffs (200 micrograms) to be inhaled when required	Patient should follow asthma treatment plan if peak flow decreases
Beclometasone inhalers	2 puffs (400 micrograms) twice a day	Asthma treatment plan that may include twice a day increasing the dose of inhaled steroids if peak flow decreases
CHD, Coronary heart disease; GI, gastro-intestinal; PPI, proton pump inhibitor.		

Table 1.9 The case of Mr JB: Monitoring criteria and patient advice

Recommendation	
Medicines that should be prescribed for CHD	
Aspirin	Ask patient about any symptoms of dyspepsia or worsening asthma
Clopidogrel	Ask patient about any symptoms of dyspepsia
Lansoprazole	If PPIs do not resolve symptoms, the primary care doctor should be consulted
Atorvastatin	Liver function tests 3 months after any change in dose or annually; creatine kinase only if presenting with symptoms of unexplained muscle pain; cholesterol levels 3 months after any change in dose, or annually if at target
Nitrates (GTN spray)	Frequency of use to be noted; increasing frequency that results in a resolution of chest pain should be reported to primary care doctor, and anti-anginal therapy may be increased Any use that does not result in resolution of chest pain requires urgent medical attention
Bisoprolol	Blood pressure and pulse monitored regularly, monitor peak flows on initiation
Ramipril	Renal function and blood pressure monitored within 2 weeks of any dose change or annually
Medicines that may have been prescribed for asthma	
Salbutamol inhaler	Salbutamol use should be monitored because any increase in requirements may require increase in steroid dose; monitor inhaler technique
Beclometasone inhaler	Monitor for oral candidiasis; monitor frequency of exacerbations and 'step up/step down' dose as required; monitor inhaler technique
CHD, Coronary heart disease; GTN, glyceryl trinitrate; PPI, proton pump inhibitor.

2 Prescribing

Helen Marlow and Cate Whittlesea

Key points

- Prescribers need to assess the potential benefits and harms of treatment to support patients to obtain the best possible outcomes from their medicines.
- Patients should receive cost-effective medication appropriate to their clinical needs, in doses that meet their requirements and for an adequate period.
- Respect for patient autonomy, obtaining consent and sharing decision making is a fundamental part of the prescribing process.
- The consultation is a fundamental part of clinical practice and requires effective interpersonal reasoning and practical skills.
- Use of a consultation framework is recommended to ensure relevant issues are covered within the consultation.
- Prescribing is influenced by a complex mix of factors including evidence, external influences and cognitive biases, and these should be recognised.

To prescribe is to authorise, by means of a written prescription, the supply of a medicine. Prescribing incorporates the processes involved in decision making undertaken by the prescriber before the act of writing a prescription. Historically prescribing has been the preserve of those professionals with medical, dental or veterinary training. As the role of other healthcare professionals, pharmacists, nurses, optometrists, physiotherapists, podiatrists and therapeutic radiographers have expanded, prescribing rights have in turn been extended to them. The premise for this development has been that it better utilises the training of these professional groups, is clinically appropriate and improves patient access to medicines.

Regardless of the professional background of the individual prescriber, the factors that motivate them to prescribe a particular medicine are a complex mix of evidence of effectiveness and harms, external influences and cognitive biases. A rational approach to prescribing uses evidence, has outcome goals and evaluates alternatives in partnership with the patient. With the advent of new professional groups of prescribers (non-medical prescribers), there is a need for a systematic approach to prescribing and an understanding of the factors that influence the decision to prescribe a medicine. These issues will be covered in the following sections. Initially the fundamentals of rational and effective prescribing will be discussed followed by a brief outline of the acquisition of prescribing rights by pharmacists and the associated legal framework. The prescribing process and factors which influence it will also be covered.

Rational and effective prescribing

Prescribing a medicine is one of the most common interventions in health care used to treat patients. Medicines have the potential to save lives and improve the quality of life, but they also have the potential to cause harm, which can sometimes be catastrophic. Therefore, prescribing of medicines needs to be rational and effective to maximise benefit and minimise harm. This is best done using a systematic process that puts the patient at the centre (Fig. 2.1).

What is meant by rational and effective prescribing?

No universally agreed-on definition of good prescribing exists. The World Health Organization (WHO) promotes the rational use of medicines, which requires that patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period and at the lowest cost to them and their community (de Vries et al., 1994). However, a more widely used framework for good prescribing has been described (Barber, 1995) and identifies what the prescriber should be trying to achieve, both at the time of prescribing and in monitoring treatment thereafter. The prescriber should have the following four aims:

- maximise effective,
- minimise risks,
- minimise costs,
- respect the patient's choices.

This model links to the four key principles of biomedical ethics – beneficence, non-maleficence, justice and veracity, and respect for autonomy – and can be applied to decision making at both an individual patient level and when making decisions about medicines for a wider population, for example, in a Drug and Therapeutics Committee. One of the strengths of this model is the consideration of the patient's perspective and the recognition of the inherent tensions among the four key aims.

Another popular framework to support rational prescribing decisions is known as STEPS (Preskorn, 1994). The STEPS model includes five criteria to consider when deciding on the choice of treatment:

- safety
- tolerability
- effectiveness
- price
- simplicity

Fig. 2.1 A framework for good prescribing. (From Background Briefing. A blueprint for safer prescribing 2009 with kind permission from the British Pharmacological Society, London.)

Inappropriate or irrational prescribing

Good prescribing is sometimes defined as the lack of irrational or inappropriate prescribing. Prescribing can be described as irrational for many reasons; for example:

- poor choice of a medicine,
- inappropriate polypharmacy or co-prescribing of interacting medicine,
- prescribing for a self-limiting condition,
- prescribing without considering the risk of harm and managing the risk,
- continuing to prescribe for a longer period than necessary,
- prescribing too low a dose of a medicine,
- prescribing without taking account of the patient's wishes.

Inappropriate or irrational prescribing can result in serious morbidity and mortality, particularly when childhood infections or chronic diseases such as hypertension, diabetes, epilepsy and mental disorders are being treated. Inappropriate prescribing also represents a waste of resources and, as in the case of antimicrobials, may harm the health of the public by contributing to increased antimicrobial resistance. Finally, an over willingness to prescribe stimulates inappropriate patient demand and fails to help patients understand when they should seek out support from a healthcare professional.

Pharmacists as prescribers and the legal framework

Evolution of non-medical prescribing

In 1986 a report was published in the UK ('Cumberlege report') which recommended that community nurses should be given authority to prescribe a limited number of medicines as part

of their role in patient care (Department of Health and Social Security, 1986). Up to this point prescribing in the UK had been the sole domain of doctors, dentists and veterinarians. This was followed in 1989 by a further report (the first Crown report) which recommended that community nurses should prescribe from a limited formulary (Department of Health [DH], 1989). The legislation to permit this was passed in 1992.

At the end of the 1990s, in line with the then UK Government's desire to give patients quicker access to medicines, improve access to services and make better use of the skills of healthcare professionals, the role of prescriber was proposed for other healthcare professionals. This change in prescribing to include non-medical prescribers (e.g. pharmacists and nurses) was developed following a further review (Crown, 1999). This report suggested the introduction of supplementary prescribers, that is, non-medical healthcare professionals who could prescribe, to provide appropriate treatment within a general care plan drawn up by another professional (usually a doctor) or team (Crown, 1999). This led to pharmacists and nurses qualifying as non-medical prescribers (initially as supplementary and then independent prescribers). Subsequently optometrists, physiotherapists, podiatrists and therapeutic radiographers were also able to qualify as independent prescribers.

Supplementary prescribing

The Health and Social Care Act 2001 allowed pharmacists and other healthcare professionals to prescribe. Following this legislation, in 2003 the Department of Health outlined the implementation guide allowing pharmacists and nurses to qualify as supplementary prescribers (DH, 2003). In 2005 supplementary prescribing was extended to physiotherapists, chiropodists/

Box 2.1 Overview of the requirements for a clinical management plan for supplementary prescribing

Legal requirements

Patient details

- Name
- Patient identification, e.g. NHS number
- Patient allergies
- Difficulties patient has with medicines

Disease and treatment

- Condition
- Class or name of medicines
- Limitations on doses, strength or time of treatment
- When to seek advice from or refer back to independent prescriber
- Arrangements for notification of adverse drug reactions or incidents

Prescriber information

- Name of independent prescriber (doctor or dentist)
- Name of supplementary prescriber (pharmacist, nurse, physiotherapists, chiropodists/podiatrists, radiographers, dietitian and optometrists)
- Start date
- Review date

podiatrists, radiographers and optometrists (DH, 2005), with dietitians gaining prescribing rights in 2016 (National Health Service [NHS] England, 2016a). Paramedics are now awaiting legislation to become independent prescribers.

Supplementary prescribing is defined as a voluntary prescribing partnership between an independent prescriber (doctor or dentist) and a supplementary prescriber, to implement an agreed patient-specific clinical management plan with the patient's consent. Currently a supplementary prescriber can be a nurse, pharmacist, chiropodist/podiatrist physiotherapist, radiographer, optometrist or dietitian. This prescribing arrangement also requires information to be shared and recorded in a common patient file. In this form of prescribing the independent prescriber, that is, the doctor or, if appropriate, the dentist, undertakes the initial assessment of the patient, determines the diagnosis and defines the initial treatment plan. The elements of this plan which are the responsibility of the supplementary prescriber are then documented in the patient-specific clinical management plan. The legal requirements for this are detailed in Box 2.1. Supplementary prescribers can prescribe controlled drugs and also both off-label and unlicensed medicines.

Non-medical independent prescribing

Following publication of a report on the implementation of nurse and pharmacist independent prescribing within the NHS in England (DH, 2006), pharmacists were enabled to become independent prescribers as defined under the Medicines and Human Use (Prescribing) (Miscellaneous Amendments) Order of May 2006. Independent prescribing is defined as 'prescribing by a practitioner (doctor, dentist, nurse, pharmacist) who is responsible and accountable for the assessment of patients with undiagnosed or diagnosed conditions and for decisions about the clinical management required including prescribing' (DH, 2006, p. 2).

Pharmacist independent prescribers were able to prescribe any licensed medicine for any medical condition within their competence except controlled drugs and unlicensed medicines. At that point there was restriction on Controlled Drugs including those in Schedule 5 (CD Inv.POM and CD Inv. P) such as co-codamol. At the same time nurses could also become qualified as independent prescribers (formerly known as Extended Formulary Nurse Prescribers) and prescribe any licensed medicine for any medical condition within their competence, including some Controlled Drugs. Since 2008 optometrists can also qualify as independent prescribers to prescribe for eye conditions and the surrounding tissue. They cannot prescribe for parenteral administration, and they are unable to prescribe Controlled Drugs. Physiotherapists can prescribe for human movement, performance and function, with podiatrists restricted to disorders of the feet, ankle and associated structures (Human Medicines Regulation, 2013). Therapeutic radiographers can prescribe within the overarching framework of cancer treatment (Human Medicines Regulation, 2016).

Following a change in legislation in 2010, pharmacist and nurse non-medical prescribers were allowed to prescribe unlicensed medicines (DH, 2010). In 2012 changes were made to the Misuse of Drugs Regulations 2001 relating to restriction on the types of controlled drugs which could be prescribed by both pharmacist and nurse independent prescribers. This allowed them to prescribe within their area of competence any Controlled Drug listed in Schedules 2–5 except diamorphine, cocaine and dipipanone for the treatment of addiction (DH, 2012).

From the above it should be evident that in the UK suitably qualified pharmacists can prescribe as either supplementary or independent prescribers. Pharmacist prescribing has been and is being considered by a number of countries. For example, legislative changes in New Zealand allowed suitably trained specialist pharmacists to become prescribers. In Canada pharmacist prescribing has been approved by provincial governments, although the scope does vary.

Accountability

Prescribers have the authority to make prescribing decisions for which they are accountable both legally and professionally. Accountability when prescribing covers three aspects: the law, the statutory professional body and the employer.

The law of Tort, the concept of a 'civil wrong', includes clinical negligence. In such a claim the patient needs to demonstrate that the prescriber caused them injury or damage. For this allegation to be substantiated the patient needs to prove that the prescriber owed them a duty of care, that this duty of care was breached and that this caused the injury identified and also that the injury was foreseeable. The law of Tort also permits actions for breach of confidentiality and also for battery should a patient be treated without consent. Therefore, prescribers (independent and supplementary) are legally and professionally accountable for their decisions. This includes decisions not to prescribe and also ensuring that the prescription is administered as directed. The legal responsibility for prescribing always lies with the individual who signed the prescription. In addition, prescribers also have a responsibility to ensure that the instructions are clear and not open to misinterpretation.

If a prescriber is an employee, then the employer expects the prescriber to work within the terms of his or her contract, competency and within the rules and policies, standard operating procedure, guidelines and so forth laid down by the organisation. Therefore, working as a prescriber, under these conditions, ensures that the employer has vicarious liability. So should any patient be harmed through the action of the prescriber and he or she is found in a civil court to be negligent, then under these circumstances the employer is responsible for any compensation to the patient. Therefore, it is important to always work within these frameworks because working outside these requirements makes the prescriber personally liable for such compensation. To reinforce this message it has been stated that the job descriptions of non-medical prescribers should incorporate a clear statement that prescribing forms part of the duties of their post (DH, 2006).

Ethical framework

Four main ethical principles of biomedical ethics have been set out for use by healthcare staff in patient–practitioner relationships (Beauchamp and Childress, 2001): respect for autonomy, non-maleficence, beneficence, and justice and veracity. These principles need to be considered at all points in the prescribing process.

Autonomy

Autonomy recognises an individual patient's right to self-determination in making judgements and decisions for himself or herself and encompasses informed patient consent. Respect for autonomy is therefore a form of personal liberty which freely permits a patient to choose whether he or she wishes to have treatment in accordance with his or her own plans.

Confidentiality. Confidentiality is a fundamental right with respect to patient autonomy. Therefore, patients have the right to confidentiality, and consent is required to disclose information regarding their health and treatment.

Consent. Obtaining consent from a patient for treatment can be divided into three components: voluntariness, information and competency. Consent, whether this is an investigation or treatment, can only be gained if the patient understands three important aspects: nature (i.e. what), purpose (i.e. why) and consequence. It also needs to be freely obtained. Consent is invalid when it is given under pressure or coercion. Therefore, it is important that consent is obtained for each act and not assumed because this is a routine assessment or procedure and therefore can be carried out automatically. It is essential that the patient understands his or her diagnosis, potential benefit, rationale and likelihood of success of the proposed treatment, and that reasonable care has been taken to ensure that the patient is aware of any material risks involved and of any reasonable potential alternative treatments. Therefore, a prescriber needs to discuss these aspects with the patient. In particular, care should be taken to understand what aspects of treatment and the risks involved would probably be deemed of significance by this particular patient to allow the patient to make a comparison with the proposed plan (Sokol, 2015). The prognosis if no treatment is prescribed should also be discussed. Such a wide-ranging discussion may require more than one appointment and reinforces the necessity for an ongoing

patient–professional relationship focused on the needs of the patient. Since the Montgomery test case in 2015 this has now been applied in several other cases. Ethically the rulings demonstrate a shift to a more cooperative approach between patient and prescriber in the consultation (Chan et al., 2017).

Associated with this is the need to determine whether the patient has the competency to make decisions for himself or herself with respect to vulnerable groups, such as those who have learning disabilities, children and the elderly. Young people aged 16 and 17 years are normally presumed to be able to consent to their own treatment.

Gillick competence is used to determine whether children have the capacity to make healthcare decisions for themselves. Children younger than 16 years can give consent as long as they can satisfy the prescriber that they have capacity to make this decision. However, with the child's consent, it is good practice to involve the parents in the decision-making process. In addition a child younger than 16 years may have the capacity to make some decisions relating to their treatment, but not others. So it is important that an assessment of capacity is made related to each decision. There is some confusion regarding the naming of the test used to objectively assess legal capacity to consent to treatment in children younger than 16 years, with some organisations and individuals referring to Fraser guidance and others Gillick competence. Gillick competence is the principle used to assess the capacity of children younger than 16, whereas Fraser guidance refers specifically to contraception (Wheeler, 2006).

The Mental Capacity Act (2005) protects the rights of adults who are unable to make decisions for themselves. The fundamental concepts within this act are the presumption that every adult has capacity to make decisions for themselves, and that they must be given all appropriate help and support to enable them to make their own decision. To obtain valid consent, the prescriber must take practicable steps to ensure the patient understands the nature, purpose and reasonable or foreseeable consequences of the proposed investigation or treatment. Therefore, patients should be able to understand the information relevant to the decision they are making. They also need to be able to retain this information, use or assess the information as part of their decision-making process and communicate their decision. The five key principles are listed in Box 2.2. Therefore, any decision made on their behalf should be as unrestrictive as possible and must be in the patient's own interest, not biased by any other individual or organisation's benefit. Therefore, when taking consent, it is extremely important to plan and consider the information needs of the patient and to communicate this information using simple terms and basic language appropriate to the individual. This may require practical steps should the patient have problems communicating. Advice regarding patient consent is listed in Box 2.3. Although there is no statutory form to record assessment of capacity, information to record in the patient's medical record are the date, decision to be made, what information needed to be understood, practical steps taken to gain consent and confirmation that the patient did not have capacity to give consent together with the reason why this was not obtained.

Non-maleficence

At the heart of the principle of non-maleficence is the concept of not knowingly causing harm to the patient. The principle is

Box 2.2 Overview of the five principles of the Mental Capacity Act

- A person is assumed to have capacity unless it is established that he/she lacks capacity.
- A person should not be treated as unable to make a decision unless all practical steps to enable them to do this have been taken without success.
- A person cannot be treated as unable to make a decision because he/she makes an unwise decision.
- Acts or decisions made for or on behalf of a person who lacks capacity must be in that person's best interests.
- Before an act or decision is made, the purpose has to be reviewed to assess if it can be achieved as effectively in a way that is less restrictive of the person's rights/freedom of action.

Box 2.3 Advice on patient consent

- Take care when obtaining consent.
- Assess the patient and ensure information presented is appropriate to the patient.
- Use simple terms and basic language.
- Ensure information provided covers the nature, purpose and consequence of the investigation/treatment using the following questions (Sokol, 2015):
 - Does the patient know about the material risks of the treatment I am proposing?
What sort of risks would a reasonable person in the patient's circumstances want to know?
What sorts of risks would this particular patient want to know?
 - Does the patient know about reasonable alternatives to this treatment?
 - Have I taken reasonable care to ensure that the patient actually knows all this?
 - Do any of the exceptions to my duty to disclose apply here?
- Give the patient understandable information about all material risks that he or she is likely to consider significant.
- Ensure the patient has the opportunity to ask questions and consider his or her options.
- Document in the patient's notes the key elements of the discussion including advice and warnings provided.
- If higher levels of risk are involved, invite the patient to sign that they understand and accept the risks explained.
- Should your patient not have capacity to give consent, record your assessment in his or her medical record, including the reason why the patient was unable to give consent.
- Record in the patient's notes if he or she declines to undergo a procedure.

expressed in the Hippocratic Oath. This obligation not to harm is distinct from the obligation to help others. Although codes of all healthcare professionals outline obligations not to harm clients, many interventions result in some harm, however transitory. Sometimes one act can be described as having a 'double effect', that is, two possible effects: one good effect (intended) and one harmful effect (unintended). The harmful effect is allowed if proportionally it is less than the good effect. Therefore, it is important for prescribers to review both the potential positive effects of treatment (e.g. symptom control) and the negative effects (e.g.

side effects). It is also important to consider both acts of commission and omission, because a failure to prescribe can also cause harm to the patient.

Beneficence

Beneficence is the principle of doing good and refers to the obligation to act for the benefit of others that is set out in codes of professional conduct, for example, Standards for pharmacy professionals (General Pharmaceutical Council, 2017). Beneficence refers to both physical and psychological benefits of actions and also relates to acts of both commission and omission. Standards set for professionals by their regulatory bodies such as the General Pharmaceutical Council can be higher than those required by law. Therefore, in cases of negligence the standard applied is often that set by the relevant statutory body for its members.

Justice and veracity

This last principle of justice and veracity is related to the distribution of resources to ensure that such division or allocation is governed by equity and fairness. This is often linked to cost-effectiveness of treatment and potential inequalities if treatment options are not offered to a group of patients or an individual. However, as a prescriber it is important to consider the evidence base for the prescribed medicine and also to review the patient as an individual to ensure the treatment offered adheres to this principle. This principle of fairness and freedom from discrimination therefore encompasses human rights including the need for assessment of medication as part of the Equality Act (2010). Healthcare professionals have a duty under this act to make reasonable adjustments to ensure that all patients have the same opportunity for good health. Therefore, a prescriber should also assess with the patient that the medication prescribed can be accessed by them. Veracity, or 'truth telling', underpins both effective communication and patient consent.

Professional frameworks for prescribing

Each professional regulatory body has standards to which their members must adhere. Members are accountable to such bodies for their practice and can be sanctioned by these bodies if their actions do not adhere to these standards. Therefore, individuals will be held accountable by their respective statutory body for their prescribing decisions.

The professional standards for pharmacists are defined within the 'Standards for Pharmacy Professionals' (General Pharmaceutical Council, 2017). In addition the Royal Pharmaceutical Society (2017) publishes 'Medicines, Ethics and Practice', a professional guide for pharmacists which provides advice on a wide range of areas encompassing core concepts and skills in addition to underpinning knowledge, legislation and professional bodies.

Off-label and unlicensed prescribing

For a medicine to be licensed for use in a specific country the manufacturer must obtain a marketing authorisation, formerly called the 'product license'. This details the patients, conditions

and purpose under which the medicine is licensed for use. Any medicine which does not have a marketing authorisation for the specific country where it is prescribed is termed ‘unlicensed’. Unlicensed medicines prescribed include new medicines undergoing clinical trial and those licensed and imported from another country but not licensed in the country where they are to be used. It also includes ‘specials’, that is, medicines manufactured to meet a specific patient’s needs, or produced when two licensed medicines are mixed together for administration to a patient.

However, if a licensed medicine is prescribed outside that specified in the marketing authorisation, then this use is described as ‘off-label’. This happens in practice; for example, many medicines are not licensed for use in children but are prescribed for them. In addition some established medicines are prescribed for conditions outside their marketing authorisation (e.g. amitriptyline for neuropathic pain and azathioprine in Crohn’s disease). The British National Formulary includes information on off-label use as an annotation of ‘unlicensed use’ to inform healthcare professionals. The details of a medicine’s marketing authorisation are provided in the Summary of Product Characteristics.

The company which holds the marketing authorisation has the responsibility to compensate patients who are proven to have suffered unexpected harm caused by the medicine when prescribed and used in accordance with the marketing authorisation. Therefore, if a medicine is prescribed which is either unlicensed or off-label, then the prescriber carries professional, clinical and legal responsibility and is therefore liable for any harm caused. Best practice on the use of unlicensed and off-label medicines is described in [Box 2.4](#). In addition all healthcare professionals have a responsibility to monitor the safety of medicines. Suspected adverse drug reactions (ADRs) should therefore be reported in accordance with the relevant reporting criteria.

Prescribing across the interface between primary and secondary care

When a patient moves between care settings, there is a risk that a ‘gap’ in care will take place. These ‘gaps’ in care are almost always as a result of poor communication and frequently involve medicines, particularly when the patient is discharged from hospital into a community setting. To date there are few evidence-based solutions to these problems. A systematic review did identify randomised controlled trials of interventions designed to improve handover between hospital and primary care when patients were discharged. However, the complexity of interventions did not allow firm conclusions about which had positive effects ([Hesselink et al., 2012](#)). The [National Institute for Health Care and Excellence \(2015\)](#) in their guidance on medicines optimisation recommend that complete and accurate information on medicines should be shared and acted upon in a timely manner when patients transfer between care settings. They also make recommendations on what information should be shared and who should be involved in this process. The primary care prescriber with the responsibility for the continuing management of the patient in the community may be required to prescribe medicines with which they are not familiar. The prescriber should be fully informed and competent to prescribe a particular medicine for his or her patient. Supporting information from the hospital, in the form of shared care guidelines, can help

Box 2.4 Advice for prescribing unlicensed and off-label medicines

Consider

- Before prescribing an unlicensed medicine, be satisfied that an alternative licensed medicine would not meet the patient’s needs.
- Before prescribing a medicine off-label, be satisfied that such use would better serve the patient’s needs than an appropriately licensed alternative.
- Before prescribing an unlicensed medicine or using a medicine off-label:
 - be satisfied that there is a sufficient evidence base and/or experience of using the medicine to show its safety and efficacy;
 - take responsibility for prescribing the medicine and for overseeing the patient’s care, including monitoring and follow-up;
 - record the medicine prescribed and, where common practice is not being followed, the reason for prescribing the medicine; you may wish to record that you have discussed this with the patient.

Communicate

- You give patients, or those authorising treatment on their behalf, sufficient information about the proposed treatment, including knowing serious or common adverse drug reactions, to enable them to make an informed decision.
- Where current practice supports the use of a medicine outside the terms of its license, it may not be necessary to draw attention to the license when seeking consent. However, it is good practice to give as much information as patients or carers require or which they see as relevant.
- You explain the reasons for prescribing a medicine off-label or prescribing an unlicensed medicine where there is little evidence to support its use, or where the use of the medicine is innovative.

From Medicines and Healthcare products Regulatory Agency. 2009. Off-label use or unlicensed medicines: prescribers’ responsibilities. Drug Safety Update 2:7 with kind permission from MHRA.

inform the prescriber about medicines with which he or she may not be very familiar. Overall the decision about who should take responsibility for continuing care or prescribing treatment after the initial diagnosis or assessment should be based on the patient’s best interests rather than on the healthcare professional’s convenience or the cost of the medicine. However, when prescribers are uncertain about their competence to prescribe, where they consider they have insufficient expertise to accept responsibility for the prescription or where the product is of a very specialised nature and/or requires complex ongoing monitoring, it is legitimate for a prescriber to refuse to prescribe and make other arrangements for continued prescribing, for example, by asking the specialist to continue to prescribe. Guidance and principles for transferring information about medicines between care settings has been published by the Royal Pharmaceutical Society in conjunction with the Royal Colleges ([Royal Pharmaceutical Society, 2012](#)).

Clinical governance

Clinical governance is defined as ‘the system through which NHS organisations are accountable for continuously improving

the quality of their services and safeguarding high standards of care, by creating an environment in which clinical excellence will flourish' (DH, 1998, p. 33). It is a process embraced by the NHS to ensure that the quality of health care embedded within organisations is continuously monitored and improved. Clinical governance parallels corporate governance within commercial organisations and as such provides a systematic set of mechanisms such as duties, accountabilities and rules of conduct to deliver quality health care.

Clinical governance is described as having seven pillars:

- patient, service user, carer and public involvement
- risk management
- clinical audit
- staffing and management
- education, training and continuing professional development
- research and clinical effectiveness
- use of information

Within the NHS, standards of practice have been developed and monitored to ensure risks are managed and controlled. As part of this framework, the performance of staff is also assessed and remedial action taken, if required. NHS organisations have clinical governance requirements for their staff which include requirements for non-medical prescribing.

Professional bodies have also incorporated clinical governance into their codes of practice. The four tenants of clinical governance are: to ensure clear lines of responsibility and accountability, a comprehensive strategy for continuous quality improvement, policies and procedures for assessing and managing risks, and procedures to identify and rectify poor performance in staff. Suggested indicators for good practice are detailed in [Box 2.5](#).

Competence and competency frameworks

Competence can be described as the knowledge, skills and attributes required to undertake an activity to a specific minimum standard within a defined environment. A competency framework is a group of competencies identified as essential to effectively perform a specific task. It can be used by an individual or an organisation to assess performance in a defined area. For example, it can be used for staff selection/recruitment, training and performance review.

The National Prescribing Centre competency framework for pharmacist prescribers was published in 2006 ([Granby and Picton, 2006](#)). In 2012 a prescribing competency framework was published to encompass all prescribers (independent and supplementary) which was subsequently reviewed and updated in 2016 ([Royal Pharmaceutical Society, 2016](#)). This framework is composed of 10 competencies assigned to 2 domains, the consultation and prescribing governance. The 10 competencies are:

- assess the patient,
- consider the options,
- reach a shared decision,
- prescribe,
- provide information,
- monitor and review,
- prescribe safely,

Box 2.5 Overview of clinical governance practice recommendations for prescribers

- Ensure effective communication with patients and carers to meet the patient's needs so that the patient can make informed choices about his or her treatment.
- Prescribe within competence (scope of practice).
- Obtain patient consent for investigations and management.
- Document in the patient's medical record a comprehensive record of the consultation and the agreed treatment plan.
- Undertake full assessment of patients competently and with consent.
- Prescribe safely, legally, appropriately, clinically and cost-effectively with reference to national and local guidelines.
- Assess and manage risk of treatment and associated investigations.
- Prescribe and refer in accordance with the clinical management plan if relevant.
- Ensure the secure storage of prescriptions and follow the relevant organisational procedures if they are lost or stolen.
- Ensure wherever possible separation of prescribing and dispensing and prescribing and administration.
- Audit prescribing practice.
- Identify and report incidents and adverse drug reactions.
- Participate and record continuing professional development relating to prescribing.
- Follow organisational procedures for dealing with the pharmaceutical industry regarding gifts and hospitality.

- prescribe professionally,
- improve prescribing practice,
- prescribe as part of a team.

Each of these competencies is supported by a series of statements, all of which an individual needs to demonstrate to achieve overall competency ([Table 2.1](#)). Prescribers can review their prescribing performance using the 10 competencies and the associated 64 statements using this framework as a self-assessment tool. Unlike the previous frameworks, some aspects of applying professionalism were not included. However, seven example statements (e.g. 'adapts consultations to meet the needs of different patients/carers') were provided within a separate section to encourage prescribers to reflect on professional practice linked to prescribing ([Royal Pharmaceutical Society, 2016](#)). The framework is particularly useful when structuring ongoing continuing professional development because it also allows prescribers to identify and reflect on strengths and areas for development.

The prescribing process

Consultation

The consultation is a fundamental part of the prescribing process, and prescribers need to understand and utilise this to help them practice effectively. The medical model of disease, diagnosis and prescribing is often central to practice, but an understanding of the patient's background together with his or her medical beliefs and anxieties is equally important in helping the prescriber

Table 2.1 Overview of the competency framework for all prescribers (Royal Pharmaceutical Society, 2016)

Domain	Competency	Statements
The consultation	Assess the patient.	8 statements For example, accesses and interprets all available and relevant patient records to ensure knowledge of the patient's management to date
	Consider the options.	10 statements For example, considers all pharmacological treatment options including optimising doses, as well as stopping treatment (appropriate polypharmacy, deprescribing)
	Reach a shared decision.	6 statements For example, explores the patient/carer understanding of a consultation and aims for a satisfactory outcome for the patient/carer and prescriber
	Prescribe.	13 statements For example, prescribes a medicine only with adequate, up-to-date awareness of its actions, indications, dose, contraindications, interactions, cautions, and unwanted effects
	Provide information.	5 statements For example, ensures that the patient/carer knows what to do if there are any concerns about the management of their condition, if the condition deteriorates or if there is no improvement in a specific time frame
	Monitor and review.	4 statements For example, ensures that the effectiveness of treatment and potential unwanted effects are monitored
Prescribing governance	Prescribe safely.	6 statements For example, prescribes within own scope of practice and recognises the limits of own knowledge and skill
	Prescribe professionally.	6 statements For example, accepts personal responsibility for prescribing and understands the legal and ethical implications
	Improve prescribing practice.	3 statements For example, reflects on own and others' prescribing practice, and acts upon feedback and discussion
	Prescribe as part of a team.	4 statements For example, acts as part of a multidisciplinary team to ensure that continuity of care across care settings is developed and not compromised

Seven example behaviours identified as applying professionalism are also provided to encourage reflection of professional practice linked to prescribing, for example, undertakes the consultation in an appropriate setting taking account of confidentiality, consent, dignity and respect.

understand his or her own role and behaviours alongside those of his or her patients. Each patient's own beliefs, values, experience and expectations are important to acknowledge, explore and incorporate into all consultations. All prescribers should employ a non-judgemental approach to the consultation and listen to patients' beliefs and concerns (National Institute for Health and Care Excellence [NICE], 2012). Consideration should also be given to the consultation environment to ensure the patient's privacy is respected and also to how to maximise the patient's participation in the consultation. Some patients might like a family member or friend to be present or participate in a consultation, and this should be discussed and accommodated. A broad range of practical skills are needed in the consultation:

Interpersonal skills: the ability to communicate and make relationships with patients, considering the most effective communication method, including large print, symbols, Braille pictures, etc. and the avoidance of jargon;

summarising information, checking the patient has understood important information and giving the patient opportunities to ask questions should also be incorporated into the consultation

Reasoning skills: the ability to gather appropriate information, interpret the information and then apply it both in diagnosis and management

Practical skills: the ability to perform physical examinations and use clinical instruments

The style in which the consultation is undertaken is also important. The paternalistic prescriber–patient relationship is no longer appropriate. This has been replaced in modern health care by a more patient-centred focus that ensures patient autonomy and consent. This model is based on an equal role for both patient and prescriber and is supported by policies which promote patient empowerment and self-care/management. This uses a task-orientated approach to keep consultation times to a reasonable

Fig. 2.2 Calgary–Cambridge consultation framework (Silverman et al., 2005). (Reproduced with kind permission from the Radcliffe Publishing Ltd., Oxford.)

duration and to set parameters to ensure a realistic expectation from the consultation.

An example of this is the Calgary Cambridge framework which can be used to structure and guide patient consultations (Silverman et al., 2005). The framework is represented in Fig. 2.2. The five key stages of the consultation are:

- initiating the session
- gathering information
- physical examination
- explanation and planning
- closing the session

In addition to these stages two key tasks are performed throughout the consultation. These are 'providing structure' and 'building the patient–prescriber relationship'. These two tasks are vital in ensuring an effective consultation. For a patient–prescriber communication to be effective, it is important that this focuses on interaction between the patient and the prescriber and is not just passive transmission of information. Feedback from the patient about the information received is essential for effective communication.

Building relationships

Non-verbal communication is important and can be used by the prescriber to gain information from the patient. Facial expressions and body posture can give clues about how the patient is

feeling (e.g. anxious or tired). Proximity and eye contact are also important to determine whether the patient is actively engaged in the conversation or is distracted. Such non-verbal clues (e.g. anxiety, tiredness and pain) can then be explored verbally with the patient.

Prescribers also need to review their own non-verbal communication to ensure this reinforces the verbal message they are giving to the patient. For example, doctors who face the patient, make eye contact and maintain an open posture were regarded by their patients to be more interested and empathic (Harrigan et al., 1985). Also healthcare professionals in primary care who demonstrated non-verbal intimacy (close distance, leaning forward, appropriate body orientation and touch) had increased patient satisfaction (Larsen and Smith, 1981).

Because eye contact is an important non-verbal form of communication, obtaining information from patient records and documenting the consultation could undermine these skills. Therefore, it is important to read notes in advance of the consultation and avoid writing up the outcome while the patient is speaking. Indicating to the patient that references need to be made to their record or information documented ensures the patient is informed about the break in the consultation. This strategy should be adopted for both paper and computer-based records.

Developing rapport is also essential to building an effective patient–prescriber relationship. This can be achieved by providing an accepting response to the patient's concerns and

expectations. This is achieved by acknowledging the patients' views, valuing their contribution and accepting this information in a non-judgemental way. This does not necessarily mean that the prescriber agrees with the information, but that he or she accepts that this is a legitimate view from the patient's perspective. This can be reinforced by summarising the patient's view. The prescriber should acknowledge the patient's coping efforts and self-care. Avoiding jargon and explaining complex concepts in simple terms, to enable patients to understand the diagnosis and management, is also important.

Providing structure

Providing structure is important in the patient–prescriber consultation to enable the five key stages to be effectively completed. The prescriber needs to establish the boundaries for the consultation. This includes the time available for the consultation, the topics covered and how to finish the consultation. Therefore, because the power in the consultation is with the prescriber, it is the prescriber's responsibility to guide the consultation and involve the patient. This is to ensure that a patient-centered collaborative partnership is established. This can be achieved by using problem identification, screening and agenda-setting skills. The use of a logical sequence, signposting from one part of the consultation to the next and including an initial and end summary, will provide an effective structure to the consultation.

Initiating the session

During the first stage of the consultation the prescriber needs to greet the patient and confirm his or her identity. Prescribers should also ensure that the environment for the consultation is appropriate for maintaining eye contact and ensuring confidentiality. Prescribers should also introduce themselves, their role and gain relevant consent. During this stage the prescriber must demonstrate respect for the patient and establish a patient-centered focus. Using initially open and then closed questions, the prescriber needs to identify the patient's problem and/or issues. By adopting this approach and actively listening, the prescriber is able to confirm the reason for the consultation and identify other issues. This allows the prescriber to negotiate an agenda for the next stages of the consultation through agreement with the patient, taking into account both the patient's and the prescriber's needs. This initial stage is vital for the success of the consultation because many patients have hidden agendas which if not identified at this stage can lead to these concerns not being addressed. [Beckman and Frankel \(1984\)](#) studied doctors' listening skills and identified that even minimal interruptions by the doctors to the initial patient's statement at the beginning of the consultation prevented the patients' concerns from being expressed. This resulted in either these issues not being identified at all, or they were raised by the patient late in the consultation.

Gathering information

The aim of this stage is to explore the problem identified from both the patient's and the prescriber's perspective to gain background information which is both accurate and complete. [Britten](#)

[et al. \(2000\)](#) identified that lack of patient participation in the consultation led to 14 categories of misunderstanding between the prescriber and the patient. These categories included patient information unknown to the prescriber, conflicting information from the patient and communication failure with regard to the prescriber's decision. During this stage, the illness framework, identified by exploring patients' ideas, concerns, expectations and experience of their condition and effect on their life, is combined with the information gained by the prescriber through their biomedical perspective. This encompasses signs, symptoms, investigations and underlying pathology. Assimilation of this information leads the prescriber to a differential diagnosis. By incorporating information from both viewpoints, a comprehensive history detailing the sequence of events can be obtained using questioning, listening and clarification. This ends with an initial summary where the prescriber invites the patient to comment and contribute to the information gathered.

Physical examination

At the start of the physical examination stage it is important to again obtain the patient's consent for any examination by explaining the process and rationale for the assessment. The environment (e.g. room temperature and screening for the examination) is important, and the prescriber should review this to ensure the patient's comfort. Guidance on maintaining clear sexual boundaries for pharmacy professionals has been published which includes advice on the use of chaperones ([General Pharmaceutical Council, 2012](#)).

Explanation and planning

The explanation and planning stage of the consultation incorporates three aspects: the differential diagnosis/hypothesis, the prescriber's management plan (investigations and alternative treatments), and explanation and negotiation of the plan of action with the patient.

In one UK study, doctors were found to overestimate the extent to which they completed the tasks of discussing the risk of medication, checking the ability of the patient to follow the treatment plan and obtaining the patient's input and view on the medication prescribed ([Makoul et al., 1995](#)).

To successfully accomplish this stage of the consultation, the prescriber needs to use a number of skills and also to involve the patient. Prescribers should ensure they give the correct type and amount of information. This is done by assessing the patient's prior knowledge employing both open and closed questions. By organising the information given into chunks which can be easily assimilated, the prescriber can then check that the patient understands the information given. Questioning the patient regarding additional information they require also helps to ensure the patient's involvement and to maintain rapport. The prescriber must determine the appropriate time to give explanations and also allow the patient time to consider the information provided. Signposting can also be a useful technique to employ during this stage. Once again the language used should be concise, easy to understand and avoid jargon. Using diagrams, models and written information can enhance and reinforce patient understanding.

The explanation should be organised into discreet sections with a logical sequence so that important information can be repeated and summarised.

To achieve shared understanding and shared decision making, it is important to incorporate the patient's perspective by relating the information given to the patient's illness framework. The patients also need to have the opportunity to ask questions, raise doubts and obtain clarification. This is especially important because national surveys of patients have identified that many patients, particularly those with long-term conditions, are less likely to report being involved in their own care ([Care Quality Commission, 2016](#)). Discussing with patients their beliefs, culture, abilities and lifestyle is important when discussing treatment options, for example, fasting during Ramadan or use of memory aids to support adherence. Prescribers should also explain their rationale for the management plan identified and also discuss possible alternatives. By involving and negotiating with the patient in this way, a mutually acceptable treatment plan can be identified which allows patients to take responsibility for their own health.

Box 2.6 summarises the issues the prescriber should consider before prescribing a medicine.

Closing the session

The effectiveness of the end of a consultation is as important as the preceding stages. A number of steps are undertaken during the closing stage. These include agreeing to a contract with the patient as to the next steps to be taken by both patient and prescriber, for example, additional investigations and/or referral. Safety net strategies are also employed and discussed so the patient can identify unexpected outcomes or treatment failure and also understand who and how to contact the prescriber or another healthcare professional if appropriate. The end summary is an essential component of this stage and is used to briefly and accurately identify the management plan established during the previous stage in the consultation. This is followed by a final check that the patient has understood and consented to this management plan. At the end of the consultation the patient is given another opportunity to ask any final questions.

Communicating risks and benefits of treatment

Shared decision making supports patients to actively participate in their care. Before this stage of the consultation is reached, the healthcare professional has to use the best available evidence about treatment and be able to apply it to the individual patient in front of them, taking into account their needs, values and preferences. This requires the healthcare professional to discuss and provide information about the risks, benefits and consequences of treatment options, check that the patient understands the information, encourage the patient to clarify what is important to them and check that their choice is consistent with this. This ensures patient's consent to treatment is informed, and that the patient has an opportunity to participate in shared decision making about his or her treatment.

It is important to be able to communicate the risks and benefits of treatment options in relation to medicines. This should be done

Box 2.6 Issues the prescriber should reflect upon before prescribing a medicine ([National Prescribing Centre, 1998](#))

- What is the drug?
 - Is it novel?
 - Is it a line extension?
- What is the drug used for?
 - What are the licensed indications?
 - Any restrictions on initiation?
 - Does first line mean first choice?
- How effective is the drug?
 - Is there good evidence for efficacy?
 - How does it compare with existing drugs?
- How safe is the drug?
 - Are there published comparative safety data?
 - Has it been widely used in other countries?
 - Are the details contained in the Summary of Product Characteristics understood?
 - Are there clinically important drug interactions?
 - Are there monitoring requirements?
 - Can it be used long-term?
- Who should not receive this drug?
 - Are there patients in whom it is contraindicated?
- Does the drug provide value for money?
 - Is there good evidence of cost-effectiveness compared with other available interventions?
 - What impact will this drug have on the healthcare budget?
- What is its place in therapy?
 - What advantages are there?
 - Are the benefits worth the cost?
 - Are there some patients who would particularly benefit?

without bias and should avoid personal anecdotal information. Most patients want to be involved in decisions about their treatment, and would like to be able to understand the risks of side effects versus the likely benefits of treatment before they commit to the inconvenience of taking regular medication. An informed patient is more likely to be concordant with treatment, reducing waste of healthcare resources including professional time and the waste of medicines which are dispensed but not taken. Healthcare professionals need to recognise that the patient's values and preferences may be different from those of the healthcare professional, and that they should avoid making assumptions about patients. This may result in the patient making a treatment decision that is different from the healthcare professional's preferred option.

Communicating risk is not simple ([Paling, 2003](#)). Many different dimensions and inherent uncertainties need to be taken into account, and patients' assessment of risk is primarily determined by emotions, beliefs and values, not facts. This is important, because patients and healthcare professionals may ascribe different values to the same level of risk. Healthcare professionals need to be able to discuss risks and benefits with patients in a context that would enable the patient to have the best chance of understanding those risks. It is also prudent to inform the patient that virtually all treatments are associated with some harm and that there is almost always a trade-off between benefit and harm. How healthcare professionals present risk and benefit can affect the patient's perception of risk.

The National Institute of Health and Care Excellence (NICE, 2012) recommends using the following principles when discussing risks and benefits with patients:

- personalise risks and benefits as far as possible;
- use absolute risk rather than relative risk (e.g. the risk of an event increases from 1 in 1000 to 2 in 1000, rather than the risk of the event doubles);
- use natural frequency (e.g. 10 in 100) rather than a percentage (10%);
- be consistent in the use of data (e.g. use the same denominator when comparing risk: 7 in 100 for one risk and 20 in 100 for another, rather than 1 in 14 and 1 in 5);
- present a risk over a defined period (months or years) if appropriate (e.g. if 100 people are treated for 1 year, 10 will experience a given side effect);
- include both positive and negative framing (e.g. treatment will be successful for 97 of 100 patients and unsuccessful for 3 of 100 patients);
- be aware that different people interpret terms such as ‘rare’, ‘unusual’ and ‘common’ in different ways, and use numerical data if available;
- think about using a mixture of numerical and pictorial formats (e.g. numerical rates and pictograms).

Visual patient decision aids are becoming increasingly popular as a tool that healthcare professionals can use to support discussions with patients by increasing their knowledge about expected outcomes and helping them to relate these to their personal values (National Prescribing Centre, 2008). Further information about using patient decision aids can be found at: <http://ipdas.ohri.ca> or <http://sdm.rightcare.nhs.uk> (NHS-specific information on patient decision aids and shared decision making).

Adherence

Adherence has been defined as the extent to which a patient’s behaviour matches the agreed recommendation from the prescriber. When a patient is non-adherent this can be classified as intentional or unintentional non-adherence (NICE, 2009). Adherence/non-adherence is a variable behaviour, rather than a trait characteristic, and is best understood in terms of the patient’s encounter with his or her specific treatment. To facilitate optimal adherence, both perceptual factors (e.g. beliefs, preferences and incentives), which are associated with intentional non-adherence, and practical factors (e.g. capacity and resources), which are associated with unintentional non-adherence, need to be addressed.

Unintentional non-adherence occurs when the patient wishes to follow the treatment plan agreed with the prescriber but is unable to do so because of circumstances beyond his or her control. Examples of this include forgetting to take the medicine at the defined time or an inability to use the device prescribed. Strategies to overcome such obstacles include medication reminder charts, use of multi-compartment medication dose systems, large print for those with poor eyesight and aids to improve medication delivery (e.g. inhaler aids, tube squeezers for ointments and creams, and eye drop administration devices). A selection of these devices is detailed in a guide to the design of dispensed medicines (National Patient Safety Agency, 2007).

Intentional non-adherence occurs when the patient decides he or she does not wish to follow the agreed treatment plan. This may occur because of the patient’s beliefs, perceptions or motivation. Therefore, it is important that all of these aspects are included in the discussion between the patient and the prescriber when the treatment plan is developed. Patients need to fully appreciate their medical condition and its prognosis to understand the rationale for the treatment options discussed. The benefits of the treatment plan, the effect of not taking the treatment, as well as the side effects all need to be explicitly explored with the patient. Patient decision aids and medicine-specific patient information leaflets can be used to support this discussion. However, evidence is inconclusive as to whether written medicines information is effective in changing knowledge, attitudes and behaviours related to medicine taking (Nicolson et al., 2009). The patient’s previous experience of medicines and associated side effects should be explored because this gives the prescriber vital information about perceptions and motivation. Adherence to existing prescribed medication should be explored non-judgementally. For example, asking the patient how often he or she missed taking doses at the prescribed time over the previous 7 days would enable the prescriber to assess adherence but also explore lifestyle factors or side effects which may impact on the patient. These can then be discussed and strategies developed to optimise adherence.

More than 40% of working-age adults are unable to understand or make use of everyday health information because of limited health literacy. Reduced health literacy is associated with poorer health outcomes including increased risk of morbidity, premature death, poorer understanding of how to take medicines and increased non-adherence. Prescribers need to recognise patients’ health literacy needs and employ a range of communication tools and strategies to support their needs (Public Health England, 2015).

Studies have demonstrated that between 35% and 50% of medicines prescribed for chronic conditions are not taken as recommended (NICE, 2009). Therefore, it is the prescriber’s responsibility to explore with patients their perceptions of medicines to determine whether there are any reasons why they may not want to or are unable to use the medicine. In addition, any barriers which might prevent the patient from using the treatment as agreed, for example, manual dexterity, eyesight and memory, should be discussed and assessed. Such a frank discussion should enable the patient and prescriber to jointly identify the optimum treatment regimen to treat the condition. In addition, information from the patient’s medical records can be used to assess adherence. For example, does the frequency of requests for repeat medication equate to the anticipated duration of use?

Review of unused medicines can be undertaken, and it is also important to assess the patient’s administration technique on an ongoing basis for devices (e.g. asthma inhalers) to optimise correct technique. This can be achieved, for example, by carrying out a medicines reconciliation on hospital admission when the patient’s prescribed medicines are compared with what the patient was taking before admission through discussion with the patient and/or carers and review of primary care records.

Because it is likely that at some point all patients will forget to take their medicine, it is important to give all patients information on what to do should a dose be missed. For individuals who are taking medication for treatment of a chronic condition, adherence

should not be assumed; therefore, assessment of adherence should form an ongoing discussion at each consultation.

Medication review

Medication review has been defined as ‘a structured, critical examination of a patient’s medicines with the objective of reaching an agreement with the patient about treatment, optimising the impact of medicines, minimising the number of medication-related problems and reducing waste’ (NICE, 2015, p. 22).

It is important that medicines are prescribed appropriately and that patients continue to achieve benefits from their medicines. The regular review of medicines is a key part of a good prescribing process and has many potential benefits for patients, including improving the management of the patient’s medical condition, optimising the use of medicines, reducing risk of ADRs and involving the patient more actively in his or her treatment and care.

Often medicines prescribed regularly on a long-term basis are for patients with multiple comorbidities. This often results in individual patients being prescribed many medicines, a term known as ‘polypharmacy’. Polypharmacy is important because evidence suggests that being on multiple medicines increases a person’s risk of harm and contributes to hospital admissions (NICE, 2015). Using a medication review process to reduce the number of inappropriate medicines a patient is taking (deprescribing) and optimise appropriate medication can minimise unwanted harms from medicines (including falls) and reduce costs. In UK primary care, repeat prescribing systems enable patients on long-term regular medication to obtain further supplies of their medicine without routinely having to see their primary care doctor or prescriber. Robust systems and processes are required for this repeat prescribing to ensure the safe and efficient use of medicines. Reviewing a patient’s medication forms is an essential element of a robust repeat prescribing process.

Specific groups of patients are recommended for a structured medication review (NICE, 2015), including all patient groups who are taking multiple medicines (polypharmacy), patients with chronic or long-term conditions and older people. Different types

of medication review are required to meet the needs of patients for different purposes. A medication review can vary from a simple review of the prescription to an in-depth structured clinical medication review. NICE (2015) recommends that a structured medication review should be carried out by a healthcare professional with a sufficient level of knowledge of processes for managing medicines and therapeutic knowledge on medicines use. The scope of this review includes the following:

- the patient’s and carer’s (if appropriate) views and understanding about their medicines;
- the patient’s and carer’s (if appropriate) concerns, questions or problems with their medicines;
- all prescribed, over-the-counter and complementary medicines that the patient is taking or using, and what these are for;
- how safe the medicines are, how well they are working, how appropriate they are and whether their use is in line with national guidance/evidence;
- whether the patient has had or has any risk factors for development of ADRs;
- what monitoring is needed.

Characteristics of the different types of medication review are described in Table 2.2.

The key elements of a structured medication review are (All Wales Medicines Strategy Group, 2014; Scottish Government, 2015):

- identify aims and objectives of drug therapy;
- identify essential drug therapy;
- assess if the patient is taking unnecessary drug therapy;
- check if the therapeutic objectives are being achieved;
- determine if the patient is at risk of ADRs or suffering an actual ADR
- consider if drug therapy is cost-effective;
- determine the patient’s willingness and ability to take their drug therapy;
- agree on actions to stop, reduce dose, continue or start drug therapy;
- communicate actions with all relevant parties;
- monitor and adjust regularly.

NO TEARS (Lewis, 2004) (Table 2.3) is a simpler tool for carrying out structured medication review. There are a number of

Table 2.2 Characteristics of types of medication review

Type of review	Purpose of the review	Requires patient to be present	Access to patient’s full clinical notes
Level 1 Prescription review	Technical review of patient’s list of medicines, e.g. dose optimisation, anomalies, changed items, cost-effectiveness	Not essential (any resulting changes to prescribed medicines must involve the patient/carer)	Not normally (community pharmacist can use Summary Care Record)
Level 2 Treatment review	Address issues relating to the patient’s medicine-taking behaviour and use of medicines, e.g. dose modification, stopping medicines	Usually (any resulting changes to prescribed medicines must involve the patient/carer)	Possibly (community pharmacist may not have access to patient’s full clinical notes)
Level 3 Clinical medication review	Address issues relating to the patient’s use of medicines in the context of his or her clinical condition	Yes	Yes

Medication reviews include all medicines, including prescription, complementary and over-the-counter medicines. Treatment and prescription review may relate to one therapeutic area only.

Adapted from Medicines Partnership, 2002.

Table 2.3 The NO TEARS approach to medication review

NO TEARS	Questions to think about
Need and indication	Why is the patient taking the medicine, and is the indication clearly documented in the notes? Does the patient still need the medicine? Is the dose appropriate? Has the diagnosis been confirmed or refuted? Would a non-drug treatment be better? Does the patient know what his or her medicines are for?
Open questions	Use open questions to find out what the patient understands about his or her medicines, and what problems the patient may be having with them.
Tests and monitoring	Is the illness under control? Does treatment need to be adjusted to improve control? What special monitoring requirements are there for this patient's medicines? Who is responsible for checking test results?
Evidence and guidelines	Is there new evidence or guidelines that mean I need to review the patient's medicines? Is the dose still appropriate? Do I need to do any other investigations or tests?
Adverse effects	Does the patient have any side effects? Are any of the patient's symptoms likely to be caused by side effects of medicines, including over-the-counter and complementary medicines? Are any of the patient's medicines being used to treat side effects of other medicines? Is there any new advice or warnings on side effects or interactions?
Risk reduction and prevention	If there is time, ask about alcohol use, smoking, obesity, falls risk or family history for opportunistic screening. Is treatment optimised to reduce risks?
Simplification and switches	Can the patient's medicines regimen be simplified? Are repeat medicines synchronised for prescribing at the same time? Explain any changes in medicines to the patient.

published tools and websites to support improving polypharmacy and deprescribing. These tools incorporate guidance on assessing appropriateness or need for medicines and assessing risk of medicines (e.g. anticholinergic burden score). Examples of such tools can be found at: <http://www.polypharmacy.scot.nhs.uk> and <http://www.prescqipp.info>.

Factors that influence prescribers

A prescriber is subject to various influences which may impact their decision making when deciding whether to prescribe a medicine and which medicine to prescribe. Some of these influences may result in poor decision making; therefore, it is important to have an understanding of these influences and how they may impact on prescribing decisions. A range of influences that affect the prescribing decisions made by primary care doctors have been identified (Fig. 2.3).

Patients and prescribing decisions

The prescribing and use of medicines is strongly influenced by cultural factors that affect patients and prescribers alike. Issues

such as whether the patient expects a prescription or whether the prescriber thinks the patient expects a prescription both influence the decision to prescribe. Patients may want a prescription for a whole variety of reasons, some of which are more valid than others. Beyond wanting a medicine for its therapeutic effect, a prescription for a medicine may demonstrate to the patient that his or her illness is recognised, may be seen as a symbol of care, may offer legitimacy for time off work because of illness or may fit with their health beliefs. Patients who frequently consult and receive a prescription are more likely to repeat the experience and expect a prescription at the next consultation.

A number of studies have found that doctors sometimes feel under pressure from patients to prescribe, although patients may not always expect a prescription from the doctor. However, even though patients often expect to receive a medicine, they also have more complex agendas that need to be explored in the consultation. Patients may have mixed attitudes towards medicines, and reluctance to take medicines is quite common. Although a medicine may be prescribed for its pharmacological effect, there may be other associated reasons to prescribe for a patient, for example, to end the consultation, to avoid doing anything else or having to say no, to maintain contact with the patient as a response to carer anxiety or to fulfil the patient's expectation.

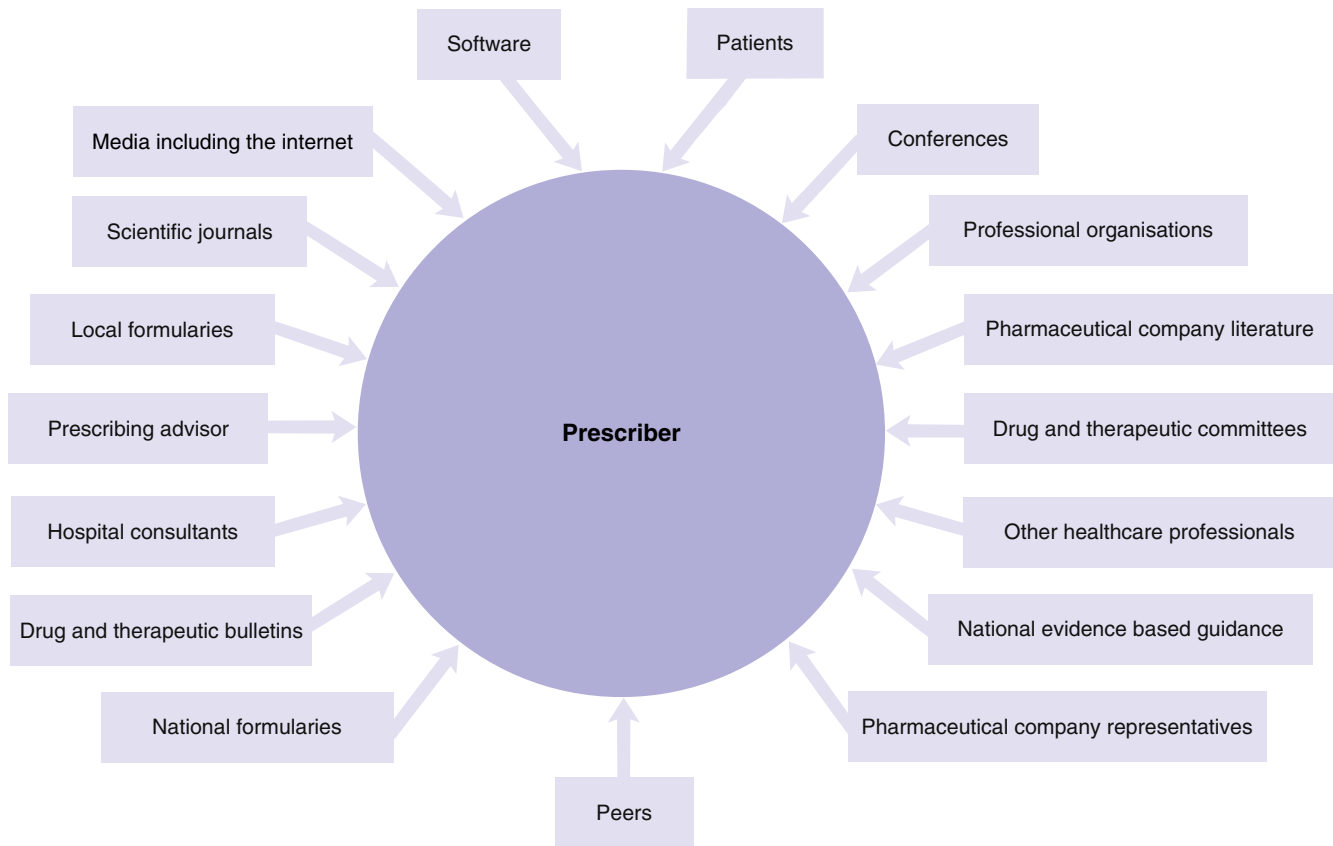

Fig. 2.3 Influences on prescribing decisions.

The informed patient

Health care is moving to a position of greater shared decision making with patients and development of the concept of patient autonomy. This is being supported through the better provision of information for patients about their prescribed medicines. The European Union directive 2001/83 (European Commission, 2001) requires that all pharmaceutical products are packaged with an approved patient information leaflet, which provides information on how to take the medicine and possible adverse effects. Patients are increasingly using the Internet and social media to learn about health and medicines. This can be challenging for healthcare professionals, particularly when the quality of information sources used may be highly variable. When media coverage does not provide balanced coverage, for example, reporting regarding the safety of measles, mumps and rubella (MMR) vaccine, this can have important consequences. In this case there was a rapid decline in MMR vaccination rates in children and a subsequent mumps outbreak (Gupta et al., 2008).

Direct advertising of medicines to patients is allowed in the USA and New Zealand, but not in Europe. Advertising medicines in this way is clearly effective in increasing sales of medicines, as evidenced by the increased spending and prescriptions for advertised drugs, compared with non-advertised drugs in these countries. This has led to concern that direct-to-consumer advertising encourages unnecessary and inappropriate use of medication. In the UK, education for patients may be provided by the manufacturer through sponsored disease awareness campaigns, but there

is concern these encourage individuals to seek advice or treatment from their doctor for previously undiagnosed conditions. These campaigns may also help to raise awareness of conditions that have not been well managed in the past. However, they can also act in a way to promote prescription medicines. Such campaigns, which may be established by a drug company with or without the endorsement of a patient group, often take place at the same time as a drug's launch and may involve aggressive promotion. As a consequence there have been calls to control the influence of companies on the production of disease awareness campaigns that impact on the individual patient, who then exerts pressure on the prescriber for a specific medicine.

Healthcare policy

National policy and guidelines, for example, guidance from the NICE and Scottish Intercollegiate Guidelines Network in the UK, have a significant influence on prescribing and uptake of new medicines (NHS England, 2016b). The uptake of guidance and impact on prescribing can show considerable variation between individual clinicians and healthcare organisations. A range of complex factors have been identified that affect the impact of national guidance (Kings Fund, 2006), for example, prescriber's knowledge, attitude and behaviour, lack of staff, resources or managerial leadership, attitudes of patients, environmental factors, such as the regulatory environment, and the structure of reimbursement mechanisms.

Colleagues

Several studies have found that healthcare professionals in primary care (both doctors and nurses) rely on advice from trusted colleagues and opinion leaders as a key source of information on how to manage patients. It has been estimated that 40% of prescribing in primary care was strongly influenced by hospitals because the choice of medicine prescribed in general practice was often guided by hospital specialists through their precedent prescribing and educational advice (National Audit Office, 2007). The pharmaceutical industry recognises the value of identifying 'key opinion' leaders amongst the medical community and will try to cultivate them to influence their peers and fellow clinicians by paying them for a consultancy, lecture fees, attendance at medical conferences, supporting research and writing articles favourable to that company's products.

Pharmacists, in both primary and secondary care, themselves have an influence on prescribing through their roles as clinical pharmacists, or as part of their work advising on prescribing in primary care. Pharmacists are often regarded as trusted colleagues, and as such can have an important influence on prescribing. In whichever sector they are working, pharmacists need to be aware that their advice and decisions may be influenced by exactly the same factors that influence the prescriber.

Pharmaceutical industry

The pharmaceutical industry has a very wide and important influence on prescribing decisions affecting every level of healthcare provision, from the medicines that are initially discovered and developed through clinical trials to the promotion of medicines to the prescriber and patient groups, the prescription of medicines and the compilation of clinical guidelines. There are more than 8000 pharmaceutical company representatives in the UK who are trying to persuade prescribers to prescribe their company's product. This represents a ratio of about 1 representative for every 7.5 doctors (House of Commons Health Committee, 2005), with 1 representative for every 4 primary care doctors (National Audit Office, 2007). Whilst representatives from the pharmaceutical industry can provide useful and important new information to prescribers about

medicines, the information presented is not without bias and rarely provides any objective discussion of available competitor products.

The influence of the pharmaceutical industry extends well beyond the traditional selling approach of using representatives and is increasingly sophisticated. The pharmaceutical industry spends millions on advertising, company-sponsored information in medical journals and supplements, sponsorship to attend conferences and meetings, and medical education. More than half of postgraduate education and training for doctors in the UK is sponsored by the pharmaceutical industry. The wide variety, volume and intensity of marketing activities the industry engages in is an important influence on prescribing by healthcare professionals. But when asked whether they are influenced by the pharmaceutical industry, prescribers usually deny that drug promotion affects their own prescribing practices, although they do believe that it affects other prescribers' prescribing habits. This is clearly not the case, because research has shown that even use of modest samples, gifts, and food exerts a significant influence on prescriber behaviour.

Cognitive factors

Most prescribing decisions are made using the processes our brains develop to handle large volumes of complex information quickly. This rapid decision making is aided by heuristics, strategies that provide shortcuts to quick decisions. This type of decision making largely relies on a small number of variables that we believe are important based on information collected by brief reading in summary journals (e.g. *Prescriber, Drug and Therapeutics Bulletin*), articles in popular doctors' and nurses' magazines mailed free of charge and talking to colleagues. However, it is important to recognise that cognitive biases affect these heuristics (or shortcuts) involved in rapid decision making, and that experts, as well as generalists, are just as fallible to cognitive biases in decision making (Makhinson, 2010). More than 50 cognitive biases and affective biases in medical decision making have been described. Some examples of cognitive biases that may affect prescribing decisions are listed in Table 2.4.

Table 2.4 Examples of types of cognitive biases which influence prescribing

Type of cognitive bias	Description
Novelty preference	The belief that the progress of science always results in improvements and that newer treatments are generally better than older treatments
Over optimism bias	Tendency of people to overestimate the outcome of actions, events, or personal attributes to a positive skew
Confirmation bias	Information that confirms one's already firmly held belief is given higher weight than refuting evidence
Mere exposure effect	More familiar ideas or objects are preferred or given greater weight in decision making
Loss aversion	To weigh the avoidance of loss more greatly than the pursuit of an equivalent gain
Illusory correlation	The tendency to perceive two events as causally related, when in fact the connection between them is coincidental or even non-existent

Strategies to influence prescribing

Healthcare organisations at local and national levels have been seeking to influence prescribing behaviour over many years, both to control expenditure on medicines and to improve quality of care. Medicines are one of the most well-researched interventions in healthcare, with a relative wealth of evidence to support their use. Despite this, there is still a wide variation in prescribing practice between clinicians and between healthcare organisations. This reflects variation in clinical practice arising from the inconsistent implementation of evidence-based medicine and the impact of the many factors that influence prescribing. Strategies to improve prescribing can be managerial and process orientated, or more supportive and educationally orientated. Strategies that use a combination of different interventions on a repeat basis are more likely to be successful at influencing prescribing.

Managerial approaches to influence prescribing

Formularies are agreed lists of medicines to which prescribers are encouraged or required to adhere. The benefits of a formulary include improving patient outcomes by optimising the use of medicines, supporting the inclusion of patient factors in decision making about medicines, improving local care pathways, reducing inappropriate variation in clinical care and ensuring more cost-effective use of resources across a health economy. In secondary care, prescribers can usually prescribe only those medicines included within the formulary, because these are the medicines stocked in the pharmacy. In primary care, a formulary is generally advisory in nature and less restrictive because community pharmacies can supply any medicine that is reimbursable on the NHS.

The NICE (2014) has published good practice recommendations on the systems and processes that should be used to develop and update local formularies. These recommendations describe best practice for how the formulary should be developed, who should be involved, how decisions should be made when including a medicine on the formulary, how the formulary should be implemented and disseminated, and how it should be updated. Some formularies are developed to cover prescribing in both primary and secondary care, which mean they can have a significant influence on prescribing patterns in the whole of a local health economy. Over recent years formularies have developed beyond just being a list of medicines and often include useful advice for prescribers; for example, they may include care pathways and guidelines for managing specific conditions or diseases.

Local and national guidelines

Guidelines for the use of a medicine, a group of medicines or the management of a clinical condition may be produced for local or national use. They can be useful tools to guide and support prescribers in choosing which medicines they should be prescribing. Ideally guidelines should make evidence-based standards of care explicit and accessible, and aid clinical decision making. The best quality guidelines are usually those produced using systematically developed evidence-based statements to assist clinicians

in making decisions about appropriate health care for specific clinical circumstances. In the UK the NICE has an accreditation scheme to recognise organisations that achieve high standards in producing health or social care guidance. Examples of accredited guidelines are those produced by the NICE (<http://www.nice.org.uk>), some Royal Colleges and the Scottish Intercollegiate Guideline Network (<http://www.sign.ac.uk>). Local guidelines are often developed to provide a local context and interpretation of national guidance, and offer guidance on managing patients between primary and secondary care. However, despite the availability of good-quality accessible clinical guidelines, implementation in practice remains variable.

Clinical decision support systems are increasingly popular as a way of improving clinical practice and influencing prescribing. These often utilise interactive computer programs that help clinicians with decision-making tasks at the point of care, and also help them keep up to date and support implementation of clinical guidelines. For example, clinical knowledge summaries (<https://cks.nice.org.uk>) is a decision support system developed for use in primary care that includes patient information leaflets, helps with differential diagnosis, suggests investigations and referral criteria, and gives screens that can be shared between the patient and the prescriber in the surgery.

Incentives

In an effort to contain prescribing costs, some healthcare systems use direct incentives to influence clinical behaviour and, in particular, prescribing. The incentives, which are usually financial, may offer some benefits to the prescriber's patients or to the prescriber's own healthcare organisation. They can have a significant impact on prescribing practice. Typically primary care doctors are given indicative prescribing budgets and are expected to meet the prescribing needs of their patients from within this budget. Financial incentive schemes to reward good fiscal management of prescribing budgets and improve the quality of prescribing are used to encourage prescribers to change their practice or maintain good practice. Incentive schemes usually influence what is prescribed, rather than whether a prescription is written. The most effective schemes are simple to understand, have achievable targets and require information about prescribing patterns to be readily available. However, incentives schemes for prescribing need to be managed carefully in order not to create perverse incentives, such as increasing the referral of patients to another part of the healthcare system or causing an increase in overall healthcare costs.

Provision of comparative (benchmarking) information

The provision of benchmarked information on comparative prescribing patterns to clinicians is an important influence on prescribing behaviour. Using appropriate benchmarking data puts the behaviour of practices into a local and national context. Benchmarking can provide the basis for making clinicians aware of the potential for change and allows them to understand the potential outcome of any action. Various prescribing indicators have been developed both locally and nationally to measure and compare quality and cost-effectiveness of prescribing. Ideally

indicators used should be evidence based, utilise available data sources and be validated.

Support and education

One of the challenges for modern healthcare organisations is to ensure consistent implementation of evidence-based interventions and the improvement of clinical practice. Simply providing prescribers with information or education about an evidence-based intervention rarely produces a change in practice. There is a need to understand the concerns that the adopting clinician may have about the change and recognise that these concerns are often legitimate. However, these may change over time, and the concerns must be addressed and overcome before successful adoption can occur. Interpersonal influence, particularly through the use of trusted colleagues or opinion leaders, is a powerful way to change practice. This is the basis for using pharmacists as prescribing advisers or ‘academic detailers’ to influence prescribing practice, particularly in primary care. Prescribing advisers present evidence-based tailored messages, allow the exchange of information and try to negotiate and persuade clinicians to change practice. Clinicians see pharmacists as a trusted and credible source of prescribing information who can be moderately successful in changing practice, particularly if linked with an incentive.

To change prescribing practice, pharmacists need to be aware of how to use an adoption model-based approach to convey key messages to prescribers to help them change practice. One such model is known as AIDA (Awareness, Interest, Decision, Action) (Table 2.5).

More sophisticated multifaceted educational interventions can also be effective at changing prescribing behaviour, but they need to be flexible to meet the needs of individual clinicians. This sort of combination approach includes small group learning, audit and feedback, practical support to make changes in practice and involvement and education of patients.

Table 2.5 AIDA adoption model for influencing prescribers

Awareness	Make the prescriber aware of the issues, prescribing data and evidence for the need to change.
Interest	Let the prescriber ask questions and find out more about the proposed change, what the benefits are and what the prescribers concerns are.
Decision	Help the prescriber come to a decision to make a change. They will need to apply the change to their practice, and may need further information, training and support to do this.
Action	Action refers to making a change by the prescriber. Support this with simple reminders, patient decision support, feedback data and audit.

Conclusion

While medicines have the capacity to improve health, they also have the potential to cause harm. Prescribing of medicines needs to be rational and effective in order to maximise benefit and minimise harm. Good prescribing should ensure the patient’s ideas, concerns and expectations are taken into account. This can be effectively managed by adopting a consultation framework and using patient decision aids to support shared decision making with the patient as an equal partner. Prescribers need to be aware of their responsibilities and accountability, particularly when prescribing off label or unlicensed medicines. They also need to work within their organisation’s clinical governance framework. The influences and biases that affect prescribing need to be recognised and minimised by utilising trusted independent sources of information to inform prescribing decisions.

Practical Pharmacokinetics

Ray W. Fitzpatrick and Katie Maddock

Key points

- Pharmacokinetics can be applied to a range of clinical situations with or without therapeutic drug monitoring (TDM).
- TDM can improve patient outcomes but is necessary only for drugs with a narrow therapeutic index, where there is a good concentration response relationship and where there is no easily measurable physiological parameter.
- Sampling before steady state is reached or before distribution is complete leads to erroneous results.
- The volume of distribution (V_d) can be used to determine the loading dose.
- The elimination half-life determines the time to steady state and the dosing interval.
- Kinetic constants determine the rate of absorption and elimination.
- Clearance determines the maintenance dose.
- Creatinine clearance can be reliably estimated from population values.
- Use of actual blood level data wherever possible to assist dose adjustment is advisable. However, population pharmacokinetic values can be used for digoxin, theophylline and gentamicin.
- Once-daily dosing of gentamicin is used as an alternative to multiple dosing.
- TDM is essential in the dose titration of vancomycin, lithium and phenytoin, but of little value for valproate or the newer anticonvulsants.

Clinical pharmacokinetics may be defined as the study of the time course of the absorption, distribution, metabolism and excretion of drugs and their corresponding pharmacological response. In practice, pharmacokinetics makes it possible to model what may happen to a drug after it has been administered to a patient. Clearly this science may be applied to a wide range of clinical situations, hence the term ‘clinical pharmacokinetics’. However, no matter how elegant or precise the mathematical modelling, the relationship between concentration and effect must be established before pharmacokinetics will be of benefit to the patient.

General applications

Clinical pharmacokinetics can be applied in daily practice to drugs with a narrow therapeutic index, even if drug level monitoring is not required.

Time to maximal response

By knowing the half-life of a drug, the time to reach a steady state may be estimated (Fig. 3.1), and also when the maximal therapeutic response is likely to occur, irrespective of whether drug level monitoring is needed.

Need for a loading dose

The same type of information can be used to determine whether the loading dose of a drug is necessary, because drugs with longer half-lives are more likely to require loading doses for acute treatment.

Dosage alterations

Clinical pharmacokinetics can be useful in determining dosage alteration if the route of elimination is impaired through end-organ failure, for example, renal failure or drug interaction. Quantitative dosage changes can be estimated using limited pharmacokinetic information, such as the fraction that should be excreted unchanged (f_e value), which can be found in most pharmacology textbooks.

Choosing a formulation

An understanding of the pharmacokinetics of absorption may also be useful in evaluating the appropriateness of particular formulations of a drug in a patient.

Application to therapeutic drug monitoring

Clinical pharmacokinetics is usually associated with therapeutic drug monitoring (TDM) and its subsequent utilisation. When TDM is used appropriately, it has been demonstrated that patients suffer fewer side effects than those who are not monitored (Reid et al., 1990). Although TDM is a proxy outcome measure, a study with aminoglycosides (Crist et al., 1987) demonstrated shorter hospital stays for patients when TDM was used. Furthermore, a study on the use of anticonvulsants (McFadyen et al., 1990) showed better epilepsy control in those patients for whom TDM was used. A literature review of the cost-effectiveness of TDM concluded that emphasis should not be placed solely on cost-effectiveness, but how TDM can be applied in a cost-effective and clinically useful

way (Touw et al., 2005). There are various levels of sophistication for the application of pharmacokinetics to TDM. Knowledge of the distribution time and an understanding of the concept of steady state can facilitate determination of appropriate sampling times.

For most drugs that undergo first-order elimination, a linear relationship exists between dose and concentration, which can be used for dose adjustment purposes. However, if the clearance of the drug changes as the concentration changes (e.g. phenytoin), then an understanding of the drug's pharmacokinetics will assist in making correct dose adjustments.

More sophisticated application of pharmacokinetics involves the use of population pharmacokinetic data to produce initial dosage guidelines, for example, nomograms for digoxin and gentamicin, and to predict drug levels. Pharmacokinetics can also assist in complex dosage individualisation using actual patient-specific drug level data.

Given the wide range of clinical situations in which pharmacokinetics can be applied, pharmacists must have a good understanding of the subject and of how to apply it to maximise their contribution to patient care.

Basic concepts

Volume of distribution

The apparent V_d may be defined as the size of a compartment which will account for the total amount of drug in the body (A)

Fig. 3.1 Time to steady state.

if it were present in the same concentration as in plasma. This means that it is the apparent volume of fluid in the body which results in the measured concentration of drug in plasma (C) for a known amount of drug given, that is:

$$C = \frac{A}{V_d}$$

This relationship assumes that the drug is evenly distributed throughout the body in the same concentration as in the plasma. However, this is not the case in practice because many drugs are present in different concentrations in various parts of the body. Thus, some drugs which concentrate in muscle tissue have a very large apparent V_d , for example, digoxin. This concept is better explained in Fig. 3.2.

The apparent V_d may be used to determine the plasma concentration after an intravenous (i.v.) loading dose:

$$C = \frac{\text{loading dose}}{V_d} \quad (1)$$

Conversely, if the desired concentration is known, the loading dose may be determined:

$$\text{loading dose} = \text{desired } C \times V_d \quad (2)$$

In the previous discussion, it has been assumed that after a given dose a drug is instantaneously distributed between the various tissues and plasma. In practice this is seldom the case. For practical purposes it is reasonable to generalise by referring to plasma as one compartment and tissue as if it were another single separate compartment. However, in reality there will be many tissue subcompartments. Thus, in pharmacokinetic terms the body may be described as if it were divided into two compartments: the plasma and the tissues.

Fig. 3.3 depicts the disposition of a drug immediately after administration and relates this to the plasma concentration–time graph.

Initially, the plasma concentration falls rapidly, due to distribution and elimination (α phase). However, when an equilibrium is reached between the plasma and tissue, that is, the distribution is complete, the change in plasma concentration is only due to elimination from the plasma (β phase), and the plasma concentration falls at a slower rate. The drug is said to follow a two-compartment model. However, if distribution is completed

Fig. 3.2 Distribution: more of drug A is distributed in the tissue compartment, resulting in a higher apparent volume of distribution than for drug B, where more remains in the plasma.

Fig. 3.3 (A) Two-compartment plasma concentration–time graph showing two phases in the plasma concentration–time profile. (B) Representation of a two-compartment model showing distribution of drug between plasma and tissue compartments.

quickly (within minutes), then the α phase is not seen, and the drug is said to follow a one-compartment model.

The practical implications of a two-compartment model are that any sampling for monitoring purposes should be carried out after distribution is complete. In addition, i.v. bolus doses are given slowly to avoid transient side effects caused by high peak concentrations.

Elimination

Drugs may be eliminated from the body by a number of routes. The primary routes are excretion of the unchanged drug in the kidneys or metabolism (usually in the liver) into a more water-soluble compound for subsequent excretion in the kidneys, or a combination of both.

The main pharmacokinetic parameter describing elimination is clearance (CL). This is defined as the volume of plasma completely emptied of drug per unit time. For example, if the concentration of a drug in a patient is 1 g/L and the clearance is 1 L/h, then the rate of elimination will be 1 g/h. Thus, a relationship exists:

$$\text{rate of elimination} = \text{CL} \times C \quad (3)$$

Total body elimination is the sum of the metabolic rate of elimination and the renal rate of elimination. Therefore:

$$\text{total body clearance} = \text{CL (metabolic)} + \text{CL (renal)}$$

Thus, if the fraction eliminated by the renal route is known (f_e), then the effect of renal impairment on total body clearance (TBC) can be estimated.

Fig. 3.4 First-order elimination.

The clearance of most drugs remains constant for each individual. However, it may alter in cases of drug interactions, changing end-organ function or auto-induction. Therefore, it is clear from Eq. (3) that as the plasma concentration changes so will the rate of elimination. However, when the rate of administration is equal to the rate of elimination, the plasma concentration is constant (C^{ss}) and the drug is said to be at a steady state; that is:

$$\text{rate in} = \text{rate out}$$

At the beginning of a dosage regimen the plasma concentration is low. Therefore, the rate of elimination from Eq. (3) is less than the rate of administration, and accumulation occurs until a steady state is reached (see Fig. 3.1):

$$\text{rate of administration} = \text{rate of elimination} = \text{CL} \times C^{ss} \quad (4)$$

It is clear from Eq. (3) that as the plasma concentration falls (e.g. on stopping treatment or after a single dose), the rate of elimination also falls. Therefore, the plasma concentration–time graph follows a non-linear curve characteristic of this type of first-order elimination (Fig. 3.4). This is profoundly different from a constant rate of elimination irrespective of plasma concentration, which is typical of zero-order elimination.

For drugs undergoing first-order elimination, there are two other useful pharmacokinetic parameters in addition to the V_d and clearance. These are the elimination rate constant and elimination half-life.

The elimination rate constant (k_e) is the fraction of the amount of drug in the body (A) eliminated per unit time. For example, if the body contains 100 mg of a drug and 10% is eliminated per unit time, then $k_e = 0.1$. In the first unit of time, 0.1×100 mg, or 10 mg is eliminated, leaving 90 mg. In the second unit of time, 0.1×90 mg, or 9 mg is eliminated, leaving 81 mg. Elimination continues in this manner. Therefore:

$$\text{rate of elimination} = k_e \times A \quad (5)$$

Combining Eqs. (3) and (5) gives:

$$\text{CL} \times C = k_e \times A$$

and because

$$C = \frac{A}{V_d}$$

then

$$CL \times \frac{A}{V_d} = k_e \times A$$

Therefore:

$$CL = k_e \times V_d \quad (6)$$

Elimination half-life ($t_{1/2}$) is the time it takes for the plasma concentration to decay by half. In five half-lives the plasma concentration will decline to approximately zero (see Fig. 3.4).

The equation which is described in Fig. 3.4 is:

$$C_2 = C_1 \times e^{-k_e \times t} \quad (7)$$

where C_1 and C_2 are plasma concentrations and t is time.

If half-life is substituted for time in Eq. (7), C_2 must be half of C_1 . Therefore:

$$\begin{aligned} 0.5 \times C_1 &= C_1 \times e^{-k_e \times t_{1/2}} \\ 0.5 &= e^{-k_e \times t_{1/2}} \\ \ln 0.5 &= -k_e \times t_{1/2} \\ 0.693 &= -k_e \times t_{1/2} \\ t_{1/2} &= \frac{0.693}{k_e} \end{aligned} \quad (8)$$

There are two ways of determining k_e : either by estimating the half-life and applying Eq. (8) or by substituting two plasma concentrations in Eq. (7) and applying natural logarithms:

$$\begin{aligned} \ln C_2 &= \ln C_1 - (k_e \times t) \\ k_e \times t &= \ln C_1 - \ln C_2 \\ k_e &= \frac{\ln C_1 - \ln C_2}{t} \end{aligned}$$

In the same way as it takes approximately five half-lives for the plasma concentration to decay to zero after a single dose, it takes approximately five half-lives for a drug to accumulate to the steady state on repeated dosing or during constant infusion (see Fig. 3.1).

This graph may be described by Eq. (9):

$$C = C^{ss} (1 - e^{-k_e \times t}) \quad (9)$$

where C is the plasma concentration at time t after the start of the infusion and C^{ss} is the steady-state plasma concentration. Thus, if the appropriate pharmacokinetic parameters are known, it is possible to estimate the plasma concentration any time after a single dose or the start of a dosage regimen.

Absorption

In the preceding sections, the i.v. route has been discussed, and with this route all of the administered drug is absorbed. However,

if a drug is administered by any other route it must be absorbed into the bloodstream. This process may or may not be 100% efficient.

The fraction of the administered dose which is absorbed into the bloodstream is the bioavailability (F). Therefore, when applying pharmacokinetics for oral administration, the dose or rate of administration must be multiplied by F . Bioavailability, F , is determined by calculating the area under the concentration time curve (AUC). The rationale for this is described below.

The rate of elimination of a drug after a single dose is given by Eq. (3). By definition the rate of elimination is the amount of drug eliminated per unit time:

Amount eliminated in any one unit of time:

$$dt = CL \times C \times dt$$

$$\text{Total amount of drug eliminated} = \sum_0^{\infty} CL \times C \times dt$$

As previously explained, CL is constant. Therefore:

$$\text{Total amount eliminated} = CL \times \Sigma C \times dt$$

from start until C is zero.

$\Sigma C \times dt$ is actually the area under the plasma concentration–time curve (Fig. 3.5).

After a single i.v. dose, the total amount eliminated is equal to the amount administered, D i.v. Therefore:

$$D \text{ i.v.} = CL \times AUC \text{ i.v.} \text{ or } CL = D \text{ i.v.} / AUC.$$

However, for an oral dose, the amount administered is

$$F \times D \text{ p.o.}$$

Because CL is constant in the same individual:

$$CL = F \times D \text{ p.o.} / AUC \text{ p.o.} = D \text{ i.v.} / AUC \text{ i.v.}$$

Rearranging gives:

$$F = (D \text{ i.v.} \times AUC \text{ p.o.}) / (D \text{ p.o.} \times AUC \text{ i.v.})$$

In this way, F can be calculated from plasma concentration–time curves.

Fig. 3.5 The area under the concentration time curve is the sum of the individual areas which are $= C \times dt$.

Dosing regimens

From the preceding sections, it is possible to derive equations which can be applied in clinical practice.

From Eq. (1) we can determine the change in plasma concentration ΔC immediately after a single dose:

$$\Delta C = \frac{S \times F \times \text{dose}}{V_d} \quad (10)$$

where F is bioavailability and S is the salt factor, which is the fraction of active drug when the dose is administered as a salt; for example, aminophylline is 80% theophylline, therefore, $S = 0.8$.

Conversely, to determine a loading dose:

$$\text{loading dose} = \frac{\text{desired change in } C \times V_d}{S \times F} \quad (11)$$

At the steady state it is possible to determine maintenance dose or steady-state plasma concentrations from a modified Eq. (4):

$$\text{rate in} = \frac{S \times F \times \text{dose}}{T} = \text{CL} \times \text{average } C^{\text{ss}} \quad (12)$$

where T is the dosing interval.

Peak and trough levels

For oral dosing and constant i.v. infusions, it is usually adequate to use the term 'average steady state plasma concentration' (average C^{ss}). However, for some i.v. bolus injections it is sometimes necessary to determine peak and trough levels, for example, gentamicin.

At the steady state, the change in concentration due to the administration of an i.v. dose will be equal to the change in concentration due to elimination over one dose interval:

$$\Delta C = \frac{S \times F \times \text{dose}}{V_d} = C_{\text{max}} - C_{\text{min}}$$

Within one dosing interval the maximum plasma concentration ($C_{\text{max}}^{\text{ss}}$) will decay to the minimum plasma concentration ($C_{\text{min}}^{\text{ss}}$) as in any first-order process.

Substituting $C_{\text{max}}^{\text{ss}}$ for C_1 and $C_{\text{min}}^{\text{ss}}$ for C_2 in Eq. (7):

$$C_{\text{max}}^{\text{ss}} = C_{\text{max}}^{\text{ss}} \times e^{-k_e \times t}$$

where t is the dosing interval.

If this is substituted into the preceding equation:

$$\frac{S \times F \times \text{dose}}{V_d} = C_{\text{max}}^{\text{ss}} - (C_{\text{max}}^{\text{ss}} \times e^{-k_e \times t})$$

Therefore:

$$C_{\text{max}}^{\text{ss}} = \frac{S \times F \times \text{dose}}{V_d (1 - e^{-k_e \times t})} \quad (13)$$

$$C_{\text{min}}^{\text{ss}} = \frac{S \times F \times \text{dose}}{V_d (1 - e^{-k_e \times t})} \times e^{-k_e \times t} \quad (14)$$

Interpretation of drug concentration data

The availability of the technology to measure the concentration of a drug in plasma should not be the reason for monitoring. A number of criteria should be fulfilled before TDM is undertaken:

- The drug should have a narrow therapeutic index.
- There should be a good concentration–response relationship.
- There are no easily measurable physiological parameters.

In the absence of these criteria being fulfilled, the only other justification for undertaking TDM is to monitor adherence or to confirm toxicity. When interpreting TDM data, a number of factors need to be considered.

Sampling times

In the preceding sections, the time to reach the steady state has been discussed. When TDM is carried out as an aid to dose adjustment, the concentration should be at steady state. Therefore, approximately five half-lives should elapse after initiation or after changing a maintenance regimen, before sampling. The only exception to this rule is when toxicity is suspected. When the steady state has been reached, it is important to sample at the correct time. It is clear from the discussion above that this should be done when distribution is complete (see Fig. 3.3).

Dosage adjustment

Under most circumstances, provided the preceding criteria are observed, adjusting the dose of a drug is relatively simple, because a linear relationship exists between the dose and concentration if a drug follows first-order elimination (Fig. 3.6, A). This is the case for most drugs.

Capacity limited clearance

If a drug is eliminated by the liver, it is possible for the metabolic pathway to become saturated because it is an enzymatic system. Initially the elimination is first-order, but once saturation of the system occurs, elimination becomes zero-order. This results in the characteristic dose–concentration graph shown in Fig. 3.6 (B). For the majority of drugs eliminated by the liver, this effect is

Fig. 3.6 Dose–concentration relationships: (A) first-order elimination, (B) capacity-limited clearance, and (C) increasing clearance.

not seen at normal therapeutic doses and occurs only at very high supratherapeutic levels, which is why the kinetics of some drugs in overdose is different from normal. However, one important exception is phenytoin, where saturation of the enzymatic pathway occurs at therapeutic doses. This will be dealt with later in the Phenytoin section.

Increasing clearance

The only other situation where first-order elimination is not seen is where clearance increases as the plasma concentration increases (see Fig. 3.6, C). Under normal circumstances, the plasma protein binding sites available to a drug far outnumber the capacity of the drug to fill those binding sites, and the proportion of the total concentration of drug which is protein bound is constant. However, this situation is not seen in one or two instances, for example, valproate and disopyramide. For these particular drugs, as the concentration increases the plasma protein binding sites become saturated and the ratio of unbound drug to bound drug increases. The elimination of these drugs increases disproportionately to the total concentration because elimination is dependent on the unbound concentration.

Therapeutic range

Wherever TDM is carried out, a therapeutic range is usually used as a guide to the optimum concentration. The limits of these ranges should not be taken as absolute. Some patients may respond to levels above or below these ranges, whereas others may experience toxic effects within the so-called therapeutic range. These ranges are only adjuncts to dose determination, which should always be done in light of the clinical response.

Clinical applications

Estimation of creatinine clearance

Because many drugs are renally excreted, and the most practical marker of renal function is creatinine clearance (CrCL), it is often necessary to estimate this to undertake dosage adjustment in renal impairment. The usual method is to undertake a 24-hour urine collection coupled with a plasma creatinine measurement. The laboratory then estimates the patient's CrCL. The formula used to determine CrCL is based upon the pharmacokinetic principles in Eq. (3).

The rate of elimination is calculated from the measurement of the total amount of creatinine contained in the 24-hour urine sample divided by 24, that is:

$$\frac{\text{amount of creatinine}}{24} = \text{rate of excretion (mg/h)}$$

Using this rate of excretion and substituting the measured plasma creatinine for C^{ss} in Eq. (4), the CrCL can be calculated.

However, there are practical difficulties with this method. The whole process is cumbersome and there is an inevitable delay in obtaining a result. The biggest problem is the inaccuracy of the 24-hour urine collection.

An alternative approach is to estimate the rate of production of creatinine (i.e. rate in) instead of the rate of elimination (rate out). Clearly this has advantages because it does not involve 24-hour urine collections and requires only a single measure of plasma creatinine. There are data in the literature that relate creatinine production to age, weight and sex because the primary source of creatinine is the breakdown of muscle.

Therefore, equations have been produced which are rearrangements of Eq. (4), that is:

$$\text{creatinine clearance} = \frac{\text{rate of production}}{C^{ss}}$$

Rate of production is replaced by a formula which estimates this from physiological parameters of age, weight and sex.

It has been shown that the equation produced by Cockcroft and Gault (1976) appears to be the most satisfactory. A modified version using SI units is shown as:

$$\text{creatinine clearance (mL/min)} = \frac{F \times [(140 - \text{age in years}) \times \text{weight (kg)}]}{\text{plasma creatinine (mmol/L)}}$$

where $F = 1.04$ (females) or 1.23 (males).

There are limitations using only plasma creatinine to estimate renal function. The modification of diet in renal disease (MDRD) formula can be used to estimate glomerular filtration rate (eGFR). This formula uses plasma creatinine, age, sex and ethnicity (Department of Health, 2006):

$$\begin{aligned} \text{eGFR} = & 175 \times [\text{plasma creatinine (mmol/L)} \times 0.011312]^{-1.154} \\ & \times [\text{age in year}]^{-0.203} \times [1.212 \text{ if patient is black}] \\ & \times [0.742 \text{ if female}] \end{aligned}$$

eGFR = glomerular filtration rate (mL/min/1.73 m²)

The MDRD should be used with care when calculating doses of drugs because most of the published dosing information is based on the Cockcroft and Gault formula. In patients with moderate-to-severe renal failure, it is best to use the Cockcroft and Gault formula to determine drug dosing.

Digoxin

Action and uses

Digoxin is the most widely used of the digitalis glycosides. Its primary actions on the heart are those of increasing the force of contraction and decreasing conduction through the atrioventricular node. Currently, its main role is in the treatment of atrial fibrillation by slowing down the ventricular response, although it is also used in the treatment of heart failure in the presence of sinus rhythm. The primary method of monitoring its clinical effect in atrial fibrillation is by measurement of heart rate, but knowledge of its pharmacokinetics can be helpful in predicting a patient's dosage requirements.

Plasma concentration–response relationship

- <0.5 microgram/L: no clinical effect
- 0.7 microgram/L: some positive inotropic and conduction blocking effects

- 0.8–2 micrograms/L: optimum therapeutic range (0.5–0.9 microgram/L in patients >65-years-old)
- 2–2.5 micrograms/L: increased risk of toxicity, although tolerated in some patients
- >2.5 micrograms/L: gastro-intestinal, cardiovascular system, and central nervous system toxicity

Distribution

Digoxin is widely distributed and extensively bound in varying degrees to tissues throughout the body. This results in a high apparent V_d . Digoxin V_d can be estimated using the equation $7.3 \text{ L/kg} \times (\text{ideal body weight [BWt]})$, which is derived from population data. However, distribution is altered in patients with renal impairment, and a more accurate estimate in these patients is given by:

$$V_d = 3.8 \times \text{ideal BWt} + (3.1 \times \text{creatinine clearance (mL/min)})$$

A two-compartment model best describes digoxin disposition (see Fig. 3.3), with a distribution time of 6–8 hours. Clinical effects are seen earlier after i.v. doses, because the myocardium has a high blood perfusion and affinity for digoxin. Sampling for TDM must be done no sooner than 6 hours post-dose; otherwise, an erroneous result will be obtained.

Elimination

Digoxin is eliminated primarily by renal excretion of unchanged drug (60–80%), but some hepatic metabolism occurs (20–40%). The population average value for digoxin clearance is:

$$\text{digoxin clearance (mL/min)} = 0.8 \times \text{BWt} + (\text{creatinine clearance (mL/min)})$$

However, patients with severe congestive heart failure have a reduced hepatic metabolism and a slight reduction in renal excretion of digoxin:

$$\text{digoxin clearance (mL/min)} = 0.33 \times \text{BWt} + (0.9 \times \text{creatinine clearance (mL/min)})$$

Ideal body weight should be used in these equations.

Absorption

Digoxin is poorly absorbed from the gastro-intestinal tract, and dissolution time affects the overall bioavailability. The two oral formulations of digoxin have different bioavailabilities:

$$F(\text{tablets}) = 0.65$$

$$F(\text{liquid}) = 0.8$$

Practical implications

Using population averages, it is possible to predict plasma concentrations from specific dosages, particularly because the time to reach the steady state is long. Population values are only averages, and individual values may vary. In addition a number of diseases and drugs affect digoxin disposition.

As can be seen from the preceding discussion, congestive heart failure, hepatic diseases and renal diseases all decrease the elimination of digoxin. In addition, hypothyroidism increases the plasma concentration (decreased metabolism and renal excretion) and increases the sensitivity of the heart to digoxin. Hyperthyroidism has the opposite effect. Hypokalaemia, hypercalcaemia, hypomagnesaemia and hypoxia all increase the sensitivity of the heart to digoxin. Numerous drug interactions have been reported of varying clinical significance. The usual cause is either altered absorption or clearance.

Theophylline

Theophylline is an alkaloid related to caffeine. It has a variety of clinical effects including mild diuresis, central nervous system stimulation, cerebrovascular vasodilatation, increased cardiac output and bronchodilatation. It is the last which is the major therapeutic effect of theophylline. Theophylline does have some serious toxic effects. However, there is a good plasma concentration–response relationship.

Plasma concentration–response relationship

- <5 mg/L: no bronchodilatation¹
- 5–10 mg/L: some bronchodilatation and possible anti-inflammatory action
- 10–20 mg/L: optimum bronchodilatation, minimum side effects
- 20–30 mg/L: increased incidence of nausea, vomiting² and cardiac arrhythmias
- >30 mg/L: cardiac arrhythmias, seizures

Distribution

Theophylline is extensively distributed throughout the body, with an average V_d based on population data of 0.48 L/kg.

Theophylline does not distribute very well into fat, and estimations should be based on ideal body weight. A two-compartment model best describes theophylline disposition, with a distribution time of approximately 40 minutes.

Elimination

Elimination is a first-order process primarily by hepatic metabolism to relatively inactive metabolites.

The population average for theophylline clearance is 0.04 L/h/kg, but this is affected by a number of diseases, drugs and pollutants. Therefore, this value should be multiplied by:

- 0.5, where there is cirrhosis, or when cimetidine, erythromycin, clarithromycin, ciprofloxacin or norfloxacin is being taken concurrently due to enzyme inhibition in the liver;
- 0.4, where there is congestive heart failure with hepatomegaly due to reduced hepatic clearance;

¹ Some patients exhibit a clinical effect at these levels which has been attributed to possible anti-inflammatory effects.

² Nausea and vomiting can occur within the therapeutic range.

- 0.8, where there is severe respiratory obstruction [forced expiratory volume in 1 second (FEV_1) < 1 L];
- 1.6, for patients who smoke (defined as >10 cigarettes/day), because smoking stimulates hepatic metabolism of theophylline.

Neonates metabolise theophylline differently, with 50% being converted to caffeine. Therefore, when it is used to treat neonatal apnoea of prematurity, a narrower therapeutic range is used (usually 5–10 mg/L) because caffeine contributes to the therapeutic response.

Product formulation

Aminophylline (the ethylenediamine salt of theophylline) is only 80% theophylline. Therefore, the salt factor (S) is 0.8. Most sustained-release (SR) preparations show good bioavailability, but not all SR preparations are the same, which is why advice in the British National Formulary (BNF) recommends patients are maintained on the same brand.

Practical implications

Intravenous bolus doses of aminophylline need to be given slowly (preferably by short infusion) to avoid side effects caused by transiently high blood levels during the distribution phase. Oral doses with SR preparations can be estimated using population average pharmacokinetic values and titrated proportionately according to blood levels and clinical response. In most circumstances SR preparations may be assumed to provide 12-hour cover. However, more marked peaks and troughs are seen with fast metabolisers (smokers and children). In these cases the SR preparation with the lowest k_a value may be used twice daily [e.g. Uniphyllin ($k_a = 0.22$)]. Alternatively, thrice-daily dosage is required if a standard ($k_a = 0.3$ – 0.4) SR product is used [e.g. Phyllocontin ($k_a = 0.37$) or Nuelin SA ($k_a = 0.33$)].

Gentamicin

Clinical use

The spectrum of activity of gentamicin is similar to other aminoglycosides, but its most significant activity is against *Pseudomonas aeruginosa*. It is still regarded by many as first choice for this type of infection.

Therapeutic range

Gentamicin has a narrow therapeutic index, producing dose-related side effects of nephrotoxicity and ototoxicity. The use of TDM to aid dose adjustment is essential if these toxic effects which appear to be related to peak and trough plasma levels are to be avoided. It is generally accepted that the peak level (drawn 1 hour post-dose after an i.v. bolus or intramuscular injection) should not exceed 12 mg/L and the trough level (drawn immediately pre-dose) should not exceed 2 mg/L.

The above recommendations relate to multiple daily dosing of gentamicin. Once-daily dosing has superseded multiple-dose gentamicin except for certain conditions. Therefore, when

once-daily dosing is used, different monitoring and interpretation parameters apply as described at the end of this section.

Distribution

Gentamicin is relatively polar and distributes primarily into extracellular fluid. Thus, the apparent V_d is only 0.3 L/kg. Gentamicin follows a two-compartment model, with distribution being complete within 1 hour.

Elimination

Elimination is by renal excretion of the unchanged drug. Gentamicin clearance is approximately equal to CrCL.

Practical implications

Because the therapeutic range is based on peak (1 hour post-dose to allow for distribution) and trough (pre-dose) concentrations, it is necessary to be able to predict these from any given dosage regimen.

Initial dosage. Initial dosage may be based on the patient's physiological parameters. Gentamicin clearance may be determined directly from CrCL. The V_d may be determined from ideal body weight. The elimination constant k_e may then be estimated using these parameters in Eq. (6). By substituting k_e and the desired peak and trough levels into Eq. (7), the optimum dosage interval can be determined (add on 1 hour to this value to account for sampling time). Using this value (or the nearest practical value) and the desired peak or trough value substituted into Eq. (13) or (14), it is possible to determine the appropriate dose.

Changing dosage. Changing dosage is not as straightforward as for theophylline or digoxin, because increasing the dose will increase the peak and trough levels proportionately. If this is not desired, then use of pharmacokinetic equations is necessary. By substituting the measured peak and trough levels and the time between them into Eq. (7), it is possible to determine k_e (and the half-life from Eq. (8) if required). To estimate the patient's V_d from actual blood level data, it is necessary to know the C_{\max}^{ss} immediately after the dose (time zero), not the 1-hour value which is measured. To obtain this, Eq. (7) may be used, this time substituting the trough level for C_2 and solving for C_1 . Subtracting the trough level from this C_{\max}^{ss} at time zero, the V_d may be determined from Eq. (10). Using these values for k_e and V_d , derived from actual blood level data, a new dose and dose interval can be determined as before.

Once-daily dosing. There are theoretical arguments for once-daily dosing of gentamicin because aminoglycosides display concentration-dependent bacterial killing and a high enough concentration to minimum inhibitory concentration (MIC) ratio may not be achieved with multiple dosing. Furthermore, aminoglycosides have a long post-antibiotic effect. Aminoglycosides also accumulate in the kidneys, and once-daily dosing could reduce renal tissue accumulation. A number of clinical trials have compared once-daily administration of aminoglycosides with conventional administration. A small number of these trials have

shown less nephrotoxicity, no difference in ototoxicity and similar efficacy with once-daily administration.

Initial dosage for a once-daily regimen is 5–7 mg/kg/day for patients with a CrCL of >60 mL/min. This is subsequently adjusted on the basis of blood levels. However, monitoring of once-daily dosing of gentamicin is different from multiple dosing. One approach is to take a blood sample 6–14 hours after the first dose and plot the time and result on a standard concentration-time plot (the Hartford nomogram; Nicolau et al., 1995; Fig. 3.7). The position of the individual patient's point in relation to standard lines on the nomogram indicates what the most appropriate dose interval should be (either 24, 36 or 48 hours). Once-daily dosing of gentamicin has not been well studied in pregnant or breastfeeding women, patients with major burns, renal failure, endocarditis or cystic fibrosis. Therefore, although once-daily dosing has superseded multiple-dose gentamicin, it cannot be recommended in these groups and multiple daily dosing should be used.

Vancomycin

Vancomycin is an amphoteric glycopeptide antibiotic which has bactericidal activity against aerobic and anaerobic Gram-positive bacteria. Vancomycin is particularly useful in severe staphylococcal infections resistant to other antibiotics and has shown efficacy in endocarditis, osteomyelitis, septicaemia and soft tissue

infections. Oral vancomycin is poorly absorbed for systemic use but is indicated for the treatment of *Clostridium difficile* colitis.

Concentration–response relationship

Although vancomycin has been in use since the late 1950s, there is conflicting evidence of the relationship between concentration and toxicity, particularly nephrotoxicity and ototoxicity. Early data suggested a link between high serum concentrations and ototoxicity, although a retrospective review of the literature has not identified a specific threshold level. Similarly nephrotoxicity has been associated with vancomycin treatment, but again the evidence is not strong enough to identify specific threshold levels. Although AUC-to-MIC ratio is the parameter which correlates best with vancomycin activity, it is impractical to use in routine clinical practice. Therefore, vancomycin trough concentrations are used as a surrogate marker. There is little justification for measuring peak concentrations. The BNF recommends trough levels are maintained in the range of 10–15 mg/L, but a slightly higher trough level range of 15–20 mg/L for endocarditis and less sensitive strains of methicillin-resistant *Staphylococcus aureus*.

Absorption and distribution

Although absorption following oral administration of vancomycin is poor, this increases where there is inflammation and

If result available within 24 h

- Use graph below to select dose interval. Use serum concentration and time interval between start of infusion and sample to plot intercept (see example given on graph).
- Give next dose (7 mg/kg by infusion as above) after interval indicated by graph.
If result falls above upper limit for Q48 h, abandon once daily regimen. Measure gentamicin concentration after another 24 h and adopt multiple daily dose regimen if result <2 mg/L.
If result falls on Q24 h sector it is not necessary to recheck gentamicin concentration within 5 days unless patient's condition suggests renal function may be compromised.

- **Graph:** Use values of plasma concentration and time interval to find intercept
(Example given of 6 mg/L after 10 h yields dose interval of 36 h)

MONITORING

- Repeat U&E daily. Calculate creatinine clearance from serum creatinine to check dose interval has not changed.
- If dose interval has to be changed, check gentamicin concentration 6–4 h after start of next infusion note time of start of infusion and time of sampling and use graph to verify correct dose interval.

Fig. 3.7 Nomogram for adjustment of once-daily gentamicin dosage (Nicolau et al., 1995).

following repeated doses. Therefore, vancomycin is given by i.v. administration for systemic use and penetrates into most body spaces, but concentrations are variable and dependent on the degree of inflammation. A two-compartment pharmacokinetic model best describes vancomycin after i.v. administration (see Fig. 3.3) with a distribution phase of 30–60 minutes in patients with normal renal function. The V_d is between 0.4 and 1 L/kg.

Elimination

When given i.v. vancomycin is excreted primarily via the kidneys and follows first-order elimination kinetics with clearance (CL) = CrCL. Oral doses are excreted primarily in the faeces. Elimination half-life is approximately 6–7 hours in patients with normal function but prolonged in those with renal insufficiency.

Practical applications

Because the AUC-to-MIC ratio is not practical to use in clinical practice, trough concentrations are used as a surrogate measure to guide safe and effective dosing.

- Intravenous doses should be administered by infusion over 60 minutes to avoid infusion-related side effects due to local irritation and transient high peaks.
- Although vancomycin has a relatively short half-life, it has a long duration of action and should be administered every 12 hours to ensure appropriate trough levels are maintained and to reduce the number of i.v. administrations for the reasons outlined above.
- Trough levels should be taken at steady state (30–35 hours), which is normally just before the third or fourth dose on a 12-hour regimen.
- Because vancomycin clearance is directly related to renal function, dosage should be reduced in patients with impaired renal function and the patient carefully monitored. The Summary of Product Characteristics (SPC) contains a dosage nomogram to assist in this.

As vancomycin follows first-order elimination, adjusting the 12-hour dose will result in a proportional increase or decrease in trough levels.

Lithium

Lithium is effective in the treatment of acute mania and in the prophylaxis of manic depression. The mechanism of action is not fully understood, but it is thought that it may substitute for sodium or potassium in the central nervous system. Lithium is toxic, producing dose-dependent and dose-independent side effects. Therefore, TDM is essential in assisting in the management of the dosage.

Dose-dependent effects

The plasma concentration–response relationship derived on the basis of the 12-hour standardised lithium level (measured 12 hours after the evening dose of lithium) is as follows:

- <0.4 mmol/L: little therapeutic effect
- 0.4–1.0 mmol/L: optimum range for prophylaxis

- 0.8–1.2 mmol/L: optimum range for acute mania
- 1.2–1.5 mmol/L: causes possible renal impairment
- 1.5–3.0 mmol/L: causes renal impairment, ataxia, weakness, drowsiness, thirst, diarrhoea
- 3.0–5.0 mmol/L: causes confusion, spasticity, dehydration, convulsions, coma, death (Levels >3.5 mmol/L are regarded as a medical emergency.)

Dose-independent effects

Dose-independent effects include tremor, hypothyroidism (approximately 10% of patients on chronic therapy), nephrogenic diabetes insipidus, gastro-intestinal upset, loss in bone density, weight gain (approximately 20% of patients gain >10 kg) and lethargy.

Distribution

Lithium is unevenly distributed throughout the body, with a V_d of approximately 0.7 L/kg. Lithium follows a two-compartment model (see Fig. 3.3) with a distribution time of 8 hours (hence the 12-hour sampling criterion).

Elimination

Lithium is excreted unchanged by the kidneys. Lithium clearance is approximately 25% of CrCL because there is extensive reabsorption in the renal tubules.

In addition to changes in renal function, dehydration, diuretics (particularly thiazides), angiotensin-converting enzyme inhibitors and non-steroidal anti-inflammatory drugs (except aspirin and sulindac) all decrease lithium clearance. Conversely, aminophylline and sodium loading increase lithium clearance.

Notwithstanding the earlier factors, there is a wide inter-individual variation in clearance, and the lithium half-life in the population varies between 8 and 35 hours, with an average of approximately 18 hours. Lithium clearance shows a diurnal variation, being slower at night than during the day.

Practical implications

In view of the narrow therapeutic index, lithium should not be prescribed unless facilities for monitoring plasma lithium concentrations are available. Because lithium excretion is a first-order process, changes in dosage result in a proportional change in blood levels. Blood samples should be drawn 12 hours after the evening dose, because this will allow for distribution and represent the slowest excretion rate. Population pharmacokinetic data (particularly the V_d) cannot be relied upon to make initial dosage predictions, although renal function may give an approximate guide to clearance. Blood level measurements are reported in SI units; therefore, it is useful to know the conversion factors for the various salts:

- 100 mg of lithium carbonate is equivalent to 2.7 mmol of lithium ions,
- 100 mg of lithium citrate is equivalent to 1.1 mmol of lithium ions.

Phenytoin

Phenytoin is used in the treatment of epilepsy (see Chapter 31). Use is associated with dose-independent side effects which include hirsutism, acne, coarsening of facial features, gingival hyperplasia, hypocalcaemia and folic acid deficiency. However, phenytoin has a narrow therapeutic index and has serious concentration-related side effects.

Plasma concentration–response relationship

- <5 mg/L: generally no therapeutic effect
- 5–10 mg/L: some anticonvulsant action with approximately 50% of patients obtaining a therapeutic effect with concentrations of 8–10 mg/L
- 10–20 mg/L: optimum concentration for anticonvulsant effect
- 20–30 mg/L: nystagmus, blurred vision
- >30 mg/L: ataxia, dysarthria, drowsiness, coma

Distribution

Phenytoin follows a two-compartment model with a distribution time of 30–60 minutes. The apparent V_d is 1 L/kg.

Elimination

The main route of elimination is via hepatic metabolism. However, this metabolic route can be saturated at normal therapeutic doses. This results in the characteristic non-linear dose–concentration curve shown in Fig. 3.6 (B). Therefore, instead of the usual first-order pharmacokinetic model, a Michaelis–Menten model, used to describe enzyme activity, is more appropriate.

Using the Michaelis–Menten model, the daily dosage of phenytoin can be described by:

$$\frac{S \times F \times \text{dose}}{T} = \frac{V_{\max} \times C^{\text{ss}}}{K_m + C^{\text{ss}}} \quad (15)$$

where K_m is the plasma concentration at which metabolism proceeds at half the maximal rate. The population average for this is 5.7 mg/L, although this value varies greatly with age and race. V_{\max} is the maximum rate of metabolism of phenytoin and is more predictable at approximately 7 mg/kg/day.

Because clearance changes with blood concentration, the half-life also changes. The usual reported value is 22 hours, but this increases as concentration increases. Therefore, it is difficult to predict when the steady state will be reached. However, as a rule of thumb, 1–2 weeks should be allowed to elapse before sampling after a dosage change.

In overdose it can be assumed that metabolism of the drug is occurring at the maximum rate of V_{\max} . Therefore, the decline in plasma concentration is linear (zero-order) at approximately 7 mg/L/day.

Practical implications

Because the dose–concentration relationship is non-linear, changes in dose do not result in proportional changes in plasma concentration (see Fig. 3.6, B). Using the Michaelis–Menten model, if the plasma concentration is known at one dosage, then

V_{\max} may be assumed to be the population average (7 mg/kg/day), because this is the more predictable parameter, and K_m is calculated using Eq. (15). The revised values of K_m can then be used in Eq. (15) to estimate the new dosage required to produce a desired concentration. Alternatively, a nomogram (orbit diagram) may be used to assist in dose adjustments (Bauer, 2008).

Care is needed when interpreting TDM data and making dosage adjustments when phenytoin is given concurrently with other anticonvulsants, because these affect distribution and metabolism of phenytoin. Because phenytoin is approximately 90% protein bound, in patients with a low plasma albumin and/or uraemia, the free fraction increases and, therefore, an adjusted total phenytoin should be calculated or a free salivary level taken. The following equation can be applied to adjust the observed concentration in hypoalbuminaemia:

$$C_{\text{adjusted}} = \frac{C_{\text{observed}}}{0.9 \times (C_{\text{albumin}}/44) + 0.1}$$

Albumin concentration is in g/L.

In uraemic patients with severe renal failure, the unbound fraction is approximately doubled, so the target concentration needs to be half the normal concentration, or apply the adjusted concentration equation if albumin level is known.

The oral formulations of phenytoin show good bioavailability. However, tablets and capsules contain the sodium salt ($S = 0.9$), whereas the suspension and infatabs are phenytoin base ($S = 1$). Intramuscular phenytoin is slowly and unpredictably absorbed, due to crystallisation in the muscle tissue, and is therefore not recommended. Fosphenytoin, a prodrug of phenytoin, is better absorbed from the intramuscular site. Doses should be expressed as phenytoin equivalent. Fosphenytoin sodium 1.5 mg is equivalent to phenytoin sodium 1 mg.

Carbamazepine

Carbamazepine is indicated for the treatment of partial and secondary generalised tonic-clonic seizures, primary generalised tonic-clonic seizures, trigeminal neuralgia, and prophylaxis of bipolar disorder unresponsive to lithium. There are a number of dose-independent side effects, including various dermatological reactions and, more rarely, aplastic anaemia and Stevens–Johnson syndrome. However, the more common side effects are concentration related.

Plasma concentration–response relationship when used in the treatment of epilepsy

- <4 mg/L: little therapeutic benefit
- 4–12 mg/L: optimum therapeutic range for monotherapy
- >9 mg/L: possible side effects of nystagmus, diplopia, drowsiness and ataxia, particularly if patients are receiving other anticonvulsant therapy
- >12 mg/L: side effects common, even on monotherapy

Distribution

Carbamazepine is widely distributed in various organs, with the highest concentration found in liver and kidneys. Carbamazepine

is 70–80% protein bound and shows a wide variation in the population average apparent V_d (0.8–1.9 L/kg). This wide variation is thought to be due to variations in absorption (because there is no parenteral form) and protein binding.

Elimination

Carbamazepine is eliminated almost exclusively by metabolism, with less than 2% being excreted unchanged in the urine. Elimination is a first-order process, but carbamazepine induces its own metabolism (auto-induction). Therefore, at the beginning of therapy, clearance is 0.01–0.03 L/h/kg, increasing to 0.05–0.1 L/h/kg on chronic therapy. Auto-induction begins in the first few days of commencing therapy and is maximal at 2–4 weeks.

Because clearance changes with time, so does half-life, with reported values as long as 35 hours after a single dose, decreasing to 5–7 hours on regular dosing.

Absorption

Absorption after oral administration is slow, with peak concentrations being reached 2–24 hours post-dose (average 6 hours). Absorption is incomplete, with bioavailability estimated at approximately 80% ($F = 0.8$). Bioavailability via rectal administration is even less, and 125 mg of suppositories is approximately equivalent to 100 mg of tablets.

Practical implications

Use of pharmacokinetic equations is limited due to the auto-induction effect. However, there are a number of important practical points:

- Blood samples should not be drawn before the steady state, which will not be achieved until 2–4 weeks after starting therapy to allow for auto-induction, or 3–4 days after subsequent dose adjustments.
- When sampling, the trough level should be measured because of the variable absorption pattern.
- Complex calculations are not helpful, but as a rule of thumb each 100 mg dose will increase the plasma concentration at steady state by approximately 1 mg/L in adults.
- A number of other drugs (including phenytoin) when given concurrently will affect carbamazepine metabolism and subsequent blood levels.

Valproate

Sodium valproate as valproic acid in the bloodstream has a broad spectrum of anticonvulsant activity, being useful in generalised absence, generalised tonic–clonic and partial seizures.

Plasma concentration–response relationship

There is no clear concentration–response relationship for valproate, although a range of 50–100 mg/L is often quoted as being optimal, with 50% of patients showing a response at levels greater than 80 mg/L. Levels greater than 100 mg/L do not confer

any additional therapeutic benefits. Although no clear relationship exists between plasma levels and toxic effects, the rare hepatotoxicity associated with valproate appears to be related to very high levels of more than 150 mg/L.

Distribution

Valproate is extensively bound to plasma protein (90–95%), and unlike other drugs it can saturate protein binding sites at concentrations greater than 50 mg/L, altering the free fraction of drug. Therefore, the apparent V_d of valproate varies from 0.1 to 0.5 L/kg.

Elimination

Elimination of valproate is almost entirely by hepatic metabolism, with less than 5% being eliminated by the kidneys.

As a result of the saturation of protein binding sites and the subsequent increase in the free fraction of the drug, clearance of the drug increases at higher concentrations. Therefore, there is a non-linear change in plasma concentration with dose, which is illustrated in Fig. 3.6 (C).

Practical implications

In view of the lack of a clear concentration–response relationship and the variable pharmacokinetics, there are limited indications for the measurement of valproate levels. In most cases dosage should be based on clinical response. Valproic acid can take several weeks to become fully active, so adjustment of doses must not be made quickly.

In a few cases where seizures are not controlled at high dosage, a plasma level may be helpful in confirming treatment failure. If monitoring is to be undertaken, levels should be drawn at steady state (2–3 days). A trough sample will be the most useful because wide fluctuations of blood levels may occur during a dose interval.

Newer epilepsy treatments

Newer epilepsy medicines include gabapentin, lamotrigine, lacosamide, vigabatrin, levetiracetam, perampanel, pregabalin, retigabine, rufinamide, tiagabine, topiramate and zonisamide. They are indicated for the treatment of a range of types of epilepsy and some with additional indications. All are used as adjunctive treatment with other anticonvulsants, and some are indicated for monotherapy.

Plasma concentration–response relationship

No clear relationship exists between plasma concentration and response for these newer anticonvulsants. The situation is further complicated because these preparations are usually used as add-on therapy with other anticonvulsants.

Practical implications

Although these newer anticonvulsants have narrow therapeutic indices and interindividual and intraindividual variation

in pharmacokinetics, there is not enough evidence to support routine TDM, and dosage should be titrated to clinical response.

Ciclosporin

Ciclosporin is a neutral lipophilic cyclic undecapeptide extracted from the fungus *Tolypocladium inflatum gams*. It is a potent immunosuppressive agent, used principally to reduce graft rejection after organ and tissue transplantation. The drug has a narrow therapeutic index, with a number of toxic effects including nephrotoxicity, hepatotoxicity, gastro-intestinal intolerance, hypertrichosis and neurological problems. Efficacy in reducing graft rejection, as well as the main toxic effects of nephrotoxicity and hepatotoxicity, appear to be concentration related.

Plasma concentration–response relationship

With all drugs that are monitored, the therapeutic range is a window with limits, which are not absolute. It is even more difficult to define a therapeutic range for ciclosporin, because there are a number of influencing factors. First, the measured concentration varies depending on sampling matrix (i.e. whole blood or plasma). Second, it depends on whether the assay is specific for ciclosporin alone or non-specific to include metabolites. A target concentration varies between centres but is commonly around 100–200 ng/mL in the first 6 months after transplantation and 80–150 ng/mL from 6 months onwards. Levels below the lower limit of this window are associated with an increased incidence of graft rejection. Levels above the upper limit are associated with an increased incidence of nephrotoxicity and hepatotoxicity.

Distribution

Ciclosporin is highly lipophilic and is widely distributed throughout the body with a V_d of 4–8 L/kg. There is variable distribution of ciclosporin within blood, because the whole blood concentration is approximately twice the plasma concentration. Within plasma, ciclosporin is 98% protein bound.

Elimination

Ciclosporin is eliminated primarily by hepatic metabolism, with wide interindividual variation in clearance (0.1–2 L/h/kg). In children these values are approximately 40% higher, with a resulting increased dosage requirement on a milligram per kilogram basis. In elderly patients or patients with hepatic impairment, a lower clearance rate has been observed.

Practical implications

In addition to the wide interpatient variability in distribution and elimination pharmacokinetic parameters, absorption of standard formulations of ciclosporin is variable and incomplete ($F = 0.2–0.5$ in normal subjects). In transplant patients this variation in bioavailability is even greater and increases during the first few months after transplant. Furthermore, a number of drugs are known to interact with ciclosporin. All of these factors suggest

that TDM will assist in optimum dose selection, but the use of population averages in dose prediction is of little benefit due to wide interpatient variation. When using TDM with ciclosporin, a number of practical points need to be considered:

- The sampling matrix should be whole blood because there is a variable distribution of ciclosporin between blood and plasma.
- Samples should represent trough levels and be drawn at the steady state, which is achieved 2–3 days after initiating or changing the dosage (average half-life is 9 hours).
- Ciclosporin concentration monitoring should be undertaken every 2–3 days in the immediate postoperative phase until the patient's clinical condition is stable. Thereafter, monitoring can be undertaken every 1–2 months.
- TDM should be performed when changing brands of ciclosporin because there are marked differences in the bioavailability of different brands.

Tacrolimus

Similar to ciclosporin, tacrolimus is a calcineurin-inhibiting immunosuppressant used to reduce graft rejection after organ and tissue transplantation. Tacrolimus has a wide range of side effects covering most of the body systems.

Plasma concentration–response relationship

A strong correlation exists between AUC and whole blood trough levels at steady state. Therefore, monitoring of whole blood trough levels provides a good estimate of systemic exposure.

Absorption

Tacrolimus has been shown to be absorbed throughout the gastro-intestinal tract. Following oral administration of a non-slow-release formulation, peak concentrations (C_{max}) of tacrolimus in blood are achieved in approximately 1–3 hours.

Distribution

Tacrolimus plasma concentration time curve after i.v. infusion follows a classic biphasic form as described in Fig. 3.3.

In the systemic circulation, tacrolimus binds strongly to erythrocytes, resulting in an approximate 20:1 distribution ratio of whole blood/plasma concentrations. Tacrolimus is extensively distributed in the body. The steady-state V_d based on plasma concentrations is approximately 1300 L (healthy subjects). Corresponding data based on whole blood averaged 47.6 L.

Elimination

Tacrolimus is widely metabolised in the liver, primarily by the cytochrome P450-3A4.

In healthy subjects, the average TBC estimated from whole blood concentrations was 2.25 L/h. In adult liver, kidney and heart transplant patients, values of 4.1, 6.7, and 3.9 L/h, respectively, have been observed. Paediatric liver transplant recipients have a TBC approximately twice that of adult liver transplant patients.

The half-life of tacrolimus is long and variable. In healthy subjects, the mean half-life in whole blood is approximately 43 hours. In adult and paediatric liver transplant patients, it averaged 11.7 and 12.4 hours, respectively, compared with 15.6 hours in adult kidney transplant recipients. Increased clearance rates contribute to the shorter half-life observed in transplant recipients.

Practical implications

The following points should be considered when using TDM for tacrolimus:

- After initial dosing and for maintenance treatment tacrolimus doses should be adjusted according to whole blood concentrations.
- Whole blood concentrations should be trough levels drawn immediately before the next dose.
- In view of the relatively short half-life in transplant recipients, steady state will be achieved in approximately 3 days.
- The majority of patients can be successfully managed if tacrolimus blood trough levels are maintained at less than 20 ng/mL. In clinical practice, whole blood trough levels have generally been in the range of 5–20 ng/mL in liver transplant recipients and 10–20 ng/mL in kidney and heart transplant patients in the early post-transplant period. Subsequently, during maintenance therapy, blood concentrations have generally been in the range of 5–15 ng/mL in liver, kidney and heart transplant recipients.
- Due to the variation in the oral formulations of tacrolimus, patients stabilised on a particular formulation of tacrolimus should be maintained on that formulation and prescription, and dispensing should be by brand name to avoid inadvertent switching.
- When strong inhibitors of CYP3A4 (such as telaprevir, boceprevir, ritonavir, ketoconazole, voriconazole, itraconazole, telithromycin or clarithromycin) or inducers of CYP3A4 (such as rifampicin and rifabutin) are prescribed with tacrolimus, tacrolimus blood levels should be monitored to adjust the tacrolimus dose appropriately.

Sirolimus

Sirolimus is a non-calcineurin-inhibiting immunosuppressant which is used for the prophylaxis of organ rejection in adult patients at low-to-moderate immunological risk receiving a renal transplant. It is recommended for use initially in combination with ciclosporin microemulsion and corticosteroids for 2–3 months and may be continued as maintenance therapy with corticosteroids only if ciclosporin microemulsion can be progressively discontinued. The most commonly reported adverse reactions to sirolimus are thrombocytopenia, anaemia, pyrexia, hypertension, hypokalaemia, hypertriglyceridaemia, abdominal pain, lymphocoele, peripheral oedema, arthralgia, acne, diarrhoea, constipation, nausea, headache, increased blood creatinine and increased blood lactate dehydrogenase.

Concentration–response relationship

The efficacy of sirolimus decreases when the trough concentrations fall below the target ranges, and the incidence of any adverse effect increases as trough levels increase.

Following initiation of sirolimus the dose should then be individualised to obtain whole blood trough levels of 4–12 ng/mL (chromatographic assay) when used in combination with ciclosporin. Ciclosporin should be progressively discontinued over 4–8 weeks, and sirolimus dose should be adjusted to obtain whole blood trough levels of 12–20 ng/mL.

Whole blood sirolimus levels should be closely monitored in patients with hepatic impairment, when CYP3A4 inducers (rifampicin) or CYP3A4 inhibitors (ketoconazole, voriconazole, diltiazem, verapamil and erythromycin) are concurrently administered, and after their discontinuation. Levels should be closely monitored if ciclosporin dosing is markedly reduced or discontinued, because ciclosporin inhibits the metabolism of sirolimus, and consequently sirolimus levels will decrease when ciclosporin is discontinued.

Therapeutic monitoring of the medicinal product should not be the sole basis for adjusting sirolimus therapy. Careful attention should be made to clinical signs/symptoms, tissue biopsies and laboratory parameters.

Absorption and distribution

Much of the general pharmacokinetic information was obtained using the sirolimus oral solution. Following administration of the oral solution, sirolimus is rapidly absorbed, with a time to peak concentration of 1 hour in healthy subjects receiving single doses and 2 hours in patients with stable renal allografts receiving multiple doses. In healthy subjects there is a difference in bioavailability between the tablets and oral solution after a single dose, but the difference is less marked upon steady-state administration to renal transplant recipients, and therapeutic equivalence has been demonstrated.

Similar to ciclosporin, sirolimus is lipophilic and is widely distributed in lipid membranes of body tissues, as well as erythrocytes, which gives rise to a high apparent V_d of 5.6–16.4 L/kg.

Elimination

Sirolimus is primarily eliminated by hepatic metabolism and similar to ciclosporin there is wide interindividual variation in clearance (0.04–0.34 L/h/kg) due to the variability in enterocyte P-glycoprotein and CYP3A4 content. Sirolimus has a relatively long terminal half-life ranging from 44 to 87 hours, although in clinical practice effective half-life is shorter and steady state is achieved in 5–7 days.

Practical applications

As with ciclosporin the wide interpatient variability in sirolimus pharmacokinetic parameters using population averages for dose prediction is of little benefit, but TDM will assist in optimum dose selection. The following points should be considered when using TDM for sirolimus:

- The sampling matrix should be whole blood because there is a variable distribution of sirolimus between blood and plasma.
- Samples should represent trough levels and be drawn at steady state.
- When switching patients between oral solution and tablet formulations, it is recommended to give the same dose and to

Table 3.1 Summary of pharmacokinetic data

Drug	Therapeutic range	V_d (L/kg)	CL (L/h/kg)	Half-life (h)
Digoxin	0.8–2.0 micrograms/L (0.5–0.9 microgram/L in patients >65 years) 1–2.6 nmol/L (0.625–1.1 nmol/L in patients >65 years)	7.3	See text	36
Theophylline	10–20 mg/L 55–110 mmol/L	0.48	0.04	8
Gentamicin	Peak 5–12 mg/L Trough <2 mg/L	0.3	1 × CL (creatinine)	2
Vancomycin	Trough 10–15 mg/L (15–20 mg/L for endocarditis and less sensitive strains of methicillin-resistant <i>Staphylococcus aureus</i>)	0.4–1	1 × CL (creatinine)	6–7
Lithium	0.4–0.8 mmol/L	0.5–1	0.25 × CL (creatinine)	18
Phenytoin	10–20 mg/L 40–80 mmol/L	1	$K_m = 5.7$ mg/L $V_{max} = 7$ mg/kg/day	
Carbamazepine	4–12 mg/L 17–50 mmol/L	0.8–1.9	0.05–1 See text	
Valproate	<100 mg/L <693 mmol/L		See text	
Ciclosporin	Varies between centres 100–200 ng/mL (first 6 months after transplantation) 80–150 ng/mL (from 6 months onwards)	4–8	0.1–2	9
Sirolimus	Trough (whole blood) 4–12 ng/mL with ciclosporin 12–20 ng/mL without ciclosporin	5.6–16.4	0.04–0.34	44–87

Population pharmacokinetic parameters are based on averages. The degree of variability around the average is different for each drug. See text for variability. CL, Clearance; K_m , plasma concentration; V_d , volume of distribution.

verify the sirolimus trough concentration 1–2 weeks later to check that it remains within recommended target ranges. Also, when switching between different tablet strengths, verification of trough concentrations is recommended.

- The target concentration range for sirolimus is different when used alone and in combination with ciclosporin.
- Careful monitoring is particularly needed in patients with hepatic impairment and where medicines which interfere with CYP3A4 are co-prescribed.

Summary pharmacokinetic data for drugs with therapeutic plasma concentrations are listed in [Table 3.1](#).

Case studies

Case 3.1

You are reviewing a formulary submission for a new formulation of a product, which has reportedly an improved side effect profile due to better absorption characteristics. However, there is conflicting evidence in the literature over the absorption of the new preparation. One paper, which is available to you, shows a concentration–time profile for the oral formulation after a single oral dose of 250 mg as in [Table 3.2](#).

The paper also quotes an area under the curve after a single i.v. dose of 200 mg as 87 mg/L/h.

Questions

1. What is the area under the curve after the single oral dose of 250 mg?
2. What is the bioavailability of the new formulation?

Answers

1. Draw the concentration–time profile on a piece of paper; try to do it reasonably accurately, but it does not have to be exact. Draw down vertical lines from the curve at each 1-hour time interval to create a series of trapeziums (the first one is actually a triangle). Calculate the area of each trapezium from the formula:

$$\text{Area of trapezium} = (\text{sum of the height of each side}/2) \times \text{width (1 h)}$$

Then add all the areas together (assume a value of 0 after 12 hours):

$$\text{AUC p.o.} = 69.99 \text{ mg/L/h}$$

2. From the equation:

$$F = \frac{D \text{ i.v.} \times \text{AUC p.o.}}{D \text{ p.o.} \times \text{AUC i.v.}}$$

$$F = 200 \times 69.99 / 250 \times 87$$

$$F = 0.64$$

Table 3.2 Concentration–time profile for the oral formulation after a single oral dose of 250 mg

Time after administration	1 h	2 h	3 h	4 h	5 h	6 h	7 h	8 h	9 h	10 h	11 h	12 h
Concentration (mg/L)	10	18	12.7	9	6.4	4.5	3.2	2.25	1.6	1.1	0.78	0.55

Case 3.2

An 86-year-old lady, Mrs EJ, is admitted to hospital by her primary care doctor, with increasing shortness of breath. She lives in a care home and is relatively immobile. Mrs EJ has a stable plasma creatinine of 150 mmol/L. She is 55 kg, 4' 11" (1.5 m) tall. She is known to have osteoporosis, ischaemic heart disease and recently diagnosed non-paroxysmal atrial fibrillation.

Mrs EJ's current medication is:

Calcium carbonate 1.25 g	2 tablets daily
Imdur	60 mg daily
Simvastatin	40 mg daily
Senna	7.5 mg daily
Digoxin	62.5 micrograms daily
Apixaban	5 mg twice daily

She has been taking digoxin in a dosage of 62.5 micrograms daily for the last 3 weeks.

Questions

1. Calculate the predicted digoxin level for Mrs EJ.
2. A digoxin blood level is reported to be 1.0 microgram/L. List the reasons for the difference between the measured and predicted digoxin levels.
3. The hospital doctor queries if he should increase the dose of digoxin because the blood level is on the low side. Use an evidence-based approach to reply to the clinician.

Answers

1. Her predicted glomerular filtration rate is calculated from Cockcroft and Gault equation:

$$\text{creatinine clearance (mL/min)} = \frac{F \times [(140 - \text{age in years}) \times \text{weight (kg)}]}{\text{plasma creatinine (mmol/L)}}$$

$$\text{creatinine clearance (CL}_{\text{cr}}) = \frac{1.04 (140 - 86) 55}{150} = 20.6 \text{ mL/min}$$

On the assumption that the patient has severe congestive heart failure, the predicted digoxin level is calculated using the equation:

$$\text{CL}_{\text{dig}} = 0.33 \times \text{IBW} + 0.9 \times \text{CL}_{\text{cr}} = (0.33 \times 55) + (0.9 \times 20.6) = 36.69 \text{ mL/min} = 2.2 \text{ L/h}$$

Ideal body weight [IBW (kg)]:

$$\text{male} = 50 + (2.3 \times \text{height in inches over 5 feet})$$

$$\text{female} = 45.5 + (2.3 \times \text{height in inches over 5 feet})$$

Eq. (4):

$$\text{rate of administration} = \text{rate of elimination} = \text{CL} \times C^{\text{ss}}$$

Rearranging Eq. (4):

$$C^{\text{ss}}_{\text{ave}} = \frac{\text{dose} \times S \times F}{\text{CL}_{\text{dig}} \times t} = \frac{62.5 \times 1 \times 0.63}{2.2 \times 24} = 0.75 \text{ micrograms/L}$$

2. The predicted level is less than the measured level, this may be because:
 - the level has been taken less than 6 hours after the oral dose,
 - non-adherence is suspected,
 - congestive heart failure has affected the renal function.
3. A subgroup analysis of the Digitalis Investigation Group suggested that participants older than 65 years who had low blood levels (0.5–0.9 microgram/L) had reductions in all-cause mortality. It has also been suggested that digoxin may be associated with an increased risk of problems in patients with atrial fibrillation (Gjesdal et al., 2008). Therefore, the dose of digoxin should not be increased.

Case 3.3

A 72-year-old man, Mr MA (80 kg, 1.70 m tall), is admitted to the medical ward with a diagnosis of infective endocarditis following an invasive dental procedure 2 weeks ago. He was commenced on i.v. vancomycin 1 g every 12 hours in accordance with the hospital protocol.

Mr MA's current laboratory results are:

Urea	9.1 mmol/L (3.2–7.5 mmol/L)
Creatinine	120 mmol/L (71–133 mmol/L)

Vancomycin levels were taken 2 and 6 hours after the first dose and reported as 28 and 25 mg/L, respectively.

Questions

1. Calculate Mr MA's elimination constant k_e .
2. Calculate the plasma concentration at C^0 immediately after the infusion.
3. Using the plasma concentration at C^0 , calculate the level you would expect the patient to achieve immediately prior to his next dose.
4. Using the vancomycin dosing nomogram, calculate the recommended 12-hourly dosage for Mr MA based upon his available laboratory results.

Answers

1. Because the two plasma levels are known, the elimination constant k_e is calculated from the following equation:

$$k_e = \frac{\ln C_1 - \ln C_2}{t}$$

Using the plasma levels reported:

$$k_e = \frac{\ln 28 - \ln 25}{4}$$

$$k_e = 0.028 \text{ h}^{-1}$$

2. The plasma concentration at C^0 immediately after the first infusion is calculated as:

$$C^t = C^0 \times e^{-k_e \times t}$$

$$28 = C^0 \times e^{-0.028 \times 4}$$

$$C^0 = 28.8 \text{ mg/L}$$

3. The plasma concentration at C^0 is then used to calculate the expected level to be achieved immediately prior to his next dose:

$$C^t = C^0 \times e^{-k^0 \times t}$$

$$C^t = 28.8 \times e^{-0.028 \times 12}$$

$$= 20.58 \text{ mg/L}$$

4. Mr MA's CrCL is calculated using the Cockcroft and Gault equation:

$$\text{creatinine clearance} \frac{F \times [(140 - \text{age in years} \times \text{weight}(\text{kg}))]}{(\text{mL/min}) \quad \text{plasma creatinine}(\text{mmol/L})}$$

$$\text{CrCL} = \frac{1.23 \times (140 - 72) \times 80}{120}$$

$$\text{CrCL} = 55.76 \text{ mL/min}$$

Convert 55.76 mL/min to mL/min/kg:

$$= \frac{55.76}{80}$$

$$= 0.7 \text{ mL/min/kg}$$

From the vancomycin dosing nomogram this equates to a dosage of 10.8 mg/kg/24 h = 864 mg/24 h = 432 mg every 12 hours.

In practice the nearest practical dose would be 450 mg every 12 hours.

Case 3.4

A 34-year-old man (75 kg), Mr RP, was taken by his wife to the emergency department with symptoms of nausea, vomiting, diarrhoea and increasing confusion. He had a fall whilst out running 2 weeks before and sprained his ankle. To alleviate the pain and inflammation of his injury, Mr RP started taking his wife's ibuprofen tablets. She thought he was taking one 400 mg tablet three times a day. Mr RP was also taking lithium for bipolar disorder and his therapy was stable.

Blood samples were taken from which the following results were obtained:

Lithium	3.1 mmol/L (0.6–1 mmol/L)
Sodium	152 mmol/L (135–145 mmol/L)
Creatinine	110 mmol/L (71–133 mmol/L)

Treatment with lithium was stopped.

Questions

1. Calculate the patient's pharmacokinetic parameters: clearance (CL), V_d and elimination constant (k_e) using population data.
2. Estimate the time for the lithium level to decrease to the middle of the normal range.
3. Briefly describe the symptoms of lithium toxicity.

Answers

1. Population data suggest that the clearance of lithium can be calculated using the following equation:

$$\text{CL} = 0.25 \times \text{CrCL} (\text{L/h})$$

The patient's CrCL is calculated using the Cockcroft and Gault equation:

$$\text{creatinine clearance} \frac{F \times [(140 - \text{age in years}) \times \text{weight}(\text{kg})]}{(\text{mL/min}) \quad \text{plasma creatinine}(\text{mmol/L})}$$

$$\text{CrCL} = \frac{1.23 \times (140 - 34) \times 75}{110}$$

$$= 88.9 \text{ mL/min}$$

Convert 88.9 mL/min to L/h:

$$= \frac{88.9 \times 60}{1000} = 5.334 \text{ L/h}$$

$$\text{lithium clearance} = 0.25 \times 5.334 = 1.3335 \text{ L/h}$$

Population data suggest that the V_d for lithium is 0.7 L/kg. Therefore, for this patient:

$$V_d = 0.7 \times 75$$

$$V_d = 52.5 \text{ L}$$

The elimination rate constant k_e is calculated by rearranging Eq. (6):

$$\text{CL} = k_e \times V_d \text{ to give } k_e = \frac{\text{CL}}{V_d}$$

$$k_e = \frac{1.3335}{52.5}$$

$$k_e = 0.0254 \text{ h}^{-1}$$

2. The time it will take for Mr RP's lithium level to return to the middle of the normal range (0.6–1 mmol/L), that is, 0.8 mmol/L, is calculated by rearranging Eq. (7):

$$\text{time to decay} = \frac{\ln C_p^1 - \ln C_p^2}{k_e}$$

$$\text{time to decay} = \frac{\ln 3.1 - \ln 0.8}{0.0254}$$

$$\text{time to decay} = 53 \text{ hours} = 2.2 \text{ days} = \text{approximately 2 days}$$

3. Acute lithium toxicity tends to present with gastro-intestinal symptoms. If the toxicity is due to an increase in dose, symptoms will include neuromuscular signs, for example, ataxia and tremor. This is sometimes referred to as acute on chronic toxicity. Chronic toxicity is harder to treat due to tissue deposition and involves neurological problems.

Case 3.5

Mr BT is a 38-year-old, 63-kg man who suffers from asthma. He has been admitted to hospital and Nuelin S.A. 500 mg 12 hourly (6 am and 6 pm) has been added to his regimen. He responds well to this treatment, but unfortunately after 2 days of treatment two doses are missed (evening dose and following morning dose). The clinical team is anxious to discharge him, so it is decided to give him a loading dose of aminophylline at 10 am before restarting him on maintenance therapy.

Questions

1. Was Mr BT at steady state before the medication was omitted?
2. What is the estimated theophylline level at 10 am?
3. The levels were then checked and the theophylline level was reported as 4 mg/L. What loading dose of i.v. aminophylline would you recommend?

Answers

1. Mr BT's pharmacokinetic parameters can be calculated from population data:

$$\text{clearance} = 63 \text{ kg} \times 0.04 \text{ L/h/kg} = 2.52 \text{ L/h}$$

$$V_d = 63 \text{ kg} \times 0.45 \text{ L/kg} = 28.3 \text{ L}$$

$$k_e = \frac{CL}{V_d}$$

$$k_e = 0.089 \text{ h}^{-1}$$

Inserting this k_e value into Eq. (8) indicates that

The patient's half-life ($t_{1/2}$) = 7.8 hours.

It can therefore be assumed that Mr BT was at steady state after 48 hours of treatment (more than $5 \times$ half-life).

2. To calculate Mr BT's levels at 10 am, it is assumed that S.R. theophylline behaves like an i.v. infusion ($F = 1.0$). Although this is not strictly true, Nuelin S.A. has a good slow-release profile. From Eq. (12):

$$\frac{S \times F \times \text{dose}}{T} = \text{average } C^{ss} \times CL$$

$$\text{average } C^{ss} = \frac{S \times F \times \text{dose}}{T \times CL}$$

$$\text{average } C^{ss} = \frac{500 \times 1}{12 \times 2.52}$$

$$\text{average } C^{ss} = 16.5 \text{ mg/L}$$

The morning dose from the previous day will have provided a steady dose of theophylline until the evening (first missed dose), the starting dose is C^{ss} . In order to calculate the theophylline concentration at 10am ($C^{10\text{am}}$) the dose will decay for 16 hours.

Inserting this k_e value into Eq. (7) indicates that:

$$C_2 = C_1 \times e^{-k_e \times t}$$

$$C^{10 \text{ am}} = 16.5 \times e^{-k_e \times 16}$$

$$C^{10 \text{ am}} = 16.5 \times e^{-0.089 \times 16}$$

$$C^{10 \text{ am}} = 3.97 \text{ mg/L}$$

3. To calculate a loading dose, the change in theophylline concentration (C) to be achieved needs to be calculated:

$$C = \text{desired } C (15 \text{ mg/L}) - \text{actual } (4 \text{ mg/L})$$

From Eq. (1):

$$\text{loading dose} = C \times V_d$$

$$\text{loading dose} = 11 \times 28.3 \text{ L}$$

$$\text{loading dose} = 311 \text{ mg of theophylline}$$

Aminophylline is only 80% theophylline; therefore:

$$\text{loading dose} = \frac{311}{0.8}$$

Aminophylline loading dose is 390 mg to be administered by slow i.v. bolus. In practice the nearest practical loading dose of 400 mg by slow i.v. bolus would be administered.

Case 3.6

A 39-year-old woman (60 kg), Ms RM, has been taking phenytoin at a dose of 250 mg daily. At her last clinic visit topiramate was added to her regimen. Ms RM is seen in the hospital outpatient department complaining of blurred vision and exhibiting nystagmus. Her phenytoin level taken in clinic is 22 mg/L.

Ms RM's current medication is:

Phenytoin capsules	250 mg daily
Topiramate tablets	200 mg daily in two divided doses

Questions

1. Calculate V_{max} and K_m for this patient.
2. How long will it take for Ms RM's phenytoin level to fall within the therapeutic range if the current dose is stopped?
3. Using these parameters, calculate the new dose to achieve a level of 15 mg/L.
4. What is the most likely reason for Ms RM's phenytoin level to go out of range?

Answers

1. From population data $V_{max} = 7 \text{ mg/kg/day} \times 60 \text{ kg} = 420 \text{ mg/day}$. Substitute this into Eq. (15) using the measured C^{ss} of 22 mg/L and Ms RM's current dose of 250 mg/day and assuming $S = 0.9$, solve for K_m :

$$\frac{0.9 \times 250}{1} = \frac{420 \times 22}{K_m + 22}$$

$$K_m + 22 = \frac{420 \times 22}{0.9 \times 250}$$

$$= \frac{9240}{225}$$

$$K_m + 22 = 41$$

$$K_m = 19 \text{ mg/L}$$

2. At supra-therapeutic levels it can be assumed that metabolism is occurring at V_{max} . By dividing V_{max} (amount eliminated from the body per day) by V_d you can calculate the rate of fall of blood level. V_d from population data is $1 \text{ L/kg} \times 60 \text{ kg} = 60 \text{ L}$. Therefore, the rate of fall in blood level is $420 \text{ mg}/60 \text{ L/day} = 7 \text{ mg/L/day}$. Therefore, withhold treatment for 1 day for the blood level to fall from 22 mg/L to 15 mg/L and recommence on new calculated dose.
3. Substitute these K_m and V_{max} values into Eq. (15) with a desired C^{ss} of 15 mg/L and assume $S = 0.9$.

$$\frac{0.9 \times \text{dose}}{1} = \frac{420 \times 15}{19 + 15}$$

$$= \frac{6300}{34}$$

$$0.9 \times \text{dose} = 185.3$$

$$\text{dose} = \frac{185.3}{0.9}$$

This gives a dose of 205.9 mg/day. This should be rounded down to 200 mg/day.

4. Interaction with topiramate which is known to increase phenytoin levels.

4 Drug Interactions

Ruben Thanacoody

Key points

- Drug interactions can cause significant patient harm and are an important cause of morbidity.
- Most clinically important drug interactions occur as a result of either decreased drug activity with diminished efficacy or increased drug activity with exaggerated or unusual effects. Drugs with a narrow therapeutic range, such as theophylline, lithium and digoxin, or a steep dose–response curve, such as anticoagulants, oral contraceptives and antiepileptics, are often implicated.
- The most important pharmacokinetic interactions involve drugs that can induce or inhibit enzymes in the hepatic cytochrome P450 system.
- Pharmacodynamic interactions are difficult to classify, but their effects can often be predicted when the pharmacology of co-administered drugs is known.
- In many cases potentially interacting drugs can be given concurrently, provided the possibility of interaction is kept in mind and any necessary changes to dose or therapy are initiated promptly. In some situations, however, concurrent use of potentially interacting drugs should be avoided altogether.
- Suspected adverse drug interactions should be reported to the appropriate regulatory authority as for other adverse drug reactions.

Drug interactions have been recognised for more than 100 years. Today, with the increasing availability of complex therapeutic agents and widespread polypharmacy, the potential for drug interactions is enormous, and they have become an increasingly important cause of adverse drug reactions (ADRs).

Despite regulatory requirements to define the safety profile of new medicines, including their potential for drug–drug interactions before marketing, the potential for adverse interactions is not always evident. This was illustrated by the worldwide withdrawal of the calcium channel blocker (CCB) mibefradil, within months of launch, following reports of serious drug interactions (Po and Zhang, 1998). Since the late 1990s, a number of medicines have either been withdrawn from the market (e.g. terfenadine, grepafloxacin and cisapride) or had their use restricted because of prolongation of the QT interval on the electrocardiogram (e.g. domperidone). Drug interactions are an important cause of QT

prolongation, which increases the risk of development of a life-threatening ventricular arrhythmia known as torsade de pointes (Roden, 2004).

The increasing availability and non-prescription use of herbal and complementary medicines has also led to greater awareness of their potential for adverse interactions. St John's wort, a herbal extract used for treatment of depression, can cause serious interactions as a result of its enzyme-inducing effects. Drug interactions with food and drink are also known to occur, exemplified by the well-known interaction between monoamine oxidase inhibitor (MAOI) antidepressants and tyramine-containing food-stuffs. Grapefruit juice is a potent inhibitor of cytochrome P450 (CYP450) 3A4 and causes clinically relevant interactions with a number of drugs, including simvastatin and atorvastatin, thereby increasing the risk of statin-induced adverse reactions such as myopathy and myositis.

Although medical literature is awash with drug interaction studies and case reports of adverse drug interactions, only a relatively small number of these are likely to cause clinically significant consequences for patients. The recognition of clinically significant interactions requires knowledge of the pharmacological mechanisms of drug interactions and a thorough understanding of high-risk drugs and vulnerable patient groups.

Definition

An interaction is said to occur when the effects of one drug are altered by the co-administration of another drug, herbal medicine, food, drink or other environmental chemical agents (Preston, 2016). The net effect of the combination may manifest as an additive or enhanced effect of one or more drugs, antagonism of the effect of one or more drugs, or any other alteration in the effect of one or more drugs.

Clinically significant interactions refer to a combination of therapeutic agents which have direct consequences on the patient's condition. Therapeutic benefit can be obtained from certain drug interactions; for example, a combination of different antihypertensive drugs may be used to improve blood pressure control, or an opioid antagonist may be used to reverse the effect of an overdose of morphine. This chapter concentrates on clinically significant interactions which have the potential for undesirable effects on patient care.

Epidemiology

Accurate estimates of the incidence of drug interactions are difficult to obtain because published studies frequently use different criteria for defining a drug interaction and for distinguishing between clinically significant and non-significant interactions.

The reported incidence of drug–drug interactions in hospital admissions ranged from 0% to 2.8% in a review which included nine studies, all of which had some design flaws (Jankel and Fitterman, 1993). In the Harvard Medical Practice Study of adverse events, 20% of events in acute hospital in-patients were drug related. Of these, 8% were considered to be due to a drug interaction, suggesting that interactions are responsible for less than 2% of adverse events in this patient group (Leape et al., 1992).

In a 1-year prospective study of patients attending an emergency department, 3.8% resulted from a drug–drug interaction, and most of these led to hospital admissions (Raschett et al., 1999). In a prospective UK study carried out on hospital in-patients ADRs were responsible for hospital admission in 6.5% of cases. Drug interactions were involved in 16.6% of adverse reactions, therefore being directly responsible for leading to hospital admission in approximately 1% of cases (Pirmohamed et al., 2004).

Few studies have attempted to quantify the incidence of drug–drug interactions in the outpatient hospital setting and in the community. In the early 1990s, a Swedish study investigated the occurrence of potential drug interactions in primary care and reported an incidence rate of 1.9% (Linnarsson, 1993). In the outpatient setting, the availability of newer drugs for a variety of chronic conditions has increased the risk of drug–drug interactions in this patient group.

Although the overall incidence of serious adverse drug interactions is low, it remains a potentially preventable cause of morbidity and mortality.

Susceptible patients

The risk of drug interactions increases with the number of drugs used. In a hospital study, the rate of ADRs in patients taking 6–10 drugs was 7%, rising to 40% in those taking 16–20 drugs, with the exponential rise being largely attributable to drug interactions (Smith et al., 1969). In a high-risk group of emergency department patients, the risk of potential adverse drug interaction was 13% in patients taking two drugs and 82% in those taking seven or more drugs (Goldberg et al., 1996).

Although polypharmacy is common and often unavoidable, it places certain patient groups at increased risk of drug interactions. Patients at particular risk include those with hepatic or renal disease, those on long-term therapy for chronic disease (e.g. HIV infection, epilepsy, diabetes), patients in intensive care, transplant recipients, patients undergoing complicated surgical procedures and those with more than one prescriber. Critically ill and elderly patients are at increased risk not only because they take more medicines but also because of impaired homeostatic mechanisms that might otherwise counteract some of the unwanted effects. Interactions may occur in some individuals, but not in others.

Box 4.1 Examples of drugs with high risk of interaction

Concentration-dependent toxicity

Digoxin

Lithium

Aminoglycosides

Cytotoxic agents

Warfarin

Steep dose–response curve

Verapamil

Sulfonylureas

Levodopa

Patient dependent on therapeutic effect

Immunosuppressives, e.g. ciclosporin and tacrolimus

Glucocorticoids

Oral contraceptives

Antiepileptics

Antiarrhythmics

Antipsychotics

Antiretrovirals

Saturable hepatic metabolism

Phenytoin

Theophylline

The effects of interactions involving drug metabolism may vary greatly in individual patients because of differences in the rates of drug metabolism and in susceptibility to microsomal enzyme induction. Certain drugs are frequently implicated in drug interactions and require careful attention (Box 4.1).

Mechanisms of drug interactions

Drug interactions are conventionally discussed according to the mechanisms involved. These mechanisms can be conveniently divided into those with a pharmacokinetic basis and those with a pharmacodynamic basis. Drug interactions often involve more than one mechanism. There are some situations where drugs interact by unique mechanisms, but the most common mechanisms are discussed in this section.

Pharmacokinetic interactions

Pharmacokinetic interactions are those that affect the processes by which drugs are absorbed, distributed, metabolised or excreted. Due to marked inter-individual variability in these processes, these interactions may be expected, but their extent cannot be easily predicted. Such interactions may result in a change in the drug concentration at the site of action with subsequent toxicity or decreased efficacy.

Absorption

Following oral administration, drugs are absorbed through the mucous membranes of the gastro-intestinal tract. A number of

factors can affect the rate of absorption or the extent of absorption (i.e. the total amount of drug absorbed).

Changes in gastro-intestinal pH. The absorption of a drug across mucous membranes depends on the extent to which it exists in the non-ionised, lipid-soluble form. The ionisation state depends on the pH of its environment, the acid dissociation constant (pK_a) of the drug and formulation factors. Weakly acidic drugs, such as the salicylates, are better absorbed at low pH because the non-ionised form predominates.

An alteration in gastric pH due to antacids, histamine H_2 antagonists or proton pump inhibitors therefore has the potential to affect the absorption of other drugs. The clinical significance of antacid-induced changes in gastric pH is not certain, particularly because relatively little drug absorption occurs in the stomach. Changes in gastric pH tend to affect the rate of absorption rather than the extent of absorption, provided that the drug is acid labile. Although antacids could theoretically be expected to markedly influence the absorption of other drugs via this mechanism, in practice there are very few clinically significant examples. Antacids, histamine H_2 antagonists and proton pump inhibitors can significantly decrease the bioavailability of ketoconazole and itraconazole, which require gastric acidity for optimal absorption, but the absorption of fluconazole and voriconazole is not significantly altered by changes in gastric pH.

The alkalinising effects of antacids on the gastro-intestinal tract are transient, and the potential for interaction may be minimised by leaving an interval of 2–3 hours between the antacid and the potentially interacting drug.

Absorption, chelation and other complexing mechanisms. Certain drugs react directly within the gastro-intestinal tract to form chelates and complexes which are not absorbed. The drugs most commonly implicated in this type of interaction include tetracyclines and the quinolone antibiotics that can complex with iron, and antacids containing calcium, magnesium and aluminium. Tetracyclines can chelate with divalent or trivalent metal cations such as calcium, aluminium, bismuth and iron to form insoluble complexes, resulting in greatly reduced plasma tetracycline concentrations.

Bisphosphonates are often co-prescribed with calcium supplements in the treatment of osteoporosis. If these are taken concomitantly, however, the bioavailability of both is significantly reduced, with the possibility of therapeutic failure.

The absorption of some drugs may be reduced if they are given with adsorbents such as charcoal or kaolin, or anionic exchange resins such as cholestyramine or colestipol. The absorption of paracetamol, digoxin, warfarin, calcitriol, thiazide diuretics, raloxifene and levothyroxine is reduced by cholestyramine.

Most chelation and adsorption interactions can be avoided if an interval of 2–3 hours is allowed between doses of the interacting drugs. For cholestyramine the advice is for the patient to take other drugs at least 1 hour before or 4–6 hours after cholestyramine to reduce possible issues with their absorption (*Joint Formulary Commission, 2017*).

Effects on gastro-intestinal motility. Because most drugs are largely absorbed in the upper part of the small intestine, drugs that alter the rate at which the stomach empties its contents can affect absorption. Drugs with anticholinergic effects, such as tricyclic antidepressants, phenothiazines and some antihistamines,

decrease gut motility and delay gastric emptying. The outcome of the reduced gut motility can be either an increase or a decrease in drugs given concomitantly. For example, tricyclic antidepressants can increase dicoumarol absorption, probably as a result of increasing the time available for its dissolution and absorption. Anticholinergic agents used in the management of movement disorders have been shown to reduce the bioavailability of levodopa by as much as 50%, possibly as a result of increased metabolism in the intestinal mucosa.

Opioids such as diamorphine and pethidine strongly inhibit gastric emptying and greatly reduce the absorption rate of paracetamol, without affecting the extent of absorption. Codeine, however, has no significant effect on paracetamol absorption. Metoclopramide increases gastric emptying and increases the absorption rate of paracetamol, an effect which is used to therapeutic advantage in the treatment of migraine to ensure rapid analgesic effect. Although metoclopramide also accelerates the absorption of propranolol, mefloquine, lithium and ciclosporin, this interaction is rarely clinically significant.

Induction or inhibition of drug transport proteins. The oral bioavailability of some drugs is limited by the action of drug transporter proteins, which eject drugs that have diffused across the gut lining back into the gut. At present, the most well-characterised drug transporter is P-glycoprotein. Digoxin is a substrate of P-glycoprotein, and drugs that inhibit P-glycoprotein, such as verapamil, may increase digoxin bioavailability with the potential for digoxin toxicity (*DuBuske, 2005*).

Malabsorption. Drugs such as neomycin may cause a malabsorption syndrome leading to reduced absorption of drugs such as digoxin. Orlistat is a specific long-acting inhibitor of gastric and pancreatic lipases, thereby preventing the hydrolysis of dietary fat to free fatty acids and triglycerides. This can theoretically lead to reduced absorption of fat-soluble drugs co-administered with orlistat. As a result, the *Medicines and Healthcare products Regulatory Agency (MHRA, 2010)* has advised of a possible impact on efficacy of co-administration of orlistat with levothyroxine, antiepileptic drugs such as valproate sodium and lamotrigine, and antiretroviral HIV drugs such as efavirenz and lopinavir.

Most of the interactions that occur within the gut result in reduced rather than increased absorption. It is important to recognise that the majority result in changes in absorption rate, although in some instances the total amount (i.e. extent of drug absorbed) is affected. For drugs that are given chronically on a multiple-dose regimen, the rate of absorption is usually unimportant provided the total amount of drug absorbed is not markedly altered. In contrast, delayed absorption can be clinically significant where the drug affected has a short half-life or where it is important to achieve high plasma concentrations rapidly, as may be the case with analgesics or hypnotics. Absorption interactions can often be avoided by allowing an interval of 2–3 hours between administrations of the interacting drugs.

Drug distribution

Following absorption, a drug undergoes distribution to various tissues, including to its site of action. Many drugs and their metabolites are highly bound to plasma proteins. Albumin is the

main plasma protein to which acidic drugs such as warfarin are bound, whereas basic drugs such as tricyclic antidepressants, lidocaine, disopyramide and propranolol are generally bound to α_1 -acid glycoprotein. During the process of distribution, drug interactions may occur, principally as a result of displacement from protein-binding sites. A drug displacement interaction is defined as a reduction in the extent of plasma protein binding of one drug caused by the presence of another drug, resulting in an increased free or unbound fraction of the displaced drug. Displacement from plasma proteins can be demonstrated *in vitro* for many drugs and has been thought to be an important mechanism underlying many interactions in the past. However, clinical pharmacokinetic studies suggest that, for most drugs, once displacement from plasma proteins occurs, the concentration of free drug rises temporarily, but falls rapidly back to its previous steady-state concentration due to metabolism and distribution. The time this takes will depend on the half-life of the displaced drug. The short-term rise in the free drug concentration is generally of little clinical significance but may need to be taken into account in therapeutic drug monitoring. For example, if a patient who is taking phenytoin is given a drug which displaces phenytoin from its binding sites, the total (i.e. free plus bound) plasma phenytoin concentration will fall even though the free (active) concentration remains the same.

There are few examples of clinically important interactions which are entirely due to protein-binding displacement. It has been postulated that a sustained change in steady-state free plasma concentration could arise with the parenteral administration of some drugs which are extensively bound to plasma proteins and non-restrictively cleared; that is, the efficiency of the eliminating organ is high. Lidocaine has been given as an example of a drug fitting these criteria.

Drug metabolism

Most clinically important interactions involve the effect of one drug on the metabolism of another. Metabolism refers to the process by which drugs and other compounds are biochemically modified to facilitate their degradation and subsequent removal from the body. The liver is the principal site of drug metabolism, although other organs such as the gut, kidneys, lung, skin and placenta are involved. Drug metabolism consists of phase I reactions such as oxidation, hydrolysis and reduction, and phase II reactions, which primarily involve conjugation of the drug with substances such as glucuronic acid and sulphuric acid. Phase I metabolism generally involves the CYP450 mixed function oxidase system. The liver is the major site of cytochrome 450-mediated metabolism, but the enterocytes in the small intestinal epithelium are also potentially important.

CYP450 isoenzymes. The CYP450 system comprises 57 isoenzymes, each derived from the expression of an individual gene. Because there are many different isoforms of these enzymes, a classification for nomenclature has been developed, comprising a family number, a subfamily letter, and a number for an individual enzyme within the subfamily (Wilkinson, 2005). Four main subfamilies of P450 isoenzymes are thought to be responsible for most (about 90%) of the metabolism of commonly used drugs in humans: CYP1, CYP2, CYP3 and CYP4. The most extensively

studied isoenzyme is CYP2D6, also known as debrisoquine hydroxylase. Although there is overlap, each cytochrome 450 isoenzyme tends to metabolise a discrete range of substrates. Of the many isoenzymes, a few (CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4) appear to be responsible for the human metabolism of most commonly used drugs.

The genes that encode specific cytochrome 450 isoenzymes can vary between individuals and, sometimes, ethnic groups. These variations (polymorphisms) may affect metabolism of substrate drugs. Interindividual variability in CYP2D6 activity is well recognised. It shows a polymodal distribution, and people may be described according to their ability to metabolise debrisoquine. Poor metabolisers tend to have reduced first-pass metabolism, increased plasma levels and exaggerated pharmacological response to this drug, resulting in postural hypotension. By contrast, ultra-rapid metabolisers may require considerably higher doses for a standard effect. About 5–10% of Caucasians and up to 2% of Asian and black people are poor metabolisers.

The CYP3A family of P450 enzymes comprises two isoenzymes, CYP3A4 and CYP3A5, so similar that they cannot be easily distinguished. CYP3A is probably the most important of all drug-metabolising enzymes because it is abundant in both the intestinal epithelium and the liver, and it has the ability to metabolise a multitude of chemically unrelated drugs from almost every drug class. It is likely that CYP3A is involved in the metabolism of more than half the therapeutic agents that undergo alteration by oxidation. In contrast with other cytochrome 450 enzymes, CYP3A shows continuous unimodal distribution, suggesting that genetic factors play a minor role in its regulation. Nevertheless, the activity of the enzyme can vary markedly among members of a given population.

The effect of a cytochrome 450 isoenzyme on a particular substrate can be altered by interaction with other drugs. Drugs may be themselves substrates for a cytochrome 450 isoenzyme and/or may inhibit or induce the isoenzyme. In most instances, oxidation of a particular drug is brought about by several CYP isoenzymes and results in the production of several metabolites. So, inhibition or induction of a single isoenzyme would have little effect on plasma levels of the drug. However, if a drug is metabolised primarily by a single cytochrome 450 isoenzyme, inhibition or induction of this enzyme would have a major effect on the plasma concentrations of the drug. For example, if erythromycin (an inhibitor of CYP3A4) is taken by a patient being given carbamazepine, which is extensively metabolised by CYP3A4, this may lead to toxicity caused by higher concentrations of carbamazepine. Table 4.1 gives examples of some drug substrates, inducers and inhibitors of the major cytochrome 450 isoenzymes.

Enzyme induction. The most powerful enzyme inducers in clinical use are the antibiotic rifampicin and antiepileptic agents such as barbiturates, phenytoin and carbamazepine. Some enzyme inducers, notably barbiturates and carbamazepine, can induce their own metabolism (auto-induction). Cigarette smoking, chronic alcohol use and the herbal preparation St John's wort can also induce drug-metabolising enzymes. Because the process of enzyme induction requires new protein synthesis, the effect usually develops over several days or weeks after starting an enzyme-inducing agent. Similarly, the effect generally persists for a similar period

Table 4.1 Examples of drug substrates, inducers and inhibitors of the major cytochrome P450 enzymes

P450 isoform	Substrate	Inducer	Inhibitor
CYP1A2	Caffeine Clozapine Imipramine Olanzapine Theophylline Tricyclic antidepressants R-warfarin	Omeprazole Lansoprazole Phenytoin Tobacco smoke	Amiodarone Cimetidine Quinolones Fluvoxamine
CYP2C9	Diazepam Diclofenac Losartan Statins Selective serotonin reuptake inhibitors S-warfarin	Barbiturates Rifampicin	Amiodarone Azole antifungals Isoniazid
CYP2C19	Cilostazol Diazepam Lansoprazole	Carbamazepine Rifampicin Omeprazole	Cimetidine Fluoxetine Tranlycypromine
CYP2D6	Amitriptyline Codeine Dihydrocodeine Flecainide Fluoxetine Haloperidol Imipramine Nortriptyline Olanzapine Ondansetron Opioids Paroxetine Propranolol Risperidone Tramadol Venlafaxine	Dexamethasone Rifampicin	Amiodarone Bupropion Celecoxib Duloxetine Fluoxetine Paroxetine Ritonavir Sertraline
CYP2E1	Enflurane Halothane	Alcohol (chronic) Isoniazid	Disulfiram
CYP3A4	Amiodarone Ciclosporin Corticosteroids Oral contraceptives Tacrolimus R-warfarin Calcium channel blockers Donepezil Benzodiazepines Cilostazol	Carbamazepine Phenytoin Barbiturates Dexamethasone Primidone Rifampicin St John's wort Bosentan Efavirenz Nevirapine	Cimetidine Clarithromycin Erythromycin Itraconazole Ketoconazole Grapefruit juice Aprepitant Diltiazem Protease inhibitors Imatinib Verapamil

following drug withdrawal. Enzyme-inducing drugs with short half-lives such as rifampicin will induce metabolism more rapidly than inducers with longer half-lives (e.g. phenytoin) because they reach steady-state concentrations more rapidly. There is evidence that the enzyme induction process is dose dependent, although some drugs may induce enzymes at any dose.

Enzyme induction usually results in a decreased pharmacological effect of the affected drug. St John's wort is now

known to be a potent inducer of CYP3A (Mannel, 2004). Thus, when a patient receiving ciclosporin, tacrolimus, HIV-protease inhibitors, irinotecan or imatinib takes St John's wort, there is a risk of therapeutic failure with the affected drug. However, if the affected drug has active metabolites, this may lead to an increased pharmacological effect. The effects of enzyme induction vary considerably between patients and are dependent upon age, genetic factors, concurrent drug treatment and disease

Table 4.2 Examples of interactions due to enzyme induction

Drug affected	Inducing agent	Clinical outcome
Oral contraceptives	Rifampicin	Therapeutic failure of contraceptives
	Carbamazepine	Additional contraceptive precautions required
	Modafinil	Increased oestrogen dose required
Ciclosporin	Phenytoin Carbamazepine St John's wort	Decreased ciclosporin levels with possibility of transplant rejection
Paracetamol	Alcohol (chronic)	In overdose, hepatotoxicity may occur at lower doses
Corticosteroids	Phenytoin Rifampicin	Increased metabolism with possibility of therapeutic failure

state. Some examples of interactions due to enzyme induction are shown in [Table 4.2](#).

Enzyme inhibition. Enzyme inhibition is responsible for many clinically significant interactions. Many drugs act as inhibitors of cytochrome 450 enzymes ([Box 4.2](#)). A strong inhibitor is one that can cause ≥ 5 -fold increase in the plasma area under the curve (AUC) value or more than 80% decrease in clearance of CYP3A substrates. A moderate inhibitor is one that can cause ≥ 2 - but < 5 -fold increase in the AUC value or 50–80% decrease in clearance of sensitive CYP3A substrates when the inhibitor is given at the highest approved dose and the shortest dosing interval. A weak inhibitor is one that can cause ≥ 1.25 - but < 2 -fold increase in the AUC values or 20–50% decrease in clearance of sensitive CYP3A substrates when the inhibitor is given at the highest approved dose and the shortest dosing interval.

Concurrent administration of an enzyme inhibitor leads to reduced metabolism of the drug and hence an increase in the steady-state drug concentration. Enzyme inhibition appears to be dose related. Inhibition of hepatic metabolism of the affected drug occurs when sufficient concentrations of the inhibitor are achieved in the liver, and the effects are usually maximal when the new steady-state plasma concentration is achieved. Thus, for drugs with a short half-life, the effects may be seen within a few days of administration of the inhibitor. Maximal effects may be delayed for drugs with a long half-life.

The clinical significance of this type of interaction depends on various factors, including dosage (of both drugs), alterations in pharmacokinetic properties of the affected drug, such as half-life, and patient characteristics such as disease state. Interactions of this type are again most likely to affect drugs with a narrow therapeutic range such as theophylline, ciclosporin, oral anticoagulants and phenytoin. For example, starting treatment with an enzyme inhibitor such as amiodarone in a patient who is taking warfarin could result in a marked

increase in warfarin plasma concentrations and increased bleeding risk. Some examples of interactions due to enzyme inhibition are shown in [Table 4.3](#).

The isoenzyme CYP3A4 in particular is present in the enterocytes. Thus, after oral administration of a drug, cytochrome 450 enzymes in the intestine and the liver may reduce the portion of a dose that reaches the systemic circulation, that is, the bioavailability of the drug. Drug interactions resulting in inhibition or induction of enzymes in the intestinal epithelium can have significant consequences. For example, by selectively inhibiting CYP3A4 in the enterocyte, grapefruit juice can markedly increase the bioavailability of some oral CCBs, including felodipine ([Wilkinson, 2005](#)). Such an interaction is usually considered to be a drug

Table 4.3 Examples of interactions due to enzyme inhibition

Drug affected	Inhibiting agent	Clinical outcome
Anticoagulants (oral)	Clarithromycin Ciprofloxacin	Anticoagulant effect increased and risk of bleeding
Azathioprine	Allopurinol	Enhancement of effect with increased toxicity of azathioprine
Clopidogrel	Omeprazole	Reduced antiplatelet effect
Carbamazepine Phenytoin Sodium valproate	Cimetidine	Antiepileptic levels increased with risk of toxicity
Sildenafil	Ritonavir	Enhancement of sildenafil effect with risk of hypotension

metabolism interaction, even though the mechanism involves an alteration in drug absorption. A single glass of grapefruit juice can cause CYP3A inhibition for 24–48 hours, and regular consumption may continuously inhibit enzyme activity. Consumption of grapefruit juice is therefore not recommended in patients who are receiving drugs that are extensively metabolised by CYP3A, such as simvastatin, tacrolimus and vardenafil.

Enzyme inhibition usually results in an increased pharmacological effect of the affected drug, but in cases where the affected drug is a pro-drug which requires enzymatic metabolism to active metabolites, a reduced pharmacological effect may result. For example, clopidogrel is metabolised via CYP2C19 to an active metabolite which is responsible for its antiplatelet effect. Proton pump inhibitors such as omeprazole are inhibitors of CYP2C19 and may lead to reduced effectiveness of clopidogrel when used in combination.

Predicting interactions involving metabolism. Predicting drug interactions is not easy for many reasons. First, individual drugs within a therapeutic class may have different effects on an isoenzyme. For example, the quinolone antibiotics ciprofloxacin and norfloxacin inhibit CYP1A2 and have been reported to increase plasma theophylline levels, whereas moxifloxacin is a much weaker inhibitor and appears not to interact in this way. While atorvastatin and simvastatin are metabolised predominantly by the CYP3A4 enzyme, fluvastatin is metabolised by CYP2C9 and pravastatin is not metabolised by the CYP450 system to any significant extent.

Identification of CYP450 isoenzymes involved in drug metabolism using *in vitro* techniques is now an important step in the drug development process. However, findings of *in vitro* studies are not always replicated *in vivo*, and more detailed drug interaction studies may be required to allow early identification of potential interactions. Nevertheless, some interactions affect only a small proportion of individuals and may not be identified unless large numbers of volunteers or patients are studied.

Suspected drug interactions are often described initially in published case reports and are then subsequently evaluated in formal studies. For example, published case reports indicated that commonly used antibiotics such as amoxicillin may reduce the effect of oral contraceptives, although this interaction has not been demonstrated in formal studies, leading to a change in the advice provided to patients who take the oral contraceptive pill and non-enzyme-inducing antibiotics. Another factor complicating the understanding of metabolic drug interactions is the finding that there is a large overlap between the inhibitors/inducers and substrates of the drug transporter protein P-glycoprotein and those of CYP3A4. Therefore, both mechanisms may be involved in many of the drug interactions previously thought to be due to effects on CYP3A4.

Elimination interactions

Most drugs are excreted in either the bile or urine. Blood entering the kidneys is delivered to the glomeruli of the tubules where molecules small enough to pass across the pores of the glomerular membrane are filtered through into the lumen of the tubules. Larger molecules, such as plasma proteins and blood cells, are retained. The blood then flows to other parts of the kidney tubules where drugs and their metabolites are removed, secreted or reabsorbed into the tubular filtrate by active and passive transport systems. Interactions can occur when drugs interfere with kidney tubule fluid pH, active transport systems or blood flow to the kidney, thereby altering the excretion of other drugs.

Changes in urinary pH. As with drug absorption in the gut, passive reabsorption of drugs depends on the extent to which the drug exists in the non-ionised lipid-soluble form. Only the non-ionised form is lipid soluble and able to diffuse back through the tubular cell membrane. Thus, at alkaline pH, weakly acidic drugs (pK_a 3.0–7.5) largely exist as ionised lipid-insoluble molecules which are unable to diffuse into the tubule cells and will therefore be lost in the urine. The renal clearance of these drugs is increased if the urine is made more alkaline. Conversely, the clearance of weak bases (pK_a 7.5–10) is higher in acid urine. Strong acids and bases are virtually completely ionised over the physiological range of urinary pH, and their clearance is unaffected by pH changes.

This mechanism of interaction is of very minor clinical significance because most weak acids and bases are inactivated by hepatic metabolism rather than renal excretion. Furthermore, drugs that produce large changes in urine pH are rarely used clinically. Urine alkalinisation or acidification has been used as a means of increasing drug elimination in poisoning with salicylates and amphetamines, respectively.

Changes in active renal tubule excretion. Drugs that use the same active transport system in the kidney tubules can compete with one another for excretion. Such competition between drugs can be used to therapeutic advantage. For example, probenecid may be given to increase the plasma concentration of penicillins by delaying renal excretion. With the increasing understanding of drug transporter proteins in the kidneys, it is now known that probenecid inhibits the renal secretion of many other anionic drugs via organic anion transporters (Lee and Kim, 2004). Increased

methotrexate toxicity, sometimes life-threatening, has been seen in some patients concurrently treated with salicylates and some other non-steroidal anti-inflammatory drugs (NSAIDs). The development of toxicity is more likely in patients treated with high-dose methotrexate and those with impaired renal function. The mechanism of this interaction may be multifactorial, but competitive inhibition of methotrexate's renal tubular secretion is likely to be involved. If patients who are taking methotrexate are given salicylates or NSAIDs concomitantly, the dose of methotrexate should be closely monitored.

Changes in renal blood flow. Blood flow through the kidney is partially controlled by the production of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited by drugs such as indometacin, the renal excretion of lithium is reduced with a subsequent rise in plasma levels. The mechanism underlying this interaction is not entirely clear, because plasma lithium levels are unaffected by other potent prostaglandin synthetase inhibitors, for example, aspirin. If an NSAID is prescribed for a patient who is taking lithium, then the plasma levels should be closely monitored.

Biliary excretion and the enterohepatic shunt. A number of drugs are excreted in the bile, either unchanged or conjugated, for example, as the glucuronide, to make them more water soluble. Some of the conjugates are metabolised to the parent compound by the gut flora and are then reabsorbed. This recycling process prolongs the stay of the drug within the body, but if the gut flora are diminished by the presence of an antibacterial, the drug is not recycled and is lost more quickly. This mechanism has been postulated as the basis of an interaction between broad-spectrum antibiotics and oral contraceptives. Antibiotics may reduce the enterohepatic circulation of ethinyl-estradiol conjugates, leading to reduced circulating oestrogen levels with the potential for therapeutic failure. There is considerable debate about the nature of this interaction because the evidence from pharmacokinetic studies is not convincing. Until a few years ago, due to the potential adverse consequences of pill failure, most authorities recommended a conservative approach, including the use of additional contraceptive precautions. This advice has now been changed to recommend that additional contraceptive precautions are not required for short-term use of antibiotics which do not induce liver enzymes (*Joint Formulary Commission, 2017*).

Drug transporter proteins. Drugs and endogenous substances are now known to cross biological membranes not just by passive diffusion but by carrier-mediated processes, often known as transporters. Significant advances in the identification of various transporters have been made and although their contribution to drug interactions is not yet clear, they are now thought to play a role in many interactions formerly attributed to cytochrome 450 enzymes (*DuBuske, 2005*).

P-glycoprotein is a large cell membrane protein that is responsible for the transport of many substrates, including drugs. It is a product of the *ABCBI* gene (previously known as the multidrug resistance gene, *MDRI*) and a member of the adenosine triphosphate (ATP)-binding cassette family of transport proteins (ABC transporters). P-glycoprotein is found in high levels in various tissues, including the renal proximal tubule, hepatocytes, intestinal mucosa, the pancreas and the blood-brain barrier.

Table 4.4 Examples of inhibitors and inducers of P-glycoprotein

Inhibitors	Atorvastatin Ciclosporin Clarithromycin Dipyridamole Erythromycin Itraconazole Ketoconazole Propafenone Quinidine Ritonavir Verapamil
Inducers	Rifampicin St John's wort

P-glycoprotein acts as an efflux pump, exporting substances into urine, bile and the intestinal lumen. Its activity in the blood-brain barrier limits drug accumulation in the central nervous system (CNS). Examples of some possible inhibitors and inducers of P-glycoprotein are listed in *Table 4.4*. The pumping actions of P-glycoprotein can be induced or inhibited by some drugs. For example, concomitant administration of digoxin and verapamil, a P-glycoprotein inhibitor, is associated with increased digoxin levels with the potential for digoxin toxicity. An overlap exists between CYP3A4 and P-glycoprotein inhibitors, inducers and substrates. Many drugs that are substrates for CYP3A4 are also substrates for P-glycoprotein. Therefore, both mechanisms may be involved in many of the drug interactions initially thought to be due to changes in CYP3A4. Digoxin is an example of the few drugs that are substrates for P-glycoprotein, but not CYP3A4.

Pharmacodynamic interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the presence of another drug at its site of action. Sometimes these interactions involve competition for specific receptor sites, but often they are indirect and involve interference with physiological systems. They are much more difficult to classify than interactions with a pharmacokinetic basis.

Antagonistic interactions

It is to be expected that a drug with an agonist action at a particular receptor type will interact with antagonists at that receptor. For example, the bronchodilator action of a selective β_2 -adrenoreceptor agonist such as salbutamol will be antagonised by β -adrenoreceptor antagonists. There are numerous examples of interactions occurring at receptor sites, many of which are used to therapeutic advantage. Specific antagonists may be used to reverse the effect of another drug at receptor sites; examples include the opioid antagonist naloxone and the benzodiazepine antagonist flumazenil. α -Adrenergic agonists such as metaraminol may be used in the management of priapism induced by α -adrenergic antagonists such as phenolamine. There are many other examples of drug classes that

Table 4.5 Examples of additive or synergistic interactions

Interacting drugs	Pharmacological effect
Non-steroidal anti-inflammatory drugs, warfarin, clopidogrel	Increased risk of bleeding
Angiotensin-converting enzyme inhibitors and K ⁺ -sparing diuretic	Increased risk of hyperkalaemia
Verapamil and β -adrenergic antagonists	Bradycardia and asystole
Neuromuscular blockers and aminoglycosides	Increased neuromuscular blockade
Alcohol and benzodiazepines	Increased sedation
Pimozide and sotalol	Increased risk of QT interval prolongation
Clozapine and co-trimoxazole	Increased risk of bone marrow suppression

have opposing pharmacological actions, such as anticoagulants and vitamin K and levodopa and dopamine antagonist antipsychotics.

Additive or synergistic interactions

If two drugs with similar pharmacological effects are given together, the effects can be additive (Table 4.5). Although not strictly drug interactions, the mechanism frequently contributes to ADRs. For example, the concurrent use of drugs with CNS-depressant effects such as antidepressants, hypnotics, antiepileptics and antihistamines may lead to excessive drowsiness, yet such combinations are frequently encountered. Combinations of drugs with arrhythmogenic potential such as antiarrhythmics, neuroleptics, tricyclic antidepressants and those producing electrolyte imbalance (e.g. diuretics) may lead to ventricular arrhythmias and should be avoided. Another example which has assumed greater importance of late is the risk of ventricular tachycardia and torsade de pointes associated with the concurrent use of more than one drug with the potential to prolong the QT interval on the electrocardiogram (Roden, 2004).

Serotonin syndrome

Serotonin syndrome (SS) is associated with an excess of serotonin that results from therapeutic drug use, overdose or inadvertent interactions between drugs. Although severe cases are uncommon, it is becoming increasingly well recognised in patients receiving combinations of serotonergic drugs (Boyer and Shannon, 2005). It can occur when two or more drugs affecting serotonin are given at the same time, or after one serotonergic drug is stopped and another started. The syndrome is characterised by symptoms including confusion, disorientation, abnormal movements, exaggerated reflexes, fever, sweating, diarrhoea and hypotension or hypertension. Diagnosis is made

when three or more of these symptoms are present and no other cause can be found. Symptoms usually develop within hours of starting the second drug, but occasionally they can occur later. Drug-induced SS is generally mild and resolves when the offending drugs are stopped. Severe cases occur infrequently and fatalities have been reported.

SS is best prevented by avoiding the use of combinations of several serotonergic drugs. Special care is needed when changing from a selective serotonin reuptake inhibitor (SSRI) to an MAOI and vice versa. The SSRIs, particularly fluoxetine, have long half-lives, and SS may occur if a sufficient washout period is not allowed before switching from one to the other. When patients are being switched between these two groups of drugs, the guidance in manufacturers' Summaries of Product Characteristics should be followed. Many drugs have serotonergic activity as their secondary pharmacology, and their potential for causing the SS may not be readily recognised. For example, linezolid, an antibacterial with monoamine oxidase inhibitory activity, has been implicated in several case reports of SS.

Many recreational drugs such as amphetamines and cocaine have serotonin agonist activity, and SS may ensue following the use of other serotonergic drugs.

Drug or neurotransmitter uptake interactions

Although seldom prescribed nowadays, the MAOIs have significant potential for interactions with other drugs and foods. MAOIs reduce the breakdown of noradrenaline in the adrenergic nerve ending. Large stores of noradrenaline can then be released into the synaptic cleft in response to either a neuronal discharge or an indirectly acting amine. The action of the directly acting amines adrenaline, isoprenaline and noradrenaline appears to be only moderately increased in patients who are taking MAOIs. In contrast, the concurrent use of MAOIs and indirectly acting sympathomimetic amines such as amphetamines, tyramine, MDMA (ecstasy), phenylpropanolamine and pseudoephedrine can result in a potentially fatal hypertensive crisis. Some of these compounds are contained in proprietary cough and cold remedies. Tyramine, contained in some foods (e.g. cheese and red wine), is normally metabolised in the gut wall by monoamine oxidase to inactive metabolites. In patients who are taking MAOI, however, tyramine will be absorbed intact. If patients who are taking MAOIs also take these amines, there may be a massive release of noradrenaline from adrenergic nerve endings, causing a sympathetic overactivity syndrome, characterised by hypertension, headache, excitement, hyperpyrexia and cardiac arrhythmias. Fatal intracranial haemorrhage and cardiac arrest may result. The risk of interactions continues for several weeks after the MAOI is stopped because new monoamine oxidase enzyme must be synthesised. Patients who are taking irreversible MAOIs should not take any indirectly acting sympathomimetic amines. All patients must be strongly warned about the risks of cough and cold remedies, illicit drug use and the necessary dietary restrictions.

Drug-food interactions

It is well established that food can cause clinically important changes in drug absorption through effects on gastro-intestinal

absorption or motility, hence the advice that certain drugs should not be taken with food, for example, iron tablets and antibiotics. Two other common examples already outlined include the interaction between tyramine in some foods and MAOIs, and the interaction between grapefruit juice and CCBs. With improved understanding of drug metabolism mechanisms, there is greater recognition of the effects of some foods on drug metabolism. The interaction between grapefruit juice and felodipine was discovered serendipitously when grapefruit juice was chosen to mask the taste of ethanol in a study of the effect of ethanol on felodipine. Grapefruit juice mainly inhibits intestinal CYP3A4, with only minimal effects on hepatic CYP3A4. This is demonstrated by the fact that intravenous preparations of drugs metabolised by CYP3A4 are not much affected, whereas oral preparations of the same drugs are. Some drugs that are not metabolised by CYP3A4, such as fexofenadine, show decreased levels with grapefruit juice. The probable reason for this is that grapefruit juice inhibits some drug transporter proteins and possibly affects organic anion-transporting polypeptides, although inhibition of P-glycoprotein has also been suggested. The active constituent of grapefruit juice is uncertain. Grapefruit contains naringin, which degrades during processing to naringenin, a substance known to inhibit CYP3A4. Although this led to the assumption that whole grapefruit will not interact, but that processed grapefruit juice will, some reports have implicated the whole fruit. Other possible active constituents in the whole fruit include bergamottin and dihydroxybergamottin.

Initial reports of an interaction between cranberry juice and warfarin, prompting regulatory advice that the international normalised ratio (INR) should be closely monitored in patients taking this combination, have not been confirmed by subsequent controlled studies.

Cruciferous vegetables, such as Brussels sprouts, cabbage and broccoli, contain substances that are inducers of the CYP450 isoenzyme CYP1A2. Chemicals formed by burning (e.g. barbecuing) meats additionally have these properties. These foods do not appear to cause any clinically important drug interactions in their own right, but their consumption may add another variable to drug interaction studies, thus complicating interpretation.

Drug–herb interactions

There has been a marked increase in the availability and use of herbal products in the UK, which include Chinese herbal medicines and Ayurvedic medicines. Up to 24% of hospital patients report using herbal remedies (Constable et al., 2007). Such products often contain pharmacologically active ingredients which can give rise to clinically significant interactions when used inadvertently with other conventional drugs.

Extracts of *Glycyrrhizin glabra* (licorice) used for treating digestive disorders may cause significant interactions in patients who are taking digoxin or diuretics. It may exacerbate hypokalaemia induced by diuretic drugs and precipitate digoxin toxicity. Herbal products such as Chinese ginseng (*Panax ginseng*), Chan Su (containing bufalin) and Danshen may also contain digoxin-like compounds which can interfere with digoxin assays, leading to falsely elevated levels being detected.

A number of herbal products have antiplatelet and anticoagulant properties and may increase the risk of bleeding when used with aspirin or warfarin. Herbal extracts containing coumarin-like constituents include alfalfa (*Medicago sativa*), angelica (*Angelica archangelica*), dong quai (*Angelica polymorpha*, *A. dahurica*, *A. atropurpurea*), chamomile, horse chestnut and red clover (*Trifolium pratense*), which can potentially lead to interactions with warfarin. Herbal products with antiplatelet properties include borage (*Borago officinalis*), bromelain (*Ananas comosus*), capsicum, feverfew, garlic, ginkgo (*Ginkgo biloba*) and turmeric, amongst others.

Other examples of drug–herb interactions include enhancement of hypoglycaemic (e.g. Asian ginseng) and hypotensive (e.g. hawthorn) effects, and lowering of seizure threshold (e.g. evening primrose oil and *Shankhapushpi*). The most widely discussed drug–herb interactions are those involving St John’s wort (*Hypericum* extract), an unlicensed herbal medicine used for depression which has been implicated in interactions, for example, with hormonal contraceptives including implants, ciclosporin and antiepileptic drugs. It is therefore imperative that patients are specifically asked about their use of herbal medicines because they may not volunteer this information.

Conclusion

Whilst one should acknowledge the impossibility of memorising all potential drug interactions, healthcare staff need to be alert to the possibility of drug interactions and take appropriate steps to minimise their occurrence. Drug formularies and the Summary of Product Characteristics provide useful information about interactions. Other resources that may also be of use to prescribers include drug safety updates from regulators such as the Medicines and Healthcare products Regulatory Agency (available at <https://www.gov.uk/drug-safety-update>), interaction alerts in prescribing software and the availability of websites which highlight interactions for specific drug classes, for example, HIV drugs (<http://www.hiv-druginteractions.org>).

Possible interventions to avoid or minimise the risk of a drug interaction include:

1. switching one of the potential interacting drugs;
2. allowing an interval of 2–3 hours between administration of the interacting drugs;
3. altering the dose of one of the interacting drugs, for example, reducing the dose of the drug which is likely to have an enhanced effect as a result of the interaction. In this case, the dose is generally reduced by one-third or half with subsequent monitoring for toxic effects either clinically or by therapeutic drug monitoring. Conversely, if the drug is likely to have reduced effects as a result of the interaction, the patient should be monitored similarly for therapeutic failure and the dose increased if necessary;
4. advising patients to seek guidance about their medication if they plan to stop smoking or start a herbal medicine, because they may need close monitoring during the transition.

Overall, it is important to anticipate when a potential drug interaction might have clinically significant consequences

for the patient. In these situations, advice should be given on how to minimise the risk of harm, for example, by recommending an alternative treatment to avoid the combination of risk, by making a dose adjustment or by monitoring the patient closely.

Case studies

Case 4.1

Mrs C is a 72-year-old woman with a history of hypertension, atrial fibrillation and hyperlipidaemia. Her current medication comprises digoxin 62.5 micrograms daily, warfarin as per INR, simvastatin 40 mg daily and amlodipine 10 mg daily. Mrs C is suffering from a respiratory tract infection and her primary care doctor has prescribed a 7-day course of clarithromycin.

Questions

1. Are there likely to be any clinically significant drug interactions?
2. What advice do you give?

Answers

1. There is potential for interaction between simvastatin and amlodipine, between simvastatin and clarithromycin and between clarithromycin and warfarin. Some statins, particularly simvastatin and atorvastatin, are metabolised by CYP450 (CYP3A4), and co-administration of potent inhibitors of this enzyme may increase plasma levels of these statins and so increase the risk of dose-related side effects, including rhabdomyolysis. Clarithromycin is a potent CYP450 enzyme inhibitor and can also inhibit the metabolism of warfarin, leading to over-anticoagulation.
2. Current advice is that amlodipine and simvastatin may be given together provided the simvastatin dose does not exceed 20 mg daily, so it is reasonable for simvastatin to be continued at a reduced dose of 20 mg. However, clarithromycin should not be given together with simvastatin. Myopathy and rhabdomyolysis have been reported in patients who are taking the combination. Mrs C should therefore be advised not to take her simvastatin while she is taking clarithromycin and to start taking it again after she has completed the course of antibiotic. During the course of clarithromycin, the daily dose of warfarin may need to be reduced; more frequent monitoring of the INR is suggested.

Case 4.2

A 19-year-old woman, Miss P, is receiving long-term treatment with minocycline 100 mg daily for acne. She wishes to start using the combined oral contraceptive, and her doctor has prescribed a low-strength pill (containing ethinylestradiol 20 micrograms with norethisterone 1 mg). The doctor contacts the pharmacist for advice on whether the tetracycline will interfere with the efficacy of the oral contraceptive.

Question

Is there a clinically significant interaction in this situation?

Answer

Contraceptive failure has been attributed to doxycycline, lymecycline, oxytetracycline, minocycline and tetracycline in about 40 reported cases, 7 of which specified long-term antibacterial use. There is controversy about whether a drug interaction occurs, but if there is one it appears to be rare. Controlled trials have not shown any effect of tetracycline or doxycycline on contraceptive steroid levels. The postulated mechanism is suppression of intestinal bacteria resulting in a fall in enterohepatic recirculation of ethinylestradiol. Overall, there is no evidence that this is clinically important.

In the case of long-term use of tetracyclines for acne, a small number of cases of contraceptive failure have been reported. Nevertheless, the only well-designed, case-control study in dermatological practice indicated that the incidence of contraceptive failure due to this interaction could not be distinguished from the general and recognised failure rate of oral contraceptives. Current guidance advises that women who are receiving long-term antibiotic therapy that does not induce liver enzymes do not need to take additional contraceptive precautions (*Joint Formulary Commission, 2017*). In addition, there is some evidence that ethinylestradiol may accentuate the facial pigmentation that can be caused by minocycline.

Case 4.3

A 48-year-old man, Mr H, with a history of epilepsy is admitted to hospital with tremor, ataxia, headache, abnormal thinking and increased partial seizure activity. His prescribed medicines are phenytoin 300 mg daily, clonazepam 6 mg daily and fluoxetine 20 mg daily. It transpires that fluoxetine therapy had been initiated 2 weeks previously. Mr H's phenytoin level is found to be 35 mg/L; at the last outpatient clinic visit 4 months ago, it was 18 mg/L.

Question

What is the proposed mechanism of interaction between fluoxetine and phenytoin and how should it be managed?

Answer

Fluoxetine is believed to inhibit the metabolism of phenytoin by the CYP450 isoenzyme CYP2C9, potentially leading to increased plasma phenytoin levels. There are a number of published case reports and anecdotal observations of phenytoin toxicity occurring with the combination, but the available evidence is conflicting. A review by the US Food and Drug Administration suggested that a marked increase in plasma phenytoin levels, with accompanying toxicity, can occur within 1–42 days (mean onset time of 2 weeks) after starting fluoxetine. If fluoxetine is added to treatment with phenytoin, the patient should be closely monitored. Ideally the phenytoin plasma levels should be monitored and there may be a need to reduce the phenytoin dosage.

Case 4.4

A 79-year-old man, Mr G, presented to hospital with a 3-day history of increasing confusion and collapse. He had a history of chronic lumbosacral pain, treated with oxycodone 10 mg twice daily and amitriptyline 75 mg daily. Five days before hospital admission Mr G had been prescribed tramadol 100 mg four times daily for worsening sciatica. On admission Mr G had a Glasgow Coma Scale

score of 11 and he was delirious and hallucinating. There were no focal neurological signs. Over the next 2 days he became increasingly unwell, confused and sweaty with pyrexia and muscular rigidity. Biochemical tests showed a metabolic acidosis (base deficit of 10.7) and an elevated creatine kinase level of 380 IU/L. There was no evidence of infection. At this stage a diagnosis of probable serotonin syndrome (SS) was made.

Questions

1. What is SS, and what drugs are most commonly associated with it?
2. How is SS managed?

Answers

1. SS is often described as a clinical triad of mental status changes, autonomic hyperactivity and neuromuscular abnormalities. However, not all these features are consistently present in all patients with the disorder. Symptoms arising from a serotonin excess range from diarrhoea and tremor in mild cases to delirium, neuromuscular rigidity, rhabdomyolysis and hyperthermia in life-threatening cases. Disturbance of electrolytes, transaminases and creatinine kinase may occur. Clonus is the most important finding in establishing the diagnosis of SS. The differential diagnosis includes neuroleptic malignant syndrome, sepsis, hepatic encephalopathy, heat stroke, delirium tremens and anticholinergic reactions. SS may not be recognised in some cases because of its protean manifestations. A wide range of drugs and drug combinations has been associated with SS, including MAOIs, tricyclic antidepressants, SSRIs, opioids, linezolid and serotonin receptor (5HT₁) agonists. Tramadol is an atypical opioid analgesic with partial μ antagonism and central reuptake inhibition of serotonin (5HT) and noradrenaline. At high doses it may also induce serotonin release. Tramadol is reported as causing SS alone (in a few case reports) and in combination with SSRIs, venlafaxine and atypical antipsychotics.
2. Management of SS involves removal of the precipitating drugs and supportive care. Many cases typically resolve within 24 hours after serotonergic drugs are stopped, but symptoms may persist in patients who are taking medicines with long half-lives or active metabolites. The 5HT_{2A}-antagonist cyproheptadine and atypical antipsychotic agents with 5HT_{2A}-antagonist activity, such as olanzapine, have been used to treat SS, although their efficacy has not been conclusively established.

Case 4.5

A 42-year-old woman, Mr M, is receiving long-term treatment with azathioprine 100 mg daily and bendroflumethiazide 2.5 mg daily. The latter was discontinued after an episode of gout, but she had three further episodes over the following year. Her doctor considers prescribing allopurinol as prophylaxis.

Question

Is this likely to cause a clinically significant interaction?

Answer

Azathioprine is metabolised in the liver to mercaptopurine and then converted to an inactive metabolite by the enzyme xanthine oxidase. Allopurinol is an inhibitor of xanthine oxidase and will lead to the accumulation of mercaptopurine, which can cause bone marrow

suppression and haematological abnormalities such as neutropenia and thrombocytopenia.

The dose of azathioprine should be reduced by at least 50%, and close haematological monitoring is required if allopurinol is used concomitantly.

Case 4.6

A 68-year-old woman, Mrs T, is receiving long-term treatment with lansoprazole for gastro-oesophageal reflux disease and warfarin for atrial fibrillation. She is admitted with haematemesis. On direct questioning, Mrs T also revealed that she takes various herbal medicines which contain chamomile, horse chestnut, garlic, feverfew, ginseng and St John's wort.

Question

What drug-herb interactions may have contributed to Mrs T's presentation to hospital?

Answer

Garlic, feverfew and ginseng all inhibit platelet aggregation by inhibiting the production or release of prostaglandins and thromboxanes. In addition, chamomile and horse chestnut contain coumarin-like constituents which can potentiate the anticoagulant effect of warfarin. St John's wort is a potent enzyme inducer and may induce the metabolism of lansoprazole via CYP2C19, thereby reducing the effectiveness of lansoprazole. Although the effects of herbs individually may be small, their combined effects may lead to serious complications.

Case 4.7

A 56-year-old man, Mr W, with ischaemic heart disease seeks advice whether he can use sildenafil for erectile dysfunction. Mr W takes aspirin, bisoprolol, isosorbide mononitrate and atorvastatin.

Question

What advice do you give?

Answer

Sildenafil is a selective inhibitor of cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase-5 inhibitor which can interact with nitrates to cause increases in cGMP leading to marked hypotension. Patients using nitrates should be advised not to use sildenafil.

Case 4.8

A 68-year-old man, Mr P, with a history of atrial fibrillation is admitted with left-sided weakness and computed tomography (CT) scan of his head showed a large intracerebral haematoma. Mr P takes dabigatran etexilate for stroke thromboprophylaxis. He was recently started on verapamil for heart rate control.

Question

What is the mechanism of action for the interaction between dabigatran and verapamil? How can the effect of the interaction be minimised?

Answer

Dabigatran etexilate is an oral direct thrombin inhibitor with potent anticoagulant effects. The pro-drug dabigatran etexilate is a P-glycoprotein substrate, but the active metabolite dabigatran is not. Verapamil is a P-glycoprotein inhibitor and leads to increased intestinal

absorption of dabigatran etexilate leading to increased plasma concentrations of dabigatran. In healthy volunteers, verapamil administered 1 hour before dosing with dabigatran etexilate caused increased plasma concentrations of dabigatran etexilate, but not when given 2 hours before. The combination of verapamil and dabigatran should be used with caution, but the interaction may be minimised by dosing verapamil at least 2–3 hours before dabigatran etexilate.

Adverse Drug Reactions

Janet Krska and Anthony R. Cox

Key points

- An adverse drug reaction is an unintended and noxious response occurring after the use of a drug, which is suspected to be associated with the drug.
- Adverse drug reactions can be classified as type A, which are most common and related to the drug's pharmacological effect, or type B, which are rare and unpredictable, although other classes of reaction can be identified.
- Few adverse reactions are identified during pre-marketing studies; therefore, pharmacovigilance systems to detect new adverse drug reactions are essential.
- Spontaneous reporting schemes are a common method of pharmacovigilance. These depend primarily on health professionals, but patients are encouraged to report suspected adverse reactions themselves in many countries.
- Adverse drug reactions are a significant cause of morbidity and mortality, are responsible for approximately 1 in 20 hospital admissions and are a considerable financial burden on health systems.
- Predisposing factors for adverse drug reactions include age, sex, ethnicity, genetic factors, comorbidities and concomitant medication.
- Many adverse drug reactions may be preventable through rational prescribing and careful monitoring of drug therapy.
- Health professionals need to be able to identify and assess adverse drug reactions and play a major role in preventing their occurrence.
- Patients want to receive information about potential side effects of medicines; therefore, communicating the risks of using medicines is an important skill for health professionals.

Introduction

All medicines with the ability to produce a desired therapeutic effect also have the potential to cause unwanted adverse effects. Health professionals should have an awareness of the following: the burden that adverse drug reactions (ADRs) place on health services and the public, the skills to identify and reduce the risk of ADRs in the patients they care for, and the duty they have to participate in post-marketing surveillance of medicines to improve medication safety.

Risks associated with medicinal substances are documented throughout history. For example, William Withering's 1785 account of digitalis provides a meticulous description of the adverse effects of digitalis toxicity. However, the thalidomide disaster and

subsequent political pressure created the modern regulatory environment for medicines. Thalidomide was first marketed by the German company Chemie Grünenthal in 1957 and distributed in the UK by Distillers Ltd., whose chief medical advisor stated, 'If all the details of this are true, then it is a most remarkable drug. In short, it is impossible to give a toxic dose' (Brynnner and Stephens, 2001). Despite an absence of supporting evidence, in 1958 thalidomide was recommended for use in pregnant and nursing mothers. An Australian doctor, Jim McBride, and a German doctor, Widukind Lenz, independently associated thalidomide exposure with serious birth defects, and thalidomide was withdrawn in December 1961. Thalidomide left behind between 8000 and 12,000 deformed children and an unknown number of deaths in utero. Many still live with this legacy.

The 1970s saw another unexpected and serious adverse reaction. The cardio-selective β -adrenergic receptor blocker practolol, launched in June 1970, was initially associated with rashes, some of which were severe. A case series of psoriasis-like rashes linked to dry eyes, including irreversible scarring of the cornea, led other doctors to report eye damage, including corneal ulceration and blindness, to regulators. Cases of sclerosing peritonitis, a bowel condition associated with significant mortality, were also reported. Practolol had remained on the market for 4 years; more than 100,000 people had been treated and hundreds were seriously affected.

Some adverse effects can be more difficult to differentiate from background events occurring commonly in the population. The cyclo-oxygenase-2 selective non-steroidal anti-inflammatory drugs (NSAIDs) celecoxib (introduced in 1998) and rofecoxib (introduced in 1999) were marketed on the basis of reduced gastro-intestinal ADRs in comparison with other non-selective NSAIDs. Apparent excesses of cardiovascular events with these drugs, which were noted during clinical trials and in elderly patient groups, were ascribed to the supposed cardioprotective effects of comparator drugs. However, in September 2004 a randomised controlled trial of rofecoxib in the prevention of colorectal cancer showed the drug to be associated with a significantly increased risk of cardiovascular events (Bresalier et al., 2005). Celecoxib was also associated with a dose-related increased risk of cardiovascular events in clinical trials. Rofecoxib was voluntarily withdrawn from the market. Further research has provided evidence of thrombotic risk with non-selective NSAIDs, in particular diclofenac. This risk appears to extend to all NSAID users, irrespective of baseline cardiovascular risk.

Reports by healthcare professionals to regulatory authorities are a major source of evidence for the majority of drug withdrawals. A total of 19 drugs were withdrawn from the market in the European Union (EU) between 2002 and 2011, most frequently because of cardiovascular problems, but also due to liver problems and neurological or psychiatric disorders (McNaughton et al., 2014). Worldwide 462 medicinal products were withdrawn from the market between 1953 and 2013, with the most common reason being hepatotoxicity. Withdrawal was less frequent in Africa compared with the rest of the world.

Not all drug safety issues are related to real effects. In 1998 a widely publicised paper by Andrew Wakefield and co-authors, later retracted, which alleged a link between measles mumps and rubella (MMR) vaccine and autism led to a crisis in parental confidence in the vaccine. This had a detrimental effect on vaccination rates, resulting in frequent outbreaks of measles and mumps, despite epidemiological and virological studies showing no link between MMR vaccine and autism. The MMR vaccine controversy illustrates how media reporting of drug safety information can influence patients' views of medicines and can cause significant harm. Poor presentation of drug safety issues in the media often creates anxiety in patients about medicines that they may be using, regardless of their benefits. As an example, the complexity of the debate on the benefits and risks of statins in the literature, when viewed through the prism of media reporting, has led to public concerns about their use in the secondary prevention of cardiovascular disease.

Assessing the safety of drugs

When drugs are newly introduced to the market, their safety profile is inevitably provisional. Although efficacy and evidence of safety must be demonstrated for regulatory authorities to permit marketing, it is not possible to discover the complete safety profile of a new drug prior to its launch. Pre-marketing clinical trials involve on average 2500 patients, with perhaps a hundred patients using the drug for longer than a year. Therefore, pre-marketing trials do not have the power to detect important reactions that occur at rates of 1 in 10,000, or fewer, drug exposures. Often only pharmacologically predictable ADRs with short onset times are identified in clinical trials, nor can relatively short trials detect ADRs which occur a long time after drug exposure. For drugs subject to an accelerated assessment process under early access schemes for unmet clinical needs, there may be a further reduction in pre-marketing safety information.

Additionally, patients within trials are often relatively healthy, without the multiple disease states, multiple risk factors or complex drug histories of patients in whom the drug will be used. Furthermore the patient's perspective is also frequently excluded from safety assessment in clinical trials, with ADRs being assessed only by the clinicians who run them (Basch, 2010). Up to 60% of drugs may also experience dose reductions following marketing (Heerdink et al., 2002). For these reasons, rare and potentially serious adverse effects often remain undetected until

a wider population is exposed to the drug. The vigilance of health professionals is an essential factor in discovering these new risks, together with regulatory authorities that continuously monitor reports of adverse effects throughout the lifetime of a marketed medicinal product. For so-called orphan drugs and those which are little used, careful monitoring is essential.

As a result of this monitoring, the safety profile of well-established drugs is often well-known, although new risks are occasionally identified. However, an important part of the therapeutic management of medical conditions is the minimisation of these well-known risks. This can best be achieved through rational prescribing, recording of previous ADRs and careful monitoring of drug therapy, and the involvement of patients, who need to be well-informed about the risks of drugs. Much evidence suggests that all of these could be improved.

Definitions

Having clear definitions of what constitutes an ADR is important. The World Health Organization's (WHO's) original definition of an ADR was 'a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of disease, or for modification of physiological function' (WHO, 1972, p. 9). The use of the phrase 'at doses normally used in man' distinguishes the noxious effects of drugs during normal medical use from toxic effects caused by poisoning. Whether an effect is considered noxious depends on both the drug's beneficial effects and the severity of the disease for which it is being used. There is no need to prove a pharmacological mechanism for any noxious response to be termed an ADR. More recently, the EU definition of an ADR has been expanded to take into account off-label use, overdose, misuse, abuse and medication errors.

The EU definition of adverse reaction is (European Medicines Evaluation Agency [EMA], 2014, p. 8):

A response to a medicinal product which is noxious and unintended.

[...]

Adverse reactions may arise from use of the product within or outside the terms of the marketing authorisation or from occupational exposure. Use outside the marketing authorisation includes off-label use, overdose, misuse, abuse and medication errors.

The terms *adverse drug reaction* (ADR) and *adverse drug effect* can be used interchangeably; adverse reaction applies to the patient's point of view, whereas adverse effect applies to the drug. The terms *suspected ADR* or *reportable ADR* are commonly used in the context of reporting ADRs to regulatory authorities, for example, through the UK's Yellow Card Scheme, operated by the Medicines and Healthcare products Regulatory Authority (MHRA). Although the terms *side effect* and *ADR* are often used synonymously, the term *side effect* is distinct from an ADR. A side effect is an unintended effect of a drug related to its pharmacological properties and can include unexpected benefits of treatment.

It is important also to avoid confusion with the term *adverse drug event* (ADE). An ADR is an adverse outcome in a patient that is attributed to a suspected action of a drug, whereas an ADE is an adverse outcome in a patient, which occurs after the use of a drug, but which may or may not be linked to use of the drug. It therefore follows that all ADRs are ADEs, but that not all ADEs will be ADRs. This distinction is important in the assessment of the drug safety literature, because the term *ADE* can be used when a causal link between a drug treatment and an adverse outcome has not been proven. The suspicion of a causal relationship between the drug and the adverse effect is central to the definition of an ADR.

Classification of adverse drug reactions

Classification systems for ADRs are useful for educational purposes, for those working within a regulatory environment and for clarifying thinking on the avoidance and management of ADRs.

Rawlins–Thompson classification

The Rawlins–Thompson system of classification divides ADRs into two main groups: type A and type B (Rawlins, 1981). Type A reactions are the normal, but quantitatively exaggerated, pharmacological effects of a drug. They include the primary effect of the drug, as well as any secondary effects of the drug, for example,

ADRs caused by the antimuscarinic activity of tricyclic anti-depressants. Type A reactions are the most common, accounting for 80% of reactions.

Type B reactions are qualitatively abnormal effects, which appear unrelated to the drug's normal pharmacology, such as hepatotoxicity from isoniazid. They are more serious in nature, more likely to cause deaths and are often not discovered until after a drug has been marketed. The Rawlins–Thompson classification has undergone further elaboration over the years (Table 5.1), to take account of ADRs that do not fit within the existing classifications (Edwards and Aronson, 2000).

The DoTS system

The DoTS classification is based on *dose* relatedness, *timing* and patient susceptibility (Aronson and Ferner, 2003). In contrast with the Rawlins–Thompson classification, which is defined only by the properties of the drug and the reaction, the DoTS classification provides a useful template to examine the various factors that both describe a reaction and influence an individual patient's susceptibility.

The DoTS system first considers the dose of the drug, because many adverse effects are clearly related to the dose of the drug used. For example, increasing the dose of a cardiac glycoside will increase the risk of digitalis toxicity. In the DoTS system reactions are divided into toxic effects (effects related to the use of drugs outside of their usual therapeutic dosage), collateral effects (effects occurring within the normal therapeutic use of the drug) and hypersusceptibility reactions (reactions occurring

Table 5.1 Extended Rawlins–Thompson classification of adverse drug reactions

Type of reaction	Features	Examples
Type A: augmented pharmacological effect	Common Predictable effect Dose dependent High morbidity Low mortality	Bradycardia associated with a β -adrenergic receptor antagonist
Type B: bizarre effects not related to pharmacological effect	Uncommon Unpredictable Not dose dependent Low morbidity High mortality	Anaphylaxis associated with a penicillin antibiotic
Type C: dose-related and time-related	Uncommon Related to the cumulative dose	Hypothalamic-pituitary-adrenal axis suppression by corticosteroids
Type D: time-related	Uncommon Usually dose-related Occurs or becomes apparent sometime after use of the drug	Carcinogenesis
Type E: withdrawal	Uncommon Occurs soon after withdrawal of the drug	Opiate withdrawal syndrome
Type F: unexpected failure of therapy	Common Dose-related Often caused by drug interactions	Failure of oral contraceptive in presence of enzyme inducer

in subtherapeutic doses in susceptible patients). Collateral effects include reactions not related to the expected pharmacological effect of the drug or off-target reactions of the expected therapeutic effect in other body systems. It is worth noting that approximately 20% of newly marketed drugs have their dosage recommendations reduced after marketing, often because of drug toxicity.

The time course of a drug's presence at the site of action can influence the likelihood of an ADR occurring. For example, rapid infusion of furosemide is associated with transient hearing loss and tinnitus, and a constant low dose of methotrexate is more toxic than equivalent intermittent bolus doses. The DoTS system categorises ADRs as either time-independent or time-dependent reactions. Time-independent reactions occur at any time within the treatment period, regardless of the length of course. Time-dependent reactions range from rapid and immediate reactions following exposure to reactions that are delayed.

The final aspect of the DoTS classification system is susceptibility, which includes factors such as genetic predisposition, age, sex, altered physiology, disease and exogenous factors such as drug interactions (Table 5.2).

Factors that affect susceptibility to adverse drug reactions

Awareness among prescribers of the factors that increase the risk of ADRs is key to reducing the burden on individual patients, and such awareness should inform all prescribing decisions. The risk that drugs pose to patients varies dependent on the population exposed and the individual characteristics of patients. Some reactions may be unseen in some populations, outside of susceptible subjects. Other reactions may follow a continuous distribution in the exposed population. Although many susceptibilities may not be known, a number of general factors that affect susceptibility to ADRs and others that affect the propensity of specific drugs to cause ADRs are well-known.

Age

Children differ from adults in their response to drugs. Neonatal differences in body composition, metabolism and other physiological parameters can increase the risk of specific adverse reactions. Higher body water content can increase the volume of distribution for water-soluble drugs, reduced albumin and total protein may result in higher concentrations of highly protein bound drugs, while an immature blood–brain barrier can increase sensitivity to drugs such as morphine. Differences in drug metabolism and elimination and end-organ responses can also increase the risk. Chloramphenicol, digoxin and ototoxic antibiotics such as streptomycin are examples of drugs that have a higher risk of toxicity in the first weeks of life.

Older children and young adults may also be more susceptible to ADRs, a classic example being the increased risk of extra-pyramidal effects associated with metoclopramide. The use of aspirin was restricted in those younger than 12 years after an association with Reye's syndrome was found in epidemiological studies. Additionally, children can be exposed to more adverse effects because of the heightened probability of dosing errors and the relative lack of evidence for both safety and efficacy.

Elderly patients may be more prone to ADRs, with age-related decline in both the metabolism and elimination of drugs from the body. They also have multiple comorbidities and are therefore exposed to more prescribed drugs. Chronological age is therefore arguably a marker for altered physiological responses to drugs and for the presence of comorbidities and associated drug use rather than a risk per se. However, with an increasingly ageing population in many countries, the mitigation of preventable ADRs in older people is of great importance.

Comorbidities and concomitant medicines use

Reductions in hepatic and renal function substantially increase the risk of ADRs, because most drugs are metabolised in the liver, renally excreted or both. Factors that predict repeat admissions

Table 5.2 DoTS system of adverse drug reaction classification

Dose relatedness	Time relatedness	Susceptibility
<i>Toxic effects:</i> ADRs that occur at doses higher than the usual therapeutic dose	Time-independent reactions: ADRs that occur at any time during treatment	Raised susceptibility may be present in some individuals, but not others. Alternatively, susceptibility may follow a continuous distribution—increasing susceptibility with impaired renal function. Factors include genetic variation, age, sex, altered physiology, exogenous factors (interactions) and disease.
<i>Collateral effects:</i> ADRs that occur at standard therapeutic doses	Time-dependent reactions: <i>Rapid reactions</i> occur when a drug is administered too rapidly. <i>Early reactions</i> occur early in treatment, then abate with continuing treatment (tolerance). <i>Intermediate reactions</i> occur after some delay, but if reaction does not occur after a certain time little or no risk exists. <i>Late reactions</i> , risk of an ADR increases with continued-to-repeated exposure, including withdrawal reactions. <i>Delayed reactions</i> occur sometime after exposure, even if the drug is withdrawn before the ADR occurs.	
<i>Hypersusceptibility reactions:</i> ADRs that occur at subtherapeutic doses in susceptible patients		

ADR, Adverse drug reaction.

to hospital with ADRs in older patients are comorbidities such as congestive heart failure, diabetes, and peripheral vascular, chronic pulmonary, rheumatological, hepatic, renal and malignant diseases. All are strong predictors of readmissions for ADRs, whereas advancing age alone is not. Reasons for this could be pharmacokinetic and pharmacodynamic changes associated with pulmonary, cardiovascular, renal and hepatic insufficiency, or drug interactions from prescribed multiple drug therapy (Zhang et al., 2009). Multiple medicine use, or polypharmacy, is strongly associated with increasing risk of both interactions and ADRs, and it is important to recognise that polypharmacy is not just a feature of ageing. Prescribed medicines use is increasing dramatically, with one study showing that the proportion of adults dispensed five or more drugs was almost 21% in 2010 (Guthrie et al., 2015).

Sex

Women may be more susceptible to ADRs, but they also receive more drugs than men. In addition, there are particular adverse reactions that appear to be more common in women. For example, impairment of concentration and psychiatric adverse events associated with the antimalarial mefloquine are more common in females.

Females are more susceptible to drug-induced torsade de pointes, a ventricular arrhythmia linked to ventricular fibrillation and death. Women are overrepresented in reports of torsades de pointes associated with cardiovascular drugs (such as sotalol) and erythromycin. This increased susceptibility in women is thought to be due to their longer QTc interval compared with men.

Ethnicity

Ethnicity has also been linked to susceptibility to ADRs, because of inherited traits of metabolism. It is known, for example, that the cytochrome P450 genotype, involved in drug metabolism, has varied distribution among people of differing ethnicity. For example, CYP2C9 alleles associated with poor metabolism occur more frequently in white individuals compared with black individuals. This has a potential effect on warfarin metabolism and increases the risk of toxicity.

Examples of ADRs linked to ethnicity include the increased risk of angioedema with the use of angiotensin-converting enzyme inhibitors in black patients (McDowell et al., 2006), the increased propensity of white and black patients to experience central nervous system ADRs associated with mefloquine compared with patients of Chinese or Japanese origin and differences in the pharmacokinetics of rosuvastatin in Asian patients, which may expose them to an increased risk of myopathy. However, susceptibility based on ethnicity could be associated with genetic or cultural factors, and ethnicity can be argued to be a poor marker for a patient's genotype.

Pharmacogenetics

Pharmacogenetics, the study of genetic variations that influence individuals' responses to drugs, examines polymorphisms that code for drug transporters, drug-metabolising enzymes and drug receptors. A greater understanding of the genetic basis of variations in individual responses to drug therapy is beginning to deliver

a new era of precision or stratified medicine. Although pharmacogenetics has yet to reach its full potential to reduce ADRs, there are now significant examples of severe ADRs that may be avoided with knowledge of a patient's genetic susceptibility.

As already noted, major genetic variation is found in the cytochrome CYP450 group of isoenzymes. This can result in either inadequate responses to drugs or increased risk of ADRs. Clinically relevant genetic variation has been seen in CYP2D6, CYP2C9, CYP2C19 and CYP3A5. A large effect on the metabolism of drugs can occur with CYP2C9, which accounts for 20% of total hepatic CYP450 content.

The narrow therapeutic index of warfarin, its high interindividual variability in dosing and the serious consequences of toxicity have made it a major target of pharmacogenomics research. Studies of genetic polymorphisms influencing the toxicity of warfarin have focused on CYP2C9, which metabolises warfarin, and vitamin K epoxide reductase (VKOR), the target of warfarin anticoagulant activity. Genetic variation in the *VKORC1* gene, which encodes VKOR, influences warfarin dosing by a threefold greater extent than CYP2C9 variants. In 2007 the US Food and Drug Administration (FDA) changed the labeling requirement for warfarin, advising that a lower initial dose should be considered in people with certain genetic variations. However, concerns exist that genetic variations account for only a proportion of the variability in drug response and that clinicians may obtain a false sense of reassurance from genetic testing, leading to complacency in monitoring of therapy. In addition, there appears to be little evidence of additional benefit, in terms of preventing major bleeding events, compared with careful monitoring of the INR (Laurence, 2009).

A success story for pharmacogenetics is the story of abacavir. Hypersensitivity skin reactions to this nucleoside analogue reverse transcriptase inhibitor are a particular problem in the treatment of human immunodeficiency virus (HIV) infection. Approximately 5–8% of patients who are taking abacavir develop a severe hypersensitivity reaction, including symptoms such as fever, rash, arthralgia, headache, vomiting, and other gastrointestinal and respiratory disturbances. Early reports that only a subset of patients was affected, a suspected familial predisposition, the short onset time (within 6 weeks of starting therapy) and an apparent lower incidence in African patients led to suspicion of a genetic cause. Subsequent research revealed a strong predictive association with the HLA-**B5701* allele in Caucasian and Hispanic patients. The presence of the allele can be used to stratify the predicted risk of hypersensitivity as high risk (>70%) for carriers of HLA-**B570* and low risk (<1%) for non-carriers of HLA-**B5701*. Evidence from practical use of HLA-**B5701* screening has shown substantial declines in the incidence of hypersensitivity reactions, as well as a more general improved compliance with the medication (Lucas et al., 2007).

Another example involves the cutaneous ADRs, Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), which are serious reactions associated with substantial morbidity and mortality. Forty percent of patients with TEN will die during an episode. SJS and TEN have been associated with numerous drugs, although the incidence of such reactions is rare. Antiepileptic drugs, such as carbamazepine and phenytoin, are known causes of SJS and TEN. Such reactions are more common in South East Asian populations (including those from China,

Thailand, Malaysia, Indonesia, the Philippines and Taiwan, and to a lesser extent, India and Japan). The presence of human leucocyte antigen (HLA) allele, HLA-B*1502, for which genetic testing is already available, indicates an increased risk of skin reactions for carbamazepine, phenytoin, oxcarbazepine and lamotrigine. The FDA has recommended HLA-B*1502 screening before using carbamazepine in South East Asian individuals (FDA, 2007).

Erythrocyte glucose-6-phosphatase dehydrogenase deficiency

Glucose-6-phosphatase dehydrogenase (G6PD) deficiency is present in more than 400 million people worldwide. It is an X-linked inherited enzyme deficiency, leading to susceptibility to haemolytic anaemia. There are many variants of the genotype, with most G6PD-deficient patients remaining asymptomatic until an oxidative stress is placed upon them. Oxidant drugs such as primaquine, sulfonamides and nitrofurantoin can act as provoking agents (Cappellini and Fiorelli, 2008).

Porphyrias

The porphyrias are a heterogeneous group of mainly autosomal dominant inherited disorders of haem biosynthesis, leading to excess porphyrin production. Patients with acute porphyrias may have life-threatening attacks precipitated by commonly prescribed drugs.

A number of drugs may induce excess porphyrin synthesis, but there is wide variation in the response, and in the dose required, between individual patients. Lists of drugs that are known to be unsafe and drugs which are thought to be safe for use in acute porphyria are available in the British National Formulary.

Immunological reactions

The immune system is able to recognise drugs as foreign substances, leading to allergic reactions. Smaller drug molecules (<600 Da) can bind with proteins to trigger an immune response, or larger molecules can trigger an immune response directly. The immune response is not related to the pharmacological action of the drug and prior exposure to the drug is required. Immunological reactions are often distinct recognisable responses.

Allergic reactions range from rashes, serum sickness and angioedema to the life-threatening bronchospasm and hypotension associated with anaphylaxis. Patients with a history of atopic or allergic disorders are at higher risk. Immunological (hypersensitivity) reactions are split into four main types (Table 5.3).

Formulation issues that contribute to adverse drug reactions

Although ADRs caused by formulation problems are rare in developed countries with stringent regulation, examples have occurred and regulatory authorities remain vigilant for such

Table 5.3 Classification of immunological (hypersensitivity) reactions

Classification	Mechanism	Symptoms/signs and examples
Type I (immediate)	Drug/IgE complex binds to mast cells which release histamine and leukotrienes	Pruritus, urticaria, bronchoconstriction, angioedema, hypotension, shock, e.g. penicillin anaphylaxis
Type II (cytotoxic)	IgG and complement binding to (usually) red blood cell Cytotoxic T cells lyse the cell	Haemolytic anaemia and thrombocytopenia, e.g. associated with cephalosporins, penicillins and rifampicin
Type III (immune complex)	Drug antigen and IgG or IgM form immune complex, attracting macrophages and complement activation	Cutaneous vasculitis, serum sickness, e.g. associated with chlorpromazine and sulfonamides
Type IV (delayed type)	Antigen presentation with major histocompatibility complex protein to T cells and cytokine and inflammatory mediator release	Usually occur after 7–20 days; macular rashes and organ failure, including Stevens–Johnson syndrome and toxic epidermal necrolysis, e.g. associated with neomycin, sulfonamides

Ig, Immunoglobulin.

problems. In 1937 the S. E. Massengill Company, in the USA, developed a liquid preparation of an early antibiotic sulfanilamide which contained 72% diethylene glycol. Over a 4-week period 353 patients received the elixir, 30% of whom died, including 34 children. Sadly, episodes of diethylene glycol poisoning have been reported in contemporary times in a number of countries including Nigeria, India, Argentina and Haiti. In 2006 cough medicines made using glycerine contaminated with diethylene glycol, sourced from China, were responsible for the suspected deaths of more than 300 people in Panama.

Osmosin was a slow-release preparation of Indometacin using a novel osmotic pump to deliver the drug through a laser-drilled hole in an impervious tablet. Osmosin was withdrawn in 1983 after 36 fatal gastro-intestinal haemorrhages were suspected to be caused by the tablet becoming lodged against the mucosa of the gastro-intestinal tract.

Adverse reactions have been associated with excipient changes. In Australia and New Zealand a decision to change the formulation of phenytoin to one in which calcium sulphate dihydrate was replaced with lactose led to previously stable patients developing severe adverse reactions, including coma. This unfortunate result

was because the calcium salt had slowed phenytoin absorption, whereas the lactose in the new formulation increased absorption.

Although excipients are often referred to as inert substances, serious adverse reactions such as anaphylaxis and angioedema have been reported to these substances. Sweeteners, flavourings, colouring agents/dyes and preservatives have been all been associated with adverse reactions (Kumar, 2003). In many countries, generic prescribing is increasing, which results in patients receiving differing formulations of medicines made by different manufacturers, who may use different excipients. It is important to recognise that this can mean that patients experience a reaction to one brand of medicine and not to another, and not to dismiss such reports.

Epidemiology of adverse drug reactions

ADRs are an important public health issue. In Sweden ADRs are suggested to be responsible for 3% of deaths (Wester et al., 2008), whereas in England ADRs were shown to occur in 0.4% of all patients admitted to hospital, with mortality being higher in those experiencing an ADR than in those who did not (Davies et al., 2009). The median length of stay in patients who experience an ADR is 20 days, compared with 8 days, and costs associated with in-patient ADRs were calculated at £171 million annually for the NHS in England (Davies et al., 2009). Costs to the NHS associated with admissions due to ADRs have been estimated as £466 million annually (Pirmohamed et al., 2004).

A systematic review of European studies found the median percentage of hospital admissions due to an ADR to be 3.5% (range 0.5–12.8%), based on 22 studies, and the proportion experiencing an ADR during hospitalisation as 10.1% (range 1.7–50.9%), based on 13 studies (Bouvy et al., 2015). An observational study of more than 6000 paediatric admissions found 2.9% of admissions were associated with ADRs (Gallagher et al., 2012).

In primary care, estimates of the incidence of ADRs are more difficult to obtain, and very few well-designed studies are to be found. Prevalence rates of approximately 7% have been found in two Swedish studies using medical records and self-report (Hakkarainen et al., 2013a, 2013b), while other studies which rely on patients' reports of ADRs, either to postal questionnaires or telephone surveys, provide estimates of around 25% in the USA (Gandhi et al., 2003) and 30% in the UK (Jarernsiripornkul et al., 2002). These higher figures relate to the methodologies used and are hampered by the lack of information about non-responders. A systematic review in 2007 found an incidence of overall ADEs, including ADRs, of 14.9 per 1000 person-months in primary care settings (Thomsen et al., 2007).

Pharmacovigilance and epidemiological methods in adverse drug reaction detection

As already noted, the inherent weaknesses of pre-marketing studies mean that post-marketing surveillance of medicines is

essential to detect previously unrecognised adverse effects. This surveillance is termed *pharmacovigilance*, which is defined as 'science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other medicine-related problem' (WHO, 2002, p. 7). Pharmacovigilance supports health professionals to make rational and safe therapeutic decisions in clinical practice. Pharmacovigilance also helps to ensure that unsafe products are withdrawn from the market. However, despite the increasing importance placed on this and improvements worldwide in the systems for detecting ADRs, the time between an ADR first being reported and the date of withdrawal has not changed in 60 years, taking approximately 6 years (Onakpoya et al., 2016).

Spontaneous reporting

Pharmacovigilance uses multiple methods, but this chapter will mainly cover spontaneous reporting systems. Spontaneous reporting systems collect data about suspected ADRs in a central database. Cases are not collected in a systematic manner, but accumulate through reports submitted spontaneously by people who make a connection between a drug and a suspected drug-induced event. In the UK, the spontaneous reporting scheme is the Yellow Card Scheme. In some countries reporting is a voluntary activity; in others reporting is a legal requirement, but there is no evidence that this increases reporting rates.

Spontaneous reporting has a number of advantages. It is relatively cheap to administer, can follow a product throughout its life and can cover all products on the market, including over-the-counter and herbal products, as well as products obtained via the Internet or by illicit means. Such schemes are, however, passive surveillance systems, which rely on the ability of the reporters to recognise possible ADRs and to distinguish these from symptoms related to the underlying disease. It is important to emphasise that only a suspicion of a causal link between a drug and an adverse event is required; confirmation of the association is not required. One disadvantage of spontaneous reporting systems is their inability to quantify any particular risk associated with an individual drug. The number of reports are known, but estimates of the incidence of reactions cannot be made, because the population exposed to the drug cannot be ascertained accurately. Furthermore, only a minority of reactions are reported. Spontaneous reports are, however, an important form of evidence leading to drug withdrawals and are crucial for generating hypotheses about potential associations between a drug and an adverse event, which can then be investigated further.

Signal detection

A signal is described as a possible causal relationship between an adverse event and a drug which was previously unknown. Using statistical approaches, run automatically by computer systems, databases of spontaneous reports are scanned for 'drug-adverse event pairs' that are disproportionately present within the database as a whole. These mathematical approaches do help to develop hypotheses, but they are not conclusive evidence of an ADR in themselves. A signal could be due to

causes other than the drug. Confounding factors, such as particular groups of patients being ‘channelled’ into receiving a drug, can influence reporting. The spontaneous reports from which signals are generated have been submitted by people with differing levels of competence, training, experience and awareness of ADRs. There is also a tendency for reporting rates to be higher with newly introduced drugs, while articles in the media, regulatory action and even legal cases can provoke reporting of particular reactions. Therefore, the strength of the signal also depends on the quality of the individual spontaneous reports. It is rare for a signal to provide strong evidence that requires immediate restriction on use of the drug or its withdrawal.

Causality assessment

Causality assessment relates to the assessment of whether a drug is responsible for a suspected ADR. This is of great importance to the regulators who license medicines and control use within a country. In the UK the regulator is the MHRA; other important regulators are the EMEA and the FDA in the USA. Such agencies exist worldwide, and most operate spontaneous reporting schemes. Many then send these reports to the WHO international monitoring centre in Uppsala, Sweden; thus, a very large database exists of spontaneous reports gathered from around the world.

A suspected ADR is rarely confirmed with a definite degree of certainty, despite the numbers of reports, the variable amounts and quality of information available in spontaneous reports, in particular the lack of any evidence derived from rechallenge with the suspected drug which is usually ethically unacceptable. Thus, causality is difficult to prove conclusively, and a high degree of suspicion is often sufficient for a regulator to take action to modify the use of the product.

One of the most common methods of causality assessment is unstructured clinical assessment, also known as global introspection. Expert review of clinical information is undertaken and a judgement is made about the likelihood of the reaction being due to drug exposure. The assessment of complex situations, often with missing information, is open to variation between different assessors, and studies have shown marked disagreements between experts. The WHO international monitoring centre uses global introspection for case assessment, assigning standardised causality categories to suspected ADRs (Table 5.4).

A number of alternative methods of assessing causality have been developed using standardised decision algorithms, in an attempt to increase objectivity and reduce assessor bias. One of the most commonly used is the Naranjo algorithm (Naranjo et al., 1981). This uses a scored questionnaire with points being added or taken away based on the response to each question, such as ‘Did the adverse reaction reappear when the drug was re-administered?’ The total score is then used to place the assessed reaction on the following scale: definite, probable, possible or doubtful. Algorithms may be less open to the effects of confounding variables, such as underlying disease states or concomitant drugs, but variation in assessor judgements still occurs.

Table 5.4 World Health Organization Uppsala Monitoring Centre causality categories

Category	Description
Certain	Pharmacologically definitive, with rechallenge if necessary
Probably/likely	Reasonable temporal relationship; unlikely to be attributed to disease processes or other drugs, with reasonable dechallenge response
Possible	Reasonable temporal relationship, but could be explained by concurrent disease or drugs; no information on withdrawal
Unlikely	Temporal relationship improbable; concurrent disease or drugs provide plausible explanation
Conditional/ unclassified	An event which requires more data for assessment
Unassessable/ unclassifiable	An event that cannot be judged because of insufficient/contradictory information which cannot be supplemented or verified

Yellow Card Scheme

The UK’s Yellow Card Scheme, now operated by the MHRA, was established in 1964 following the thalidomide tragedy. All healthcare professionals are encouraged to submit reports of suspected ADRs using a Yellow Card (found in the British National Formulary), online (<https://yellowcard.mhra.gov.uk>) or via an application for mobile phones. It is not necessary to confirm an association between the medicine and the event; a suspicion is sufficient for a report to be submitted. The MHRA requests that all serious suspected ADRs to established drugs are reported, but for newer drugs, all suspected ADRs should be reported, even minor events. Newer drugs under intensive surveillance are identified with an inverted black triangle symbol (▼) in product information, including both Summaries of Product Characteristics (SPCs) and patient information leaflets (PILs), and standard prescribing texts. Black triangle status is generally maintained for at least 2 years, but the period varies, depending on how much information is obtained about a product’s continued safety.

Community pharmacists are particularly encouraged to report suspected ADRs to over-the-counter medicines and herbal products, as they are providers of these and people are most likely to inform them of any problems encountered. The Yellow Card Scheme now also includes medical devices, counterfeit products and defective medicines. Suspected ADRs to biological products are particularly desired, as the variation between brands and even between batches can be significant.

All information from Yellow Card reports is entered into a database, and the suspected reactions are categorised using the internationally accepted Medical Dictionary for Regulatory Affairs (MedDRA), which provides a hierarchical taxonomy of ADRs by system organ class. All resultant signals generated by the reports are assessed for causality. Where there is a valid signal that may be an ADR, further work is usually then required to

further assess the association. This may involve requesting further details from reporters, contacting manufacturers, searching the literature for case reports and other evidence (cohort or case-control studies) or asking pharmaceutical manufacturers to carry out pharmacoepidemiological studies. The MHRA estimates that about 40% of the safety signals it investigates are generated from spontaneous reports.

When new ADRs are identified and an association confirmed, the MHRA may take action in the form of changes to the SPC and/or the PIL, restricting usage or withdrawing marketing authorisation for the medicine. Withdrawal of marketing authorisation or change in use requires that prescribers and suppliers are informed immediately, but such information is also usually publicised in the media and online; hence patients are often aware of these actions and may present with requests for information and advice.

Unfortunately all spontaneous reporting systems, including the Yellow Card Scheme, suffer from severe under-reporting. A systematic review estimated this to be between 82% and 98% (Hazell and Shakir, 2006). There are a variety of reasons for under-reporting, including lack of certainty that the medicine caused the symptom, but it is important to emphasise that such certainty is not required. There is also no requirement to provide the patient name or contact details, only those of the actual reporter, hence confidentiality, also cited as a reason for under-reporting, is not an issue. Furthermore, the MHRA has systems in place to check for duplicate reports covering the same incident; therefore, concerns about two people submitting reports about the same event in a given patient is also not a valid reason for failing to report a suspected ADR.

Direct patient reporting

It is important to recognise that a patient is frequently the first person to suspect an ADR, and given there is no requirement for causality to be confirmed in order to submit a report about a suspected ADR, patients are capable of doing so themselves. Patient reports have been accepted by the FDA for many years; since October 2005 patients have been permitted to report directly to the MHRA, and increasingly other countries are allowing direct reporting. It has been suggested that direct reporting by patients has advantages such as faster signal generation, avoiding the filtering effect of interpretation of events by health professionals and, not least, maintaining the number of reports at a time when reporting by health professionals may be reducing.

Respondents to a survey of UK patient reporters indicated that facility to report was important and most had an understanding of the purpose of reporting. Many considered it provided an opportunity to influence the content of PILs, so that other patients may be better informed. However, there remains a need to further increase awareness of direct patient reporting amongst both the public and health professionals. Despite this limited awareness of the facility, people find it relatively easy to report suspected ADRs (McLernon et al., 2009). The majority of people who reported a suspected ADR identified it through issues relating to timing, as outlined in the causality methods used by pharmacovigilance experts, or by accessing information about

the medicine from the PIL (Krska et al., 2010). A comparison of the ADRs reported by patients and health professionals to the MHRA in the first 2 years of the scheme indicated that patient reports covered a wider range of drugs and ADRs than health professional reports, that patients were more likely to describe the impact of the ADR than health professionals, but that the proportion of serious reactions was similar between patients and health professionals (Avery et al., 2011). Overall, evaluations have concluded that patient reports make a useful contribution to pharmacovigilance.

Published case reports

In addition to reporting via the Yellow Card Scheme, practitioners may also report individual cases in the literature, especially when the event is previously unknown or unpredictable. As seen with thalidomide and practolol, astute and vigilant clinicians submitting case reports to the medical press has been of importance in drug safety. Case reports are less common than in the past and are now more likely to require that a causal link is established, or that a case series is gathered to form a more comprehensive article. Both this and the time taken to draft a case report for publication mean that this is a lesser used mechanism for identifying suspected ADRs. Interestingly case reports were cited as evidence in almost all 19 drug withdrawals which took place between 2002 and 2011 (McNaughton et al., 2014) and in 78% of all withdrawals between 1953 and 2013 (Onakpaya et al., 2016). It may take several months for a case report about a suspected ADR to be published, during which time more patients may be exposed to the potential risk. However, published case reports can alert others to the possibility of ADRs, which may encourage them to be more observant in their own practice.

Cohort studies

Cohort studies are prospective pharmacoepidemiological studies that monitor a large group of patients who are taking a particular drug over a period of time. Ideally such studies compare the incidence of a particular adverse event in two groups of patients: those taking the drug of interest and another group, matched for all important characteristics except the use of the drug. Such studies can indicate the relative risks associated with the adverse event in people exposed to the drug being studied. A very large cohort study conducted in Denmark followed women aged 15–49 years with no history of thrombotic disease from January 2001 to December 2009 to determine the proportion who developed a deep vein thrombosis in those who used oral contraception compared with those who did not (Lidegaard et al., 2011). This study found the relative risk of developing a deep vein thrombosis associated with oral contraception was 2.9 [95% confidence interval (CI): 2.2–3.8]. Another example of cohort studies being used to investigate suspected ADRs is the risk of bleeding with selective serotonin reuptake inhibitors (SSRIs). Four cohort studies included in a meta-analysis found the odds ratio (OR) for bleeding risk was 1.68 (95% CI: 1.13–2.50), which was similar to that found in 10 case-control studies (OR 1.66; 95% CI: 1.44–1.92) (Anglin et al., 2014).

Case-control studies

Case-control studies compare the extent of drug usage in a group of patients who have experienced the adverse event with the extent of usage among a matched control group who are similar in potentially confounding factors, but have not experienced the event. By comparing the prevalence of drug taking between the groups, it may be possible to identify whether significantly more people who experienced the event also took a particular drug. Examples of associations that have been established by case-control studies are Reye's syndrome and aspirin, and the relationship between maternal diethylstilboestrol ingestion and vaginal adenocarcinoma in female offspring. Case-control studies are an effective method of confirming whether a drug causes a given reaction once a suspicion has been raised through signal generation. Being retrospective, they rely on good record-keeping about drug use and alone are not capable of detecting previously unsuspected adverse reactions. They are particularly good at investigating rare adverse events.

Roles of health professionals

Ensuring medicines are used safely is fundamental to the role of all health professionals who prescribe, supply, administer, monitor or advise on medicines. When selecting a medicine for an individual patient, whether this is to be prescribed or sold, all health professionals should take account of all relevant patient factors, which may predispose to ADRs. As outlined earlier this includes comorbidities, concomitant drugs, renal and liver function, and genetic predisposition. Importantly it is invaluable to have information about the patient's ADR history. Studies have repeatedly shown that this is poorly documented, leading to inappropriate re-use of medicines which have previously caused problems. Hence another important role of all health professionals is documentation of identified ADRs. The patient may have information about this, if documentation is insufficient; therefore, questioning the patient about his or her ability to tolerate specific medicines or extracting a full ADR history should be considered at every opportunity.

Identifying and assessing adverse drug reactions in clinical practice

As well as being of importance for pharmacovigilance, the identification of potential ADRs is an essential component of clinical practice. Although such assessments may lack the formality of expert or algorithmic assessment, they are likely to take into account similar factors, such as whether the clinical event is commonly drug-related, the temporal relationship with drug use, a dose relationship and exclusion of other possible causes. A list of such factors is set out in [Box 5.1](#).

Many triggers could lead to the suspicion of an ADR – for example, changes in medicines, dose reduction, prescription of medicines used to treat allergic reactions or those frequently used to counteract the effects of other drugs. Simple questioning of patients could easily be incorporated into many aspects of routine care to increase the chances of detecting potential ADRs.

Box 5.1 Factors that may raise or suppress suspicions of a drug-induced event (Shakir, 2004)

The **temporal relationship** between the exposure to the drug and the subsequent event

The **clinical and pathological characteristics of the event** – events which are known to be related to drug use, rather than disease processes

The **pharmacological plausibility** – based on the observer's knowledge of pharmacology

Existing information in published drug information sources – whether the event has been noted by others

Concomitant medication – which may be considered the cause of an event

Underlying and concurrent illnesses – may alter the event or be considered the cause of the event

Dechallenge – disappearance of symptoms after dose reduction or cessation of therapy

Rechallenge – reappearance of symptoms after dose increases or recommencement of therapy

Patient characteristics and medical history – history of the patient may colour the view of the event

The potential for **drug interactions**

The process of identifying an ADR then involves making a judgement about whether a particular event, such as a symptom, condition or abnormal test result, could be related to a drug used in the patient who is experiencing the event. The prior experiences of the patient with other medicines should also be taken into consideration.

Every opportunity should be taken to question patients about their experiences, to determine whether they perceive any adverse events that could be due to medicines. While routinely asking simple questions is important, it is equally important to develop a positive attitude to patients' perceptions of suspected ADRs. There is some evidence that health professionals may dismiss patients who report that they have experienced an ADR, but recent work ([Krska et al., 2010](#)) shows that many patients identify such problems appropriately, using factors such as onset, effect of dose change, effect of dechallenge or even rechallenge, as well as the information sources freely accessible to them. To ascertain whether a symptom reported by a patient can be reasonably suspected of being an ADR requires careful questioning.

The key questions that health professionals need to ask may be summarised by the mnemonic SCOOTA. These cover:

Symptoms/severity: What exactly were the symptoms experienced and how severe are/were they?

Cause: What medicine do they suspect caused the symptoms?

Outcomes: Have the symptoms gone away, reduced or are they still causing problems?

Other causes: Could other medicines being taken, medical conditions or allergies explain the symptoms?

Timing: When did the symptoms start in relation to taking the medicine? Have they changed with changes in dose?

Actions: What actions have already been taken? Has the medicine been stopped? Has a health professional already been consulted?

As already stated, the MHRA encourages reporting of all serious suspected ADRs to established drugs and all suspected ADRs

to new drugs or vaccines. This is thus an important role for all health professionals. If not reporting themselves, health professionals should consider encouraging others to report instead. For example, a community pharmacist may have insufficient information to fully complete a Yellow Card, so he or she may encourage a primary care doctor to report or a hospital pharmacist may report on behalf of a consultant clinician. Encouraging others to report also extends to providing information about reporting and educating others, including patients, to report. Community pharmacies and primary care medical practices should all have a supply of Yellow Cards for patients, but patients may require advice and support in completing these. Pharmacists in particular, because of their role in dispensing prescriptions written by others, may also be involved in educating and supporting others in preventing ADRs and in developing methods for detecting ADRs through prescription monitoring.

Preventing adverse drug reactions

The majority of ADRs are theoretically preventable; hence there is potential to dramatically reduce the costs associated with ADRs and possibly also deaths. Assessing preventability is a difficult area because it involves judgements and many different methods have been developed for making these judgements. The method developed by Hallas et al. (1990) is widely used, providing definitions of 'avoidability' which range from definite (due to a procedure inconsistent with present-day knowledge or good medical practice) to unevaluable (poor data or conflicting evidence). Recent estimates suggest that 52% of ADRs seen at admission were preventable, and 45% (95% CI: 33–58%) of ADRs in in-patients were preventable (Hakkarainen et al., 2012). However, not all ADRs are absolutely preventable, and assessments using hindsight are unlikely to replicate clinical decision making at the point of prescribing. Preventability also varies; sometimes there are clear solutions, such as avoiding prescribing a teratogenic drug to a female of child-bearing age, but others, such as a drug that increases the risk of an event occurring within a population, are less easy to prevent.

ADRs can most easily be prevented by good clinical practice and rational drug use. This means ensuring that ADRs are fully documented and this information is transferred between care settings; checking a patient's previous ADR history before prescribing, dispensing or administering drugs; minimising the use of drugs known to carry a high risk of ADRs; and tailoring drug selection to individuals based on the factors that predispose them to ADRs. Many recent initiatives have the potential to minimise the burden of ADRs. Wider use of computer systems that incorporate clinical decision support, and improved transfer and sharing of information about patients between healthcare providers, including centrally stored electronic health records, should help to ensure more accurate drug histories and avoidance of inappropriate prescribing. In addition, the increasing availability of guidance on drug selection and appropriate use, combined with increasing regular review of medicines, should also help to increase rational prescribing, which may ultimately have an effect on the incidence of ADRs.

Monitoring therapy

Monitoring the effects of drugs, either by direct measurement of plasma concentrations or by measurements of physiological markers, is another potential mechanism to reduce the risk of ADRs. For example, it has been estimated that one in four preventable drug-related hospital admissions are caused by failure to monitor renal function and electrolytes (Howard et al., 2003).

There is good evidence that monitoring can be effective. Clozapine, used for the management of treatment-resistant schizophrenia and psychosis, is associated with significant risk of agranulocytosis. Mandatory monitoring of white blood cell counts has led to more than 90% of fatal agranulocytosis cases being prevented.

Ideally guidance on monitoring should be clear and provide an evidence-based frequency of monitoring and acceptable reference values. However, robust evidence for optimal monitoring frequency is limited for many drugs, hampering specific guidance, which tends to vary between various expert bodies and drug information sources. An examination of the adequacy of manufacturers' advice on monitoring for haematological ADRs found that advice was too vague to be useful to prescribers (Ferner et al., 2005).

Even when guidance is clear, monitoring can be neglected, although practitioners may take greater care when treating the elderly and those with more comorbidities (McDowell, 2010). The need for baseline parameters to be measured before drugs are started, such as liver function tests for statins, is often ignored; thus, changes due to drug treatment become difficult to confirm. Despite a clearly defined monitoring requirement, warfarin remains one of the top 10 drugs involved in drug-induced admissions.

Explaining risks to patients

Evidence shows that patients want to receive information about side effects; however, health professionals view providing side effect information with far less importance than the patients receiving it. One of the main sources of information about ADRs is clearly the PIL, which, in the EU, must be provided every time a medicine is prescribed or supplied. Ultimately patients then have to make a decision about whether to use the medicine, and health professionals are increasingly encouraged to involve patients in this decision. Therefore, patients have both a right to, and a need for, understandable information about the potential for harm that medicines may cause, to enable them to make informed decisions. Although there may still be debate about whether the provision of information on side effects encourages reduced adherence to taking medicines or spurious reporting of adverse effects, it is clear that this information is useful to patients and its availability has increased dramatically in recent decades in most countries. Patients often use the PIL when suspected adverse events are experienced to assist in assessing the cause of the problem; therefore, as outlined earlier, side effect information should be understandable and the EU requires that information leaflets are tested with patients prior to use to ensure this is the case.

Patients increasingly also access a wider range of information sources about medicines and about ADRs themselves; indeed they are actively encouraged to do so. SPCs are easily accessed by patients, as are the Drug Analysis Prints produced by the

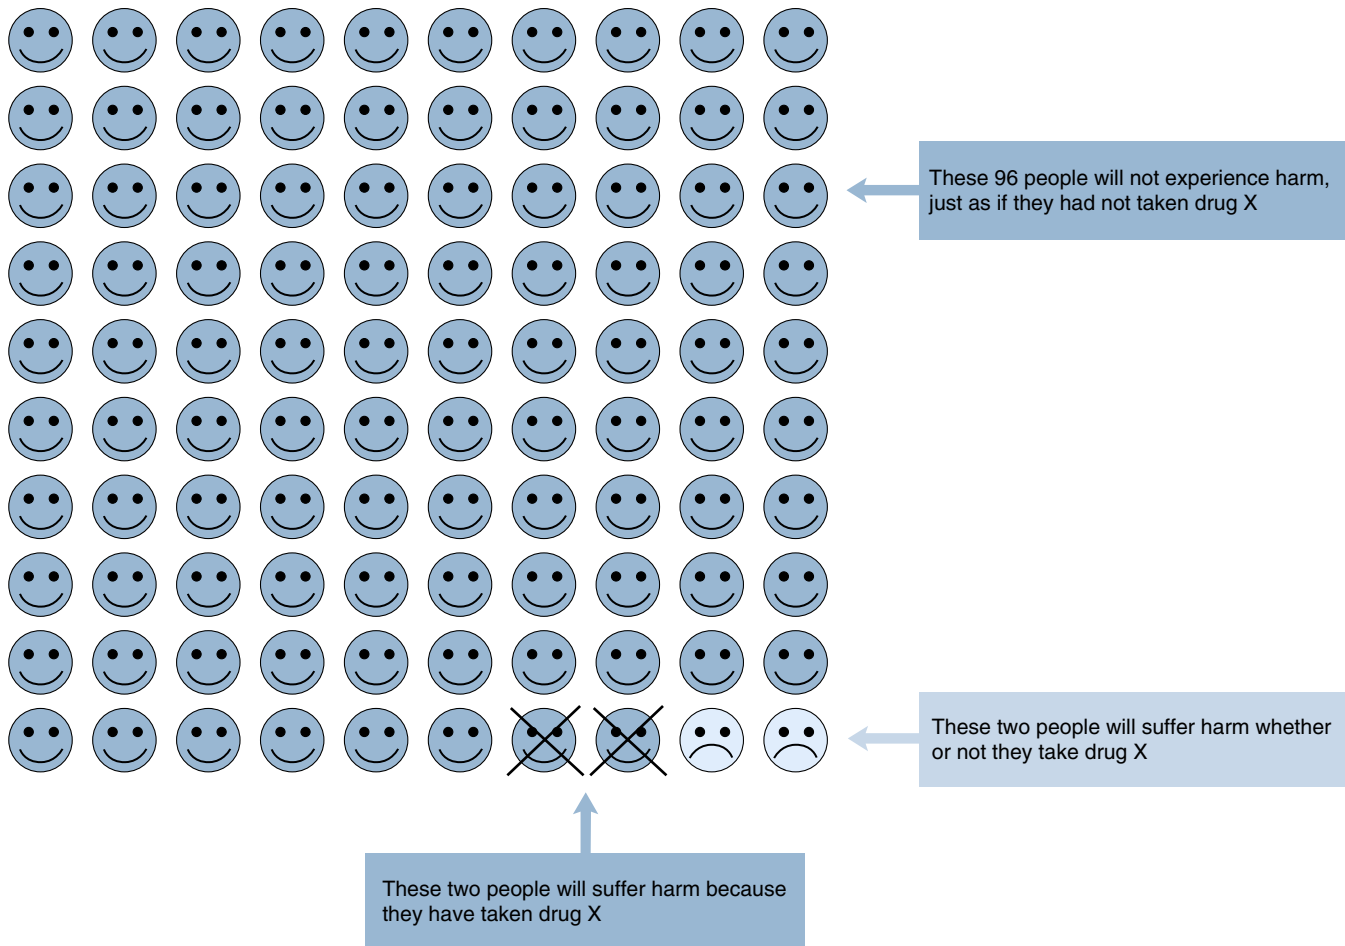

Fig. 5.1 A Cates plot in 100 people showing how drug X doubles the risk of an unspecified harm compared with no treatment. (From [Cox and Butt, 2012](#), with permission.)

MHRA, which summarise the data obtained from the Yellow Card reports they receive. Hence patients may question judgments about individual products they have been prescribed or sold. In this situation the health professional must be able to interpret information accessed by patients to ensure that the information they use to make decisions about whether to take a medicine is unbiased and accurate.

The EU recommends using verbal terms to describe the risk of experiencing an ADR, ranging from ‘very common’ (for rates of >1 in 10) to ‘very rare’ (for rates of <1 in 10,000). The MHRA advocates combining words with frequencies, for example, ‘Common (affects >1 in 100 persons)’. Studies show that patients tend to over-estimate the risk when these are described using words only and that patients differ in their understanding of what the terms mean. Percentages, particularly those less than 1%, are also not understood by everybody. This lack of understanding of the risks of experiencing ADRs can potentially reduce willingness to use the medicine.

Another approach is the use of pictures, such as faces, graphs or charts. One example is the ‘Paling palette’, which is a grid of 1000 stick figures (100×100) to convey information on the chances of experiencing a particular outcome. A similar method is a ‘Cates plot’, which is a grid of 100 faces (10×10), coloured differently

and either smiling or downcast, depending on the outcome. These types of icon grids are mainly used to convey the potential benefits and risks of a particular action, which can include the risk of getting a side effect. They are increasingly used in patient decision aids, now being produced by the National Institute for Health and Care Excellence (NICE). A generic example of a decision aid is shown in [Fig. 5.1](#). However, there are people who do not find these easy to understand ([Ancker et al., 2006](#)).

It is important to appreciate that, when communicating information about potential ADRs, how risks are perceived will be affected by the relationship between the health professional and the patient, the patient’s prior experiences and beliefs, how information is framed and the context in which it is given. Patients may also have views on the acceptability of ADRs, which should be taken into account when selecting a product for an individual. An ADR that is viewed as minor by health professionals may be considered to reduce quality of life by one patient, while another patient may be happy to accept this for the potential benefit the medicine offers. Even when drugs are withdrawn from the market for safety reasons, significant numbers of patients will feel they were willing to accept the harm-benefit of the drug. Communicating the harms and benefits of medicines is therefore an important role of health professionals.

Case studies

Case 5.1

Mr KM is a fairly active 69-year-old. He has regularly presented his repeat prescription for atenolol 50 mg daily, aspirin 75 mg daily and simvastatin 40 mg daily to the same community pharmacy for several years. Last month diltiazem SR 60 mg twice daily was added, as he had been experiencing increasing angina symptoms. He asks for a topical product to treat neck pain, which has developed in the last few days, which he puts down to a 'frozen shoulder'.

Questions

1. Could this be an ADR, and why did it develop now?
2. Is it appropriate to change to another statin?
3. What actions should the pharmacist take?

Answers

1. Neck pain, 'frozen shoulder' and such descriptions are typical of the muscular pain which is induced by statins. The onset varies from a few weeks to more than 2 years after starting treatment, the incidence is dose-related and the severity ranges from mild aches to severe pain, causing reduced mobility. Older people, who may have reduced renal function or liver function, are at greater risk of statin-induced myopathy.
Diltiazem can inhibit the metabolism of simvastatin because of its actions on cytochrome P450 isoenzyme CYP3A4, thereby increasing the risk of myopathy.
Statin-induced myopathy ranges from mild myopathies and myalgias, to myositis, to rare cases of potentially life-threatening rhabdomyolysis, in which muscle cell walls are disrupted and the contents leak into the systemic circulation. Muscle pain in patients who are taking statins should therefore always be taken seriously.
2. The problem is associated with all drugs in the class. Although simvastatin and atorvastatin, the most widely prescribed, are both lipophilic and metabolised by cytochrome P450 3A4 and, therefore, may be most likely to cause muscle pain, there is no reliable comparative data on different statins.
3. Creatinine kinase (CK) levels should have been measured before initiating statin therapy, but regardless of whether this was done, a CK level should be measured now, plus liver function tests. Mr KM's primary care doctor should be contacted to inform him about the suspected ADR, and the patient encouraged to report the ADR via the Yellow Card scheme. It may be appropriate to discontinue or reduce the dose of the simvastatin, depending on the result of the CK level and the severity of the symptoms. The problem may not resolve immediately on discontinuation. Because grapefruit juice can increase blood levels of simvastatin and high alcohol intake increases the risk of myopathy, the pharmacist should also warn Mr KM about avoiding these.

Case 5.2

Mr SC, a 39-year-old man who is taking varenicline for smoking cessation, reports that he has been suffering from vivid dreams and has become increasingly aggressive towards his family. Last night he had a major argument with his wife. His wife mentioned he had not been the same since he started the varenicline and he would like to know if this was a possible cause.

Questions

1. Is varenicline a possible cause of Mr SC's vivid dreams and aggression?
2. Is this a reportable ADR?

Answers

1. Varenicline has been associated with neuropsychiatric ADRs, including depression, suicidal thoughts, suicidal behaviour and aggression. Vivid dreams and other sleep disorders have also been reported. Prescribers have been warned that such reactions have been reported, although a meta-analysis and systematic review has questioned the association (Thomas et al., 2015). Assessing the cause of this reaction is difficult because smoking cessation itself is associated with exacerbations of underlying psychiatric illness and the risk of symptoms of depression. As varenicline dosing starts 1–2 weeks before stopping smoking, a key question is how long the patient has been taking the drug and if the symptoms appeared before the smoking cessation date.
2. If a health professional considers that a patient's symptoms are a possible ADR, then they should be reported to regulatory authorities (in the UK, this would be through the MHRA's Yellow Card scheme). Only a suspicion is necessary to report a reaction, not proven causality. In the case of new drugs, any reaction, no matter how trivial, should be reported. Patients can also report directly to regulatory authorities in some countries, including the UK. Neuropsychiatric reactions such as this are commonly reported by patients.

Case 5.3

Mr AG, a 65-year-old man with heart failure, is admitted to hospital with a potassium level of 7.1 mmol/L (range 3.4–5.0 mmol/L). Already stabilised on lisinopril 20 mg daily, he had recently been started on spironolactone 25 mg daily. He had a serum creatinine of 160 micromol/L (range 75–155 micromol/L).

Questions

1. What is the mechanism of any possible ADR?
2. How should future episodes of hyperkalaemia be avoided?

Answers

1. Spironolactone, an aldosterone receptor antagonist, has a beneficial effect on mortality and hospital admission in patients with heart failure. However, spironolactone can increase potassium serum levels because of its effect on aldosterone. When used in combination with angiotensin-converting enzyme inhibitors, serious hyperkalaemia can occur.
Although clinical trials of spironolactone showed no risk, cases have been reported in the literature, and other epidemiological studies have indicated that in real-world clinical situations the incidence of hyperkalaemia is increased (MHRA, 2016).
2. Care taken should be taken when prescribing spironolactone outside of trial criteria, particularly with regard to renal function. Other susceptibilities for the development of hyperkalaemia include diabetes and the elderly due to reduced aldosterone production. Changes in other therapy should be monitored, as well as episodes of acute illness. Those with mildly increased serum potassium should have a reduced dose of spironolactone. More intensive monitoring of potassium levels at the commencement of therapy might be useful, although the hyperkalaemia can occur months after initiation.

Case 5.4

Mrs KT, a 55-year-old woman attending a warfarin outpatient clinic, has a raised INR. On questioning it is discovered that she has recently started taking glucosamine for muscle aches for the last 2 weeks.

Questions

1. What is the likelihood that glucosamine was responsible for the rise in the INR?
2. Should this reaction be reported to regulatory authorities?

Answers

1. Glucosamine is a popular supplement purchased for 'joint health'. It is commonly used by older patients. Spontaneous reports of

interactions between warfarin and glucosamine have been submitted to UK, Australian and US regulators. Additional cases have been reported in the literature (Knudsen and Sokol, 2008). While there is no known mechanism and no formal interaction studies, the published cases and spontaneous reports are sufficient evidence to suggest a potential interaction. Given the wide use of glucosamine, the interaction may be rare, although under-reporting is common.

Assessment of this individual case requires further questioning to eliminate other confounding factors such as changes in diet or adherence issues.

2. Interactions with, or adverse reactions to, complementary and alternative remedies can be reported to spontaneous reporting schemes, such as the UK Yellow Card scheme. Collation of such reports allows regulators to gather further information on the suspected reaction and any susceptibilities that may in time provide useful information to other users.

Laboratory Data

John Warburton and Lee Beale

Key points

- Haematological and biochemical tests provide useful information for the diagnosis, screening, management, prognosis and monitoring of disease and its response to treatment.
- Reference ranges are important guides which generally represent the test values from 95% of the healthy population (mean \pm 2 standard deviations); however, interlaboratory difference will be observed.
- A series of values, rather than a single test value, is often required to ensure clinical relevance and eliminate erroneous values due to patient variation and analytical or sampling errors.
- A wide variety of intracellular enzymes may be released into the blood following damage to tissues such as hepatocytes and skeletal muscle. These can be measured in serum to provide useful diagnostic information. Commonly requested haematological test profiles include full blood count, differential white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), serum folate and vitamin B₁₂ and iron status, and clotting screen.
- Commonly requested biochemical test profiles include the so-called 'U and Es' (urea and electrolytes), liver function tests, troponins and C-reactive protein.
- Drug therapy can cause abnormal test results.
- Drugs can have an important role in preventing or treating abnormalities.

This chapter will consider the common haematological and biochemical tests that are of clinical and diagnostic importance. For convenience, each individual test will be dealt with under a separate heading, and a brief review of the physiology and pathophysiology will be given where appropriate to explain the basis of haematological and biochemical disorders.

It is usual for a reference range to be quoted for each individual test (see ranges at the start of each section). This range is based on data obtained from a sample of the general population served by the testing laboratory, which is assumed to be from healthy, disease-free individuals. The reference ranges in this chapter are intended as a guide only, and specific local reference ranges, particular to the type of assay, should be used in clinical practice. Many test values have a normal distribution, and the reference values are taken as the mean \pm 2 standard deviations (SD). This includes 95% of the population. The 'normal' range must always be used with caution because it takes little account of an individual's age, sex, weight, height, muscle mass or disease state, many of which variables can influence the value obtained. Although reference ranges are

valuable guides, they must not be used as sole indicators of health and disease. A series of values rather than a simple test value may be required in order to ensure clinical relevance and to eliminate erroneous values caused, for example, by spoiled specimens or interference from diagnostic or therapeutic procedures. Furthermore, a disturbance of one parameter often cannot be considered in isolation without looking at the pattern of other tests within the group.

Further specific information on the clinical and therapeutic relevance of each test may be obtained by referral to the relevant chapter in this book.

Haematology data

The haematology profile (Table 6.1) is an important part of the investigation of many patients and not just those with primary haematological disease. It is commonly termed the full blood count (FBC). The test is performed on a small quantity of anticoagulated blood; the anticoagulant used routinely is ethylenediaminetetraacetic acid (EDTA). The FBC gives information on the different cells that together form the blood – red blood cells (RBCs), platelets and WBCs – and their differentials. All of these cells are formed from the same multipotential stem cells within the bone marrow (Fig. 6.1). Cell production is under the control of a number of growth factors, including erythropoietin and colony stimulating factor (CSF); the coagulation screen gives information with regard to haemostasis. We will consider each of these in turn. Typical measurements reported in a haematology screen, with their normal values, are shown in Table 6.1, and a list of the common descriptive terms used in haematology is presented in Table 6.2.

Red blood cells

The main role of the RBC is to deliver oxygen to the tissues and remove carbon dioxide to the lungs. The oxygen and carbon dioxide are both carried by the haemoglobin molecules attached to the red blood cell.

Red blood cell count

RBCs are produced in the bone marrow by the process of erythropoiesis under the control of erythropoietin. Erythropoietin is produced predominantly in the kidney in response to a decrease in oxygen delivery. Erythropoietin stimulates the bone marrow

Table 6.1 Normal values in haematology

Laboratory test	Reference range	
FBC		
Haemoglobin	115–165 g/L	
White blood cell (WBC)	4.0–11.0 × 10 ⁹ /L	
Platelets	150–450 × 10 ⁹ /L	
Red blood cell (RBC)	3.8–4.8 × 10 ¹² /L	
Reticulocytes	50–100 × 10 ⁹ /L	
Packed cell volume (PCV)	0.36–0.46 L/L	
Mean cell volume (MCV)	83–101 FL	
Mean cell haemoglobin (MCH)	27–34 pg	
Mean cell haemoglobin concentration (MCHC)	31.5–34.5 g/dL	
WBC differential		
Cell type	Percentage of WBC count	
Neutrophils	40–75%	2.0–7.0 × 10 ⁹ /L
Lymphocytes	5–15%	1.5–4.0 × 10 ⁹ /L
Monocytes	2–10%	0.2–0.8 × 10 ⁹ /L
Basophils	<1%	<0.1 × 10 ⁹ /L
Eosinophils	1–6%	0.04–0.4 × 10 ⁹ /L
Coagulation		
PT	10–14 seconds	
APTT	35–45 seconds	
Fibrinogen	1.5–4 g/L	
APTT, activated partial thromboplastin time; FBC, full blood count; PT, prothrombin time; WBC, white blood cell.		

to produce more RBCs by the conversion of immature erythroblasts to mature erythrocytes which are released into the circulation. Prior to their release the RBCs shed the nucleus and adopt a biconcave disc shape. Normally, only non-nucleated mature erythrocytes are seen in the peripheral blood:

The lifespan of a mature RBC is usually between 110 and 120 days, and during this time it travels 300 miles through the circulatory system. A decrease in RBC lifespan, as, for instance, in haemolysis, reduces the circulating mass of RBCs, and with it the supply of oxygen to tissues is decreased. In these circumstances, RBC production is enhanced in healthy bone marrow by an increased output of erythropoietin by the kidneys. Under normal circumstances RBCs are destroyed by lodging in the spleen due to decreasing flexibility of the cells. They are removed by the reticuloendothelial system.

A high RBC count (erythrocytosis or polycythaemia) indicates increased production by the bone marrow and may occur as a physiological response to hypoxia, as in chronic airway disease, or as a malignant condition of RBCs, such as in polycythaemia rubra vera.

Reticulocytes

Reticulocytes are the earliest non-nucleated RBCs. They owe their name to the fine, net-like appearance of their cytoplasm, which can be seen, after appropriate staining, under the microscope and contain fine threads of ribonucleic acid (RNA) in a reticular network. Reticulocytes normally represent between 1% and 2% of the total RBC count and do not feature significantly in a normal blood profile. However, increased production (reticulocytosis) can be detected in times of rapid RBC regeneration, as occurs in response to haemorrhage or haemolysis. At such times the reticulocyte count may reach 40% of the RBCs. The reticulocyte count may be useful in assessing the response of the marrow to iron, folate or vitamin B₁₂ therapy. The count peaks at about 7–10 days after starting such therapy and then subsides.

Haemoglobin

The primary role of the RBC is to transport oxygen. The adult haemoglobin molecule is composed of four polypeptide chains, two alpha (α) and two beta (β). Contained within each of the four polypeptide chains is a haem molecule that consists of a ferrous iron (Fe²⁺) and protoporphyrin. It is the iron that binds reversibly with the oxygen.

It is the haemoglobin level that is of interest and the concentration in whole blood, measured in grams/litre (g/L). Haemoglobin levels are used as a marker of anaemia, when the concentration of haemoglobin is below that expected for the person's age and sex. The haemoglobin concentration in men is normally greater than in women, reflecting in part the higher RBC count in men. Lower concentrations in women are due, at least in part, to menstrual loss. Increased haemoglobin may reflect a polycythemia (reactive or neoplastic) or be due to dehydration.

In some relatively rare genetic diseases, the haemoglobinopathies, alterations in the structure of the haemoglobin molecule can be detected by electrophoresis. Abnormal haemoglobins which can be detected in this manner include HbS (sickle haemoglobin in sickle cell disease) and HbA₂ found in β-thalassaemia carriers.

Of note is that in 2013 the units of measurement of haemoglobin were standardised across Europe, with the units changing from grams/decilitre to grams/litre, a factor of 10 increase.

Fig. 6.1 The differentiation pathway of multipotent stem cells.

Mean cell volume

The mean cell volume (MCV) is the average volume of a single RBC and is measured in femtolitres (10^{-15} L). A RBC can be described as microcytic, normocytic or macrocytic, which are descriptive of a low, normal or high MCV, respectively. They are useful in the process of identification of various types of anaemia (Table 6.3).

Packed cell volume

The packed cell volume (PCV) or haematocrit is the ratio of the volume occupied by RBCs to the total volume of blood. It can be

measured by centrifugation of a capillary tube of blood and then expressing the height of RBCs in a capillary tube to the height of the total height of the blood column. It is reported as a fraction of unity or as a percentage (e.g. 0.45 L/L or 45%). The use of modern laboratory analysers has removed the need to directly measure the PCV. PCV is now derived from the multiplication of the MCV and RBC count. The PCV often reflects the RBC count and will, therefore, be decreased in bleeding or a dilution anaemia (where excess intravenous fluid has been given) and raised in polycythaemia. It may, however, be altered irrespective of the RBC count, when the size of the RBC is abnormal, as in macrocytosis and microcytosis.

Table 6.2 Descriptive terms in commonly used in haematology

Anisocytosis	Abnormal variation in cell size (usually refers to RBCs), e.g. red cells in iron deficiency anaemia
Agranulocytosis	Lack of granulocytes (principally neutrophils)
Aplastic	Depression of synthesis of all cell types in bone marrow (as in aplastic anaemia)
Basophilia	Increased number of basophils
Hypochromic	MCHC low, red cells appear pale microscopically
Leucocytosis	Increased white cell count
Leucopenia	Reduced white cell count
Macrocytic	Large cells
Microcytic	Small cells
Neutropenia	Reduced neutrophil count
Neutrophilia	Increased neutrophil count
Normochromic	MCHC normal; red cells appear normally pigmented
Pancytopenia	Decreased number of all cell types: it is synonymous with aplastic anaemia
Poikilocytosis	Abnormal variation in cell shape, e.g. some red cells appear pear shaped in macrocytic anaemias
Thrombocytopenia	Lack of platelets
MCHC, mean cell haemoglobin concentration.	

Table 6.3 Causes of anaemia according to mean cell volume

Low MCV (<83 fL)	Normal MCV (83–101 fL)	High MCV (>101 fL)
<i>Microcytic</i>	<i>Normocytic</i>	<i>Macrocytic</i>
<i>Iron deficiency</i>	<i>Acute blood loss</i>	<i>B₁₂ deficiency</i>
Thalassaemic disorders	Early iron deficiency	Folate deficiency
	Chronic renal insufficiency	Alcohol abuse
MCV, mean cell volume.		

Mean cell haemoglobin

The mean cell haemoglobin MCH is the average weight of haemoglobin contained in an RBC. It is measured in picograms (10^{-12} g) and is calculated from the relationship:

$$\text{MCH} = \frac{\text{haemoglobin}}{\text{RBC count}}$$

Box 6.1 Drugs known to cause platelet dysfunction

- Caffeine
- Colchicine
- Furosemide
- Hydroxychloroquine
- Hydralazine
- Nonsteroidal anti-inflammatory drugs
- Penicillin
- Theophylline
- Tricyclic antidepressants
- Vincristine

Cells with a reduced MCH will appear pale in comparison and are termed hypochromic, whereas those with a normal MCH are termed normochromic. The MCH is dependent on the size of the RBCs and the concentration of haemoglobin in the cells. Thus, it is usually low in iron-deficiency anaemia when there is microcytosis and there is less haemoglobin in each cell, but it may be raised in macrocytic anaemia.

Mean cell haemoglobin concentration

The mean cell haemoglobin concentration (MCHC) is a measure of the average concentration of haemoglobin per unit weight of RBCs. It is usually expressed as grams per litre but may be reported as a percentage. The MCHC will be reported as low in the same conditions that give rise to a low MCV and MCH, namely, iron-deficiency anaemia. A raised MCHC, in contrast, is associated with a range of congenital or acquired conditions. These include spherocytosis or in other congenital haemolytic anaemias, including sickle cell anaemia and haemoglobin C disease.

Platelets

Platelets (thrombocytes) are small disk-shaped cells formed in the bone marrow from megakaryocytes. Damage caused to the vascular endothelium is plugged by the aggregation of platelets to form an occlusive plug; they also act in the initiation of the coagulation process. Platelets are normally present in the circulation for 8–12 days.

A reduction in platelet number (thrombocytopenia) may reflect either a depressed synthesis in the marrow or consumption of formed platelets. A small fall in the platelet count may be seen in pregnancy and following viral infections. Severe thrombocytopenia may result in spontaneous bleeding. The short lifespan of a platelet is useful to bear in mind when evaluating a possible drug-induced thrombocytopenia because recovery should be fairly swift when the offending agent is withdrawn. An increased platelet count (thrombocytosis) occurs in malignancy, inflammatory disease and in response to blood loss.

The FBC will show the actual platelet count and gives no indication of platelet function. The function of platelets can be inhibited by many drugs (Box 6.1); the most commonly used is aspirin, which acts to inhibit the production of thromboxane A₂ for the life of the platelet.

Table 6.4 White blood cell differential

Granulocytes	Agranulocytes
Neutrophils	Lymphocytes
Eosinophils	Monocytes
Basophils	

White blood cell count

A haematology profile often reports a total WBC count and a differential count, the latter separating the composition of WBCs into the various types. WBCs (leucocytes) are of two types: the granulocytes and the agranulocytes (Table 6.4). Each of the different cells serves a particular function and will be reviewed individually in the following sections.

Neutrophils

Neutrophils or polymorphonucleocytes (PMNs) are the most abundant type of WBC. Neutrophils rapidly migrate to the sites of inflammation with the role of removing foreign material. At the site of inflammation, neutrophils engulf the foreign material through phagocytosis and the release of preformed granular enzymes to remove the pathogen. Neutrophils are formed in the bone marrow from stem cells which form myoblasts and develop through a number of stages to become a functional neutrophil. Neutrophils have a classical appearance of a multi-segmented nucleus and constitute approximately 40–75% of circulating WBCs in normal, healthy blood. They have a remarkably short lifespan with a circulating half-life of 6–8 hours and thus are produced at a high rate of up to 10×10^{10} cells per day. The neutrophil count increases in response to infection, tissue damage (e.g. infarction) and inflammation (e.g. vasculitis). Neutropenia, also described as agranulocytosis in its severest forms, is associated with malignancy and drug toxicity but may also occur in viral infections such as influenza, infectious mononucleosis and hepatitis.

The highly destructive capacity of neutrophils can lead to the damage of healthy tissues; this phenomenon is observed in inflammatory diseases such as inflammatory bowel disease and rheumatoid arthritis.

Basophils

Basophils normally constitute a small proportion of the WBC count (<1%). Their function is not well understood, but they play a role in parasitic infections and acute hypersensitivity reactions. They contain numerous vesicles within their cytoplasm that contain inflammatory mediators, including heparin and histamine. Basophilia is also observed in various malignant and pre-malignant disorders, including chronic myeloid leukaemia and myelofibrosis.

Eosinophils

Eosinophils normally constitute less than 6% of WBCs. Their function appears to be concerned with inactivation of

mediators released from mast cells, and eosinophilia is, therefore, apparent in many allergic conditions, such as asthma, hay fever and drug sensitivity reactions, as well as some malignant diseases.

Lymphocytes

Lymphocytes are the second most abundant WBCs in the circulating blood, but the majority of them are found in the spleen and other lymphatic tissue. They are formed in the bone marrow. An increase in lymphocyte numbers occurs particularly in viral infections such as rubella, mumps, infectious hepatitis and infectious mononucleosis.

Monocytes

Monocytes circulate in the blood and have a key role during inflammation and pathogen challenge. Monocytes enter the tissues and there undergo a transformation to macrophages. Macrophages are phagocytic cells which produce numerous inflammatory cytokines and act as accessory cells to T-lymphocytes by presenting antigens to them. A monocytosis is observed in some infections, such as typhoid, sub-acute bacterial endocarditis, infectious mononucleosis and tuberculosis.

Coagulation

The haemostatic system is a critical defense mechanism for protecting the vascular system. Haemostasis is activated within seconds of injury to the endothelium and can be considered in two stages. Primary haemostasis is the formation of the initial 'platelet plug', and secondary haemostasis is the formation of a fibrin clot. The formation of a stable fibrin clot was classically described as a coagulation cascade, a complex biochemical cascade where inactive coagulation factors, known as zymogens (non-enzymatic precursors), are activated to enzymes. Many of the coagulation factors are referred to by Roman numerals and depicted by suffixing the letter 'a' when activated. The cascade is formed of two independent cascades, the intrinsic and extrinsic pathways that culminate in the final common pathway (Fig. 6.2).

The current model of coagulation has been updated to better represent the *in vivo* activity (Hoffman and Monroe, 2001). The model consists of three overlapping steps: initiation, amplification and propagation. This cellular model of normal haemostasis is shown in Fig. 6.3. The initiation phase leads to small amounts of factor IIa (thrombin) being produced by cells containing tissue factor (TF) (e.g. smooth muscle or fibroblasts). The level of thrombin production is too low to convert fibrinogen to fibrin, requiring a second phase, amplification, leading to platelet activation at the site of injury. Thrombin cleaves the factor VIII/vWF complex and activates factors V, VIII and XI, which adhere to the platelets. The third phase is propagation where the activated platelets generate large amounts of thrombin to cleave fibrinogen into fibrin and form a crosslinked clot in conjunction with factor XIIIa. To prevent inappropriate propagation of the thrombus, the process is controlled by naturally occurring

Fig. 6.2 Classical coagulation cascade. Ca, calcium.

anticoagulants and the fibrinolytic system, the final effector of which is plasmin, which cleaves fibrin into soluble degradation products.

Despite the complexity of this model, the basic coagulation tests can still be interpreted in relation to the ‘intrinsic’, ‘extrinsic’ and ‘final common pathway’ components of the traditional cascade.

Monitoring coagulation

The standard laboratory screening test of coagulation includes the prothrombin time (PT), activated partial thromboplastin time (APTT) and fibrinogen level and is performed on citrated platelet-poor plasma. These tests do not reflect the complexity of haemostasis *in vivo* or the risk of bleeding and require interpretation in relation to clinical context.

Prothrombin time

The PT tests the extrinsic and common pathways and represents the time taken to fibrin strand formation in platelet-poor plasma and is reported in seconds. The PT is measured by adding calcium and thromboplastin (tissue factor and phospholipid) to citrated plasma. The PT clotting time depends on factors I (fibrinogen), II (prothrombin), V, VII and X and is prolonged by liver disease, disseminated intravascular coagulation (DIC) and vitamin K deficiencies (factors II, VII and X are vitamin K dependent). It is most commonly employed in the monitoring of warfarin anticoagulation therapy through the International Normalised Ratio (INR).

International Normalised Ratio

The normal range for the PT varies by laboratory, reagent and equipment configuration. The INR, unlike the PT, allows for the comparison of results from different laboratories, times and locations. The INR represents the ratio of the patient’s PT to a laboratory control PT obtained and the international sensitivity index (ISI) applied.

$$\text{INR} = \left[\frac{\text{patient's PT}}{\text{laboratory control PT}} \right]^{\text{ISI}}$$

The ISI is based on an international World Health Organization (WHO) reference thromboplastin reagent and represents the sensitivity of a given thromboplastin to the depression of factors II, VII and X. The more responsive a thromboplastin is to change, the lower its ISI value.

The target value varies according to the indication for the anticoagulant, but for most, including for thromboembolic prophylaxis in atrial fibrillation, it is 2.5. For some indications, including recurrent deep vein thrombosis and pulmonary embolism whilst on warfarin, the target is higher at 3.5.

The most common use of the PT and INR is to monitor oral anticoagulant therapy, but the PT is also useful in assessing liver function because of its dependence on the activity of clotting factors II, V, VII and X, which are produced in the liver.

Activated partial thromboplastin time

The activated partial thromboplastin time (APTT) tests the intrinsic and common pathways and is the time, in seconds, to fibrin formation. The APTT is measured by incubating platelet-poor

Fig. 6.3 The cell-based coagulation theory: (a) initiation, (b) amplification, (c) propagation. (Adapted from Bahuleyan, 2015.)

plasma with a phospholipid (a platelet substitute) and an activator such as kaolin. It is the lack of TF that distinguishes it from the PT. The sample is then recalcified, and the time to clot formation is the APTT. It is designed to detect deficiencies in factor VIII, IX and XI. It is the most common method for monitoring unfractionated heparin (UFH) therapy. The desirable APTT for optimal heparin therapy is between 1.5 and 2.5 times the normal control.

Low-molecular-weight heparins (LMWH) are commonly used for the prevention and treatment of venous thromboembolism, and because they provide more predictable anticoagulant activity than unfractionated heparin, it is not usually necessary to monitor them during treatment. Unlike with UFH, the APTT is considered suboptimal for monitoring LMWH. Anti-factor Xa is the gold standard and relates well with the concentration of LMWH in the blood, but it correlates less well with the effect of the drug in vivo. The APTT gives little indication of bleeding tendencies, as the presence of a lupus anticoagulant prolongs the APTT, but the patient has thrombotic tendencies. Factor XII deficiency gives rise to a long APTT but rarely a bleeding tendency.

Fibrinogen

The laboratory standard for the measurement of fibrinogen is the von Clauss assay. First, plasma is diluted to remove clotting inhibitors (e.g. heparin), and then a high concentration of thrombin is added, which allows comparison with controls to derive the fibrinogen concentration. The normal concentration in the blood (Table 6.1) varies between individuals and increases in inflammation because it is an acute-phase reactant. There is evidence to suggest that a level of over 1.0 g/L is required for sufficient clot stabilisation, and the British Committee for Standards in Haematology (BCSH) recommends the use of cryoprecipitate when fibrinogen is less than 1 g/L in severe bleeding.

Urea and electrolytes

The homeostasis of various elements, water and acid–base balance are interrelated. Standard biochemical screening includes several measurements (Table 6.5) which provide a picture of fluid and electrolyte balance and renal function. These are colloquially referred to as ‘U and Es’ (urea and electrolytes), and the major tests are described in the following sections.

Fluid homeostasis

In order to contextualise abnormal findings in urea and electrolyte levels, it is important to understand the movement of water in healthy individuals. Water constitutes approximately 60% of body weight in men and 55% in women (women have a greater proportion of adipose tissue, which contains little water). Approximately two-thirds of body water is found in the intracellular fluid (ICF) and one-third in the extracellular fluid (ECF), which is divided between the interstitial fluid and serum (Fig. 6.4). Total body water is regulated by the renal action of

antidiuretic hormone (ADH, sometimes referred to as vasopressin), the renin–angiotensin–aldosterone system, noradrenaline and by thirst, which is stimulated by rising plasma osmolality.

Water can permeate freely from the vascular compartment to the intracellular compartment via the interstitial space. Water and solutes pass through the capillary wall and the cell wall, two semipermeable membranes, to get from one to the other. Osmotic pressure in each compartment determines the direction of movement, with water moving from low to high solute concentration. Water movement reduces as the oncotic pressure between compartments equalises; that is, they become isotonic, which ensures normal cell membrane integrity and cellular processes.

The osmolality of the ECF is largely determined by sodium and its associated anions, chloride and bicarbonate, whereas the major contributor to the osmolality of the ICF is potassium. Glucose and urea have a lesser, but nevertheless important, role in determining

ECF osmolality. Protein, especially albumin, makes only a small (0.5%) contribution to the osmolality of the ECF but is a major factor in determining water distribution between the two compartments. The contribution of proteins to the osmotic pressure of serum is known as the colloid osmotic pressure or oncotic pressure.

Fluid balance

The amount of water taken in and lost by the body depends on intake, diet, activity and environmental conditions. Over time the intake of water is normally equal to that lost (Table 6.6). The minimum daily intake necessary to maintain this balance is approximately 1100 mL. Of this, 500 mL is required for normal excretion of waste products in urine, whereas the remaining volume is lost to insensible losses via the skin in sweat, via the lungs in expired air, and in faeces. The kidneys regulate water balance, with water being filtered, then reabsorbed in variable amounts depending primarily on the level of ADH.

An imbalance in the intake versus loss of water, without the intake or loss of the corresponding electrolytes, will result in changes to solute concentrations and hence osmolality. For example, a loss of water from the ECF will increase its osmolality and result in the movement of water from the ICF to the ECF. This increase in ECF osmolality will stimulate the hypothalamic thirst centres to encourage drinking while also stimulating the release of ADH, which promotes water reabsorption with subsequent concentration of the urine. The secretion of ADH is also

Table 6.5 Standard values for urea, electrolytes and associated tests

Laboratory test	Reference range
Urea and electrolytes (U & Es)	
Sodium	135–145 mmol/L
Potassium	3.4–5.0 mmol/L
Urea	3.1–7.9 mmol/L
Creatinine	75–155 mmol/L

stimulated by angiotensin II, baroreceptors, volume receptors, stress (including pain), exercise and drugs, including morphine, nicotine, tolbutamide, carbamazepine and vincristine.

Water depletion

Water depletion will occur if intake is inadequate or loss excessive. Excessive loss of water through the kidney is unusual, except in diabetes insipidus or following the overuse of diuretics.

Water depletion can occur with diarrhoea and increased sweating due to fever, amongst other reasons. Such a loss is usually compensated for, in the first instance by increasing water intake if the thirst mechanism is intact or can be acted upon, but this may not occur in patients who are unconscious, have swallowing difficulties or are disabled. Severe water depletion may induce cerebral dehydration causing confusion, fits, coma and circulatory failure.

The underlying cause for the water depletion should be identified and treated. Replacement water should be given orally, where possible, or by nasogastric tube, intravenously or subcutaneously as necessary. Fluid therapy should be individualised for each patient taking in to account both the need for water and supplementation of electrolytes. These requirements will dictate which fluid is prescribed from physiologically balanced solutions like compound sodium lactate to the very rarely used hypotonic solutions.

Water excess

Water excess is usually associated with an impairment of water excretion, such as that caused by renal failure or the syndrome of inappropriate secretion of the antidiuretic hormone arginine vasopressin (SIADH). This syndrome has several causes, including pneumonia and some tumours, particularly small cell carcinoma of the lung. Excess intake is rarely a cause of water excess because the healthy adult kidney can excrete water at a rate of up to 2 mL/min. Patients affected usually present with signs consistent with cerebral overhydration, although if it is of gradual onset, over several days, they may be asymptomatic.

Sodium

Sodium distribution

The body of an average 70-kg man contains approximately 3000 mmol of sodium. Most of this sodium is freely exchangeable and is extracellular. In contrast to the normal plasma concentration (Table 6.5), the ICF concentration of sodium is only about 10 mmol/L. The ECF volume is dependent upon total body sodium because sodium is almost entirely restricted to the ECF, and water intake and loss are regulated to maintain a constant concentration of sodium in the ECF compartment.

Sodium regulation

Each day approximately 1000 mmol of sodium is secreted into the gut and 25,000 mmol filtered by the kidney. The bulk of this is recovered by reabsorption from the gut and renal tubules. Sodium balance is maintained by renal excretion. Normally, 70% of filtered sodium is actively reabsorbed in the proximal tubule, with further

reabsorption in the loop of Henle. Less than 5% of the filtered sodium load reaches the distal tubule where aldosterone can stimulate further sodium reabsorption. It should be clear, therefore, that partial failure of homeostatic control can potentially have major consequences.

Other factors, such as natriuretic peptide hormone, can affect sodium reabsorption. This hormone is secreted by the cardiac atria in response to atrial stretch following a rise in atrial pressure associated with volume expansion. It is natriuretic (increases sodium excretion in urine) and, amongst other actions, reduces aldosterone concentration.

Hyponatraemia

Inadequate oral intake of sodium is rarely the cause of sodium depletion. A fall in the serum sodium level can be the result of sodium loss, inappropriate secretion of ADH or water retention in excess of sodium, usually resulting from defects in free water excretion caused by low ECF volume. Increased water intake without corresponding sodium, also known as a dilutional hyponatraemia, may also contribute and can occur with inappropriate parenteral treatment using hypotonic solutions.

Sodium depletion commonly occurs alongside water loss, resulting in dehydration or volume depletion. The normal response of the body to the resulting hypovolaemia includes an increase in aldosterone secretion (which stimulates renal sodium reabsorption) and an increase in ADH secretion if ECF volume depletion is severe. A number of drugs have also been implicated in causing hyponatraemia (Box 6.2).

Inappropriate secretion of ADH is the mechanism underlying many drug-induced hyponatraemias. In this syndrome, the drug may augment the action of endogenous ADH (e.g. tolbutamide or lamotrigine), increase the hypothalamic production of ADH (e.g. carbamazepine) or have a direct ADH-like action on the kidney (e.g. oxytocin or, more obviously, desmopressin). Hyponatraemia can also be induced by mechanisms different from those just described. Lithium may cause renal damage and a failure to conserve sodium. Likewise, the natriuretic action of diuretics can predispose to hyponatraemia.

Clinical features. Hyponatraemia can present asymptotically; however, vomiting, drowsiness, headache and seizures may

Box 6.2 Examples of drugs known to cause hyponatraemia

- Fosfomycin
- Lactulose
- Lithium
- Micafungin
- Oral contraceptives
- Phenytoin
- Sodium bicarbonate

be associated with rapid onset or severe hyponatraemia. These symptoms present as a result of cerebral oedema and raised intracranial pressure. Chronic hyponatraemia must be corrected slowly so as not to cause neurological damage as a result of pontine demyelination.

Hypernatraemia

Hypernatraemia, or sodium excess, can be a result of either increased intake or decreased excretion. Excessive intake is not a common cause, although hypernatraemia can be associated with excessive intravenous saline infusion or unreplaced hypotonic water excretion as a result of impaired access to free water or impaired thirst.

Sodium excess is usually attributable to impaired excretion. It may also be caused by a primary mineralocorticoid excess, for example, Cushing's syndrome or Conn's syndrome. However, it is often the result of a secondary hyperaldosteronism associated with, for example, heart failure, nephrotic syndrome, hepatic cirrhosis with ascites or renal artery stenosis. Sodium and water retention causes oedema.

Drug-induced hypernatraemia is either the result of a defect in ADH secretion (central diabetes insipidus) or poor response of the renal tubules to ADH (nephrogenic diabetes insipidus). The affected patient presents with polyuria, polydipsia or dehydration.

- Lithium causes a nephrogenic diabetes insipidus, which has been reported after only 2 weeks of therapy. The syndrome is usually reversible on discontinuation. Whilst affected, however, many patients are unresponsive to exogenous ADH.
- Demeclocycline can also cause diabetes insipidus and can be used in the management of patients with SIADH.
- Phenytoin generally has a less pronounced effect on urinary volume than lithium or demeclocycline and does not cause nephrogenic diabetes insipidus. It inhibits ADH secretion at the level of the central nervous system.

Hypernatraemia can be caused by a number of other drugs (Box 6.3) and by a variety of mechanisms; for example, hypernatraemia secondary to sodium retention is known to occur with corticosteroids, and the administration of sodium-containing drugs parenterally in high doses (e.g. benzylpenicillin) also has the potential to cause hypernatraemia.

Clinical features and management. The signs and symptoms of hypernatraemia are those associated with neuronal cell

shrinkage and include irritability, lethargy, confusion and seizures. It is likely that the patient may display signs consistent with the associated dehydration, including muscle weakness and orthostatic hypotension. Hypernatraemia should be corrected slowly: not more than half of the water deficit should be corrected in the first 12 to 24 hours.

Potassium

Potassium distribution

The total amount of potassium in the body, like sodium, is 3000 mmol. About 10% of the total body potassium is bound in RBCs, bone and brain tissue and is not exchangeable. The remaining 90% of total body potassium is free and exchangeable, with the vast majority having an intracellular location, being pumped in and out by Na/K-ATPase pumps. This is controlled by mechanisms aimed at ensuring stable intracellular to extracellular ratios and hence correct muscular and neuronal excitability. Only 2% of the exchangeable total body potassium is in the ECF, the compartment from where the serum concentration is sampled and measured. Consequently, the measurement of serum potassium is not an accurate index of total body potassium, but together with the clinical status of a patient, it permits a sound, practical assessment of potassium homeostasis.

Potassium regulation

The serum potassium concentration is controlled mainly by the kidney, with the gastro-intestinal tract normally having a minor role. The potassium filtered in the kidney is almost completely reabsorbed in the proximal tubule. Potassium secretion is largely a passive process in response to the need to maintain membrane potential neutrality associated with active reabsorption of sodium in the distal convoluted tubule and collecting duct. The extent of potassium secretion is determined by a number of factors, including:

- the amount of sodium available for exchange in the distal convoluted tubule and collecting duct;
- the availability of hydrogen and potassium ions for exchange in the distal convoluted tubule or collecting duct;
- the ability of the distal convoluted tubule or collecting duct to secrete hydrogen ions;
- the concentration of aldosterone;
- tubular fluid flow rate.

As described previously, both potassium and hydrogen can neutralise the membrane potential generated by active sodium reabsorption, and consequently, there is a close relationship between potassium and hydrogen ion homeostasis. In acidosis, hydrogen ions are normally secreted in preference to potassium, and potassium moves out of cells; thus, hyperkalaemia is often associated with acidosis, except in renal tubular acidosis. In alkalosis, fewer hydrogen ions will be present, potassium moves into cells and potassium is excreted; thus, hypokalaemia is often associated with alkalosis.

The normal daily dietary intake of potassium is of the order of 60–200 mmol, which is more than adequate to replace that lost

from the body. It is unusual for a deficiency in intake to account for hypokalaemia. A transcellular movement of potassium into cells, loss from the gut and excretion in the urine are the main causes of hypokalaemia.

Hypokalaemia

Transcellular movement into cells. The shift of potassium from the serum compartment of the ECF into cells accounts for the hypokalaemia reported following intravenous or, less frequently, nebulised administration of β -adrenoreceptor agonists such as salbutamol. Parenteral insulin also causes a shift of potassium into cells and is used for this purpose in the acute management of patients with hyperkalaemia. Catecholamines, for example, adrenaline and theophylline, also have this effect.

Loss from the gastro-intestinal tract. Although potassium is secreted in gastric juice, much of this, together with potassium ingested in the diet, is reabsorbed in the small intestine. Stools do contain some potassium, but in a patient with chronic diarrhoea or a fistula, considerable amounts of potassium may be lost and precipitate hypokalaemia. Likewise, the abuse of laxatives increases gastro-intestinal potassium loss and may precipitate hypokalaemia. Analogous to the situation with diarrhoea, the potassium secreted in gastric juice may be lost following persistent vomiting and can also contribute to hypokalaemia.

Loss from the kidneys. Mineralocorticoid excess, whether it be a result of primary or secondary hyperaldosteronism or Cushing's syndrome, can increase urinary potassium loss and cause hypokalaemia. Likewise, increased excretion of potassium can result from renal tubular damage. Nephrotoxic antibiotics such as gentamicin have been implicated.

Many drugs which can induce hypokalaemia do so by affecting the regulatory role of aldosterone upon potassium–sodium exchange in the distal tubule and collecting duct. Administered corticosteroids mimic aldosterone and can, therefore, increase potassium loss.

The most commonly used groups of drugs that can cause hypokalaemia are thiazide and loop diuretics. Both groups of drugs increase the amount of sodium delivered and available for reabsorption at the distal convoluted tubule and collecting ducts. Consequently, this will increase the amount of potassium excreted from the kidneys. Some of the drugs known to cause hypokalaemia are shown in [Box 6.4](#).

Clinical features and management. The patient with moderate hypokalaemia may be asymptomatic, but the symptoms of more severe hypokalaemia include muscle weakness, hypotonia, paralytic ileus, depression and confusion. Typical changes on the electrocardiogram (ECG) are ST depression, T wave depression/inversion and prolonged P–R interval, and as a result, cardiac arrhythmias may occur. Although hypokalaemia tends to make antiarrhythmic drugs less effective, the action of digoxin, in contrast, is potentiated, leading to increased signs of toxicity. Insulin secretion in response to a rising blood glucose concentration requires potassium, and this mechanism may be impaired in hypokalaemia. Rarely there may be impaired renal concentrating ability with polyuria and polydipsia.

Box 6.4 Examples of drugs known to cause hypokalaemia

- Amphotericin
- Aspirin
- Benzylpenicillin
- Corticosteroids
- Diuretics (loop and thiazide)
- Fluconazole
- Insulin
- Laxatives
- Piperacillin/tazobactam
- Salbutamol
- Sodium bicarbonate

Hypokalaemia is managed by giving either oral potassium or suitably dilute intravenous potassium solutions, depending on its severity and the clinical state of the patient.

Hyperkalaemia

Hyperkalaemia may arise from excessive intake, decreased elimination or a shift of potassium from cells to the ECF. It is rare for excessive oral intake to be the sole cause of hyperkalaemia. The inappropriate use of parenteral infusions containing potassium is probably the most common iatrogenic cause of excessive intake. Hyperkalaemia is a common problem in patients with renal failure because of their inability to excrete a potassium load.

The combined use of potassium-sparing diuretics such as amiloride or spironolactone with an angiotensin-converting enzyme (ACE) inhibitor, which will lower aldosterone, is a recognised cause of hyperkalaemia, particularly in the elderly. Mineralocorticoid deficiency states such as Addison's disease, where there is a deficiency of aldosterone, also decrease renal potassium loss and contribute to hyperkalaemia. Those at risk of hyperkalaemia should be warned not to take dietary salt (NaCl) substitutes in the form of potassium chloride (KCl).

The majority of body potassium is intracellular. Severe tissue damage, catabolic states or impairment of the energy-dependent sodium pump, caused by hypoxia or diabetic ketoacidosis, may result in apparent hyperkalaemia as a result of potassium moving out of, and sodium moving into cells. If serum potassium rises, insulin release is stimulated, which, through increasing activity in Na/K-ATPase pumps, causes potassium to move into cells. [Box 6.5](#) gives examples of some drugs known to cause hyperkalaemia.

Haemolysis during sampling or a delay in separating cells from serum will result in potassium escaping from blood cells into the serum causing an artefactual hyperkalaemia.

Clinical features and management. Hyperkalaemia can be asymptomatic but fatal. An elevated potassium level has many effects on the heart: notably the resting membrane potential is lowered and the action potential shortened. Characteristic changes of the ECG, reduced P wave and 'tented' T wave, precede ventricular fibrillation and cardiac arrest.

In the emergency management of a patient with hyperkalaemia (>6.5 mmol/L \pm ECG changes), calcium gluconate (or chloride) at a dose of 10 mL of 10% solution is given intravenously over 5 minutes. This does not reduce the potassium concentration but

Box 6.5 Examples of drugs known to cause hyperkalaemia

- Angiotensin-converting enzyme inhibitors
- β -Adrenoceptor blockers
- Ciclosporin

- Propofol
- Suxamethonium

antagonises the effect of potassium on cardiac tissue particularly sodium channels. Immediately thereafter, glucose 50 g with 20 units of soluble insulin by intravenous infusion will lower serum potassium levels within 30 minutes by increasing the shift of potassium into cells. Sodium bicarbonate, in the case of acidosis, will also promote cellular uptake of potassium.

The long-term management of hyperkalaemia may involve the use of oral or rectal polystyrene cation-exchange resins which remove potassium from the body. Chronic hyperkalaemia, in renal failure, is managed by a low-potassium diet.

Urea

The catabolism of dietary and endogenous amino acids in the body produces large amounts of ammonia. Ammonia is toxic, and its concentration is kept very low by conversion in the liver to urea. Urea is eliminated in urine and represents the major route of nitrogen excretion. Urea is filtered from the blood at the renal glomerulus and undergoes significant tubular reabsorption of 40–50%. This tubular reabsorption is pronounced at low rates of urine flow but is reduced in advanced renal failure. Serum urea is a less reliable marker of glomerular filtration rate (GFR) than creatinine. Urea levels vary widely with diet, rate of protein metabolism, liver production and the GFR. A high protein intake from the diet, tissue breakdown, major haemorrhage in the gut with consequent absorption of the protein from the blood, and corticosteroid therapy may produce elevated serum urea levels (up to 10 mmol/L). Urea concentrations of more than 10 mmol/L are usually a result of renal disease or decreased renal blood flow following shock or dehydration. As with serum creatinine levels, serum urea levels do not begin to increase until the GFR has fallen by 50% or more. Elevated urea levels can influence the protein binding of some drugs, such as phenytoin, leading to a greater free fraction.

Production is decreased in situations where there is a low protein intake and in some patients with liver disease. Thus, non-renal and renal influences should be considered when evaluating changes in serum urea concentrations.

Creatinine

Serum creatinine concentration is largely determined by its rate of production, rate of renal excretion and volume of distribution. It is frequently used to evaluate renal function.

Creatinine is produced at a fairly constant rate from creatinine and creatinine phosphate in muscle. Daily production is a function of muscle mass and declines with age from 24 mg/kg/day in a healthy 25-year-old to 9 mg/kg/day in a 95-year-old. Creatinine undergoes complete glomerular filtration with little reabsorption by the renal tubules. Its clearance is, therefore, usually a good indicator of the GFR. As a general rule, and only at the steady state, if the serum creatinine doubles this equates to a 50% reduction in the GFR and consequently renal function. The serum creatinine level can be transiently elevated following meat ingestion, but less so than urea, or strenuous exercise. Individuals with a high muscle bulk produce more creatinine and, therefore, have a higher serum creatinine level compared to an otherwise identical but less muscular individual.

The value for creatinine clearance is higher than the true GFR because of the active tubular secretion of creatinine. In a patient with a normal GFR, this is of little significance. However, in an individual in whom the GFR is low (<10 mL/min), the tubular secretion may make a significant contribution to creatinine elimination and overestimate the GFR. In this type of patient, the breakdown of creatinine in the gut can also become a significant source of elimination. Some drugs, including trimethoprim and cimetidine, inhibit creatinine secretion, possibly through competitive inhibition of active secretion, reducing creatinine clearance and elevating serum creatinine without affecting the GFR.

Measured and estimated GFR. GFR measured as the urinary or plasma clearance of an ideal filtration marker, such as inulin, is the best overall measure of kidney function, but techniques are complex and expensive. Urinary clearance of creatinine allows estimation of GFR, but blood sampling and timed urine collection have practical difficulty and are subject to error.

More commonly, laboratory-reported creatinine levels are accompanied by an estimated glomerular filtration rate. The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation is the recommended calculation for adults, giving the best all-around approximation of eGFR when compared with the Modification of Diet in Renal Disease (MDRD) formula. Both are adjusted for body surface area, unlike the Cockcroft-Gault equation (Jones, 2011).

Caution should be exercised when interpreting eGFR results over 60 mL/min/1.73 m² and in people with extremes of muscle mass. A reduced muscle mass will lead to overestimation; increased muscle mass to underestimation of the GFR. In patients with a low body mass index (BMI), and the elderly, the Cockcroft–Gault estimation of creatinine clearance remains a good alternative. The Schwartz formula is a widely used, and more appropriate, alternative for calculating GFR in children (Jones, 2011).

Magnesium

Magnesium is an essential cation, found primarily in bone, muscle and soft tissue, with around 1% of the total body content in the ECF. As an important cofactor for numerous enzymes and ATP, it is critical in energy-requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contraction, hormone secretion and in intermediary metabolism. Serum magnesium levels

are usually maintained within a tight range (0.7–1.0 mmol/L). Although a serum concentration of less than this usually indicates some level of magnesium depletion, serum levels may be normal in spite of low intracellular magnesium due to magnesium depletion. Hypocalcaemia is a prominent manifestation of moderate to severe magnesium deficiency in humans.

Hypomagnesaemia

Hypomagnesaemia is frequently seen in critically ill patients. Causes include excessive gastro-intestinal losses, renal losses, surgery (particularly oesophageal), trauma, infection, malnutrition and sepsis. The drugs most likely to induce significant hypomagnesaemia are cisplatin, amphotericin B and ciclosporin, but it is also a potential complication of treatment with aminoglycosides, laxatives, pentamidine, tacrolimus and carboplatin. A hypomagnesaemic effect of furosemide and hydrochlorothiazide is questionable, and routine monitoring and treatment are not required. Use of digoxin has been associated with hypomagnesaemia, possibly by enhancing magnesium excretion, which may predispose to digoxin toxicity, for example, dysrhythmias.

Manifestations of hypomagnesaemia may include muscle tremor, cardiac arrhythmia, loss of appetite and fatigue. Where treatment is indicated, oral supplements are available, but because of their slow onset of action and gastro-intestinal intolerance, the intravenous route is often preferred and especially in critically ill patients with severe symptomatic hypomagnesaemia.

Hypermagnesaemia

Hypermagnesaemia is most commonly caused by renal insufficiency and excess iatrogenic magnesium administration. It may remain undetected for some time as around 80% remain asymptomatic. Bradycardia, uncharacteristic ECG changes, hypotension and nausea and vomiting have been described in some cases.

Liver profile and associated tests

Routine liver function tests (LFTs), shown in Table 6.7, give information regarding the activity or concentrations of enzymes and compounds in serum, rather than quantifying specific hepatic functions. Therefore they must be interpreted in the context of the patient's characteristic and the pattern of the abnormalities. Results are useful in confirming or excluding a diagnosis of clinically suspected liver disease and monitoring its course.

Serum albumin levels and prothrombin time (PT) indicate hepatic protein synthesis; bilirubin is a marker of overall liver function. Transaminase levels indicate hepatocellular injury and death, whereas alkaline phosphatase levels estimate the amount of impedance of bile flow.

Bilirubin

At the end of their life, RBCs are broken down by the reticuloendothelial system, mainly in the spleen. The liberated haemoglobin molecules are split further into globin and haem. The

Table 6.7 Standard values in a liver profile

Laboratory test	Reference range
Liver function tests	
Albumin	34–50 g/L

AST	<35 U/L
ALP	35–120 U/L
Amylase	<100 U/L
γ-GT	<70 U/L
Associated tests	
Ammonia	Male: 15–50 mmol/L Female: 10–40 mmol/L
ALT, alanine transaminase; AST, aspartate transaminase; ALP, alkaline phosphatase; γ-GT, gamma-glutamyl transpeptidase.	

globin enters the general protein pool, the iron in haem is recycled, and the remaining tetrapyrrole ring of haem is degraded to bilirubin. Unconjugated bilirubin is lipophilic and is transported to the liver tightly bound to albumin. Unconjugated hyperbilirubinaemia in adults is most commonly the result of haemolysis, or Gilbert's syndrome resulting from genetic defects in UDP-glucuronyltransferase. It is actively taken up by hepatocytes, conjugated with glucuronic acid and excreted into bile. The conjugated bilirubin is water soluble and secreted rapidly into the gut, where it is broken down by bacteria into urobilinogen, a colourless compound, which is subsequently oxidised in the colon to urobilin, a brown pigment excreted in faeces. Some of the urobilinogen is absorbed, and most is subsequently re-excreted in bile (enterohepatic circulation). A small amount is absorbed into the systemic circulation and excreted in urine, where it too may be oxidised to urobilin. The presence of increased conjugated bilirubin is usually a sign of liver disease.

The liver produces 300 mg of bilirubin each day. However, because the mature liver can metabolise and excrete up to 3 g daily, serum bilirubin concentrations are not a sensitive test of liver function. As a screening test they rarely do other than confirm the presence or absence of jaundice. In chronic liver disease, however, changes in bilirubin concentrations over time do convey prognostic information.

An elevation of serum bilirubin concentration above 50 mmol/L (i.e. approximately 2.5 times the normal upper limit) will reveal itself as jaundice, seen best in the sclerae and skin. Elevated bilirubin levels can be caused by increased production of bilirubin (e.g. haemolysis, ineffective erythropoiesis), impaired transport into hepatocytes (e.g. interference with bilirubin uptake by drugs such as rifampicin or as a result of hepatitis), decreased excretion (e.g. with drugs such as rifampicin and

methyltestosterone, intrahepatic obstruction caused by cirrhosis, tumours) or a combination of these factors.

The bilirubin in serum is normally unconjugated and bound to protein; it is not filtered by the glomeruli and does not normally appear in the urine. Bilirubin in the urine (bilirubinuria) is usually the result of an increase in serum concentration of conjugated bilirubin and indicates an underlying pathological disorder.

Enzymes

The enzymes measured in routine LFTs are listed in Table 6.7. Enzyme concentrations in the serum of healthy individuals are normally low. When cells are damaged, increased amounts of enzymes are detected as the intracellular contents are released into the blood.

It is important to remember that the assay of 'serum enzymes' is a measurement of catalytic activity and not actual enzyme concentration and that activity can vary depending on assay conditions. Consequently, the reference range may vary widely between laboratories.

While the measurement of enzymes may be very specific, the enzymes themselves may not be specific to a particular tissue or cell. Many enzymes arise in more than one tissue, and an increase in the serum activity of one enzyme can represent damage to any one of the tissues which contain the enzymes. In practice, this problem may be clarified because some tissues contain two or more enzymes in different proportions, which are released on damage. For example, alanine and aspartate transaminase both occur in cardiac muscle and liver cells, but their site of origin can often be differentiated because there is more alanine transaminase in the liver than in the heart. In those situations where it is not possible to look at the relative ratio of enzymes, it is sometimes possible to differentiate the same enzyme from different tissues. Such enzymes have the same catalytic activity but differ in some other measurable property and are referred to as isoenzymes.

The measured activity of an enzyme will be dependent on the time it is sampled relative to its time of release from the cell. If a sample is drawn too early after a particular insult to a tissue, there may be no detectable increase in enzyme activity. If it is drawn too late, the enzyme may have been cleared from the blood.

Transaminases

The two transaminases of diagnostic use are aspartate transaminase (AST), also known as aspartate aminotransferase, and alanine transaminase (ALT), also known as alanine aminotransferase. These enzymes catalyse the transfer of α -amino groups from aspartate and alanine to the α -keto group of ketoglutaric acid to generate oxaloacetic and pyruvic acid. They are found in many body tissues, with the highest concentration in hepatocytes and muscle cells. In the liver, ALT is localised solely in cytoplasm, whereas AST is cytosolic and mitochondrial.

Serum AST levels are increased in a variety of disorders, including liver disease, crush injuries, severe tissue hypoxia, myocardial infarction, surgery, trauma, muscle disease and pancreatitis. ALT is elevated to a similar extent in the disorders listed which involve the liver, although to a much lesser extent in the other disorders, making it more specific for liver damage. In the

context of liver disease, increased transaminase activity indicates deranged integrity of hepatocyte plasma membranes and/or hepatocyte necrosis. They may be raised in all forms of viral and non-viral, acute and chronic liver disease, most markedly in acute viral, drug-induced (e.g. paracetamol poisoning), alcohol-related and ischaemic liver damage. Non-alcoholic fatty liver disease is now the most common cause of mild alteration of aminotransferase levels in the developed world.

Alkaline phosphatase

Alkaline phosphatase is an enzyme which transports metabolites across cell membranes. Alkaline phosphatases are found in the canalicular plasma membrane of hepatocytes, in bone where they reflect bone building or osteoblastic activity, and in the intestinal wall and placenta, kidneys and leucocytes. Hepatic alkaline phosphatase is also present on the surface of bile duct epithelia. Each site of origin produces a specific isoenzyme of alkaline phosphatase, which can be electrophoretically separated if concentrations are sufficiently high.

Disorders of the liver which can elevate alkaline phosphatase include intra- or extra-hepatic cholestasis, space-occupying lesions (e.g. tumour or abscess) and hepatitis. Drug-induced liver injury, for example, by ACE inhibitors or oestrogens, may present with a cholestatic pattern, that is, a preferential increase in alkaline phosphatase.

Physiological increases in serum alkaline phosphatase activity can also occur in pregnancy, as a result of release of the placental isoenzyme, and during periods of growth in children and adolescents when the bone isoenzyme is released.

Pathological increases in serum alkaline phosphatase of bone origin may arise in disorders such as osteomalacia and rickets, Paget's disease of bone, bone tumours, renal bone disease, osteomyelitis and healing fractures. Alkaline phosphatase is also raised as part of the acute-phase response; for example, intestinal alkaline phosphatase may be raised in active inflammatory bowel disease. If in doubt, the origin of the enzyme can be indicated by assessment of γ -glutamyl transpeptidase or electrophoresis to separate alkaline phosphatase isoenzymes.

γ -Glutamyl transpeptidase

γ -Glutamyl transpeptidase (gamma GT), also known as γ -glutamyl transferase, is present in high concentrations in the liver, kidney and pancreas, where it is found within the endoplasmic reticulum of cells. It is a sensitive indicator of hepatobiliary disease but does not differentiate a cholestatic disorder from hepatocellular disease. It can also be elevated in alcoholic liver disease, hepatitis, cirrhosis and non-hepatic disease such as pancreatitis, heart failure, chronic obstructive pulmonary disease and renal failure.

Serum levels of γ -glutamyl transpeptidase activity can be raised by enzyme induction by certain drugs, such as phenytoin, phenobarbital, rifampicin and oral contraceptives.

Serum γ -glutamyl transpeptidase activity is usually raised in an individual with alcoholic liver disease. However, it can also be raised in heavy drinkers of alcohol who do not have liver damage, as a result of enzyme induction. Its activity can remain elevated for up to 4 weeks after stopping alcohol intake.

Although it lacks specificity, it has a high sensitivity for liver disease and is thus useful for identifying the cause of a raised alkaline phosphatase level.

Albumin

Albumin is quantitatively the most important protein synthesised in the liver, with 10–15 g/day being produced in a healthy man. About 60% is located in the interstitial compartment of the ECF, with the remainder in the smaller, but relatively impermeable, serum compartment where it is present at a higher concentration. The concentration in the serum is important in maintaining its volume because it accounts for approximately 80% of serum colloid osmotic pressure. A reduction in serum albumin concentration often results in oedema as a result of fluid redistribution into the extravascular compartment.

Many molecules bind to albumin including calcium, bilirubin and many drugs (e.g. warfarin and phenytoin), and assays of these may need adjusting as a result. A reduction in serum albumin will increase free levels of agents which are normally bound, and adverse effects can result if the 'free' entity is not rapidly cleared from the body.

The serum concentration of albumin depends on its rate of synthesis, volume of distribution and rate of catabolism. Synthesis falls in parallel with increasing severity of liver disease or in malnutrition states where there is an inadequate supply of amino acids to maintain albumin production. Synthesis also decreases in response to inflammatory mediators such as interleukin. A low serum albumin concentration will occur when the volume of distribution of albumin increases, as happens, for example, in cirrhosis with ascites, in fluid-retention states such as pregnancy or where a shift of albumin from serum to interstitial fluid causes dilutional hypoalbuminaemia after parenteral infusion of excess protein-free fluid. The movement of albumin from serum into interstitial fluid is often associated with increased capillary permeability in postoperative patients or those with septicæmia.

Other causes of hypoalbuminaemia include catabolic states associated with a variety of illnesses and increased loss of albumin, either in urine from damaged kidneys, as occurs in the nephrotic syndrome, or via the skin following burns or a skin disorder such as psoriasis, or from the intestinal wall in a protein-losing enteropathy. The finding of hypoalbuminaemia and no other alteration in liver tests virtually rules out hepatic origin of this abnormality.

Albumin's serum half-life of approximately 20 days precludes its use as an indicator of acute change in liver function, but levels are of prognostic value in chronic disease.

An increase in serum albumin is rare and can be iatrogenic, for example, inappropriate infusion of albumin, or the result of dehydration or shock.

A shift of protein is known to occur physiologically when moving from lying down to the upright position. This can account for an increase in the serum albumin level of up to 10 g/L and can contribute to the variation in serum concentration of highly bound drugs which are therapeutically monitored.

Table 6.8 Normal values for calcium and phosphate

Laboratory test	Reference range
Calcium (total adjusted)	2.12–2.60 mmol/L
Calcium (ionised)	1.19–1.37 mmol/L
Phosphate	0.80–1.44 mmol/L

Amylase

The pancreas and salivary glands are the main producers of the digestive enzyme amylase. The serum amylase concentration rises within the first 24 hours of an attack of pancreatitis and then declines to normal over the following week. Although a number of abdominal and extra-abdominal conditions, including loss of bowel integrity through infarction or perforation, chronic alcoholism, postoperative states and renal failure, can result in a high amylase activity, in patients with the clinical picture of severe upper abdominal symptoms the specificity and sensitivity of an amylase level over 1000 U/L in the diagnosis of pancreatitis is more than 90%. There is a lack of prognostic significance of absolute values of amylase because values are directly related to the degree of pancreatic duct obstruction and inversely related to the severity of pancreatic disease.

Ammonia

The concentration of free ammonia in the blood is very tightly regulated and is exceeded by two orders of magnitude by its derivative, urea. The normal capacity for urea production far exceeds the rate of free ammonia production by protein catabolism under normal circumstances, such that any increase in free blood ammonia concentration is a reflection of either biochemical or pharmacological impairment of urea cycle function or fairly extensive hepatic damage. Clinical signs of hyperammonaemia occur at concentrations greater than 60 mmol/L and include anorexia, irritability, vomiting, somnolence, disorientation, asterixis, seizures, cerebral oedema, coma and death; the appearance of these findings is generally proportional to free ammonia concentration. Causes of hyperammonaemia include genetic defects in the urea cycle and disorders resulting in significant hepatic dysfunction. Ammonia plays an important role in the increase in brain water, which occurs in acute liver failure. Measurement of the blood ammonia concentration in the evaluation of patients with known or suspected hepatic encephalopathy can help in diagnosis and assessing the effect of treatment. Valproic acid can induce hyperammonaemic encephalopathy as one of its adverse neurological effects.

Calcium and phosphate

Calcium

Calcium distribution

The regulation of calcium and regulation of phosphate levels, whilst measured independently (Table 6.8), are undoubtedly interrelated. An adult contains around 1000 g of calcium, and

Fig. 6.5 Approximate distribution of calcium in a 70-kg adult.

Box 6.6 Formula for correction of total serum calcium concentration for changes in albumin concentration

For albumin < 40 g/L
 Corrected calcium = $[Ca] + 0.02 \times (40 - [alb])$ mmol/L

Albumin concentration = [alb] (albumin units = g/L);
 calcium concentration = [Ca] (total calcium units = mmol/L)

Box 6.7 Drugs that are known to cause hypercalcaemia

- Thiazide diuretics
- Lithium
- Theophylline
- Tamoxifen
- Calcium supplements

more than 99% of this is bound within bone. Total calcium in the plasma is made up of ionised (which is free and biologically active), protein bound (predominantly to albumin but also to globulin) and complexed to anions like phosphates, sulphates, lactate and citrate (Fig. 6.5).

Calcium regulation

Calcium metabolism is regulated by parathyroid hormone (PTH), secreted by the parathyroid glands in response to a fall in serum calcium. PTH acts on the kidneys to increase tubular calcium reabsorption and bone resorption by activation of osteoclasts. PTH also stimulates the release of dihydroxycholecalciferol (vitamin D), which promotes gastro-intestinal absorption of calcium from the duodenum. PTH is under negative feedback control: as calcium increases, PTH decreases.

The serum calcium level is often determined by measuring total calcium, that is, both free and bound calcium. Normal values can be seen in Table 6.8. Changes in albumin can result in changes of the total calcium concentration while the ionised calcium remains unchanged. Therefore, measurement of free ionised calcium is important. Decreased total calcium with normal ionised calcium is referred to as pseudohypocalcaemia. Various equations are available to estimate the calcium concentration, and many laboratories report total and adjusted calcium routinely. A commonly used formula is shown in Box 6.6. Caution must be taken when using such a formula in the presence of disturbed blood hydrogen ion concentrations.

Acid–base balance plays a role in ionised calcium levels; alkalosis decreases ionised calcium levels, as hydrogen ions dissociate from albumin, and calcium binding to albumin increases, together with an increase in complex formation. If the concentration of ionised calcium falls sufficiently, clinical symptoms of

hypocalcaemia may occur despite the total serum calcium concentration being unchanged. The reverse effect, that is, increased ionised calcium, occurs in acidosis.

Hypercalcaemia

Hypercalcaemia may be caused by a variety of disorders, the most common being primary hyperparathyroidism, often a single adenoma secreting excess PTH. Hypercalcaemia can also be as a result of malignancy, for example, in multiple myeloma or bony metastases as a result of increased osteoclast activity leading to increased bone resorption. However, in squamous carcinoma of the bronchus, hypercalcaemia occurs as a result of a peptide with PTH-like activity that is released by the tumour. Hypercalcaemia is also observed in thyrotoxicosis, vitamin A, vitamin D intoxication and sarcoidosis. PTH measurement can be pivotal in the establishment of the cause of hypercalcaemia. Drugs that can cause hypercalcaemia are shown in Box 6.7.

An artefactual increase in total serum calcium may sometimes be seen as a result of a tourniquet being applied during venous sampling. The resulting venous stasis may cause redistribution of fluid from the vein into the extravascular space, and the temporary haemoconcentration will affect albumin levels.

Clinical features and management. Hypercalcaemia can present with symptoms of general malaise, depression, bone pain, abdominal pain and renal stones and is classically described by ‘moans, stones, groans and bones’. Mild hypercalcaemia ($Ca^{2+} < 3$ mmol/L) is often asymptomatic.

Management of acute hypercalcaemia involves correction of any dehydration with intravenous fluid (sodium chloride 0.9%). Following rehydration intravenous bisphosphonates, for example, zoledronic acid or pamidronate, are given to inhibit bone

Box 6.8 Drugs that are known to cause hypocalcaemia

- Aminoglycosides
- Bisphosphonates
- Calcitonin
- Caspofungin
- Cisplatin
- Denosumab
- Furosemide
- Phenobarbital
- Phenytoin

turnover. Further treatment options include glucocorticoids (inhibit 1,25-[OH]₂D₃ production) or calcitonin.

Hypocalcaemia

Hypocalcaemia occurs mainly as a result of disorders of PTH or vitamin D. Inadequate intake of oral calcium is rarely the cause, whereas absorptive hypocalcaemia can occur as a result of dietary insufficiency of vitamin D or impaired production of vitamin D as seen in chronic kidney disease. Hypoparathyroidism, as a result of surgery or autoimmune conditions, results in decreased PTH production, which can be a cause of hypocalcaemia. Other causes include pancreatitis, reduced exposure to sunlight, acid–base disturbance and hypoalbuminaemia. Drugs that have been implicated as causing hypocalcaemia are shown in **Box 6.8**.

Clinical features. Hypocalcaemia results in increased excitability of nerves. It can present with numbness, commonly around the mouth and in the peripheries; later signs include cramps, tetany, convulsions and death.

Phosphate

Phosphate distribution

An adult contains around 700 g of phosphate, and 85% is in bone, where it is complexed with calcium. Phosphate is an intracellular anion, and its concentration is 100-fold higher than in the plasma.

Phosphate regulation

Phosphorus is an essential element and has roles in cell structure, cellular metabolism (ATP generation), cellular signalling, bone mineralisation and acid–base balance. Serum levels are regulated by absorption from the diet (both passive and active uptake). Vitamin D increases active absorption from the gut and bone, whereas PTH controls excretion by the kidneys and resorption from bone. Fibroblast growth factor 23, a phosphatonin, is released in response to hyperphosphatemia and reduces renal reabsorption of phosphate.

Hyperphosphataemia

Hyperphosphataemia occurs in chronic renal failure and is reduced by dietary phosphate binders. Less common causes are secondary to rhabdomyolysis, tumour lysis or severe haemolysis. Hyperphosphataemia can cause hypocalcaemia as a result

Table 6.9 Standard values of inflammatory markers

Laboratory test	Reference range
Erythrocyte sedimentation rate (ESR)	Younger adults <15 mm/h Male over 50 <20 mm/h Female over 50 <30 mm/h
C-reactive protein (CRP)	<5 mg/L
Procalcitonin	<0.05 ng/mL

of binding of calcium to phosphate. Treatment of hyperphosphataemia requires identification and correction of the underlying cause.

Hypophosphataemia

Severe hypophosphataemia can cause general debility, anorexia, anaemia, muscle weakness and wasting and some bone pain and skeletal wasting. Because phosphorus is ubiquitous in various foods, inadequate dietary phosphorus intake requires near starvation. Refeeding of those recovering from energy depletion, as a result of alcoholic bouts or diabetic ketoacidosis without adequate provision of phosphorus, can precipitate hypophosphataemia.

Inflammatory markers

The inflammatory process can be measured using a number of biochemical markers, including erythrocyte sedimentation rate, C-reactive protein and procalcitonin (**Table 6.9**).

Erythrocyte sedimentation rate

The erythrocyte sedimentation rate (ESR) is a measure of the settling rate of RBCs in a sample of anticoagulated blood, over a period of 1 hour, in a cylindrical tube. The ESR strongly correlates with the ability of RBCs to aggregate into orderly stacks or rouleaux. In disease, the most common cause of a high ESR is an increased protein level in the blood, such as the increase in acute-phase proteins seen in inflammatory diseases. Proteins are thought to affect the repellent surface charges on RBCs and cause them to aggregate into rouleaux, and hence the sedimentation rate increases.

In children, the normal value is often less than 10 mm/h, but normal values do rise with age. A normal ESR for men and women over 50 years old is 20 mm/h and 30 mm/h, respectively. The Westergren method, performed under standardised conditions, is commonly used. Although some conditions may cause a low ESR, the test is principally used to monitor inflammatory diseases such as rheumatoid arthritis, inflammatory bowel disease, malignancy and infection. The ESR is non-specific and, therefore, of little diagnostic value, but serial tests can be helpful in following the progress of disease and its response to treatment

C-reactive protein

C-reactive protein (CRP) is an acute-phase protein and named for its capacity to precipitate the somatic C-polysaccharide of *Streptococcus pneumoniae*. This nonspecific acute-phase response is instigated by tissue damage, infection, inflammation and malignancy. Production of CRP is rapidly and sensitively upregulated in hepatocytes under the control of cytokine (IL-6) originating at the site of pathology. CRP is recognised by, and subsequently activates, the complement system whilst also generating proinflammatory cytokines and aiding in the activation of the adaptive immune system.

Serum concentrations rise by about 6 hours, peaking around 48 hours. The serum half-life is around 19 hours, so serum level is determined by synthesis rate, which therefore reflects the intensity of the pathological process stimulating this, and falls rapidly when this ceases. CRP values are not diagnostic and can only be interpreted with the knowledge of all other clinical and pathological results. In most diseases, the circulating value of CRP reflects ongoing inflammation or tissue damage more accurately than other acute-phase parameters, such as serum viscosity or ESR. Drugs including HMG-CoA reductase inhibitors ('statins') have been shown to reduce CRP values potentially by affecting the underlying pathology providing the acute-phase stimulus.

Procalcitonin

Procalcitonin, a polypeptide, is one of many bloodstream biomarkers investigated as an early predictor of sepsis. It is produced rapidly in response to bacterial stimulus but not in systemic inflammatory response syndrome of noninfectious origin. Diagnostic thresholds for a positive procalcitonin, indicative of sepsis, have been proposed between 1.0 and 2.0 ng/mL. Although this approach has been demonstrated to change clinical practice in the diagnosis and treatment of sepsis, it is not yet embedded in routine practice.

Special tests

Several standalone tests are not routinely included in the various profiles discussed so far but are essential to the diagnosis and monitoring of certain conditions (Table 6.10).

Glucose

The serum glucose concentration is largely determined by the balance of glucose moving into, and leaving, the extracellular compartment. In a healthy adult, this movement and cellular metabolism are capable of maintaining serum levels below 10 mmol/L, regardless of the intake of meals of varying carbohydrate content.

The renal tubules have the capacity to reabsorb glucose from the glomerular filtrate via sodium glucose cotransporters (SGLT2), and minimal glucose is normally lost from the body. Glucose in the urine (glycosuria) is normally only present when the concentration in serum exceeds 10 mmol/L, the renal threshold for total reabsorption.

Table 6.10 Standard values of specialist tests

Laboratory test	Reference range
Glucose (fasting)	3.3–6.0 mmol/L
HbA _{1c} (DCCT)	4–6%
HbA _{1c} (IFCC)	20–42 mmol/mol
Glycosylated haemoglobin (HbA _{1c})	4–5.9%
Troponin I (99th percentile of upper reference limit)	<0.04 microgram/L
Lactate dehydrogenase (LDH)	240–480 U/L
Beta-D-glucan (BDG)	<6 pg/mL
D-dimer	<0.5 microgram/mL
Creatine kinase (CK)	Male: 30–200 U/L Female: 20–170 U/L
Uric acid	180–420 mmol/L

DCCT, Diabetes Control and Complications Trial; IFCC, International Federation for Clinical Chemistry.

Capillary blood glucose testing using a finger-tip sample is the mainstay of routine serum glucose monitoring. Serum glucose concentrations are also displayed routinely on arterial blood gas reports.

Normal ranges for serum glucose concentrations are often quoted as non-fasting (<11.1 mmol/L) or fasting (3.3–6.0 mmol/L) concentration ranges. Fasting serum glucose levels between 6.1 and 7.0 mmol/L indicate impaired glucose tolerance. When symptoms are typical of diabetes, a fasting level above 7.0 mmol/L or a 2-hour post-glucose or random serum glucose level ≥ 11.1 mmol/L is consistent with a diagnosis of diabetes. Other signs and symptoms, if present, are notably those attributable to an osmotic diuresis and will suggest clinically the diagnosis of diabetes mellitus.

Glycated haemoglobin

Glucose binds to a part of the haemoglobin molecule to form a small glycated fraction. Normally, about 5% of haemoglobin is glycated, but this amount is dependent on the average blood glucose concentration over the lifespan of the RBCs (about 120 days), and where RBC lifespan is reduced, this leads to low glycated haemoglobin levels. The major component of the glycated fraction is referred to as HbA_{1c}.

Measurement of HbA_{1c} is well established as an indicator of chronic glycaemic control in patients with diabetes. Guidelines for the diagnosis and monitoring of diabetes now stipulate that methods for measuring HbA_{1c} must have been calibrated to the International Federation for Clinical Chemistry (IFCC) standardisation. These newer laboratory methods have a higher specificity for HbA_{1c}, and so results cannot be directly compared with the old Diabetes Control and Complications Trial (DCCT) method (National Institute for Health and Care

Excellence [NICE], 2015). One method adopted for preventing direct comparison is by moving to standard units of mmol/mol. Some reports will also report a percentage, comparable to the older assay, which is by a conversion calculation rather than performing both tests.

Cardiac markers

Troponins

Cardiac troponin I (cTnI) and cardiac troponin T (cTnT) are regulatory proteins that control the calcium-mediated interaction between actin and myosin in cardiac muscle. Both are comparable in diagnostic and prognostic efficacy, and the local decision may be a balance between cost and specific assay performance. Troponins offer extremely high cardiac tissue specificity and clinical sensitivity for myocardial necrosis but do not discriminate between ischaemic and non-ischaemic mechanisms, including myocarditis, cardiac surgery and sepsis.

Conventional approved cTn assays display a coefficient of variance of less than 20%. The major international cardiac societies (Daubert and Jeremias, 2010) define myocardial infarction through the detection of a 20% rise or fall with respect to the 99th percentile of the upper reference limit plus one of the following:

1. Symptoms of ischaemia
2. ECG evidence of ischaemia (e.g. ST-elevation or left bundle branch block)
3. Cardiac imaging findings consistent with ischaemia
4. Identification of an intracoronary thrombus by angiography

Sampling of cTn at two time points, usually admission and 12 hours from the worst pain, is usually needed, although if it is entirely clear that there has been a myocardial infarction, particularly in a late presentation, a second sample may not be needed. Newer high-sensitivity tests have much lower variance ($\leq 10\%$) and, unlike conventional assays, can detect baseline cTn in healthy individuals. High sensitivity tests require careful interpretation through sex-specific reference ranges but potentially reduce the time to diagnosis through shorter sampling intervals (3–6 hours between the first and second test).

Lactate dehydrogenase

Lactate dehydrogenase (LDH) has five isoenzymes (LD1–LD5). Total LDH activity is rarely measured because of the lack of tissue specificity. Levels of activity are elevated following damage to the liver, skeletal muscle and kidneys, in both megaloblastic and immune haemolytic anaemias, and in intravascular haemolysis as seen in thrombotic thrombocytopenic purpura and paroxysmal nocturnal haemoglobinuria. In lymphoma, a high LDH activity indicates a poor prognosis. Elevation of LD1 and LD2 occurs after myocardial infarction, renal infarction or megaloblastic anaemia; LD2 and LD3 are elevated in acute leukaemia; LD3 is often elevated in some malignancies; and LD5 is elevated after damage to liver or skeletal muscle.

Beta-D-glucan

Beta-D-glucan (BDG) is a cell wall component released by most fungi and as such can be used as a serum marker of invasive fungal infection. BDG has been shown to have good diagnostic accuracy for identifying invasive fungal infections, particularly those attributable to *Candida* or *Aspergillus* species.

D-dimers

D-dimers are degradation products of fibrin clots, formed by the sequential action of three enzymes, thrombin, factor XIIIa and plasmin, which degrades cross-linked fibrin to release fibrin degradation products and expose the D-dimer antigen. D-dimer assays measure an epitope on fibrin degradation products using monoclonal antibodies. Because each has its own unique specificity, there is no standard unit of measurement or performance. Levels of D-dimers in the blood are raised in conditions associated with coagulation and are used to detect venous thromboembolism, although they are influenced by the presence of comorbid conditions such as cancer, surgery and infectious diseases. D-dimer measurement has been most comprehensively validated in the exclusion of venous thromboembolism in certain patient populations and in the diagnosis and monitoring of coagulation activation in disseminated intravascular coagulation. Diagnosis of deep vein thrombosis (DVT) or pulmonary embolism (PE) should include a clinical probability assessment as well as D-dimer measurements. In patients with a low clinical probability of pulmonary embolism, a negative quantitative D-dimer test result effectively excludes PE. In suspected DVTs, D-dimer measurements combined with a clinical prediction score and compression ultrasonography study have a high predictive value. More recently, assays are being used in the prediction of the risk of venous thromboembolism (VTE) recurrence.

Xanthochromia

Xanthochromia is a yellow discolouration of cerebrospinal fluid caused by haemoglobin catabolism. It is thought to arise within several hours of subarachnoid haemorrhage (SAH) and can help to distinguish the elevated RBC count observed after traumatic lumbar puncture from that observed following SAH, particularly if few RBCs are present. Spectrophotometry is used to detect the presence of both oxyhaemoglobin and bilirubin, both of which contribute to xanthochromia following SAH, although some hospitals rely on visual inspection.

Creatine kinase

Creatine kinase (CK) is an enzyme present in relatively high concentrations in the heart muscle, skeletal muscle and brain, in addition to being present in smooth muscle. Levels are markedly increased following shock and circulatory failure, myocardial infarction and muscular dystrophies. Less marked increases have been reported following muscle injury, surgery,

Table 6.11 Medications and toxic substances that increase the risk of rhabdomyolysis

Direct myotoxicity	Indirect muscle damage
HMG-CoA reductase inhibitors, especially in combination with fibrate-derived lipid-lowering agents such as niacin (nicotinic acid)	Alcohol
Ciclosporin	Central nervous system depressants
Itraconazole	Cocaine
Erythromycin	Amphetamine
Colchicine	Ecstasy (MDMA)
Zidovudine	LSD
Corticosteroids	Neuromuscular blocking agents

HMG-CoA, 3-Hydroxy-3-methylglutaryl coenzyme A; LSD, lysergic acid diethylamide; MDMA, methylene dioxymethamphetamine.

physical exercise, muscle cramp, an epileptic fit, intramuscular injection and hypothyroidism. The most important adverse effects associated with statins are myopathy and an increase in hepatic transaminases, both of which occur infrequently. Statin-associated myopathy represents a broad clinical spectrum of disorders, from mild muscle aches to severe pain and restriction in mobility, with grossly elevated CK levels. In rhabdomyolysis, a potentially life-threatening syndrome resulting from the breakdown of skeletal muscle fibres as a result of, for example, ischaemic crush injury where large quantities of CK are measurable in the blood with the level of CK predicting the developments of acute renal failure. Medications and toxic substances that increase the risk of rhabdomyolysis are shown in Table 6.11.

CK has two protein subunits, M and B, which combine to form three isoenzymes, BB, MM and MB. BB is found in high concentrations in the brain, thyroid and some smooth muscle tissue. Little of this enzyme is present in the serum, even following damage to the brain. The enzyme found in serum of normal subjects is the MM isoenzyme, which originates from skeletal muscle.

Cardiac tissue contains more of the MB isoenzyme than skeletal muscle. Following a myocardial infarction there is a characteristic increase in serum CK activity. Although measurement of activity of the MB isoenzyme was used in the past to detect myocardial damage, cardiac troponin measurement is now the preferred biomarker.

Immunoglobulins

Immunoglobulins are antibodies which are produced by B lymphocytes. They are detected by electrophoresis as bands in three regions: α , β and γ , with most occurring in the γ region. Hypergammaglobulinaemia may result from stimulation of B cells and produces an increased staining of bands in the γ region on electrophoresis. This occurs in infections, chronic liver disease and autoimmune disease.

Table 6.12 Standard values in iron, B₁₂ and folate

Laboratory test	Reference range
Iron studies	
Iron	11–29 mmol/L
Ferritin	15–300 micrograms/L
Transferrin	1.7–3.4 g/L
Transferrin saturation	20–50%
Associated tests	
Folate	2.7–21.0 ng/mL
B ₁₂	0.13–0.68 nmol/L

In some diseases, such as chronic lymphatic leukaemia, lymphoma and multiple myeloma, a discrete, densely staining band (paraprotein) can be seen in the γ region. In multiple myeloma, abnormal fragments of immunoglobulins are produced (Bence-Jones protein), which clear the glomerulus and are found in the urine.

Uric acid

The production of uric acid, the end product of purine metabolism, is catalysed by xanthine oxidase, an enzyme linked to oxidative stress, endothelial dysfunction and heart failure. The purines, which are used for nucleic acid synthesis, are produced by the breakdown of nucleic acid from ingested meat or synthesised within the body.

Monosodium urate is the form in which uric acid usually exists at the normal pH of body fluids. The term *urate* is used to represent any salt of uric acid.

Two main factors contribute to elevated serum uric acid levels: an increased rate of formation or a reduced excretion. Uric acid is poorly soluble, and an elevation in serum concentration can readily result in deposition, as monosodium urate in tissues or joints. Deposition usually precipitates an acute attack of gouty arthritis. The aim of treatment is to reduce the concentration of uric acid and prevent further attacks of gout. It has been hypothesised that measurement of urate could serve as a marker of cardiovascular risk because the serum uric acid level is an independent predictor of all causes of mortality in patients at high risk of cardiovascular disease, independent of diuretic use.

Iron, transferrin and iron binding Iron

Iron (Table 6.12) is a trace element and required for numerous cellular functions, but it is particularly important in cells producing haemoglobin and myoglobin. The adult body contains 3–4 g of iron, around 70% in heme compounds (e.g. haemoglobin). Iron circulates in the blood bound to transferrin, which transports it to the bone marrow, where it is incorporated into

haemoglobin in developing RBCs. Iron intake from the diet is around 1–2 mg/day, whereas 40–60 mg/day is derived from the reticuloendothelial system from senescent red blood cells.

Serum iron levels are extremely labile and fluctuate throughout the day and, therefore, provide little useful information about iron status.

Iron balance is regulated by hepcidin, a circulating peptide hormone, which aims to provide iron as needed whilst avoiding excess iron promoting the formation of toxic oxygen radicals. Genetic iron overload results from mutations in molecules which regulate hepcidin production or activity.

Ferritin

Ferritin is an iron storage protein found in cell cytosol. It acts as a depot, accepting excess iron and allowing for mobilisation of iron when needed. Serum ferritin measurement is the test of choice in patients suspected of having iron-deficiency anaemia.

In normal individuals, the serum ferritin concentration is directly related to the available storage iron in the body. The serum ferritin level falls below the normal range in iron-deficiency anaemia, and its measurement can provide a useful monitor for repletion of iron stores after iron therapy. Raised ferritin can occur as a result of raised iron stores, but ferritin is an acute-phase protein and is released from damaged hepatocytes. Levels therefore can be raised in inflammatory disorders, liver disease or malignancy.

Transferrin

Transferrin, a simple polypeptide chain with two iron binding sites, is the plasma iron binding protein which facilitates its delivery to cells bearing transferrin receptors. Measurement of total iron binding capacity (TIBC), from which the percentage of transferrin saturation with iron may be calculated, gives more information. Saturation of 20% or lower is usually taken to indicate an iron deficiency, as is a raised TIBC of greater than 70 mmol/L.

Vitamin B₁₂ and folate

In the haematology literature, B₁₂ refers not only to cyanocobalamin but also to several other cobalamins with identical nutritional properties. Folic acid, which can designate a specific compound, pteroylglutamic acid, is also more commonly used as a general term for the folates. Deficiency of cobalamin can result both in macrocytic anaemia and neurological disease, including neuropathies, dementia and psychosis. Folate deficiency produces macrocytic anaemia, depression, dementia and neural tube defects.

Liver disease tends to increase B₁₂ levels, and they may be reduced in folate-deficient patients; malabsorption of B₁₂ may result from long-term ingestion of antacids, proton-pump inhibitors and H₂-receptor antagonists, or biguanides (e.g. metformin). Serum folate levels tend to increase in B₁₂ deficiency, and alcohol can reduce levels. RBC folate is a better measure of folate tissue stores.

Table 6.13 Tumour markers and their clinical application

Tumour marker	Primary malignancy	Clinical application
Prostate-specific antigen (PSA)	Prostate	Primary screening, determining prognosis and monitoring therapy
CA 125	Ovarian	Primary screening, determining prognosis and monitoring therapy
CA 19-9	Pancreatic	Monitoring therapy
CA 15-3	Breast	Monitoring therapy
Human chorionic gonadotropin (HCG)	Trophoblastic	Primary screening, determining prognosis and monitoring therapy
Human epidermal growth factor receptor 2 (HER-2)	Breast	Predicting response to therapy
Alpha-fetoprotein (AFP)	Hepatocellular	Primary screening and monitoring therapy
Pepsinogen	Gastric	Primary screening

Tumour markers

Tumour markers are defined as a qualitative or quantitative alteration or deviation from normal of a molecule, substance or process that can be detected by some form of assay above and beyond routine clinical and pathological evaluation. They may be detected within malignant cells, in surrounding stroma or metastases, or as soluble products in blood, secretions or excretions. In order to be useful clinically, the precise use of the marker in altering clinical management should have been defined by data based on a reliable assay and a validated clinical outcome trial.

Tumour markers could potentially be used in the diagnosis of cancers in asymptomatic individuals; however, they are more commonly used in contributing to the diagnosis in symptomatic patients. Tumour markers may be used to differentiate between benign and malignant disease (e.g. prostate-specific antigen), predicting response to therapeutic agents (e.g. human epidermal growth factor receptor-2 for trastuzumab therapy) and assessing prognosis following surgical removal (Table 6.13).

Arterial blood gases

Arterial blood gas analysis provides a rapid and accurate assessment of oxygenation, alveolar ventilation and acid–base status (Table 6.14), the three processes which maintain pH homeostasis.

Table 6.14 Standard values for arterial blood gases

Laboratory test	Reference range
Arterial blood gas	
pH	7.35–7.45
PaCO ₂	4.6–6.1 kPa
PaO ₂	10.6–13.3 kPa
HCO ₃ ⁻	22–28 mmol/L
BE	±2 mmol/L

BE, Base excess; HCO₃⁻, bicarbonate; PaCO₂, arterial partial pressure of carbon dioxide; PaO₂, arterial partial pressure of oxygen.

Box 6.9 Henderson–Hasselbalch equation

$$\text{pH} = \text{pK}_a + \log \frac{A^-}{HA}$$

A⁻, molar concentration of this acid's conjugate base (HCO₃⁻); HA, molar concentration of the dissociated weak acid (H₂CO₃); pH, plasma pH; pK_a, logarithm of the dissociation constant of carbonic acid.

pH

A normal physiological pH (7.4) is required for many physiological functions, from enzymatic function to influencing oxygen release from haemoglobin. An acidosis is indicated by a pH less than 7.35; an alkalosis by a pH greater than 7.45. Two compensatory mechanisms exist to maintain the optimum physiological pH: the regulation of carbon dioxide concentration in the blood by the lungs (respiratory) and the excretion of hydrogen ions or reabsorption of bicarbonate by the kidneys (metabolic). Bicarbonate in the blood acts as an intermediary buffer, which is best represented by the Henderson–Hasselbalch equation (Box 6.9).

Carbon dioxide

The maintenance of arterial CO₂ tension (PaCO₂) depends on the quantity of CO₂ produced in the body and its removal through alveolar ventilation. High PaCO₂ (>6.1 kPa) indicates alveolar hypoventilation and without compensation would result in a respiratory acidosis. Low PaCO₂ (<4.5 kPa) implies alveolar hyperventilation and would in isolation result in a respiratory alkalosis.

Oxygenation

The adequate delivery of oxygen to the tissues depends on the cardiopulmonary system, PaO₂, oxygen fraction in inspired air (FiO₂) and haemoglobin content and its affinity for oxygen. Oxygen saturation is measured by pulse oximetry or by arterial blood gas analysis. Hypoxaemia is defined as a PaO₂ of less than 12 kPa at sea level in an adult patient breathing room air (FiO₂ = 0.21).

Table 6.15 Arterial blood gas interpretation

Step 1: Acidosis/ alkalosis	Acidosis (pH < 7.35)		Alkalosis (pH > 7.4)	
Step 2: Primary cause	Respiratory pCO ₂ > 6.1 kPa	Metabolic HCO ₃ ⁻ < 22 mmol/L	Respiratory pCO ₂ < 4.6 kPa	Metabolic HCO ₃ ⁻ > 28 mmol/L
Examples	COPD Guillain– Barre	DKA Sepsis Aspirin overdose	PE Anxiety	Diuretic use Severe vomiting
Step 3: Compen- sation	Metabolic HCO ₃ ⁻ > 28 mmol/L	Respiratory pCO ₂ < 4.6 kPa	Metabolic HCO ₃ ⁻ < 22 mmol/L	Respiratory pCO ₂ > 6.1 kPa

COPD, Chronic obstructive pulmonary disease; DKA, diabetic ketoacidosis; HCO₃⁻, bicarbonate; PaCO₂, arterial partial pressure of carbon dioxide; PE, pulmonary embolus.

Bicarbonate

A raised bicarbonate on its own would cause metabolic alkalosis; a reduced bicarbonate metabolic acidosis. Bicarbonate is not the only base in the system, and the base deficit quantifies the amount of bicarbonate that theoretically must be added (or taken away) to achieve physiological pH. The base excess (BE) describes this explanation in reverse or the negative base deficit (BE = –[BD]).

Interpreting arterial blood gases

Arterial blood gases should always be interpreted in clinical context and not in isolation. The configuration of various parameters in the arterial blood gases can lead to a high suspicion of certain diagnoses combined with relevant signs and symptoms (Table 6.15).

The respiratory system can compensate for a metabolic abnormality and vice versa. This may not be seen immediately because whilst modification of the respiratory rate can occur within minutes, the renal response may take several days.

Case studies

Case 6.1

A 78-year-old man, Mr KB, with a history of atrial fibrillation on digoxin and apixaban is admitted with a 2-day history of vomiting, headache, dizziness and palpitations. He was recently started on furosemide for worsening leg oedema which was particularly troubling him. The results of his admission blood tests are as follows:

Sodium	135 mmol/L	(135–145 mmol/L)
Potassium	2.5 mmol/L	(3.4–5.0 mmol/L)
Creatinine	140 mmol/L	(75–155 mmol/L)
Urea	12 mmol/L	(3.1–7.9 mmol/L)

Questions

1. What is a possible diagnosis?
2. What additional tests might you perform to confirm your diagnosis?
3. Why has this occurred?
4. Mr KB is given 1 L of sodium chloride 0.9% with 40 mmol of potassium. A further sample shows a sodium of 152 mmol/L and potassium of 5.7 mmol/L. What has caused this?

Answers

1. Digoxin toxicity precipitated by hypokalaemia
2. Serum digoxin levels would be useful in confirming this diagnosis. The timing since the last dose should be confirmed if possible to ensure that the result is relevant. Other features of toxicity could include bradycardia, diarrhoea, yellow vision and rash. An ECG may display down-sloping ST-segment depression also known as the 'reverse tick'.
3. The initiation of furosemide has increased potassium excretion, which has not been sufficiently replaced. The resulting hypokalaemia has precipitated digoxin toxicity.
4. Beware of sudden changes in consecutive samples; always ask if they have been taken appropriately. The follow-up sample was taken from the line being used to infuse the fluid, giving an artificially high value of both electrolytes.

Case 6.2

A 23-year-old woman, Miss CB, is brought to the emergency department by ambulance late on a Friday night. Her respiratory rate is 10 breaths/min, and she is unconscious. Her arterial blood gas shows the following:

pH	7.25	(7.35–7.45)
PaCO ₂	8.2 kPa	(4.6–6.1 kPa)
PaO ₂	8.6 kPa	(10.6–13.3 kPa)
Bicarbonate	26 mmol/L	(22–28 mmol/L)

Questions

1. Describe Miss CB's acid–base status.
2. When trying to place an intravenous cannula, you notice injection marks on the inside of the arms and groin. On further examination, Miss CB has pinpoint pupils. What is the most likely diagnosis?
3. What treatment would you consider?

Answers

1. Respiratory acidosis with no metabolic compensation
2. Opiate overdose produces a respiratory acidosis by depressing respiratory drive. Hypoventilation causes accumulation of carbon dioxide, which tips the balance towards acidosis. The lack of compensation by the renal mechanism demonstrates the acute nature of this presentation.
3. A trial dose of naloxone, a competitive and specific opioid antagonist, would be expected to improve respiration if the intoxication was caused by an opiate overdose alone. Repeated doses or an infusion may be necessary because of the short half-life of the antidote.

Case 6.3

A 35-year-old obese information technology (IT) worker, Mr JC, complains of general aches and pains over the past few months. His friend has said that he has not been himself for the past few

weeks and appears 'under the weather'. A blood sample was taken and a bone profile requested; the results are as follows:

Ca ²⁺	4.01 mmol/L	
Ca ²⁺ (corrected)	4.09 mmol/L	(2.12–2.60 mmol/L)
Phosphate	0.41 mmol/L	(0.80–1.44 mmol/L)
Albumin	41 g/L	(34–50 g/L)

Questions

1. What is the cause of Mr JC's symptoms?
2. What further test would you request?
3. If that test returns high, what is the diagnosis?
4. How would you treat the patient?

Answers

1. Mr JC has hypercalcaemia. Patients with a high calcium often present with 'bones, stones and moans'.
2. Parathyroid releasing hormone (PTH)
3. A raised PTH would suggest a primary hyperparathyroidism, although a normal PTH would still be abnormal because PTH is under a negative feedback control from calcium. This is suggestive of a parathyroid adenoma that is producing PTH.
4. Management of hypercalcaemia includes i.v. rehydration with sodium chloride 0.9% and, following rehydration, the addition of an i.v. bisphosphonate. Ultimately, surgical removal of the parathyroid adenoma would be indicated.

Case 6.4

A 34-year-old aid worker, Miss AS, has just returned from Africa, having become increasingly unwell over the last month. She has been feverish on and off for the last 4 weeks with a worsening headache and abdominal pain, and she has noticed a yellow discolouration to her eyes. Miss AS's initial blood test shows the following:

Haemoglobin	8.5 g/L	(115–165 g/L)
Platelets	60 × 10 ⁹ /L	(150–450 × 10 ⁹ /L)
WBC	11.5 × 10 ⁹ /L	(4.0–11.0 × 10 ⁹ /L)
MCV	90 fL	(83–101 fL)
MCH	30 pg	(27–34 pg)

Questions

1. Describe this haematology profile.
2. What additional tests should be requested?
3. Given the clinical picture, what would you expect to see in these tests?

Answers

1. This profile shows a normocytic normochromic anemia with thrombocytopenia.
2. Liver function tests would be useful given Miss AS's possible jaundice and nonspecific abdominal pain. Given her recent travel, consideration must be given to various tropical diseases.
3. The clinical picture of jaundice would suggest a bilirubin of more than 50 mmol/L, over which it is usually detectable. Combined with her normocytic normochromic anaemia, Miss AS has a high probability of malaria where jaundice in adults can be attributable to a cholestatic picture. It is likely that the ALP and gamma-GT would also be raised whilst transaminases may be normal. Further specific investigations would be needed to confirm a diagnosis of malaria.

Parenteral Nutrition

Susanna J. Harwood and Alan G. Cosslett

Key points

- Parenteral nutrition is indicated in people who are malnourished or at risk of malnutrition as a result of a nonfunctional, inaccessible or perforated gastro-intestinal tract or who have inadequate or unsafe enteral nutritional intake.
- Combinations of oral diet, enteral feeding and parenteral nutrition, either peripherally or centrally, may be appropriate.
- Parenteral nutrition regimens should be tailored to the nutritional needs of the patient and should contain a balance of seven essential components: water, L-amino acids, glucose, lipids with essential fatty acids, vitamins, trace elements and electrolytes.
- Advances in technology alongside expertise in pharmaceutical stability often permit the required nutrients to be administered from a single container. Increasingly, standard formulations are used, including licensed preparations.
- Parenteral nutrition must be compounded under validated aseptic conditions by trained specialists.
- Prescriptions are guided by baseline nutritional assessment, calculation of requirements, knowledge of the patient's disease status and ongoing monitoring.
- The incidence of complications with parenteral nutrition is reducing; knowledge of management is improving.
- Many patients on parenteral nutrition are now being cared for successfully in the home environment.

Introduction

Malnutrition

Malnutrition can be described as a deficiency, excess, or imbalance of energy, protein, and other nutrients that causes measurable adverse effects on body tissue, size, shape, composition, function and clinical outcome.

In UK hospitals, most malnutrition appears to be a general undernutrition of all nutrients (protein, energy and micronutrients) rather than marasmus (insufficient energy provision) or kwashiorkor (insufficient protein provision). Alternatively, there may be a specific deficiency, such as thiamine in severe hepatic disease.

Multiple causes may contribute to malnutrition. They may include inadequate or unbalanced food intake, increased demand as a result of clinical disease status, defects in food digestion or absorption or a compromise in nutritional metabolic pathways. Onset may be acute or insidious. Even mild malnutrition can result in problems with adverse effects on clinical, physical and

psychosocial status. Symptoms may include impaired immune response, reduced skeletal muscle strength and fatigue, reduced respiratory muscle strength, impaired thermoregulation and impaired skin barrier and wound healing. In turn, these predispose the patient to a wide range of problems including infection, delayed clinical recovery, increased clinical complications, inactivity, psychological decline and reduced quality of life. Because symptoms may be nonspecific, the underlying malnutrition may be left undiagnosed. Early nutritional intervention is associated with reduced average length of hospital stay and linked cost savings.

Nutrition screening

Routine screening is recommended by the Malnutrition Advisory Group of the British Association of Parenteral and Enteral Nutrition (BAPEN). This group has worked to promote awareness of the clinical significance of malnutrition and has produced guidelines to monitor and manage malnutrition. Screening criteria and tools have been developed and refined to assess nutritional status. Examples include the relatively simple and reproducible body mass index (BMI) tool with consideration of other key factors (Table 7.1). Body weight should not be used in isolation; significant weight fluctuations may reflect fluid disturbances, and muscle wasting may be a result of immobility rather than undernutrition. BAPEN has developed a new web-based nutritional care tool. This tool enables BAPEN to monitor the effectiveness of nutritional care plans.

Incidence of undernutrition

The incidence of undernutrition in hospitalised patients is not accurately known, although it is estimated as being between 20% and 40%.

Table 7.1 Body mass index as a screening tool

BMI (kg/m ²)	BMI category
<18.5	Underweight
18.5–25	Ideal BMI
25–29.9	Overweight
>30	Obese

BMI, Body mass index. BMI = weight (kg)/height (m²).

Indications for parenteral nutrition

Parenteral nutrition (PN) is a nutritionally balanced aseptically prepared or sterile physicochemically stable solution or emulsion for intravenous administration. It is indicated whenever the gastro-intestinal tract is inaccessible, perforated or nonfunctional or when enteral nutrition is inadequate or unsafe. PN should be considered if the enteral route is not likely to be possible for more than 5 days. PN may fulfil the total nutritional requirements or may be supplemental to an enteral feed or diet.

The simplest way to correct or prevent undernutrition is through conventional balanced food; however, this is not always possible. Nutritional support may then require oral supplements or enteral tube feeding. Assuming the gut is functioning normally, the patient will be able to digest and absorb their required nutrients. These include water, protein, carbohydrate, fat, vitamins, minerals and electrolytes; however, if the gut is not accessible or functioning adequately, or if gut rest is indicated, then PN may be used. Although the enteral route is the first choice, this may still fail to provide sufficient nutrient intake in a number of patients. Complications and limitations of enteral nutrition need to be recognised.

A decision pathway can be followed to guide initial and ongoing nutritional support. Although many are published, a locally tailored and regularly updated pathway is favoured. A useful starting point may be found in Fig. 7.1.

Close monitoring should ensure the patient's needs are met; a combination of nutrition routes is sometimes the best course. Where possible, patients receiving PN should also receive enteral intake; even minor gut stimulation has been linked with a reduction in the incidence of bacterial translocation through maintaining gut integrity and preventing overgrowth and cholestatic complications. PN should not be stopped abruptly but should be gradually reduced in line with the increasing enteral diet.

Nutrition support teams

A report published by the **Kings Fund Report (1992)** highlighted the issue of malnutrition both in the hospital and home setting. The findings led to the development of the BAPEN and nutrition support teams throughout the UK. These multidisciplinary nutrition support teams comprise a doctor, nurse, pharmacist and dietitian. They function in a variety of ways, depending on the patient populations and resources. In general, they adopt either a consultative or an authoritative role in nutrition management. Many studies have shown their positive contribution to the total nutritional care of the patient through efficient and appropriate selection and monitoring of feed and route (**Gales and Gales, 1994**).

Components of a parenteral nutrition regimen

In addition to water, six main groups of nutrients need to be incorporated in a PN regimen (**Table 7.2**).

Water volume

Water is the principal component of the body and accounts for approximately 60% and 55% of total body weight in men and women, respectively. Usually, homeostasis maintains appropriate fluid levels and electrolyte balance, and thirst drives the healthy person to drink; however, some patients are not able physically to respond by drinking, and so this homeostasis is ineffective. There is risk of over- or underhydration if the range of factors affecting fluid and electrolyte balance is not fully understood and monitored. In general, an adult patient will require 20–40 mL/kg/day fluid; however, **Table 7.3** describes other factors that should be considered in tailoring input to needs.

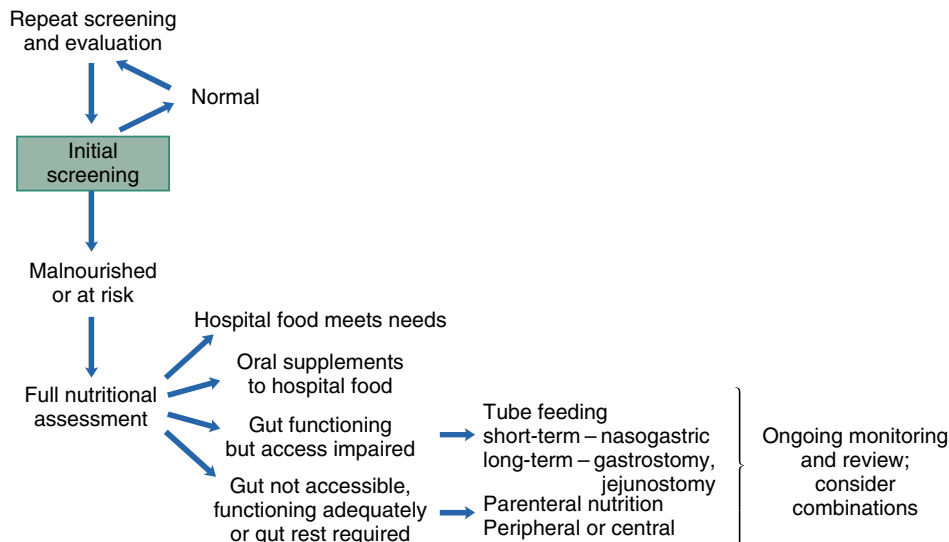

Fig. 7.1 Decision pathway to guide initial and ongoing nutritional support.

Table 7.2 Oral and equivalent parenteral nutrition source

Oral diet	Parenteral nutrition source
Water	Water
Protein	L-Amino acid mixture
Carbohydrate	Glucose
Fat with essential fatty acids	Lipid emulsions with essential fatty acids
Vitamins	Vitamins
Minerals	Trace elements
Electrolytes	Electrolytes

Table 7.3 Factors affecting fluid requirements

Consider increasing fluid input	Consider reducing fluid input
Signs/symptoms of dehydration	Signs/symptoms of fluid overload
Fever: increased insensible losses from lungs in hyperventilation and from skin in sweating; allow 10–15% extra water per 10 °C above normal	High humidity: reduced rate of evaporation
Acute anabolic state: increased water required for increased cell generation	Blood transfusion: volume input
High environmental temperature or low humidity: increased rate of evaporation	Cardiac failure: may limit tolerated blood volume
	Drug therapy: assess volume and electrolyte content of infused drug
Abnormal gastro-intestinal loss (vomiting, wounds, ostomies, diarrhoea): consider both volume loss and electrolyte content	
Burns or open wound(s): increased water evaporation	
	Renal failure: fluid may accumulate, so reduce input accordingly or provide artificial renal support
Blood loss: assess volume lost and whether replaced by transfusion, colloid, crystalloid	

Amino acids

Twenty L-amino acids are required for protein synthesis and metabolism, and the majority of these can be synthesised endogenously. Eight are called ‘essential’ amino acids because they cannot be synthesised (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan and valine). A further group of ‘conditionally essential’ amino acids (arginine, choline, glutamine, taurine and *S*-adenosyl-L-methionine) are defined as the patient’s needs exceed synthesis in clinically stressed conditions. Also, because of the immature metabolic pathways of neonates, infants and children, some other amino acids are essential in the young patient; these include histidine, proline, cysteine, tyrosine and taurine. Immature neonatal metabolism does not fully metabolise glycine, methionine, phenylalanine and threonine, and so requirements are reduced.

To balance the patient’s amino acid requirements and the chemical characteristics of the amino acids (solubility, stability and compatibility), commercially available licensed solutions have been formulated that contain a range of amino acid profiles (Table 7.4). Aminoplasmal, Aminoven, Synthamin and Vamin are

Table 7.4 Examples of amino acid and consequential nitrogen content of licensed amino acid solutions available in the UK

Name	Nitrogen content (g/L)	Electrolytes present
Aminoplasmal 5% E	8	Potassium, magnesium, sodium and phosphate
Aminoplasmal 10%	16	
Aminoplasmal 15%	24	
Aminoven 25	25.7	
Glamin	22.4	
Primene 10%	15	
Synthamin 9	9.1	Potassium, magnesium, sodium and phosphate
Synthamin 9 EF	9.1	
Synthamin 14	14	Potassium, magnesium, sodium and phosphate
Synthamin 14 EF	14	
Synthamin 17	17	Potassium, magnesium, sodium and phosphate
Synthamin 17 EF	17	
Vamin 14	13.5	Potassium, magnesium, sodium and calcium
Vamin 14EF	13.5	
Vamin 18EF	18	

designed for adult patients. The amino acid profiles of Primene, Vaminolact and Aminoplasmal Paediatric are specifically tailored to neonates, infants and children (reflecting the amino acid profile of maternal cord blood and breast milk, respectively).

L-Glutamine was initially excluded from formulations because of its low solubility and relatively poor stability in the aqueous environment; however, it is recognised that there is a clinical need for this amino acid in catabolic stress, and it is now available as an additive (Dipeptiven) and as an amino acid solution containing a dipeptide form of glutamine (Glamin) in which the peptide bond cleaves in the blood, releasing free L-glutamine.

Assuming adequate energy is supplied, most adult patients achieve nitrogen balance with approximately 0.2 g nitrogen/kg/day, although care should be taken with overweight patients. A 24-hour urine collection can be used as an indicator of nitrogen loss, assuming all urine is collected and urea or volume output is not compromised by renal failure; however, a true nitrogen output determination requires measurement of nitrogen output from all body fluids, including urine, sweat, faeces, skin and wounds. Nitrogen balance studies can indicate the metabolic state of the patient (positive balance in net protein synthesis, negative balance in protein catabolism). Urinary urea constitutes approximately 80% of the urinary nitrogen. The universally accepted conversion factor for nitrogen to protein is 1 g nitrogen per 6.25 g of protein.

Amino acid solutions are hypertonic to blood and should not be administered alone into the peripheral circulation.

Energy

Many factors affect the energy requirement of individual patients, and these include age, activity and illness (both severity and stage). Predictive formulae can be applied to estimate the energy requirement, for example, the Harris–Benedict equation or the more commonly used Henry equation, which is shown in [Table 7.5 \(Henry, 2005\)](#).

Alternatively, calorimetry techniques can be used; however, no single method is ideal or suits all scenarios. Often it is found that two methods result in different recommendations. The majority of adults can be appropriately maintained on 25–35 non-protein

kcal/kg/day. There is debate over whether to include amino acids as a source of calories because it is simplistic to assume they are either all spared for protein synthesis or fed into the metabolic pathways (Krebs cycle) and contribute to the release of energy-rich molecules. In general, the term to ‘non-protein energy’ is used, and sufficient lipid and glucose energy is supplied to spare the amino acids. As a rough guide, the ratio of non-protein energy to nitrogen is approximately 150:1, although an ideal ratio for all patients has not been absolutely defined. A lower ratio is considered for critically ill patients, whereas higher ratios are considered for less catabolic patients.

Dual energy

In general, energy should be sourced from a balanced combination of lipid and glucose; this is termed ‘dual energy’ and is more physiological than an exclusive glucose source. Typically, the fat-to-glucose ratio remains close to the 60:40–40:60 ranges.

Dual energy can minimise the risk of giving too much lipid or glucose because complications increase if the metabolic capacity of either is exceeded. A higher incidence of acute adverse effects is noted with faster infusion rates and higher total daily doses, especially in patients with existing metabolic stress. It is, therefore, essential that the administered dose complements the energy requirements and the infusion rate does not exceed the metabolic capacity. While effectively maintaining nitrogen balance, lipid inclusion is seen to confer a number of advantages ([Box 7.1](#)). Some patients, notably long-term home patients, do not tolerate daily lipid infusions and need to be managed on an individual basis. Depending on the enteral intake and nutritional needs, lipids are prescribed for a proportion of the days. A trial with the newer-generation lipid emulsions may be appropriate.

Glucose

Glucose is the recommended source of carbohydrate (1 g anhydrous glucose provides 4 kcal). [Table 7.6](#) indicates the energy provision and tonicity for a range of concentrations. Glucose 5% is regarded as isotonic with blood. The higher concentrations

Table 7.5 Henry equation

	Age (years)	Kcal (day) (W = weight)
Male	10–18	18.4W + 581
	18–30	16.0W + 545
	30–60	14.2W + 593
	60–70	13.0W + 567
	70+	13.7W + 481
Female	10–18	11.1W + 761
	18–30	13.1W + 558
	30–60	9.74W + 694
	60–70	10.2W + 572
	70+	10.0W + 577

Adapted from [Henry \(2005\)](#).

Box 7.1 Examples of the advantages of dual-energy systems over glucose-only energy systems

- Minimise risk of hyperglycaemia and related complications
- Prevent and reverse fatty liver (steatosis)
- Reduce carbon dioxide production and respiratory distress
- Meet higher calorie requirements of septic and trauma patients when glucose oxidation reduced and lipid oxidation increased
- Reduce metabolic stress
- Support immune function
- Improve lean body mass and reduce water retention
- Permit peripheral administration, through reduced tonicity
- Facilitate fluid restriction, as lipid is a concentrated source of energy
- Are a source of essential fatty acids, preventing and correcting deficiency

Table 7.6 Energy provision and tonicity of glucose solutions

Concentration (w/v)	Energy content (kcal/L)	Osmolarity (mOsmol/L)
5%	200	278
10%	400	555
20%	800	1110
50%	2000	2775
70%	2800	3885

cause phlebitis if administered directly to peripheral veins and should, therefore, be given by a central vein or in combination with compatible solutions to reduce the tonicity.

The glucose infusion rate should generally be between 2 and 4 mg/kg/min. An infusion of 2 mg/kg/min (equating to approximately 200 g [800 kcal] per day for a 70-kg adult) represents the basal glucose requirement, whereas 4 mg/kg/day is regarded as the physiologically optimal rate. Higher levels are tolerated by some patients, especially those at home on PN, but monitoring of blood glucose is required at least initially. Care needs to be taken because glucose oxidation occurs where there is an increased conversion to glycogen and fat. If excess glucose is infused and the glycogen storage capacity exceeded, the circulating glucose level rises, *de novo* lipogenesis occurs (production of fat from glucose) and there is an increased incidence of metabolic complications.

Lipid emulsions

Lipid emulsions are used as a source of energy and for the provision of the essential fatty acids, linoleic and alpha-linolenic acid. Supplying 10 kcal energy per gram of lipid, they are energy rich and can be infused directly into the peripheral veins because they are relatively isotonic with blood.

Typically, patients receive up to 2.5 g lipid/kg/day. Details of lipid emulsions available within the UK can be found in Table 7.7.

Lipid emulsions are oil-in-water formulations. Fig. 7.2 shows the structure of triglycerides (three fatty acids on a glycerol backbone) and a lipid globule, stabilised at the interface by phospholipids. Ionisation of the polar phosphate group of the phospholipid results in a net negative charge of the lipid globule and an electromechanically stable formulation. The lipid globule size distribution is similar to that of the naturally occurring chylomicrons (80–500 nm), as indicated in Fig. 7.3.

The first-generation lipid emulsions have been in use since the 1970s and utilise soybean oil as the source of long-chain fatty acids. More recent research on lipid metabolic pathways and clinical outcomes has indicated that the fatty acid profile of soybean oil alone is not ideal (Klek, 2016). For example, it is now recognised that these lipid emulsions contain excess essential polyunsaturated fatty acids, resulting in a qualitative and quantitative compromise to the eicosanoid metabolites that have important

Table 7.7 Examples of licensed lipid emulsions available in the UK

Lipid emulsion type	Details of products
Soybean oil	Intralipid 10%, 20%, 30%
Purified olive oil/soybean oil	ClinOleic 20%
Medium chain triglycerides/soybean oil	Lipofundin MCT/LCT 10%, 20%
Omega-3-acid triglycerides/soybean oil/medium-chain triglycerides	Lipidem
Fish oil/olive oil/soybean oil/medium-chain triglycerides	SMOFLipid

roles in cell structure, haemodynamics, platelet function, inflammatory response and immune response.

The molecular structure of the fatty acids has an important impact on the patient's oxidative stress. Two strategies have been applied to overcome this: a reduction in the polyunsaturated fatty acid content through an improved balance of fatty acids or the inclusion of medium chain fatty acids. This has resulted in the development of lipid emulsions that include olive oil (rich in monounsaturated oleic acid and antioxidant α -tocopherol with an appropriate level of essential polyunsaturated fatty acids), fish oil (rich in omega-3 fatty acids) and medium-chain triglycerides (reduced long-chain fatty acid content). Clinical application of these newer lipid emulsions depends on good clinical studies within the relevant patient population. Such studies should evaluate the efficacy of energy provision and clinical tolerance and report improvements in the eicosanoid-dependent functions or oxidative stress.

Both egg and soybean phospholipids include a phosphate moiety. There is a debate as to whether this is bioavailable. Therefore, some manufacturers include the phosphate content in their stability calculations, whereas others do not.

Fig. 7.3 Lipid-globule size-distribution curve of Ivelip 20%.

Micronutrients

Micronutrients naturally fall into two groups, the trace elements and vitamins, and they have a key role in intermediary metabolism, as both cofactors and coenzymes. For example, zinc is required by more than 200 enzyme systems and affects many diverse body functions, including acid–base balance, immune function and nucleic acid synthesis. It is evident, therefore, that the availability of micronutrients can affect enzyme activity and total metabolism. When disease increases the metabolism of the major substrates, the requirement for micronutrients is increased. Some of the micronutrients also play an essential role in the free-radical scavenging system. These include the following:

- Copper, zinc and manganese, in the form of superoxide dismutase, dispose of superoxide radicals.
- Selenium, in the form of glutathione peroxidase, removes hydroperoxyl compounds.
- Vitamin C is a strong reducing agent.
- Vitamins A and E and β -carotene react directly with free radicals.

By the time a patient starts PN, he or she may have already developed a deficiency of one or more essential nutrients. By the time a specific clinical deficiency is observed, for example, depigmentation of hair in copper deficiency or skin lesions in zinc deficiency, the patient will already have tried to compensate to maintain levels, compromised intracellular enzyme activity and antioxidant systems and expressed nonspecific symptoms such as fatigue and impaired immune response. A summary of factors that affect micronutrient needs is presented in **Box 7.2**. Measuring blood levels of vitamins and trace elements in acutely ill patients is of limited value. It is recommended that these are measured every 1–6 months, depending on levels, and in patients at home on PN ([National Institute for Health and Care Excellence \[NICE\], 2006](#)). Deficiency states are clinically significant, but with nonspecific symptoms, they are often difficult to diagnose.

Micronutrients should be included daily from the start of the PN. The requirements are increased during critical illness and in chronically depleted patients. Their supplementation may influence the outcome of the disease. Even if the patient has reasonable levels and reserves initially, they can

Box 7.2 Factors affecting micronutrient requirements

Baseline nutritional state on starting parenteral nutrition

- Acute or chronic onset of illness
- Dietary history
- Duration and severity of inadequate nutritional intake

Increased loss

- Small bowel fistulae/aspirate: rich in zinc
- Biliary fluid loss: rich in copper
- Burn fluid loss: rich in zinc, copper, selenium

Increased requirement

- Increased metabolism: acute in anabolic phase following catabolic phase of critically ill
- Active growth

Organ function

- Liver failure: copper and manganese clearance reduced
- Renal failure: aluminium, chromium, zinc and nickel clearance reduced

quickly become depleted if they are not supported by daily administration. Additional oral or enteral supplements may be considered if there is some intestinal absorption. However, copper deficiency can increase iron absorption and zinc intake can decrease copper absorption. Micronutrient preparations have been developed to provide more than basal amounts of all micronutrients. They should, therefore, meet the requirements of most patients, given they are administered intravenously. Micronutrients should be added to all PN infusions under appropriate, controlled environmental conditions prior to administration ([NICE, 2006](#)).

Trace elements

Trace elements are generally maintained at a relatively constant tissue concentration and are present to a level of less than 1 mg/kg body weight. They are essential; deficiency results in structural and physiological disorders which, if identified early enough, can be resolved by re-administration. Ten essential trace elements are known: iron, copper, zinc,

Table 7.8 UK reference nutritional intake (RNI) for trace elements in adults

	RNI (males)	RNI (females)
Iron (milligrams/day)	8.7	8.7
Zinc (milligrams/day)	9.5	7.0
Copper (milligrams/day)	1.2	1.2
Selenium (micrograms/day)	75	60
Iodine (micrograms/day)	140	140

fluorine, manganese, iodine, cobalt, selenium, molybdenum and chromium.

Because the controversy which exists around the amount of trace elements to administer, the American Society of Enteral and Parenteral Nutrition (ASPEN) established a task force to consider this issue. The task force published guidelines for the trace element requirements during PN (Vanek et al., 2012). UK adult reference nutritional intake and ASPEN trace element requirements during PN can be found in Table 7.8. The differences in the advised amounts reflect the efficiency of the gut to absorb the various micronutrients.

Currently, three preparations are commercially available for adults (Tracutil, Additrace, Nutryelt), together with a single paediatric preparation (Peditrace).

Vitamins

There are two groups of vitamins: the water-soluble vitamins and the fat-soluble vitamins. Fat-soluble vitamins are stored in the body fat, whereas excess water-soluble vitamins are renally cleared; therefore, if there is inadequate provision, deficiency states for the water-soluble vitamins reveal themselves first. UK adult reference nutritional intake and ASPEN vitamin requirements during PN can be found in Table 7.9. Commercially available preparations are Solivito N (water soluble), Vitlipid N Adult/Infant (fat soluble) and Cernevit (water and fat soluble, except vitamin K).

In an attempt to reduce the risk of osteoporosis, especially in home PN patients, vitamin D is essential. Patients on long-term PN should have vitamin D levels measured every 6 months. If low, this should be supplemented to help protect against osteoporosis, which is a well-recognised complication of home PN. Although oral vitamin D is of benefit, patients should be encouraged to allow sunlight exposure to the skin. By doing so, not only can the skin generate large amounts of vitamin D, but also this is not affected by intestinal absorption of oral vitamin D. The recommended dietary vitamin D intakes for patients at risk of vitamin D deficiency 600 IU/day for those 19–70 years of age and 800 IU/day for more than 7 years (Holick et al., 2011).

Table 7.9 UK reference nutritional intake (RNI) for vitamins in adults

	RNI (males)	RNI (females)
Vitamin A (micrograms/day)	700	600
Vitamin C (milligrams/day)	40	40
Vitamin D (micrograms/day)	10	10
Vitamin B1 (Thiamin) (milligrams/day)	0.9	0.8
Vitamin B2 (Riboflavin) (milligrams/day)	1.3	1.1
Vitamin B6 (milligrams/day)	1.4	1.2
Vitamin B12 (micrograms/day)	1.5	1.5
Niacin (milligrams/day)	16	12
Folate (micrograms/day)	200	200

RNI, reference nutritional intake.

Electrolytes

Electrolytes are included to meet the patient's needs. Typical daily parenteral requirements are:

- sodium (1–1.5 mmol/kg),
- potassium (1–1.5 mmol/kg),
- calcium (0.1–0.15 mmol/kg),
- magnesium (0.1–0.2 mmol/kg),
- phosphate (0.5–0.7 mmol/kg).

Depending on the stability of the patient's clinical state, they are kept relatively constant or adjusted on a near daily basis, reflecting changes in blood biochemistry. Hypophosphataemia and hypomagnesaemia should be corrected before starting parenteral or enteral nutrition to avoid the refeeding syndrome. Varying amounts of electrolytes are lost from the different gastrointestinal secretions. Table 7.10 gives an indication of the content of various gastro-intestinal secretions. This should be taken into account when formulating PN for a patient who may have such losses.

Administration of parenteral nutrition

Routes of administration

PN can be administered peripherally or centrally.

Peripheral route

Administration of PN via a peripheral venous catheter should be considered for patients who are likely to need short-term feeding

Table 7.10 Electrolyte content of gastro-intestinal secretions

Intestinal tract locality	Volume (mL)	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)	Bicarbonate (mmol/L)
Saliva	1500	10	25	10	30
Gastric juice (fasting)	1500	60	15	90	15
Pancreatic fistula	700	140	5	75	120
Biliary fistula	500	145	5	100	40
Jejunostomy	2000–3000	110	5	100	30
Ileostomy	500	115	8	45	30
Proximal colostomy	300	80	20	45	30
Diarrhoea	500–1500	120	25	90	45

(<14 days) and who have no other need for central venous access. Peripheral lines are less costly than central lines, and they may be inserted at the bedside providing the patient has good venous access. Ultrasound machines may be used to aid placement. There is no need for a chest X-ray to confirm placement because the line does not reach the central circulation. Mid-lines should be considered, which are usually about 20 cm long. Care should be taken when formulating PN to be administered via a peripheral catheter with regard to the tonicity of the solution. Some indications and contraindications to the use of the peripheral route are summarised in [Box 7.3](#).

Peripheral administration is sometimes complicated or delayed by phlebitis, where an insult to the endothelial vessel wall causes inflammation, redness, pain and possible extravasation. Hot and cold compresses have been used to treat this. A 5 mg glyceryl trinitrate patch placed where the line tip is estimated to be may cause some local vasodilation, which is believed to prevent thrombophlebitis ([Khawaja and Williams, 1991](#)). Peripheral tolerance can be influenced by a range of factors ([Box 7.4](#)).

Many consider that the tonicity of the infused solution or emulsion is a key factor defining peripheral infusion tolerance. The total number of osmotically active particles in the intracellular and extracellular fluids is essentially the same, approximately 290–310 mOsmol/L. When a lipid emulsion is included, infusions of approximately three times this osmolarity are generally well tolerated via the peripheral route, and there are reports of success with higher levels. However, other factors should also be considered. Patient factors, such as vein fragility and blood flow, may mean that some infusion episodes are better tolerated than others. The osmolarity of a PN formulation can be estimated by applying the following equation:

$$= \frac{\sum [\text{osmolarity}_n (\text{mOsmol/L}) \times \text{volume}_n (\text{L})]}{\text{Total volume (L)}}$$

where n indicates the component.

By considering the macronutrients included in the regimen, that is, the amino acids, glucose and lipid, an estimation of the osmolarity can be made. The value will be increased by

Box 7.3 Indications and contraindications for the use of peripheral parenteral nutrition

Indications

- Duration of feed likely to be short-term
- Supplemental feeding
- Compromised access to central circulation, e.g. local trauma, surgery or thrombosis
- No immediate facilities or trained staff to insert central catheter
- High risk of fungal or bacterial sepsis, e.g. patients with purulent tracheostomy secretions, immune deficiency state, history of repeated sepsis
- Contraindication to central venous catheterisation

Contraindications

- Inadequate or inaccessible peripheral veins
- Large volumes of administration
- High calorie/nitrogen requirements alongside fluid restrictions (admixture osmolarity too high)

Box 7.4 Factors that improve tolerance to peripheral lines

- Aseptic insertion and line care
- Selection of large vessel with good blood flow and direct path, e.g. cephalic vein
- Fine-bore catheter (22G) for minimal trauma on insertion and disturbance of blood flow
- Fine polyurethane catheter
- Secured catheter to minimise physical trauma
- Glyceryl trinitrate patch placed distal to insertion site, over tip, to vasodilate vein
- Flushing of lines not in use
- Low-tonicity infusions
- Inclusion of lipid emulsion; venoprotective and isotonic with blood

electrolyte or micronutrient additions; however, because the peripheral tolerance is affected by so many factors, including tonicity, and because the limit is only an estimate, the effect of these additions is relatively low unless high levels of monovalent ions are included.

Central route

The central venous route is indicated when longer-term feeding is anticipated, high-tonicity or large-volume formulations are required, or the peripheral route is inaccessible. The rapid and turbulent blood flow in the central circulation and the constant movement of the heart ensure rapid mixing and reduce the risk of osmotically induced injury to the endothelium.

Single-, double-, triple- and quadruple-lumen central lines are available, and one lumen must be dedicated for the intravenous nutrition. These lines require skilful insertion, usually into the jugular or subclavian vein, and confirmation of their position by X-ray. This relatively invasive and costly procedure is performed by trained medical staff. Tunnelling of the line to an appropriate exit site facilitates line care and may reduce the incidence of line sepsis. The femoral route is not favoured because of a higher incidence of sepsis. If cared for well, a tunnelled central line placed in a patient receiving home PN may last for many years.

Peripherally inserted central catheters

Peripherally inserted central catheters (PICCs) are typically inserted into a peripheral vein, usually the cephalic or basilic in the upper arm, with the exit tip in the superior vena cava just above the right atrium. As the name suggests, they are used for the central administration of infusions. Single- and double-lumen versions are available; some also have a one-way valve to prevent backflow. Insertion is less invasive than for conventional central lines and can be undertaken by trained nurse practitioners at the bedside. A chest X-ray is necessary to confirm placement.

Infusion control

Pumps

PN must always be administered under the control of an infusion pump. Acute overload of fluid, nutrition and electrolytes can have morbid consequences.

Infusion pumps should be used with an appropriate infusion or giving set which is compatible with both the infusion pump and the PN admixture. For home patients, small, simple battery-powered ambulatory pumps are favoured.

Temperature

PN should be at room temperature when it is infused. It must, therefore, be removed from the refrigerator in which it is stored approximately 2 hours before connection. No external heat should be applied, although intermittent inversion of the bag may help.

If a cold admixture is infused, the patient may experience infusion discomfort, and the acute release of gas from where it was dissolved in the admixture may cause the pump to alarm 'air in line'.

Compounded formulations

Historically, PN was administered from a series of separate bottles, where healthcare staff had to accurately and safely manage a combination of giving sets, infusion rates and total infusion

times. Patients now receive their complete nutrition from a single daily bag of a pharmaceutically stable PN formulation.

Various terms are used to describe the PN formulation, depending on whether lipid is included. If it contains lipid, it is called a 3-in-1, ternary or all-in-one admixture; if no lipid is present, the terms 2-in-1, binary or aqueous admixture are used. Various methods now exist for compounding PN. These range from high-tech, computer-run compounding machines through to basic-principle techniques such as gravity filling.

Formulations

Depending on the type (size and specialty) of the hospital, various formulations are used. The range is specifically selected to meet the needs of the patients managed by the hospital and will typically include a low-tonicity regimen suitable for peripheral administration, a higher calorie and nitrogen regimen for central administration to catabolic patients and a high-tonicity regimen for fluid-restricted patients. Baseline electrolytes will generally be included, although the flexibility for reduced levels is usually offered.

Licensed, ready-to-use products

Various licensed, ready-to-use preparations are available and should have micronutrients added prior to infusing. For convenience, baseline electrolyte levels are included in many formulations and meet the needs of most patients, and additional electrolytes may be added up to the limits set by the manufacturer. Electrolyte-free options are also available. Some are licensed for use in paediatrics and/or for peripheral use. Manufacturers advise on stability and shelf-life for electrolyte and micronutrient additions. The range of ready-to-use products includes the following:

- Triple-chamber bags (Triomel, Kabiven, SmofKabiven and Nutriflex Lipid ranges): chambers separately prefilled with lipid, amino acid and glucose and terminally sterilised. These are activated by applying external pressure so that weak seals peel open, mixing the contents to form a 3-in-1 formulation.
- Dual-chamber bags (Clinimix and Nutriflex ranges): chambers separately prefilled with amino acid and glucose and terminally sterilised. These are activated to form a 2-in-1 formulation. They provide the flexibility to allow staff to omit or add a compatible lipid.

The range of commercially available PN formulations is continually expanding. For hospital pharmacies without compounding facilities, this offers an opportunity to ensure the correct formulation is given to meet individual patient needs. PN formulations are now available with micronutrients added and with extended shelf-lives when stored in a refrigerator.

Cyclic infusions

Cyclic PN is when the daily requirements are administered over a short period. A classic example is stable home patients who administer their feed overnight, freeing themselves from the constraints of an infusion during the day. This enables them to have more physical freedom and improves their quality of life. Some patients, however, prefer to administer their PN during the day

time. This is made possible by use of a small ambulatory pump and a backpack in which they may carry their PN.

Because cyclic feeding more closely simulates the human feeding pattern and is a closer match to normal hormonal and metabolic cycles, it also offers a range of metabolic and clinical advantages. Steatosis, fatty infiltration of the liver, is less common and may be corrected by employing cyclic feeding because the feed-free period facilitates lipolysis and fat mobilisation. Peripheral tolerance may be improved as the endothelia recover between infusion periods. Initially, the patient should receive the PN infusion slowly over the full 24 hours; as tolerated, the rate of infusion can be increased slowly to decrease the infusion time. This should be done over a series of days. During this period, the patient must be monitored closely for any signs of fluid, electrolyte or acid–base imbalance and hyper-/hypoglycaemia. For example, on stopping the infusion, rebound hypoglycaemia may occur.

Pharmaceutical issues

Having identified the balance of nutrients required for a patient in a single day, it is necessary to formulate a physically and chemically stable aseptically prepared admixture. PN admixtures contain more than 50 chemical entities and, as such, are extremely complex and have many chemical interactions taking place, which could lead to instability in the final formulation. Professional advice or appropriate reference material should be sought and used before compounding and administering of PN takes place. Manufacturers and third-party experts can advise on stability issues.

Physical stability

Physical instability takes a number of forms, including precipitation of crystalline material and breakdown of the lipid emulsion.

Precipitation

Precipitation carries two key risks. First, the potential to infuse solid particles to the narrow pulmonary capillaries may result in fatal emboli. Second, the prescribed nutrients may not be infused to the patient. Clinically dangerous precipitates may not always be visible to the naked eye, especially if lipid emulsion is present. They may also develop over time, and an apparently ‘safe’ admixture may develop fatal precipitates when in use.

Precipitation of solids is epitomised by the formation of calcium phosphate; this is of special concern in neonatal admixtures where the requirements to prevent hypophosphataemic rickets and severe osteopenia may exceed the safe concentrations. Such concentrations are rarely seen in adult regimens. It is known that calcium and phosphate can form a number of different salt forms, each with different solubility profiles – for example, $\text{Ca}(\text{H}_2\text{PO}_4)_2$, which is highly soluble in comparison to CaHPO_4 and $\text{Ca}_3(\text{PO}_4)_2$. $\text{Ca}_3(\text{PO}_4)_2$ precipitation occurs relatively immediately and has a white, fluffy amorphous appearance; however, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ precipitation is time mediated and has a more crystalline appearance.

Factors affecting calcium phosphate precipitation are shown in Table 7.11. Practical measures can be taken to minimise the risks; these include accurate calculation of the proposed formulation, comparison against professionally defined comprehensive matrices and thorough mixing. Solubility curves and algorithms should be used with extreme caution, even if they are quoted for a specific amino acid source; this is because they do not consider all the factors and do not consistently identify risk. Assuming the sodium content can be tolerated, use of an organic phosphate salt form may be beneficial because of the higher solubility of the sodium glycerophosphate salt form.

Trace elements have also been associated with clinically significant precipitation; these include iron phosphate and copper sulphide (hydrogen sulphide from the minor degradation of

Table 7.11 Factors affecting calcium phosphate precipitation

Factor	Mechanism and effect
pH	Low pH supports solubility, whereas a higher pH supports precipitation. Depending on the amount and buffering capacity of the amino acids, this can be affected by different concentrations and sources of glucose solution and acetate salt forms.
Temperature	Higher temperatures are associated with greater precipitation, increased availability of free calcium to interact and a shift to the more insoluble salt forms.
Amino acids	Buffer pH changes. Complex with calcium, so less available to react with phosphate. Both the source of amino acid and the relative content are important.
Magnesium	Complex with phosphate forming soluble salts rather than less soluble calcium salts.
Calcium salt form	Calcium chloride dissociates more readily than calcium gluconate, releasing it to react with the phosphate.
Phosphate salt form	Monobasic salts (e.g. dipotassium phosphate) dissociate more readily than dibasic salts (e.g. potassium acid phosphate), releasing phosphate to react with the calcium. Organic salts, such as sodium glycerophosphate and glucose-1-phosphate, are more stable.
Mixing order	Optimum stability is achieved by only permitting calcium and phosphate to come together in a large volume admixture. Agitate between additions to avoid pockets of concentration.

cysteine/cystine). These very fine precipitate forms are less likely to cause occlusion of catheters or lung capillaries but have been associated with significant clinical delivery losses when they are taken up by inline filtration devices.

Lipid destabilisation

The oil-in-water lipid emulsions are sensitive to destabilisation by a range of factors, including the presence of positively charged ions, pH changes and changes in environmental temperature. The lipid globules may come together and coalesce to form larger globules and release free oil; this could occlude the lung microvasculature and cause respiratory and circulatory compromise and lead to death.

Positively charged ions destabilise the admixture by drawing the negatively charged lipid globules together, overwhelming the electromechanical repulsion of the charged phospholipids and increasing their tendency to join or coalesce. Divalent and trivalent ions have a more significant effect; therefore, there are tightly defined limits for the amount of Ca^{2+} , Mg^{2+} and Fe^{3+} that can be added to a 3-in-1 admixture. Although the limits for the other polyvalent ions (such as zinc and selenium) are also controlled, they are less of a problem because they are given in micromolar or nanomolar quantities. Low concentrations of amino acids and extremes of glucose concentration (high and low) also reduce the stability of the emulsion and increase the tendency for creaming and cracking of the lipid emulsion.

The naked eye can identify large-scale destabilisation, as shown in Table 7.12; however, the limitations of this method need to be recognised because clinically significant destabilisation might not be visible to the naked eye. In practice, stability laboratories use specialised technical equipment to determine defined criteria so as to establish the physical stability of a formulation. These tests include assessing changes in the size distribution of lipid globules with optical microscopes and variety of particle-size-analysis instruments against the defined limits of pharmaceutical acceptance. A wide safety margin is applied.

Chemical stability

Chemical stability takes many forms, notably chemical degradation of the vitamins and amino acids.

Vitamin stability

Many vitamins readily undergo chemical degradation, and vitamin stability often defines the shelf-life of a given formulation.

Vitamin C (ascorbic acid), the least stable component, is generally regarded as the marker for vitamin degradation. Vitamin C oxidation is accelerated by heat, oxygen and certain trace elements, including copper. Other examples include vitamin A photolysis and vitamin E photo-oxidation. Measures that minimise oxygen presence, such as minimal aeration during compounding, evacuation of air at the end of compounding and use of multi-laminated oxygen barrier bags, and light protection of admixture containers and delivery sets are recommended.

Amino acid stability

The amino acid profile should be maintained for the shelf-life of the formulation, and manufacturers perform assays to confirm this prior to issuing stability reports.

Maillard reaction

The Maillard reaction is a complex pathway of chemical reactions that starts with a condensation of the carbonyl group of the glucose and the amino group of the amino acid. At present, relatively little is known about the clinical effects of these Maillard reaction products; however, it is prudent to minimise their presence by protecting from light and avoiding high temperatures.

Microbial contamination

PN is a highly nutritious medium whose hypertonicity will partially limit microbial growth potential. Growth in the presence of lipid emulsion is greater. Pharmaceutical developments have enabled terminal sterilisation of many of the components, including the multi-chamber bag presentations; however, additional manipulations should only be performed using validated aseptic techniques in appropriate pharmaceutically clean environments by suitably trained staff. Nurses, patients and carers must be trained to apply aseptic methods when connecting and disconnecting infusions. For this reason, many centres have documented line care and PN protocols.

Table 7.12 Lipid instability

	Description	Visual observation
Stable, normal emulsion	Lipid globules equally dispersed. Suitable for administration.	Normal emulsion
Light creaming	Lipid globules rising to the top of the bag. Slight layering visible. Readily redisperses on inverting the bag. Suitable for administration.	Light creaming
Heavy creaming, flocculation	Lipid globules coming together but not joining. Rising to the top of the bag. More obvious layering visible. Readily redisperses on inverting the bag. Acceptable for administration.	Heavy creaming
Coalescence	Lipid globules come together, coalesce to form larger globules and rise to the surface. Larger globules join, releasing free oil. Irreversible destabilisation of the lipid emulsion. Not suitable for administration.	Cracked; oil layer viewed close up

Shelf-life and temperature control

The manufacturer may be able to provide physical and chemical stability data to support a formulation for a shelf-life of up to 90 days at 2–8°C followed by 24 hours at room temperature for infusion; this assumes that a strict aseptic technique is used during compounding. Units holding a manufacturing license covering aseptic compounding of PN are potentially able to assign this full shelf-life (if stability data are available), whereas unlicensed units are limited to a maximum shelf-life of 7 days.

PN must be stored and transported within the defined temperature limits and should not be exposed to temperature cycling (e.g. the formulations must not freeze); for this reason, a validated cold-chain must be employed, especially when delivering formulations to home care patients. Pharmaceutical-grade fridges should be used and monitored to ensure appropriate air cycling and temperature maintenance. The temperature during the infusion period should be known. Because neonatal units and their patient incubators are classically maintained at higher temperatures, formulations used for this environment must have been stability-validated at these temperatures.

Drug stability

The addition of drugs to PN admixtures, or Y-site coadministration, is actively discouraged unless the compatibility has been formally confirmed. Wherever possible, the PN should be administered through a dedicated line. Multilumen catheters can be used to infuse PN separately from other infusion(s); however, extreme competition for intravenous access may prompt consideration of drug and PN combinations. Many factors need to be considered: the physical and chemical stability of the PN, the physical and chemical stability of the drug, the bioavailability of the drug (especially when a lipid emulsion is present) and the effect of stopping and starting Y-site infusions on the actual administration rates. It is not possible to reliably extrapolate data from a specific PN composition, between brands of solutions and salt forms or between brands or doses of drugs. Various studies have been performed and published; however, these should be used with caution.

In practice, drugs should only be infused with PN when all other possibilities have been exhausted. These may include gaining further intravenous access and changing the drug(s) to clinically acceptable non-intravenous alternatives. The relative risks of stopping and starting the PN infusion and repeatedly breaking the infusion circuit should be fully considered before sharing a line for separate infusions of PN and drug. In most cases, the risks outweigh the benefits; however, if this option is adopted, the line must be flushed before and after with an appropriate volume of solution known to be stable with both the PN and the drug. Strict aseptic technique should be adopted to minimise the risk of contaminating the line and infusions.

Filtration

All intravenous fluids pass through the delicate lung microvasculature with its capillary diameter of 8–12 micrometers. The presence of particulate matter has been demonstrated to cause direct

embolisation, direct damage to the endothelia, formation of granulomata and formation of foreign body giant cells and to have a thrombogenic effect. In addition, the presence of microbial and fungal matter can cause a serious infection or inflammatory response.

Precautions taken to minimise the particulate load of the compounded admixture must include:

- use of filter needles or straws (5 micrometers) during compounding to catch larger particles, such as cored rubber from bottles and glass shards from ampoules;
- air particle levels kept within defined limits in aseptic rooms by the use of air filters and non-shedding clothing and wipes;
- use of quality raw materials with minimal particulate presence, including empty bags and leads;
- confirmation of physical and chemical stability of the formulation prior to aseptic compounding applying approved mixing order (stability for the required shelf-life time and conditions).

Guidelines have been published that endorse the use of filters, especially for patients requiring intensive or prolonged parenteral therapy, including home patients, the immunocompromised, neonates and children (Bethune et al., 2001). The filter should be placed as close to the patient as possible and validated for the PN to be used. For 2-in-1 formulations, 0.2-micrometers filters may be used; for 3-in-1 formulations, validated 1.2-micrometers filters may be used.

Light protection

It is widely recognised that exposure to light, notably phototherapy light and intense sunlight, may increase the degradation rate of certain constituents such as vitamins A and E. It is recommended that all regimens should be protected from light both during storage and during infusion for the following reasons:

- The presence of a lipid emulsion does not totally protect against vitamin photodegradation.
- The Maillard reaction is influenced by light exposure.
- Ongoing research suggests lipid peroxidation is accelerated by a range of factors, including exposure to certain wavelengths of light.

Additionally, only validated bag and delivery set covers should be used.

Nutritional assessment and monitoring

Initial assessment

Once screening has identified that a patient is in need of nutritional intervention, a more detailed assessment is performed. This will include an evaluation of nutritional requirements, the expected course of the underlying disease, consideration of the enteral route and, where appropriate, identification of access routes for PN. This will be supported by a clinical assessment that will include:

- clinical history;
- dietary history;
- physical examination;
- anthropometry including muscle function tests;
- biochemical, haematological and immunological review.

Monitoring

PN monitoring has a number of objectives:

- evaluate ongoing nutritional requirements, including fluid and electrolytes;
- determine the effectiveness of the nutritional intervention;
- facilitate early recognition of complications;
- identify any deficiency, overload or toxicity to individual nutrients;
- determine discrepancies between prescribed, delivered and received dose.

Regular monitoring contributes to the success of the PN, and a monitoring protocol should be in place for each individual patient. Baseline data should be recorded so that deviations can be recognised and interpreted. In the early stages, while the patient is in

the acute stage of the illness and the nutritional requirements are being established, the frequency of monitoring will be greatest. As the patient's status stabilises, the frequency of monitoring will reduce, although the range of parameters monitored is likely to increase. NICE (2006) has issued a comprehensive guideline for laboratory monitoring of nutrition support. Examples of parameters monitored can be found in Table 7.13.

Complications

Complications of PN fall into two main categories: catheter related and metabolic (Box 7.5). Overall, the incidence of such complications has reduced because of increased knowledge and

Table 7.13 Examples of parameters monitored during parenteral nutrition therapy

Parameter	Additional information
Clinical symptoms at presentation	May be specific (e.g. thrombophlebitis) or nonspecific (e.g. confusion)
Temperature, blood pressure and pulse	Vigilance for the risk of sepsis
Fluid balance and weight	Acute weight changes reflect fluid gain or loss and prompt review of the volume of the PN. Slow, progressive changes are more likely to reflect nutritional status.
Nitrogen balance	An assessment of urine urea and insensible loss and their relation to nitrogen input. It is difficult to obtain accurate figures.
Visceral proteins	Albumin levels may indicate malnutrition, but its long half-life limits sensitivity to detect acute changes in nutritional status. Other markers with a shorter half-life may be more useful, e.g. transferrin.
Haematology	Platelet counts and clotting studies for thrombocytopenia
C-reactive protein	Monitor the inflammatory process.
Blood glucose	Hyperglycaemia is a relatively frequent complication. Management includes either a reduction in the infused dose of glucose or lengthening of the infusion period. If these measures fail, insulin may be used. Hyperglycaemia may also indicate sepsis. Rebound hypoglycaemia can occur when an infusion is stopped. If this is a problem, the infusion should be tapered off during the last hour or two of the infusion. Some infusion pumps are programmed to do this automatically.
Lipid tolerance	Turbidity, cholesterol and triglyceride profiles are required.
Electrolyte profile	Indicates appropriate provision or complicating clinical disorder. In the first few days, low potassium, magnesium and/or phosphate with or without clinical symptoms may reflect the refeeding syndrome.
Liver function tests	An abnormal liver profile may be observed, and it is often difficult to identify a single cause. PN and other factors, such as sepsis, drug therapy and underlying disease, may all interplay. In adults, PN-induced abnormalities tend to be mild, reversible and self-limiting. In the early stages, fatty liver (steatosis) is seen. In longer-term patients, a cholestatic picture tends to present. Varying the type of lipid used and removing lipid from some formulations may be of benefit.
Anthropometry	Assesses longer-term status
Acid–base profile	Indicative of respiratory or metabolic compromise and may require review of PN formulation
Vitamin and trace element screen	A range of single compounds or markers to consider tolerance and identify deficiencies, although of limited value because some tests are nonspecific and inaccurate
Catheter entry site	Vigilance for phlebitis, erythema, extravasation, infection, misplacement
PN, Parenteral nutrition.	

Box 7.5 Examples of complications during parenteral nutrition

Catheter related

- Thrombophlebitis (peripheral)
- Catheter-related infection, local or systemic
- Venous thrombosis
- Line occlusion (lipid, thrombus, particulate, mechanical)
- Pneumothorax, catheter malposition, vessel laceration, embolism, hydrothorax, dysrhythmias, incorrect placement (central)

Metabolic

- Hyperglycaemia or hypoglycaemia
- Electrolyte imbalance
- Lipid intolerance
- Refeeding syndrome
- Dehydration or fluid overload
- Specific nutritional deficiency or overload
- Liver disease or biliary disease
- Gastrointestinal atrophy
- Metabolic bone dysfunction (in long-term)
- Thrombocytopenia
- Adverse events with parenteral nutrition components
- Essential fatty acid deficiency

skills together with more successful management (Maroulis and Kalfarentzos, 2000).

Line sepsis

Line sepsis is a serious and potentially life-threatening condition. Monitoring protocols should ensure that signs of infection are identified early, and a local decision pathway should be in place to guide efficient diagnosis and management. Management will depend on the type of line and the source of infection. Alternative sources of sepsis should be considered. Initially, the PN is usually stopped.

Line occlusion

Line occlusion may be caused by a number of factors, including:

- fibrin sheath forming around the line, or a thrombosis blocking the tip;
- internal blockage of lipid, blood clot or salt and drug precipitates;
- line kinking;
- particulate blockage of a protective inline filter.

Management will depend on the cause of the occlusion; in general, the aim is to save the line and resume feeding with minimum risk of the patient. The use of locks and flushes with alteplase (for fibrin and thrombosis), ethanol (for lipid deposits) and dilute hydrochloric acid (for salt and drug precipitates) may be considered. In some cases, the lines may need to be replaced. These complications can be minimised by having a dedicated line for PN and flushing the line well with sodium chloride 0.9% before and after use; a regular slow flush of ethanol 20% may be used to prevent lipid deposition.

Refeeding syndrome

Patients should be assessed as to their risk of developing refeeding syndrome (see Table 7.14). Refeeding syndrome can be

Table 7.14 Risk factors for developing refeeding syndrome (NICE, 2006)

One or more of the following	Two or more of the following
BMI <16 kg/m ²	BMI <18.5 kg/m ²
Unintentional weight loss greater than 15% within the last 3–6 months	Unintentional weight loss greater than 10% within the last 3–6 months
Little or no nutritional intake for more than 10 days	Little or no nutritional intake for more than 5 days
Low levels of potassium, phosphate or magnesium prior to feeding	A history of alcohol abuse or drugs including insulin, chemotherapy, antacids or diuretics

BMI, Body mass index.

defined as ‘the potentially fatal shifts in fluids and electrolytes that may occur in malnourished patients receiving nutrition’ (Mehanna et al., 2008). Undernourished patients are catabolic, and their major sources of energy are fat and muscle. As the PN infusion (which contains glucose) starts, this catabolic state is pushed to anabolic, which in turn causes a surge of insulin. As the insulin levels increase, there is an intracellular shift of magnesium, potassium and phosphate, and acute hypomagnesaemia, hypokalaemia and hypophosphataemia result. This can cause cardiac and neurological dysfunction and may be fatal. PN should be gradually increased over a period of 2–7 days, depending on the patient’s BMI and risk of developing refeeding syndrome. Thiamine is an essential coenzyme in carbohydrate metabolism and deficiency results in Wernicke’s encephalopathy (ocular abnormalities, ataxia, confusional state, hypothermia, coma) or Korsakoff’s syndrome (retrograde and anterograde amnesia, confabulation). For these reasons, oral thiamine and vitamin B compound strong or full-dose intravenous vitamin B preparation may be administered before PN is started and for the first few days of infusion.

Specific disease states**Liver**

Abnormal liver function tests associated with short-term PN are usually benign and transient. However, liver dysfunction in long-term PN patients is one of the most prevalent and severe complications. The underlying pathophysiology largely remains to be elucidated. The content of PN should be examined, and care should be taken not to overfeed with glucose and/or lipid. Various lipid preparations are now available, including preparations containing fish oils, which have been reported to be beneficial in reversing liver disease (De Meijer et al., 2009). Lipid emulsions containing a mix of medium- and long-chain triglycerides are also available and have an improved liver tolerability. Because of the complexity of liver function, the range of potential disorders and the liver’s role in metabolism, the use of PN in liver disease can cause problems. Consensus guidelines for the use of PN in

liver disease have been published (Plauth et al., 2009). Nutritional intervention may be essential for recovery, although care must be exercised with amino acid input and the risk of encephalopathy, calorie input and metabolic capacity, and the reduced clearance of trace elements such as copper and manganese (Maroulis and Kalfarentzos, 2000). Low-sodium, low-volume feeds are indicated if there is ascites. Cyclic feeding appears useful, especially in steatosis.

Renal failure

Fluid and electrolyte balance demand close attention, and guidelines for nutrition in adult renal failure are available (Cano et al., 2009). A low-volume and poor-quality urine output may necessitate a concentrated PN formulation with a reduction in electrolyte content, particularly a reduction in potassium and phosphate. In the polyuric phase or the nephrotic syndrome, a higher-volume formulation may be required. If there is fluid retention, ideal body weight should be used for calculating requirements rather than the actual body weight.

The metabolic stress of acute renal failure and the malnutrition of chronic renal failure may initially demand relatively high nutritional requirements; however, nitrogen restriction may be necessary to control uraemia in the absence of dialysis or filtration and to avoid uraemia-related impaired glucose tolerance, because of peripheral insulin resistance, and lipid clearance. Micronutrient requirements may also change in renal disease. For example, renal clearance of zinc, selenium, fluoride and chromium is reduced, and there is less renal 1α -hydroxylation of vitamin D.

Intradialytic PN (IDPN) may be administered at the same time as dialysis; however, this is not without complications. High blood sugars and fluid overload can be a problem, and there is uncertainty as to how much of the PN is retained by the body and how much is removed by dialysis. Administration requires local guidelines and monitoring to be in place (Dukkipati et al., 2010; Lazarus, 1999).

Pancreatitis

Acute pancreatitis is a metabolic stress that requires high-level nutritional support and pancreatic rest to recover. Guidelines for nutrition in acute pancreatitis are available (Gianotti et al., 2009). Whereas enteral nutrition stimulates the pancreas, PN does not appear to. Hyperglycaemia may occur and require exogenous insulin.

Sepsis and injury

Significant fluctuations in macronutrient metabolism are seen during sepsis and injury. There are two metabolic phases: the 'ebb' phase of 24–48 hours and the following 'flow' phase. The initial hyperglycaemia, reflecting a reduced utilisation of glucose, is followed by a longer catabolic state with increased utilisation of lipid and amino acids. The effect of the different lipid emulsions on immune function is the subject of much research. It is important not to overfeed and also to consider the reduced glucose tolerance during the critical days. This is a result of increased insulin resistance and incomplete glucose oxidation. Exogenous insulin may be required.

Respiratory

Whereas underfeeding and malnutrition can compromise respiratory effort and muscle function, overfeeding can equally compromise respiratory function as a result of increased carbon dioxide and lipid effects on the circulation. Although chronic respiratory disease may be linked with a long-standing malnutrition, the patient with acute disease will generally be hypermetabolic.

Heart failure

Heart failure and multiple-drug therapy may limit the volume of PN that can be infused. Concentrated formulations are used and, as a consequence of the high tonicity, administered via the central route. Close electrolyte monitoring and adjustment are required. Cardiac drugs may affect electrolyte clearance. Although central lines may already be in use for other drugs or cardiac monitoring, it is essential to maintain a dedicated lumen or line for the feed.

Diabetes mellitus

Diabetic patients can generally be maintained with standard dual-energy regimens. It is important to use insulin to manage blood glucose rather than reduce the nutritional provision of the feed. Close glucose monitoring will guide exogenous insulin administration. This should be given as a separate infusion (sliding scale) or, if the patient is stable, in bolus doses. Insulin should not be included within the PN formulation because of stability problems and variable adsorption to the equipment. Y-site infusion with the PN should be avoided because changes in insulin rates will be delayed, and changes in feed rates will result in significant fluctuations in insulin administration. Long-term PN patients may need differing insulin regimens, depending on the glucose load (aqueous/lipid) in the formulation. Although using oral antihypoglycaemic agents with PN may be considered, care should be taken as to the potentially erratic absorption and thus varying blood glucose levels.

Cancer and palliative care

The worldwide debate over the use of artificial nutrition and hydration in cancer and palliative care remains controversial. Nutritional support in cancer and palliative care is guided by the potential risks and benefits of the intervention, alongside the wishes of the patient and carers. Further research is required to evaluate the effects of PN on length and quality of life. Guidelines have been developed on ethical aspects of artificial nutrition (Druml et al., 2016). PN may be useful during prolonged periods of gastro-intestinal toxicity, as in bone marrow transplant patients.

Pre- and postsurgery

Only a minority of patients require pre- and postsurgical PN, as most are eating normal food within 1–3 days. In patients with severe undernutrition and who cannot be fed adequately enterally, 7–10 days preoperative PN improves postoperative outcome. Postoperative PN is recommended in patients who cannot meet their calorie requirements enterally within 7–10 days following surgery.

Short bowel syndrome

The small intestine is defined as ‘short’ if it is less than 100 cm. Treatment options depend on which part of the gut has been removed and the functional state of the remaining organ. The surface area for absorption of nutrition and reabsorption of fluid and electrolytes is significantly compromised. Fluid and electrolyte balance needs to be managed closely because of the high-volume losses. High-volume PN formulations with raised electrolyte content (notably sodium and magnesium) may be required. Vitamin and trace element provision is very important.

Long-term parenteral nutrition

Comprehensive guidelines have been developed for adult patients with chronic intestinal failure (Pironi et al., 2016). Chronic intestinal failure is described as ‘the long lasting reduction of gut function below the minimum necessary for the absorption of macronutrients with or without water and electrolytes, such that intravenous supplementation is required to maintain health with or without growth’ (Pironi et al., 2016).

Home care is well established in the UK, with some patients successfully supported for over 20 years. There are an increasing number of patients receiving long-term PN at home. In these patients, total or supplemental PN may be appropriate. Trace elements, notably selenium, should be managed closely because a patient’s requirements may be increased.

Many patients are trained to connect and disconnect their PN and to care for their central lines. Patients are encouraged to lead as active and normal a life as possible. Foreign travel is now possible for patients on home PN, as are most other normal daily activities and sports (Staub et al., 2009). Most patients are extremely well informed about their underlying disease and their PN; many also benefit from the support group Patients on Intravenous and Nasogastric Nutrition Therapy (PINNT) and from Looking into the Requirements for Equipment (LITRE), a standing committee of BAPEN which looks at equipment issues.

Before patients are discharged home on PN, medication should be optimised to reduce the amount of PN they require. Medication therapy is used to reduce gut transit time, so loperamide is frequently prescribed. In practice, the dose of loperamide often exceeds the maximum dose recommended by the manufacturer. Opioids such as codeine phosphate may also be used to reduce gut transit time. However, loperamide is preferred to opiate drugs because it is not addictive or sedative. Proton pump inhibitors are also used to reduce gastric secretion and thereby reduce the amount of fluid lost through high-output stomas.

Paediatric parenteral nutrition

Nutritional requirements

Early nutritional intervention is required in paediatric patients because of their low reserve, especially in neonates. Where possible, premature neonates should commence feeding from day 1. In addition to requirements for the maintenance of body tissue, function and repair, it is also important to support growth and development.

Typical guidelines for average daily requirements of fluid, energy and nitrogen are shown in Table 7.15. The dual-energy approach is favoured in paediatrics. Most centres gradually increase the lipid provision from day 1 from 1 g/kg/day to 2 g/kg/day and then 3 g/kg/day, monitoring lipid clearance through the serum triglyceride level. This ensures the essential fatty acid requirements of premature neonates are met.

Formulation and stability issues

Many centres use PN formulations that include specific paediatric amino acid solutions (Primene, Vaminolact or Aminoplasmal Paediatric). Prescriptions and formulations are tailored to reflect clinical status, biochemistry and nutritional requirements. Micronutrients are included daily. Paediatric licensed preparations are available and are included on a mL/kg basis up to a maximum total volume (Peditrace, Solivito N and Vitlipid N Infant). Electrolytes are also monitored and included in all formulations on a mmol/kg basis. Acid–base balance should be considered. Potassium and sodium acetate salt forms are used in balance with the chloride salt forms in neonatal formulae to avoid excessive chloride input contributing to acidosis (acetate is metabolised to bicarbonate, an alkali). In the initial stages, neonates tend to be hypernatraemia as a result of relatively poor renal clearance; this should be reflected in the standard formulae used. If calcium gluconate is used, it must be from plastic containers because of the concerns over contamination with aluminium.

As a result of the balance of nutritional requirements, a relatively high glucose requirement with high calcium and phosphate provision, the neonatal and paediatric prescription may be supplied by a 2-in-1 formulation and separate lipid infusion. These are generally given concurrently, joining at a Y-site. Older children can sometimes be managed with 3-in-1 formulations. A single infusion is particularly useful in the home care environment. Some ready-to-use formulations are licensed for use in paediatrics.

Improved stability profiles with the new lipid emulsions, and increasing stability data, may support 3-in-1 formulations that meet the nutritional requirements of younger children.

Heparin

Historically, low concentrations of heparin were included in 2-in-1 formulations in an attempt to improve fat clearance through enhanced triglyceride hydrolysis, prevent the formation of fibrin around the infusion line, reduce thrombosis and reduce thrombophlebitis during peripheral infusion. However, this is no longer recommended because it was recognised that when the 2-in-1 formulation comes into contact with the lipid phase, calcium-heparin bridges form between these lipid globules, destabilising the formulation. Also, there is limited evidence of clinical benefit of the heparin inclusion.

Route of administration

Peripheral administration is less common in neonates and children because of the risk of thrombophlebitis; however, it is useful when low-concentration, short-term PN is required and there is

Table 7.15 Suggested paediatric daily parenteral nutrition requirements

		Day 1	Day 2	Day 3	Day 4	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺
		>1 month but <10 kg				mmol/kg/day			
Fluid requirement	100 mL/kg								
						3	2.5	0.6	0.1

Lipid	g/kg	1	2						
Phosphate ^a	mmol/kg/day	0.18	0.25						

^aIncludes phosphate from lipid emulsion and Vitlipid preparations.
Adapted from Koletzko et al., (2005).

good peripheral access. The maximum glucose concentration for peripheral administration in paediatrics is generally regarded to be 12%. However, considering all the other factors that can affect the tonicity of a regimen and peripheral tolerance, it is clear that this is a relatively simplistic perspective. Many centres favour a limit of 10% with close clinical observation. Tonicity of the formulation should also be used when reviewing the route of administration.

Central administration is via a PICC a long-term tunnelled central line or a jugular or subclavian line. Femoral lines are a less preferred option because of their location and, therefore, high risk of becoming infected.

Case studies

Case 7.1

Mrs AB is 40-year-old and has been admitted to hospital for an elective bowel resection. She has suffered from Crohn's disease for 20 years and has had many previous episodes of surgery. Over the last 3 months Mrs AB has lost 6 kg body weight. Her current weight is 45 kg, and she is 1.6 m tall. Mrs AB is admitted 2 weeks prior to surgery for elective preoperative intravenous feeding to maximise the success of surgery.

Post-operatively, Mrs AB is left with an ileostomy, and her surgical notes inform you she has just 90 cm of small bowel remaining. There is no plan for further surgery.

Questions

1. Calculate Mrs AB's fluid requirements and nutritional requirements using the Henry equation.
2. What sort of intravenous access would be appropriate for Mrs AB's preoperative PN?
3. What electrolytes and vitamins may need to be supplemented as PN starts, and why?
4. What sort of access should be considered for postoperative PN?
5. What changes would you expect to see in Mrs AB's PN formulation?
6. What long-term care plan would you expect to see for Mrs AB?

Answers

1. The provision of 20–40 mL/kg fluid gives a requirement of between 900 mL and 1800 mL/day. Using the Henry equation Mrs AB's nutritional requirements are 1132 kcal/day ($[9.74 \times 45] + 694 = 1132$ kcal/day).
2. Given Mrs AB's current weight of 45 kg and having calculated her fluid and nutritional requirements, it can be seen that they are not excessively high. Providing Mrs AB has good peripheral access, a long peripheral line would be suitable. This can be inserted at the bedside and is good for short-term feeding. PN suitable for peripheral infusion should be formulated.
3. Mrs AB is at risk of refeeding syndrome given that her BMI is 17.6 ($\text{BMI} = \text{weight [kg]} / \text{height [m}^2\text{]}$) and she has lost more than 10% of her body weight in the last 6 months. With this in mind potassium, magnesium and phosphate should be monitored closely and supplemented where necessary. Vitamin B compound strong or intravenous vitamin B should be given.
4. Given that Mrs AB now has a 'short bowel' (i.e. <100 cm), it is likely she will require long-term parenteral nutrition. For this reason, a more permanent central line should be considered, such as a tunnelled central line.

5. With only 90 cm of short bowel, Mrs AB will have a high-output ileostomy, likely greater than 1000 mL/day output. This means the volume of PN will need to be increased to prevent dehydration and to replace losses. Ileostomy secretions are rich in sodium, and therefore sodium will need to be increased. Magnesium loss will also mean an increased requirement in the PN.
6. It is likely Mrs AB will need to go home on PN. Prior to this, medication to slow gut transit time should be optimised. Her prescription may look like the following:

Codeine phosphate 60 mg four times a day
Loperamide 6 mg four times a day
Omeprazole 40 mg once a day

Once medication has been optimised, PN formulation should be stabilised—namely, electrolytes and fluid. Mrs AB may not need PN every day. The multidisciplinary nutrition team should then work to train Mrs AB to connect and disconnect her own PN and to care for her central line. A home care package and PN equipment installation will then be required before Mrs AB is discharged into the community. There will be close follow-up and regular outpatient clinic appointments.

Case 7.2

You arrive at work on a Monday morning to find the nutrition support pharmacist has phoned in sick and you have been asked to cover PN. During the course of the morning, you receive a referral for a patient who needs to start PN. You and the rest of the nutrition support team go to review the patient and find the following clinical details:

- The patient, Mrs T, is 40-year-old and weighs 70 kg.
- Mrs T has been diagnosed with a postoperative ileus following elective surgery. She is now 7 days post-op.
- Mrs T has no history of weight loss or malnutrition. Preoperatively, she was well, with a good healthy diet.
- Mrs T has a triple-lumen central line in situ, which was placed during surgery. One lumen has been used for intravenous fluids, another for intravenous antibiotics. The third lumen has not been used.
- Mrs T has no gastro-intestinal losses. Unfortunately, the last set of blood biochemistry taken was 3 days ago. The results that are available are all within normal limits.

Questions

1. Describe what course of action you would take to initiate PN, paying particular attention to the following:
 - a. Nutritional requirements
 - b. Fluid requirements
 - c. Electrolyte requirements
 - d. Intravenous access
2. Back in the pharmacy, you check which ready-to-use products are stocked. You find the following products on the shelf:

	Product 1	Product 2	Product 3
Volume (mL)	1500	2000	2500
Kcal	900	1720	2200
Nitrogen (g)	6.0	10.4	13.6
Sodium (mmol)	31.5	70	100
Potassium (mmol)	24	60	70
Magnesium (mmol)	3.3	8	8
Calcium (mmol)	3.0	7	8
Phosphate (mmol)	12.7	30	30

2. Describe which product is most suitable for Mrs T, and suggest any additions to be made.

The next day, the PN pharmacist is still off sick. You join the rest of the nutrition support team to review Mrs T. Her blood biochemistry results from yesterday are now available:

Sodium	130 mmol/L	(135–145 mmol/L)
Potassium	4.5 mmol/L	(3.4–5 mmol/L)
Magnesium	0.58 mmol/L	(0.7–1.0 mmol/L)
Corrected calcium	2.25 mmol/L	(2.12–2.6 mmol/L)
Phosphate	1.3 mmol/L	(0.8–1.44 mmol/L)

You find Mrs T to be afebrile but in a positive fluid balance of 800 mL. On examination you observe mild ankle oedema.

3. Comment on the biochemistry and clinical findings, and describe what course of action you would take from a PN-formulation point of view.
4. Mrs T asks you if she is able to have some time not connected to the PN to take a walk on the ward. What is your response?
5. It is now Friday, and the PN pharmacist is still off sick. Mrs T has started to eat and drink and is progressing well. Describe what PN formulations you would compound for her for the weekend.

Answers

1. a. In discussion with the dietician, you estimate energy requirements to be 25–35 kcal/kg = 1750–2450 kcal/kg and protein to be 0.2 gN/kg/day = 14g.
- b. Given that there are no gastro-intestinal losses which need replacing, Mrs T's fluid requirements can be estimated as 20–40 mL/kg/day = 1400–2800 mL/day.
- c. Given that there is no recent blood biochemistry, basal requirements should be calculated and a set of blood taken for analysis. These results will then be available to aid compounding the next day.

Sodium 1–1.5 mmol/kg	= 70–105 mmol
Potassium 1–1.5 mmol/kg	= 70–105 mmol
Calcium 0.1–0.15 mmol/kg	= 7–10.5 mmol
Magnesium 0.1–0.2 mmol/kg	= 7–14 mmol
Phosphate 0.5–0.7 mmol/kg	= 35–49 mmol

- d. Given that Mrs T has a central line in situ, one port should be dedicated to PN. The central line should be examined to ensure the site is clean and well dressed.
2. The most suitable formulation is product 3. This formulation more or less meets all Mrs T's requirements. Only vitamins and trace elements need to be added to the bag prior to infusing.
3. Sodium abnormalities always warrant careful management. Given that Mrs T has no gastro-intestinal losses, she is in a positive fluid balance and she has ankle oedema, the low sodium is likely to be a result of fluid overload rather than sodium deficiency. Therefore fluid restriction is the correct course of action rather than administering a greater amount of sodium. The formulation should be changed to product 2. This means a reduction in volume to 2000 mL. Note also the reduced amount of sodium in this bag compared with product 3. However, even the 70 mmol sodium in product 2 meets Mrs T's basal requirements, and so there would be no need to increase further in the PN. Sodium level should come up with fluid restriction alone. The low magnesium is likely to be attributable to the fact that Mrs T has not received any magnesium supplementation postoperatively, and this is, therefore, a genuinely low level. The product literature for the chosen formulation should be checked to elucidate the maximum amount of magnesium that may be added to the bag. This should then be added as a manual addition in the pharmacy aseptic unit. Some other parameters in product 2 are slightly lower than the calculated requirements; however, these differences are negligible and are of secondary importance to the correction of sodium and fluid balance. Monitoring will continue during the course of treatment.
4. The first infusion should always be over 24 hours. Providing blood sugar levels are stable and within normal limits, the infusion time may then be reduced. You could suggest a 4-hour rest period on day 2 of PN, then a 6-hour rest period on day 3 of PN.
5. Given the good prognosis, it is likely Mrs T will no longer require PN by Monday. PN should, therefore, be tapered off over the weekend as oral diet increases. One possible way of doing this is to give just half the PN infusion over a 12-hour overnight period. Any remaining solution must be discarded once the PN is disconnected. This could be given Friday and Saturday nights and then no PN on Sunday. Mrs T should then be reviewed again on Monday morning with the intention of stopping PN and removing the central line, providing oral nutritional intake is deemed adequate.

8

Pharmacoeconomics

Jonathan Cooke

Key points

- Expenditure on medicines is increasing at a greater rate than other healthcare costs.
- Increasingly, governments are employing health economics to help prioritise between different medicines and other health technologies.
- In health economics, the consequences of a treatment can be expressed in monetary terms (cost–benefit), natural units of effectiveness (cost–effectiveness) and in terms of patient preference or utility (cost–utility).
- Head-to-head studies offer the best way of determining overall effectiveness and cost–effectiveness.
- Sensitivity analysis can be used to address areas of uncertainty.
- Medication non-adherence, medication errors and unwanted drug effects place a considerable burden on societal healthcare costs.
- Decision analysis techniques offer a powerful tool for comparing alternative treatment options.

The demand for and the cost of health care are growing in all countries. Many governments are focusing their activities on promoting the effective and economic use of resources allocated to health care. The increased use of evidence-based programmes not only concentrates on optimising health outcomes but also utilises health economic evaluations. Spending on health across the Organisation for Economic Co-operation and Development (OECD) edged up slightly in 2013, with preliminary estimates pointing to a continuation of this trend in 2014. The slow rise comes after health spending growth ground to a halt in 2010 in the wake of the global financial and economic crisis (OECD, 2016).

Although there have been marked gains in life expectancy in those countries which make up the OECD, health costs have also risen in all of them. The USA spent 16.4% of its national income (gross domestic product [GDP]) on health in 2013, a value considerably greater than many other OECD countries and almost twice that of the UK (Fig. 8.1).

Medicines form a small but significant proportion of total healthcare costs; this has been increasing consistently as new medicines are marketed. For example, the overall National Health Service (NHS) expenditure on medicines in 2014–15 was £15.5 billion, an increase of 7.8% from £14.4 billion in 2013–14 and an increase of 19.4% from £13.0 billion in 2010–11. In 2014–15 hospital use accounted for 42.9% of the total cost, up from

40.1% in 2013–14 and up from 32.1% in 2010/11. Expenditure on medicines rose by 7.8% overall and by 15.4% in hospitals from 2013–14 to 2014–15. The expenditure on medicines in hospitals has risen by 59.8% since 2010–11 (Health and Social Care Information Centre, 2015).

There are a number of reasons why prescribing costs are increasing:

- Demographic changes have resulted in an ageing population, with individuals living longer and with greater needs for therapeutic interventions. This patient group is more susceptible to unwanted effects of medicines which in turn consume more resources.
- More patients have complex clinical problems and comorbidities that have a higher dependency on medicines.
- Health screening programmes and improved diagnostic and imaging techniques are uncovering previously nonidentified diseases, which subsequently require treatment.
- New medicines that offer more effective and less toxic alternatives to existing agents are being marketed. Invariably these are more expensive, especially biotechnology medicines, such as monoclonal antibodies, which can cost in excess of £30,000 per patient per year.
- The use of existing agents is becoming more widespread as additional indications for their use are found.
- Increasing numbers of standards in guidelines for care are being set by national bodies, such as the National Institute for Health and Care Excellence (NICE).
- The public and patients have a higher expectation of their rights to access high-cost health care.
- Higher acquisition costs are also a result of inflation and currency fluctuations.

In the UK, health reforms over the past two decades have addressed the quality of care through the promotion of quality and safety standards. The formation of NICE in 1998 ‘to improve standards of patient care and to reduce inequities in access to innovative treatment’ has formalised this process. NICE undertakes appraisals of medicines and other treatments (health technologies) and addresses the clinical and cost-effectiveness of therapies and compares outcomes with alternative use of NHS funds. The increased use of evidence-based programmes not only concentrates on optimising health outcomes but also utilises health economic evaluations. Formalised health technology assessments provide an in-depth and evidence-based approach to this process.

Fig. 8.1 Comparison of health spending as a percentage of gross domestic product in different countries in 2015. (© Organisation for Economic Co-operation and Development, 2016.)

Terms used in health economics

Pharmacoeconomics can be defined as the measurement of both the costs and consequences of therapeutic decision making. Pharmacoeconomics provides a guide for decision makers on resource allocation but does not offer a basis on which decisions should be made. Pharmacoeconomics can assist in the planning process and help assign priorities where, for example, medicines with a worse outcome may be available at a lower cost, and medicines with better outcome and higher cost can be compared.

When economic evaluations are conducted, it is important to categorise various costs. Costs can be direct to the organisation – physicians’ salaries, the acquisition costs of medicines, consumables associated with drug administration, staff time in preparation and administration of medicines, laboratory charges for monitoring effectiveness and adverse drug reactions. Indirect costs include lost productivity from a disease, which can manifest itself as a cost to the economy or taxation system, as well as economic costs to the patient and the patient’s family. All aspects of the use of medicines may be allocated costs, both direct, such as acquisition and administration costs, and indirect, such as the cost of a given patient’s time off work because of illness, in terms of lost output and social security payments. The consequences of drug therapy include benefits for both the individual patient and society at large and may be quantified in terms of health outcome and quality of life, in addition to the purely economic impact.

It is worthwhile here to describe a number of definitions that further qualify costs in a healthcare setting. The concept of ‘opportunity cost’ is at the centre of economics and identifies the value of opportunities which have been lost by utilising resources in a particular service or health technology. This can be valued as the benefits that have been forsaken by investing the resources in the best alternative fashion. Opportunity cost recognises that there are limited resources available for utilising every treatment, and therefore the rationing of health care is implicit in such a system.

Average costs are the simplest way of valuing the consumption of healthcare resources. Quite simply, they represent the total costs (i.e. all the costs incurred in the delivery of a service) of a healthcare system divided by the units of production. For example, a hospital might treat 75,000 patients a year (defined as finished consultant episodes [FCEs]) and have a total annual revenue cost of £150 million. The average cost per FCE is therefore £2000.

Fixed costs are those that are independent of the number of units of production and include heating, lighting and fixed staffing costs.

Variable costs, on the other hand, are dependent on the numbers of units of productivity. The cost of the consumption of medicines is a good example of variable costs.

The inevitable increases in the medicines budget in a particular institution which is treating more patients, or treating those with a more complex pathology, have often been erroneously

interpreted by financial managers as a failure to effectively manage the budget. To better describe the costs associated with a healthcare intervention, economists employ the term *marginal costs* to describe the costs of producing an extra unit of a particular service. The term *incremental cost* is employed to define the difference between the costs of alternative interventions.

Choice of comparator

Sometimes a claim is made that a treatment is cost-effective. But cost-effective against what? As in any good clinical trial, a treatment has to be compared against a reasonable comparator. The choice of comparator is crucial to this process. A comparator that is no longer in common use or in a dose that is not optimal will result in the evaluated treatment being seen as more effective than it actually is. Sadly, many evaluations of medicines fall into this trap, as sponsors seldom wish to undertake head-to-head studies against competitors. Again, the reader has to be careful when interpreting economic evaluations from settings which are different from those in local practice. A common error can be made when viewing international studies that have different healthcare costs and ways of treating patients and translating them directly into 'one's own practice'. This is sometimes referred as *generalisability* or *external validity*.

In addition, hospital charges, including those for hotel services such as heating and lighting overheads, meals and accommodation, which may constitute a major cost, should be considered. These are frequently included in an average cost per patient day.

Types of health economic evaluations

Cost-benefit analysis

In cost-benefit analysis (CBA), consequences are measured in terms of the total cost associated with a programme, where both costs and consequences are measured in monetary terms. Although this type of analysis is preferred by economists, its use in health care is problematic because it is frequently difficult to ascribe monetary values to clinical outcomes such as pain relief, avoidance of stroke or improvements in quality of life.

Methods are available for determining cost-benefit for individual groups of patients that centre around a concept known as *contingent valuation*. Specific techniques include 'willingness to pay', where patients are asked to state how much they would be prepared to pay to avoid a particular event or symptom, for example, pain or nausea following day-care surgery. Willingness to pay can be fraught with difficulties of interpretation in countries with socialised healthcare systems, which are invariably funded out of general taxation. 'Willingness to accept' is a similar concept but is based on the minimum amount an individual person or population would receive in order to be prepared to lose or reduce a service.

CBA can be usefully employed at a macro level for strategic decisions on healthcare programmes. For example, a country-wide immunisation programme can be fully costed in terms of resource utilisation consumed in running the programme. This can then be valued against the reduced mortality and morbidity that occur as a result of the programme.

CBA can be useful in examining the value of services – for example, centralised intravenous additive services where a comparison between a pharmacy-based intravenous additive service and ward-based preparation by doctors and nurses may demonstrate the value of the centralised pharmacy service, or a clinical pharmacokinetics service where the staffing and equipment costs can be offset against the benefits of reduced morbidity and mortality.

Cost-effectiveness analysis

Cost-effectiveness analysis (CEA) can be described as an examination of the costs of two or more programmes which have the same clinical outcome as measured in physical units (e.g. lives saved or reduced morbidity). Treatments with dissimilar outcomes can also be analysed by this technique. Where two or more interventions have been shown to be or are assumed to be similar, then if all other factors are equal, for example, convenience, side effects, availability, and so forth, selection can be made on the basis of cost. This type of analysis is called *cost-minimisation analysis* (CMA). CMA is frequently employed in formulary decision making where often the available evidence for a new product appears to be no better than that for existing products. This is invariably what happens in practice because clinical trials on new medicines are statistically powered for equivalence as a requirement for licensing submission.

As previously described, CEA examines the costs associated with achieving a defined health outcome. Although these outcomes can be relief of symptoms such as nausea and vomiting avoided, pain relieved, and so forth, CEA frequently employs years of life gained as a measure of the success of a particular programme. This can then offer a method of incrementally comparing the costs associated with two or more interventions. For example, consider a hypothetical case of the comparison of two drug treatments for the management of malignant disease.

Treatment 1 represents a 1-year course of treatment for a particular malignant disease. Assume that this is the current standard form of treatment and that the average total direct costs associated with this programme are £A per year. This will include the costs of the medicines, antiemetics, in-patient stay, radiology and pathology. Treatment 2 is a new drug treatment for the malignancy which has demonstrated, through comparative controlled clinical trials, an improvement in the average life expectancy for this group of patients from 3.5 years for treatment 1 to 4.5 years for treatment 2. The average annual total costs for treatment 2 are £B. A comparative table can now be constructed.

Strategy	Treatment costs	Effectiveness
Treatment 1	£A	3.5 years
Treatment 2	£B	4.5 years

Incremental cost-effectiveness ratio: = $\text{£B} - \text{£A}/(4.5 - 3.5)$ per life-year gained.

Cost-utility analysis

An alternative measurement of the consequences of a healthcare intervention is the concept of utility. Utility provides a method

Table 8.1 Parameters for economic evaluation of infections due to surgical site infection in patients undergoing colorectal surgery (Information from NHS Payment by Results [PBR] Tariff 2012–13 [Classen et al., 1992; Frampton, 2010])

Description	
Probability of SSI in patients receiving antibiotic prophylaxis on time	0.0059
Probability of SSI in patients receiving antibiotic prophylaxis too early or late	0.03
Average cost of colorectal surgery	£5,901
Average additional cost of SSI in patients undergoing colorectal surgery	£10,366
SSI, Surgical site infection.	

for estimating patient preference for a particular intervention in terms of the patient's state of well-being. Utility is described by an index which ranges between 0 (representing death) and 1 (perfect health). The product of utility and life years gained provides the term *quality-adjusted life-year* (QALY).

There are a number of methods for the calculation of utilities:

- The 'Rosser–Kind matrix' relies on preferences from population samples from certain disease groups.
- The 'visual analogue scale' method seeks to obtain patient preferences for their perceived disease state by scoring themselves on a line scaled between 0 and 1 as previously described.
- The 'standard gamble' method requires individuals to choose between living the rest of their lives in their current state of health or making a gamble on an intervention which will restore them to perfect health. Failure of the gamble will result in instant death. The probabilities of the gamble are varied until there is indifference between the two events.
- The 'time trade-off' method requires individuals to decide how many of their remaining years of life expectancy they would be prepared to exchange for complete health.

Using the previous model, if treatment 1 provides on average an increase of 3.5 years of life expectancy, but this is valued at a utility of 0.9, then the health gain for this intervention is $0.9 \times 3.5 = 3.15$ QALYs. Similarly, if the increase in life expectancy with treatment 2 only has a utility of 0.8 (perhaps because it produces more nausea), then the health gain for this option becomes $0.8 \times 4.5 = 3.6$ QALYs. An incremental CUA can be undertaken as follows:

Strategy	Treatment costs	Effectiveness	Utility
Treatment 1	£A	3.5 years	0.9
Treatment 2	£B	4.5 years	0.8

Incremental cost–utility ratio: = $(£B - £A)/[(4.5 \times 0.8) - (3.5 \times 0.9)]$ per QALY gained.

The calculation of QALYs provides a method which enables decision makers to compare different health interventions and assign priorities for decisions on resource allocation. However, the use of QALY league tables has provided much debate amongst stakeholders of health care as to their value and use.

According to NICE, there is no empirical basis for assigning a particular value (or values) to the cutoff between cost-effectiveness and cost-ineffectiveness. The general view is that those interventions with an incremental cost-effectiveness ratio

of less than £20,000 per QALY should be supported and that there should be increasingly strong reasons for accepting cost-effective interventions with an incremental cost-effectiveness ratio of over £30,000 per QALY.

Costs and consequences

Discounting

Discounting is an economic term which is based mainly on a time preference that assumes individuals prefer to forego a part of the benefits of a programme if they can have those benefits now rather than fully in an uncertain future. The value of this preference is expressed by the discount rate. There is intense debate amongst health economists regarding the value for this annual discount level and whether both costs and consequences should be subjected to discounting. If a programme does not exceed 1 year, then discounting is felt to be unnecessary. The current rate that is proposed by NICE is 3.5% per annum, although lower rates may be accepted in certain circumstances (NICE, 2013).

Decision analysis

Decision analysis offers a method of pictorial representation of treatment decisions. If the results from clinical trials are available, probabilities can be placed within the arms of a decision tree, and outcomes can be assessed in either monetary or quality units. An example of this can be found in the assessment of the timing of antibiotics used as prophylaxis to prevent surgical site infections (Classen et al., 1992). A pivotal large prospective study monitored the timing of antibiotic prophylaxis and studied the occurrence of surgical-wound infections. To populate a decision tree, it is necessary to obtain information from the literature on the probabilities for the clinical benefits and risks of each time frame (Table 8.1). The costs of the various procedures, consumables and bed stay are then calculated or taken from the literature. From these a decision tree can be constructed that determines the cost-effectiveness of one intervention over another (Fig. 8.2).

If there is uncertainty about the robustness of the values of the variables within the tree, they can be varied within defined ranges to see if the overall direction of the tree changes. This is referred to as *sensitivity analysis* and is one of the most powerful tools available in an economic evaluation.

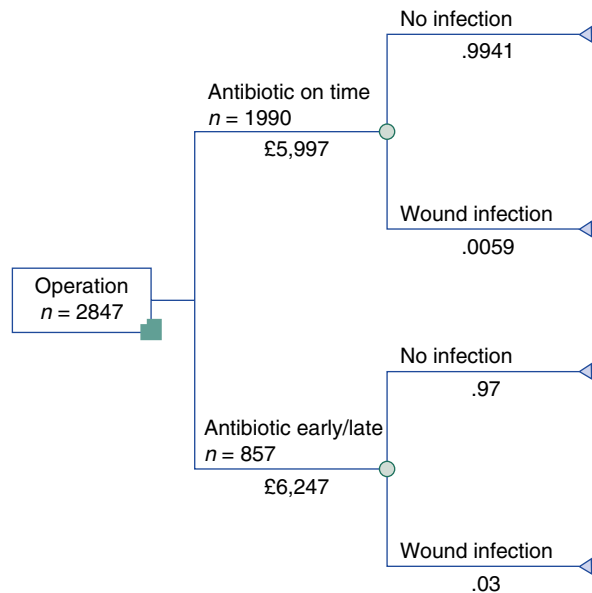

Fig 8.2 Decision tree for costs and outcomes on the effects of timing of antibiotic prophylaxis on surgical site infections. (Data from Classen et al., 1992.)

Economic evaluation of medicines

A number of countries have introduced explicit guidelines for the conduct of economic evaluations of medicines. Others require economic evaluations before allowing a medicine onto an approved list or formulary. Guidelines have been published which aim to provide researchers and peer reviewers with background guidance on how to conduct an economic evaluation and how to check its quality (Husereau et al., 2013), whereas others have set out how they incorporate health economics in the evaluation of medicines (NICE, 2014).

Risk management of unwanted drug effects

Avoiding the adverse effects of medicines has become a desirable goal of therapeutic decision makers as well as those who promote quality assurance and risk management. Not only can there be significant sequelae in terms of increased morbidity associated with adverse drug effects; the economic consequences can be considerable. For example, gentamicin is often regarded as a relatively inexpensive antibiotic, but in the USA, each case of nephrotoxicity has been reported to cost several thousands of pounds in terms of additional resources consumed even without any assessment of the reduction in a patient's quality of life. The increasingly litigious nature of society has resulted in the economic valuation of perceived negligence, for example, with irreversible vestibular toxicity associated with prolonged unmonitored aminoglycoside therapy. As a result, many healthcare systems have targeted a significant reduction in the number of serious errors in the use of prescribed medicines.

Medication non-adherence

The costs of non-adherence with medicines are considerable. In the USA, it has been calculated that 11% of all admissions to hospital are directly associated with some form of non-adherence.

Box 8.1 Ten examples of the application of pharmacoeconomics in practice

- The value of one treatment over another in terms of the cost for each unit of health gained
- Avoidance of costs associated with the failure to use an appropriate medicine, e.g. antimicrobial surgical prophylaxis
- Avoidance of the costs of the side effects or adverse effects of a medicine
- Financial planning and horizon scanning for new medicines
- Prioritisation of healthcare resources
- Health gain, quality-of-life issues and patient preferences
- Duration of care and balance between in-patient, day care and outpatient care
- Changes in legislative controls, e.g. reclassification of medicines from prescription-only to pharmacy status
- Costs of concordance and non-concordance
- Economics of health service delivery

This equates to 2 million hospital admissions a year in the USA resulting from medication non-adherence, at a total cost of over £5 billion. In addition, lost work productivity through non-adherence has been estimated to cost in excess of a further £3 billion per year. The scale of the problem in the UK is probably similar.

In the UK, between a half and one-third of all medicines prescribed for long-term conditions are not taken as recommended (Horne et al., 2005), and the estimated drug cost of unused or unwanted medicines in the NHS in England is around £300 million a year (Trueman et al., 2010). National guidance on medication adherence has been issued (NICE, 2009).

Incentives and disincentives

There are good examples of both incentives and disincentives being used in the NHS to save money. In England, the contract for hospitals penalises those organisations that fail to achieve their targets for reducing *Clostridium difficile* infections. Good antimicrobial stewardship is essential for addressing this, as each case of *C. difficile* infection can cost at least £4000. Reduction in prescribing of both fluoroquinolones and second- and third-generation cephalosporins is associated with a reduction in *C. difficile* infection (Department of Health and the Health Protection Agency, 2008). It follows from this that reducing the use of these agents can reduce acquisition costs of the medicines.

Examples of incentives to reduce expenditure can be seen within the NHS commissioning processes in England. A typical example involves a scheme where commissioners must make 1.5% of contract value (or equivalent non-contract activity value) available for each provider's quality and innovation scheme, and these include prescribing targets (NHS England 2015).

Conclusion

A fundamental element of the use of pharmacoeconomics in practice is the viewpoint from which the analysis is conducted. Ideally this should be from a societal perspective, but frequently it is from a government or Department of Health viewpoint.

Purchasers of health care may also have a different perspective from provider units, and the viewpoint of clinicians may differ from that of the patient. The pharmaceutical industry will probably have another viewpoint that will be focused on its particular products. As a consequence, with all economic evaluations, the perspective from which they have been analysed should be clear.

The effect of having budgets that are rigorously defended in every section of the health service, as occurs with the medicines budget, is to deny the application of economic decision making in the most efficient way for the population served. It is clear that pharmacoconomics has an important part to play in the practice of therapeutics (Box 8.1) and needs to be an integral part of all planned therapeutic developments.

SECTION **2**

LIFE STAGES

9

Neonates

Martin P. Ward-Platt

Key points

- The survival of very premature babies has been greatly increased through the use of antenatal glucocorticoids and neonatal surfactant treatment to prevent and treat surfactant deficiency.
- The feto-placental unit creates a unique route for drug delivery.
- Drug disposition and metabolism in the neonate are very different from those at any other time of life.
- Preterm babies grow very fast, so doses have to be re-calculated at regular intervals.
- Drug elimination in the neonate can be much slower than in children, especially in the first week, so dose intervals have to be longer initially but may shorten as babies grow and mature.

The earliest in pregnancy at which newborn babies can sometimes survive is around 23 weeks' gestation, when survival, which used to be about 10%, is now more than 50% for live-born babies. In contrast, very few babies born at 22 weeks survive. Conventionally, any baby born at less than 32 weeks is regarded as being at relatively high risk of death or disability. About 7.5% of all births in the UK are technically 'premature' (<37 weeks), but only 1.4% of births take place before 32 weeks of gestation. Likewise, 7% of all babies are low birth weight (LBW), for example, less than 2500 g, and 1.4% are very low birth weight (VLBW). However, it is the gestation at birth rather than the birth weight which is of more practical and prognostic value. Over three-quarters of babies born at 25 weeks' gestation now survive to discharge home. The definitions of selected terms used for babies are given in [Table 9.1](#).

Because mothers with high-risk pregnancies will often be transferred for delivery to a hospital capable of providing neonatal intensive care, the proportion of preterm and LBW babies cared for in such units is greater than that in smaller maternity units in peripheral hospitals. In the population as a whole, between 1% and 2% of all babies will receive intensive care, and the most common reason for this among preterm babies is the need for respiratory support of some kind.

Babies in between 28 and 32 weeks' gestation invariably need some degree of special or intensive care and generally go home when they are feeding adequately, somewhere between 35 and 40 weeks of postmenstrual age. Babies born at 23–25 weeks, however, need prolonged intensive care and may well go home some weeks after their due date. So although in epidemiological terms

the neonatal period is defined as up to 28 postnatal days, babies may be 'neonatal' in-patients for as long as 4 or 5 months; during this time their weight may triple or quadruple, and their physiology and metabolism change dramatically.

Drug disposition

Absorption

An important and unique source of drug absorption, available until birth, is the placenta. Maternal drugs pass to the fetus and back again during pregnancy, but from delivery, any drugs present in the neonatal circulation can no longer be eliminated by that route and must be dealt with by the baby's own systems. Important examples of maternal drugs which may adversely affect the newborn baby include opiates given for pain relief during labour and β -adrenergic blockers given for pregnancy-induced hypertension, such as labetalol.

The placental route may also be used deliberately to give a mother drugs with the intention of treating not her but her fetus. There are two important and quite common examples of this. The first is the use of corticosteroids to promote fetal lung maturation when preterm delivery is planned or expected. In this situation, betametasone or dexamethasone are normally the drugs of choice because prednisolone is metabolised in the placenta and does not reach the fetus. The second example is the administration of magnesium sulfate to mothers in, or at high risk of preterm labour; the magnesium sulfate protects against subsequent cerebral palsy in their babies. Rarely, mothers may be given anti-arrhythmic drugs, such as flecainide, to control tachyarrhythmias in the fetus.

Enteral drug absorption is potentially erratic in any newborn baby and may be unavailable in the ill baby because the stomach does not always empty effectively. Therefore, most drugs are given intravenously to ensure maximum bioavailability. Some drugs, such as paraldehyde and diazepam (for neonatal seizures) and paracetamol (for simple analgesia), can be given rectally. The trachea may be used as the preferred route of administration when surfactant administration is required or where adrenaline (epinephrine) is given during resuscitation. The buccal route may be used to administer glucose gel in the treatment of hypoglycaemia, or for midazolam to control seizures. Intramuscular injection is generally avoided because of pain and low muscle bulk, although the widespread use of intramuscular vitamin K, to prevent bleeding caused by vitamin K deficiency, flies in the face of this precept.

Table 9.1 Definitions of terms

Normal length of human pregnancy (term)	40 weeks (280 days), range 37 up to 42 completed weeks of gestation
Preterm	<37 weeks of gestation at birth
Post-term	42 completed weeks onwards
Neonatal period	Up to the 28th postnatal day
Low birth weight (LBW)	<2500 g
Very low birth weight (VLBW)	<1500 g
Extremely low birth weight (ELBW)	<1000 g
Extremely low gestational age (ELGAN)	<28 weeks

In the very preterm baby of 28 weeks' gestation or less, the keratin layer of the skin is extremely thin and a poor barrier to water loss; consequently, it is also permeable to substances in contact with it. This is harmful to the baby if there is prolonged skin contact with alcohol, as in chlorhexidine in 70% methylated spirit, because it causes a severe chemical burn and can lead to systemic methyl alcohol poisoning.

Distribution

Drugs are distributed within a baby's body as a function of their lipid and aqueous solubility, as at any other time of life. The main difference in the neonate is that the size of the body water pool under renal control is related not to the baby's surface area but to body weight. Furthermore, the absolute glomerular filtration rate increases logarithmically with postmenstrual age irrespective of the length of a baby's gestation. This has implications for predicting the behaviour of water-soluble drugs such as gentamicin.

The amount of adipose tissue can vary substantially between different babies. Any baby born more than 10 weeks early, and babies of any gestation who have suffered intrauterine growth restriction, may have little body fat. Conversely, the infant of a diabetic mother may have a particularly large fat layer, and this affects the retention of predominantly lipid-soluble drugs.

Protein binding in the plasma is influenced by the amount of albumin available, and this in turn is related to gestation, with albumin values found 12 weeks before term being only two-thirds of adult concentrations.

Metabolism

The metabolic fate of drugs in the newborn is not qualitatively different from that in the older child, for example, hydroxylation, oxidation and conjugation to sulphate or glucuronate. It is the efficiency with which these processes are carried out that distinguishes the baby from the older person. In addition to the

immaturity of the metabolic pathways for drug disposal, drug metabolism is also affected by the physiological hyperbilirubinaemia common in the newborn. The bilirubin can compete both for enzyme-binding sites and for glucuronate and may thus affect drug metabolism for as long as unconjugated hyperbilirubinaemia persists.

Elimination

The relative immaturity of hepatic and renal function results in correspondingly slow elimination of most drugs from the neonate. This is not necessarily a problem, so long as due account is taken of the slow elimination and dose intervals are modified accordingly. It may even be a useful property, as with phenobarbital, which when given as a loading dose (usually 20 mg/kg) will remain in circulation for days in useful therapeutic quantities, often avoiding the need for further doses. On the other hand, drugs such as gentamicin and vancomycin, which have a relatively narrow therapeutic index, must be given far less frequently than in children or adults, and serum drug levels must be assayed to avoid toxicity.

There has been little study of pharmacodynamics in the term or preterm neonate. Most clinicians work on the assumption that the kinetics of drug behaviour are so different in this group of patients that the pharmacodynamic properties must follow the same pattern. In practice, the most important pharmacodynamic effect is probably that of the behaviour of opiates derived from the mother in labour. Pethidine and diamorphine are the opiates most likely to cause significant respiratory depression in the neonate. Such respiratory depression can be treated with naloxone, and a special neonatal preparation (20 micrograms/mL) is available. However, after birth, the opiates and their metabolites have a long serum half-life in the baby, whereas the naloxone is rapidly eliminated. The initial dramatic effect of naloxone can give a false sense of security because the baby may become narcosed after a few hours after transfer to the postnatal ward. To try to prevent this late-onset narcosis, adult naloxone (400 micrograms/mL) may be given intramuscularly to ensure it remains active over several hours. Even when the respiratory effects have disappeared, opiates may have prolonged behavioural effects on both mother and baby.

Major clinical disorders

Respiratory distress syndrome

Classical respiratory distress syndrome (RDS), caused by lung immaturity as defined by surfactant insufficiency at the time of birth, is now relatively uncommon for several reasons: It is prevented by the use of antenatal glucocorticoids in the mother; most very preterm babies are given early postnatal surfactant; and the very early use of continuous positive airway pressure in these babies can achieve lung distension without respiratory distress. However, there is not always time to administer corticosteroids if delivery occurs rapidly and unexpectedly, so variants of RDS related to surfactant deficiency still occur. The condition is rare in babies born at or near term and becomes increasingly likely the more preterm a birth takes place. Alternative terminology is shown in [Box 9.1](#).

Box 9.1 Respiratory distress syndrome: alternative terminology

Respiratory distress syndrome (RDS): The clinical appearance of a baby with increased work of breathing, nasal flaring, rib recession, tachypnoea, a requirement for oxygen therapy and/or retention of carbon dioxide on blood gas analysis. There are many causes for this clinical picture in addition to surfactant deficiency.

Surfactant-deficiency lung disease: A more precise term describing the most common underlying cause of respiratory distress in preterm babies.

Hyaline membrane disease (HMD): The histological appearance of lungs affected by lack of surfactant, first described in babies who had died of the condition without ever having been ventilated. Much of the alveolar air space is taken up with homogeneous pink-staining 'hyaline membranes' of proteinaceous exudate, and there is an accompanying inflammatory response.

Antenatal glucocorticoids given to the mother reduce the incidence, severity and mortality of RDS caused by surfactant deficiency. It is also better in terms of surfactant production for a baby to undergo labour rather than be delivered by caesarean section without labour. Babies of less than 32 weeks' gestation gain most benefit from antenatal corticosteroids because they are at greatest risk of death and disability from RDS, but net benefit continues up to 38 weeks for babies born by elective caesarean section. Optimum treatment is four oral doses of 6 mg betametasone, each given 12-hourly, or two doses of 12 mg intramuscularly 24 hours apart.

A relatively big baby born around 32–34 weeks of gestation with mild RDS is usually treated with continuous positive airway pressure and some extra oxygen, delivered via the nose by a flow driver. In contrast, smaller, more premature or more severely affected babies often need artificial ventilation using an endotracheal tube. A few babies require high inspired concentrations of oxygen (up to 100%) for several days. Fortunately, pulmonary oxygen toxicity is not as much a problem for the neonate as it is for the adult, although it may have a causal role in the development of bronchopulmonary dysplasia (neonatal chronic lung disease; see later section). Oxygen therapy has to balance the concern about increasing the chance of retinopathy of prematurity with the knowledge from recent studies that targeting oxygen saturations more than 90% conveys a lower overall mortality.

Many sick, ventilated babies develop a degree of hypotension. In addition to volume expansion with boluses of normal saline, some of these babies are given inotropes to support their blood pressure. Adrenaline, dopamine, or dobutamine infusions are widely used in neonatal care, but there are no randomised controlled trials to guide either the first choice of inotrope or the exact indications for using it.

Paralysing agents such as pancuronium are sometimes given to ventilated neonates, but these only prevent the baby from moving and are not sedative. Pancuronium is widely used, partly because it wears off slowly so that the baby is not suddenly destabilised; vecuronium infusions are sometimes used. Shorter-acting agents such as atracurium are often given for temporary paralysis for

intubation. Whether or not the baby is paralysed, morphine is commonly given, either as intermittent doses or as an infusion, to provide narcosis and analgesia to reduce the distress of neonatal intensive care.

Persistent pulmonary hypertension commonly complicates early-onset septicaemia and meconium aspiration syndrome. Inhaled nitric oxide, which is added to the ventilator circuit, dilates the pulmonary arterioles and lowers the excessive pulmonary blood pressure, and it is both more effective than the previously used drug therapies and much less likely to lead to systemic hypotension. For some babies of at least 34 weeks of gestation and at least 2 kg birth weight, extracorporeal membrane oxygenation (ECMO), in which a baby is, in effect, put on partial heart–lung bypass for a few days, may be life-saving if ventilation and nitric oxide fail to reverse hypoxaemia.

Patent ductus arteriosus

Patent ductus arteriosus (PDA) can be a problem in the recovery phase of respiratory distress syndrome in very preterm babies and usually shows itself as a secondary increase in respiratory distress and/or ventilatory requirement, an increasing oxygen requirement, wide pulse pressure and a characteristic heart murmur. The reason that an open duct becomes a problem is that as pressure in the pulmonary artery falls, the duct allows blood from the aorta to flow into the pulmonary artery, which is the opposite of what was happening in the fetus. This elevated pulmonary flow engorges the lungs and reduces their compliance while putting strain on the heart. Echocardiography is used to confirm the clinical suspicion. About one-third of all babies with birth weights less than 1000 g will develop signs of PDA, but treatment is mostly given when the baby is haemodynamically compromised. However, the optimum timing and selection of babies for treatment of the open duct remain controversial and have not yet been resolved in spite of years of research. When treatment is needed, the options are either medical treatment (with indometacin or ibuprofen) or surgical ligation.

Ibuprofen has largely replaced indometacin because it is equally efficacious and better tolerated. Potential serious side effects of both drugs include renal impairment, gastric haemorrhage and gut perforation. Surgery to ligate the duct is generally considered when one or more courses of medical treatment fail to close it, or if drugs are contraindicated.

Bronchopulmonary dysplasia

Bronchopulmonary dysplasia (BPD), also sometimes generically known as chronic lung disease of prematurity, most frequently occurs in very premature babies who have undergone prolonged respiratory support. The factors predisposing to BPD are the degree of prematurity, the severity of RDS, infection, the occurrence of PDA, oxygen toxicity and probably intrinsic genetic factors. BPD is diagnosed from the chest X-ray appearances of a baby who remains either on respiratory support or on oxygen, but who no longer has an acute respiratory illness.

Established BPD that is not severe enough to need continuous mechanical ventilation is either treated with nasal continuous positive airway pressure with or without oxygen supplementation

or, if less severe, may be treated with supplemental high-flow or low-flow oxygen through nasal cannulae.

BPD leads to increases in both pulmonary artery pressure and lung water content. The consequent strain on the heart can lead to heart failure, with excessive weight gain, increasing oxygen requirements and clinical signs such as oedema, enlarged liver and a cardiac ‘gallop’ rhythm. The first-line treatment for heart failure is with diuretics. Diuretics improve pulmonary mechanics and treat heart failure. Sometimes furosemide is used, but its side effects are significant and include urinary loss of potassium and calcium and renal calcification. An alternative is to combine a thiazide diuretic with spironolactone, which causes less calcium and potassium loss. By reducing lung water content, diuretics can also improve lung compliance and reduce the work of breathing. However, BPD is not routinely treated with diuretics because many babies do well without specific treatment beyond oxygen supplementation.

A chronic inflammatory process is part of the pathology of BPD, and for this reason, much attention has been given to the role of glucocorticoids (generally dexamethasone) in treating it. Steroid use generally results in a rapid fall in oxygen requirements but has not yet been shown to improve mortality. Trials have shown that when dexamethasone is used early, within the first 1 or 2 postnatal weeks, there is an increased rate of cerebral palsy, so one of the principal indications for steroid use is when a baby remains ventilator dependent at the age of 4 weeks or more. Widely varying treatment regimens have been used in trials, and there is no standard approach; the initial dose (usually between 50 and 250 micrograms/kg/day) is dependent on physician preference and experience, whereas the rate of reduction of dose is generally individualised to the baby. Side effects such as hypertension and glucose intolerance are common but seldom require modification of the steroid dose or other treatment, but the effects on linear growth can be significant if steroids are given for a long time.

For some babies with severe BPD, in whom echocardiography demonstrates pulmonary arterial pressures close to, or greater than, systemic pressure, many neonatologists try sildenafil because there has been considerable experience using this drug off-label to prevent pulmonary hypertensive crises in babies after cardiac surgery. There are no randomised controlled trials of sildenafil in BPD. Systemic hypertension sometimes occurs among babies with BPD even without steroid exposure and may need treatment with antihypertensive drugs such as nifedipine.

Significantly preterm babies still in oxygen at 36 weeks’ post-menstrual age are almost certain to need oxygen at home after discharge, and home oxygen programmes for ex-premature babies with BPD are now widespread. Most babies manage to wean off supplementary oxygen in a few months, but a very few may need it for up to 2 years.

Bacterial infection

Important pathogens in the first 2 or 3 days after birth are group B β -haemolytic streptococci and a variety of Gram-negative organisms, especially *Escherichia coli*. Coagulase-negative staphylococci and *Staphylococcus aureus* are more important subsequently. In line with good antimicrobial stewardship, it is

Table 9.2 Serious neonatal infections and common pathogens

Septicaemia	<i>Staphylococcus epidermidis</i> , group B streptococci, <i>Escherichia coli</i>
Systemic fungal infection	<i>Candida</i> spp.
Necrotizing enterocolitis	No single causal pathogen
Osteomyelitis	<i>Staphylococcus aureus</i>
Meningitis	Group B streptococci, <i>E. coli</i>

wise to use narrow-spectrum antibiotics when possible, to give them in short courses, and to discontinue treatment quickly if the blood culture is negative. The most serious neonatal infections are listed in [Table 9.2](#).

Superficial candida infection is common in all babies, but systemic candida infection is a particular risk in very preterm babies, especially those receiving prolonged courses of broad-spectrum antibiotics, with central venous access or receiving intravenous feeding. Routine use of either enteral nystatin or systemic fluconazole is highly effective at preventing systemic candidiasis.

It is usual to give babies antibiotics prophylactically when preterm labour is unexplained, where there has been prolonged rupture of the fetal membranes before delivery, when a mother is known to carry group B streptococci but did not get intrapartum penicillin, and when a baby is ventilated from birth. A standard combination for such early treatment, now enshrined in [National Institute of Health and Care Excellence \(NICE, 2012\)](#) guidance is penicillin G and an aminoglycoside, to cover group B streptococci and the common Gram-negative pathogens. Treatment can be stopped after 36 or 48 hours (depending on local laboratory techniques) if cultures prove negative. The treatment of suspected infection that starts when a baby is more than 48 hours old has to take account of the expected local pathogens but will always include cover for *S. aureus*.

Meticillin-resistant *S. aureus* (MRSA) has emerged as a real problem in hospitals in recent years, but there is little evidence that neonatal units have any more problems than other intensive care areas. *Clostridium difficile* is not a problem pathogen in neonatal care.

Viral infections

The most important viral infection in neonates is cytomegalovirus (CMV). It may present as a congenital infection with a seriously ill baby or be a cause of later respiratory illness. CMV is a common cause of non-hereditary sensorineural hearing loss among term babies, for whom prolonged treatment with oral valganciclovir can greatly improve auditory outcome.

For HIV, the goal of management is to prevent ‘vertical’ transmission from mother to baby. The main strategy is to use aggressive maternal treatment throughout pregnancy to suppress the maternal viral load. After delivery, if the mother has a low viral load, the baby is given zidovudine as a single agent for 4 weeks. If the maternal load is high, the baby gets conventional triple therapy.

Ex-preterm babies often contract respiratory syncytial virus (RSV)-positive bronchiolitis once at home, especially if they are on home oxygen and have been discharged during the winter when bronchiolitis is epidemic. Palivizumab, an anti-RSV immunoglobulin, is recommended for prophylaxis and has to be given to the infant as monthly intramuscular injections for the duration of the annual epidemic. It is also good practice to ensure that oxygen-dependent babies and their families receive the seasonal flu immunisation.

The major emergent virus which may infect the fetus and has implications for the newborn is Zika virus (ZIKV). This flavivirus is unusual in that it is transmitted by *Aedes* mosquitoes, but it behaves clinically much like rubella in the pre-immunisation days, causing a mild exanthematous illness in adults and children but being capable of infecting pregnant mothers and their fetuses. Fetal infection can damage the brain and give rise to neonatal microcephaly. Unlike rubella, there is no vaccine as yet, but as ZIKV continues to spread into densely populated areas of Central and North America, it is likely that there will be a concerted effort to produce a vaccine as soon as possible.

Necrotizing enterocolitis

Necrotising enterocolitis (NEC) can arise in any baby, but it is most common, and generally most lethal, in babies less than 27 weeks' gestation. There is general agreement that the pathophysiology is related to damage to the gut mucosa, which may occur because of hypotension or hypoxia, coupled with the presence of certain organisms in the gastro-intestinal tract that invade the gut wall to give rise to the clinical condition. Early 'trophic' feeding, feeding with the mother's expressed breast milk and enteral probiotics appear to be protective.

A baby who becomes ill with NEC is often septicaemic and may present acutely with a major collapse, respiratory failure and shock or more slowly with abdominal distension, intolerance of feeds with discoloured gastric aspirates and sometimes blood in the stool. The medical treatment is respiratory and circulatory support if necessary, broad-spectrum antibiotics and switching to intravenous feeding for a period of time, usually 7–10 days. The antibiotic strategy for NEC is to cover Gram-positive, Gram-negative and anaerobic bacteria. Metronidazole is used to cover anaerobes in the UK, but clindamycin is still used in some other countries. One of the most difficult surgical judgements is deciding whether and when to operate to remove necrotic areas of gut or deal with a perforation.

Apnoea

Apnoea is the absence of breathing. Babies (and adults) normally have respiratory pauses, but preterm babies in particular are prone to prolonged pauses in respiration of longer than 20 seconds which can be associated with significant falls in arterial oxygenation. Apnoea usually has both central and obstructive components, is often accompanied by bradycardia and requires treatment to prevent life-threatening episodes of arterial desaturation.

The main goal of medical treatment is to reduce the number and severity of the apnoeic episodes without having to resort to

Box 9.2 Grading of neonatal hypoxic-ischaemic encephalopathy

Grade 1: Short-lived (<24 h) increase in tone; often high-pitched cry; sometimes difficult to feed. No seizures.

Grade 2: More prolonged but usually <1 week; lethargy and reduced tone; usually needs tube feeding for some time; may have seizures.

Grade 3: Comatose, floppy, often apnoeic and needing ventilation; seizures not always present clinically but if present, often difficult to control; highly abnormal cerebral function monitor trace, usually very suppressed initially.

artificial ventilation, so using either nasal continuous positive airway pressure, or caffeine or both is the first-line treatment. Caffeine both reduces apnoea in the short-term and improves neurodevelopmental outcome. Doxapram is occasionally given in addition to caffeine to avoid resorting to mechanical ventilation. Most clinicians stop giving caffeine when the baby is around 34 weeks' postmenstrual age, by which time most babies will have achieved an adequate degree of cardiorespiratory stability.

Hypoxic-ischaemic encephalopathy

Hypoxic-ischaemic encephalopathy (HIE) usually results either from intrapartum asphyxia or from an antepartum insult such as placental abruption. It is conventionally graded into three divisions (see Box 9.2). However, it is important to remember that although hypoxia-ischaemia is by far the most common cause of a neonatal encephalopathy, it is not the only one: metabolic disease, cerebral infarction and infection need to be considered as possibilities too.

No drug has been shown to improve outcome when given after a hypoxic-ischaemic insult has occurred, but cooling a baby to between 33 and 34 °C for 72 hours reduces the degree of neuro-disability among survivors and is now standard therapy. In the trials of cooling therapy, it was babies with a grade 3 encephalopathy in whom benefit was shown, but currently, many babies at the worse end of grade 2 encephalopathy are cooled too. Cooling is a benign and well-tolerated therapy, so the tendency is to use it rather than not in borderline cases.

Assessing cerebral electrical activity using the cerebral function monitor (CFM) is now standard practice and helps in the decision making as to whether a particular baby should be offered cooling therapy. HIE of grades 2 and 3 may give rise to clinical seizures, or subclinical seizures may show up on the CFM. In the neonate, the first-choice anticonvulsant for the acute treatment of seizures in HIE is usually phenobarbital because it seldom causes respiratory depression and is active for many hours or days because of its long elimination half-life. Diazepam is best avoided because it upsets temperature control, causes unpredictable respiratory depression, and is very sedating compared with phenobarbital. Paraldehyde is occasionally used because it is easy to give rectally, is relatively non-sedating and is short acting. It is excreted by exhalation, and the smell can make the working environment quite unpleasant for staff. Phenytoin is often used when fits remain uncontrolled after two loading doses of phenobarbital (total 40 mg/kg) but is not usually given long-term because

of its narrow therapeutic index, and its anti-inotropic effect can be a problem if there is ischaemic cardiomyopathy. When seizures are difficult to control, further options include clonazepam, midazolam or lidocaine; the last two can be given as infusions. There is little experience with intravenous sodium valproate in the neonate, but increasingly levetiracetam is being prescribed and appears to be very effective.

A therapeutic dilemma lies in the degree of aggression with which seizures should be treated because no anticonvulsant is reliably effective in reducing electrocerebral seizure activity, even when the clinical manifestations of seizures are abolished. In any case, seizures tend naturally to cease after a few days. However, seizures that compromise respiratory function need to be treated to prevent serious falls in arterial oxygen tension and possible secondary neurological damage. Also, babies with frequent or continuous seizure activity are difficult to nurse and cause great distress to their parents. Therefore, in practice, it is usual to try to suppress the clinical manifestation of seizure activity, and phenobarbital remains the most commonly used first-line treatment. Where a decision is taken to keep a baby on anticonvulsant medication, therapeutic drug monitoring can provide helpful information and may need to be repeated from time to time during follow-up.

Seizures may occur as isolated events in term or near-term babies in whom there is neurological normality between seizure episodes; this is sometimes seen in perinatal strokes. Seizures seldom complicate the course of very premature babies because cerebral injury in these babies is now a rare event. Investigations in term babies with seizures are directed to finding an underlying cause, but in about half of those having fits without an encephalopathy, no underlying cause can be found.

Haemorrhagic disease of the newborn

Haemorrhagic disease of the newborn, better described as vitamin K-dependent bleeding, is very rare but it may cause death or disability if it presents with an intracranial bleed. Except in the case of malabsorption, it affects only breastfed babies because they get very little vitamin K in maternal milk, and their gut bacteria do not synthesise it. Formula-fed infants get sufficient vitamin K in their milk, and only in the very rare situation of fat malabsorption do they need supplementing.

There are several possible strategies for giving vitamin K with a view to preventing haemorrhagic disease. An intramuscular injection of phytomenadione 1 mg (0.5 mL) can be given either to every newborn baby or selectively to babies who have certain risk factors such as instrumental delivery or preterm birth. Vitamin K can be given orally, so long as an adequate number of doses is given, and this has been shown to be effective in preventing disease. Intramuscular injections are an invasive and unpleasant intervention for the baby because muscle bulk is small in the newborn, and particularly the preterm, and other structures such as the sciatic nerve can be damaged even if the intention is to give the injection into the lateral thigh. Intramuscular injections can be reserved for those babies with doubtful oral absorption, for example, all those admitted for special care, or at high risk because of enzyme-inducing maternal drugs such as anticonvulsants.

Principles and goals of therapy

The ultimate aim of neonatal care at all levels is to maximise disability-free survival and identify treatable conditions that would otherwise compromise growth or development. It follows that potential problems should be anticipated, and the complexities of intensive care should be avoided if at all possible.

Many of the drugs used in neonatal care are not licensed for such use or are used off-label. There is a high potential for errors because of the small doses used, which sometimes calls for unusual levels of dilution when drawing up drugs. Constant vigilance and the use of specialised neonatal formularies are important in preventing harm; interestingly, there is at present little evidence of added safety from electronic prescribing.

Rapid growth

Once the need for intensive care has passed, the growth of a premature baby can be very rapid if the child is being fed with a high-calorie formula modified for use with preterm infants. Indeed, most babies born at 27 weeks and weighing around 1 kg can be expected to double their birth weight by the time they are 8 weeks old, and babies born at 23 or 24 weeks may triple or quadruple their weight before discharge home. Because the dose of all medications is calculated on the basis of body weight, constant review of the dose is necessary to maintain efficacy, particularly for drugs that may be given for several weeks, such as respiratory stimulants and diuretics. Conversely, all that is necessary to gradually wean a baby from a medication is to hold the dose constant so that the baby gradually 'grows out' of the drug. This practice is frequently used with diuretic medication in BPD, the need for which becomes less as the baby's somatic growth reduces the proportion of damaged lung in favour of healthy tissue.

Therapeutic drug monitoring

The assay of serum concentrations of various drugs has a place in neonatal medicine, particularly where the therapeutic index of a drug is narrow. It is routine to assay trough levels of certain antibiotics: for aminoglycosides, accumulation must be avoided, and for vancomycin, both avoiding accumulation and demonstrating adequate trough levels are desirable. Only rarely is it necessary to assay minimal inhibitory or bactericidal concentrations of antibiotics in blood or cerebrospinal fluid if serious infections are being treated, and constraints on sampling limit the frequency with which this may be undertaken.

Where phenobarbital or other anticonvulsants are given long-term intermittent measurement of serum levels can be a useful guide to increasing the dose. All these drugs have a long half-life, so it is most important that drug concentrations are not measured too early, or too frequently, to prevent inappropriate changes in dose being made before a steady state is reached.

Avoiding harm

Intramuscular injections are considered potentially harmful because of the small muscle bulk of babies. However, it is not

always easy to establish venous access, and occasionally it may be necessary to use the intramuscular route instead. For vaccines, the intramuscular route is unavoidable.

For sick preterm infants ventilated for respiratory failure, handling of any kind is a destabilising influence, so the minimal necessary intervention should be the rule. Merely opening the doors of an incubator can destabilise a fragile baby. It is, therefore, a good practice to minimise the frequency of drug administration and to try to coordinate the doses of different medications.

Medication errors in neonatal care have been the subject of extensive study, but it is sufficient to say here that the root causes of error are most commonly one or more human factors relating to dose calculation, distraction, urgency, poor team function, and other factors commonly found in intensive care environments. Encouraging a culture of reporting, investigating, understanding and learning from errors and near misses remains the keystone of improving safety and minimising harm.

Time scale of clinical changes

In babies, the time scale for starting drug treatments is very short because the clinical condition of any baby can change with great rapidity. For example, where a surfactant is required it should be given as soon as possible after birth to premature babies who are intubated and ventilated. Similarly, infection can be rapidly progressive, so starting antibiotics is a priority when the index of suspicion is high or where congenital bacterial infection is likely. The same applies for antiretroviral drugs when a baby is born to a mother positive for HIV, especially if the maternal viral load is high.

For the sick preterm infant, this model applies to a wide range of interventions. It is seldom possible to wait a few hours for a given drug, and this has obvious implications for the level of support required by a neonatal service.

Early urgent immunisation with hepatitis B vaccine and the administration of anti-hepatitis B immunoglobulin are very important in preventing vertical transmission of hepatitis B when the mother is e-antigen positive. Of less urgency, but considerable importance, is making sure that premature babies who are still on the neonatal unit 8 weeks after birth get their routine immunisations because these should be given according to chronological age irrespective of prematurity.

Patient and parent care

It is all too easy to take a mechanistic approach to neonatal medicine, on the grounds that premature infants cannot communicate their needs. Such an approach to therapy is inappropriate. Even when receiving intensive care, any infant who is not either paralysed or very heavily sedated does in fact respond with a wealth of cues and nonverbal communication in relation to their needs. Monitors, therefore, do not replace clinical skills but provide supplementary information and potentially advance warning of problems. Even the most premature babies show individual characteristics, which emphasises that individualised care is as important in this age group as in any other. In particular, neonatal pain and distress have effects on nociception and behaviour well into childhood.

It has become increasingly apparent in recent years that involvement of parents in every aspect of care is a necessary goal with clear advantages to the baby in relation to developmental outcome. Not only is care increasingly regarded as a partnership between professionals and parents rather than the province of professionals alone, but it makes sense to involve parents in as many aspects of care with which they feel comfortable. For babies who have special rather than intensive care needs, provision of single rooms with parent facilities, as is standard in paediatric care, has many advantages. In the traditional model, parents only visit until a day or two before discharge when they are encouraged to room-in with their baby for the first time, but this increasingly looks out of touch with the way parents and babies should be kept together. Routine administration of oral medication is thus an act in which parents may be expected to participate, and for those whose baby has to be discharged home still requiring continuous oxygen, the parent will rapidly obtain complete control, with support from the hospital and the primary healthcare team. The growing number of babies who survive very premature birth but whose respiratory state requires continued support after discharge presents an increasing therapeutic challenge for the future.

Case studies

Case 9.1

Ms A went into labour as a result of an antepartum haemorrhage at 28 weeks of gestation. There was no time to give her steroids when she arrived at the maternity unit, and her son, J, was born by vaginal delivery in good condition. However, he required intubation and ventilation at the age of 10 minutes to sustain his breathing; surfactant was immediately given down the endotracheal tube. He was not weighed at the time but was given intramuscular vitamin K and then taken to the special care unit. On arrival in the unit, baby J was weighed (1270 g) and placed in an incubator for warmth. He was connected to a ventilator. Blood was taken for culture and basic haematology, and he was prescribed antibiotics. A radiograph showed well-aerated lungs.

Questions

- Which antibiotic(s) would be appropriate initially for baby J?
After 12 hours, baby J was extubated onto continuous positive airway pressure and remained on antibiotics. Parenteral feeding was commenced on day 1 as per unit policy, and simultaneously very slow continuous milk feeding into his stomach was started. Blood cultures were negative at 48 hours, and the antibiotics were stopped.
On day 5, baby J looked unwell, with a rising oxygen requirement, increased work of breathing and poor peripheral perfusion. Examination revealed little else except that his liver was enlarged and a little firm, his pulses rather full and easy to feel and there was a moderate systolic heart murmur. One possibility was infection.
- Which antibiotics would be appropriate for baby J on day 5?
Another possibility was a patent arterial duct leading to heart failure.
- How could his heart failure and patent ductus arteriosus be treated?
After appropriate treatment he looked progressively better, and when the blood culture was negative after 2 days, the antibiotics

were stopped. By the age of 10 days, baby J was on full milk feeds, and the duct had closed. He was in air. However, he began to have increasingly frequent episodes of spontaneous bradycardia, sometimes after apnoeic spells in excess of 20 seconds in duration. Examination between episodes showed a healthy, stable baby. Investigations such as haematocrit, serum sodium and an infection screen were normal.

- At 2 weeks, which drug of choice could be used to treat his apnoea and bradycardia? What would be the expected duration of treatment with this drug?

Answers

- Antibiotic cover is usually started without knowledge of any organism until negative blood cultures are received. Penicillin and gentamicin provide good cover for streptococci and Gram-negative organisms, which are the most likely potential pathogens at this stage, and is the combination recommended by NICE (2012). If cultures were negative at 48 hours, antibiotics could be stopped provided that there were no clinical indications to continue.
- At day 5, antibiotic therapy should take account of the likely pathogens such as *S. aureus* and others causing nosocomial infections. A suitable choice for the former would be flucloxacillin, if there was no concern about MRSA, or vancomycin if there was. The addition of another agent with good Gram-negative activity such as gentamicin or a third-generation cephalosporin would provide appropriate broad-spectrum cover.
- Intravenous indometacin or ibuprofen would be suitable for the treatment of patent ductus arteriosus. Furosemide is the drug of choice for acute heart failure.
- Caffeine is now the drug of choice. A suitable dose of caffeine for baby J would be a loading dose of 20 mg/kg with maintenance dose of 5 mg/kg/day, increasing to 10 mg/kg/day if necessary. The frequency of episodes of apnoea and bradycardia should decline immediately. The treatment is likely to continue until he is about 34 weeks of postmenstrual age, when his control of breathing should be mature enough to maintain good respiratory function. In some units, a loading dose of caffeine is given routinely just before extubation.

Case 9.2

Baby B was born at 25 weeks' gestation and was ventilated for 5 days before being extubated onto continuous positive airway pressure. On extubation she was initially in air, but now at the age of 4 weeks, she is mostly in about 30% oxygen, fully fed on milk, and growing well. Her chest X-ray showed the pattern typical of chronic lung disease. One morning she is noticed to be in 45% oxygen. She has had a large weight gain, and she looks quite oedematous all over.

Questions

- What do these symptoms suggest?
After careful evaluation, baby B is given an oral dose of furosemide 1 mg/kg, after which the oedema settles, her weight falls and her oxygen requirement returns to 30%.
- What are the disadvantages of giving regular furosemide in this situation?
A thiazide diuretic and spironolactone are prescribed. Four days later, routine biochemistry tests show a sodium of 125 mmol/L.
- What is the choice the attending team has to make?

Answers

- The symptoms suggest heart failure. Medical examination would probably have revealed an enlarged liver, and the heart might also have had a 'gallop' rhythm. In babies, the symptoms and signs commonly suggest both left and right ventricular failure.
- Regular treatment with furosemide causes hypercalciuria, as well as excessive loss of sodium and potassium. Chronic hypercalciuria can lead to nephrocalcinosis. For this reason, a combination of thiazide diuretics and spironolactone is commonly used.
- The sodium is low. The normal range in preterm babies is 130–140 mmol/L, lower than in children and adults. That it is low is probably an effect of the diuretics. The choice is between carrying on with the diuretics and supplementing the sodium intake or stopping the diuretics and observing the baby for any recurrence of heart failure.

10 Paediatrics

Catrin Barker and Octavio Aragon Cuevas

Key points

- Children are not small adults.
- Patient details such as age, weight and surface area need to be accurate to ensure appropriate dosing of medicines.
- Weight and surface area may change in a relatively short time period and necessitate dose adjustment.
- Pharmacokinetic changes in childhood are important and have a significant influence on drug handling and need to be considered when choosing an appropriate dosing regimen for a child.
- The ability of the child to use different dosage forms changes with age, so a range of formulations should be available, for example, oral liquid, dispersible tablets and capsules.
- The availability of a medicinal product does not mean it is appropriate for use in children.
- The use of an unlicensed medicine in children is not illegal, although it must be ensured that the choice of drug and dose is appropriate.

Paediatrics is the branch of medicine dealing with the development, diseases and disorders of children. Infancy and childhood are periods of rapid growth and development. The various organs, body systems and enzymes that handle drugs develop at different rates; hence, drug dosage, formulation, response to drugs and adverse reactions vary throughout childhood. Compared with adult medicine, drug use in children is not extensively researched, and the range of licensed medicines in appropriate dosage forms is limited.

For many purposes, it has been common to subdivide childhood into the following periods:

- neonate: the first 4 weeks of life,
- infant: from 4 weeks to 1 year,
- child: from 1 to 12 years.

For the purpose of drug dosing, children older than 12 years are often classified as adults. This is inappropriate because many 12-year-olds have not been through puberty and have not reached adult height and weight. The International Committee on Harmonization ([European Medicines Agency \[EMA\], 2001](#)) suggested that childhood be divided into the following age ranges for the purposes of clinical trials and licensing of medicines:

- preterm newborn infants,
- term newborn infants (0–27 days),
- infants and toddlers (28 days to 23 months),
- children (2–11 years),
- adolescents (12–16/18 years).

These age ranges are intended to reflect biological changes: the newborn (birth to 4 weeks) covers the climacteric changes

after birth, 4 weeks to 2 years covers the early growth spurt, 2–11 years covers the gradual growth phase and 12–18 years covers puberty and the adolescent growth spurt to final adult height. Manufacturers of medicines and regulatory authorities are still working towards standardising the age groups quoted in each product's Summary of Product Characteristics.

Demography

The population of the UK in 2016 was reported to be 65.6 million, of which 12 million were children younger than 16 years ([Office of National Statistics, 2017a](#)). But figures published by the Office for National Statistics in 2017 indicate that over the last 25 years the percentage of the population aged 16 years and younger has decreased from 21% to 19%. This trend is predicted to continue, and by 2036 the percentage of the population younger than 16 years is predicted to be 18%.

Children make substantial use of hospital-based services. In 2016 there were 23.57 million attendances at England's accident and emergency (A&E), and on average, one-quarter of these were for patients aged 19 or younger ([Baker, 2017](#)).

Congenital anomalies

Congenital anomalies remain an important cause of infant and child mortality. A congenital anomaly is an abnormality of structure, function or metabolism present at birth that results in physical or mental disability or is fatal. Congenital anomalies may be inherited or sporadic, and some may result from environmental causes, including diet, drugs, toxins, radiation or infection. Up to 1 in 20 babies are born with problems such as cleft palate, spina bifida or Down's syndrome. Screening during pregnancy can detect some congenital anomalies, whereas some are found at birth. Others become obvious only as a baby grows older.

Rare diseases affect a small number of people compared with the general population and, because they are rare, can be difficult to diagnose, treat and/or prevent. A disease is considered to be rare when it affects 1 person in 2000 or fewer ([Genetic Alliance UK, 2016](#)). The National Congenital Anomaly and Rare Disease Registration Service (NCARDRS) was established by Public Health England in 2013–14 and records those people with congenital abnormalities and rare diseases across the whole of England.

Cancer

Cancer is very rare in childhood. The most common cancers diagnosed in childhood are leukaemias and malignant neoplasms of the brain. As a consequence of the technical advances in treatment and the centralisation of services in specialist centres, much greater numbers of childhood cancer sufferers are surviving into adulthood. For all childhood cancers combined, the trend for children (0–14 years) diagnosed between 1990 and 2014 is of an increasing 5-year survival; 5-year survival is predicted to be 83.9% for children diagnosed in 2015 (Office of National Statistics, 2017b).

Asthma, eczema and allergy

Asthma, eczema and hay fever (allergic rhinitis) are among the most common chronic diseases of childhood, and most of the affected children are managed in primary care. During the 1970s and 1980s there was considerable expansion of epidemiological research into these disorders, prompted mainly by concern about the increase in hospital admissions for childhood asthma despite the availability of effective anti-asthma medication. These studies failed to identify any demographic, perinatal or environmental factor that could explain more than a small proportion of the large changes in prevalence of asthma, hay fever or eczema. Asthma continues to be an important childhood illness placing a burden on the health service. One in 11 children is reported to have asthma, and it is the most common long-term medical condition (Asthma UK, 2017). Asthma prevalence is thought to have plateaued since the late 1990s, although the UK still has some of the highest prevalence rates in Europe.

Prevalence rates for food allergy have also increased, with peanut allergy now affecting 1 in 70 children in the UK (Grundty et al., 2002). This is reflected in a documented increase in admission rates of children with very severe (anaphylactic) reactions (Turner et al., 2015).

Allergic diseases are not static. The distribution and pattern of disease change as the child matures. Infants are more likely to present with atopic eczema, food allergy, gastro-intestinal symptoms and wheezing, whilst older children typically present with asthma and allergic rhinoconjunctivitis. These observed differences are frequently referred to as the allergic march, which recognises the association between these diseases and the tendency for children to 'outgrow' certain aspects of their allergic disease (e.g. eczema or milk allergy).

Infections

Despite a dramatic decline in the incidence of childhood infectious diseases during the 20th century, they remain an important cause of ill health in childhood. Major advances in the prevention of infections have been achieved through the national childhood vaccination programme (information available at <https://www.gov.uk/government/publications/the-complete-routine-immunisation-schedule>).

The importance of maintaining high vaccine uptake has been demonstrated by the resurgence of vaccine-preventable diseases where children have not been vaccinated. Adverse publicity

surrounding the measles, mumps and rubella (MMR) vaccine, involving a possible association with Crohn's disease and autism, resulted in a loss of public confidence in the vaccine and a decrease in MMR coverage. However, evidence does not support an association between measles vaccine and bowel disease (Davis and Bohlke, 2001) or autism (Jain et al., 2015).

Meningococcal disease occurs as a result of a systemic bacterial infection by *Neisseria meningitidis*. Meningococci colonise the nasopharynx of humans and are frequently harmless commensals. It is not fully understood why disease develops in some individuals but not in others. Meningococcal infection most commonly presents as either meningitis or septicaemia, or a combination of both. Early symptoms and signs are usually malaise, pyrexia and vomiting. Headache, neck stiffness, photophobia, drowsiness or confusion and joint pains may variably occur. In meningococcal septicaemia, a rash may develop, along with signs of advancing shock and isolated limb and/or joint pain. The rash may be nonspecific early on, but as the disease progresses, the rash may become petechial or purpuric and may not blanch. This can readily be confirmed by gentle pressure with a glass (the 'glass test') when the rash can be seen to persist. In young infants particularly, the onset may be insidious, and the signs may be nonspecific, without 'classical' features of meningitis, including the rash.

In January 2013, a four-component meningococcal B (4CMenB) protein vaccine was authorised for use by the European Medicines Agency. In 2015 4CMenB was added to the routine UK immunisation schedule, and the MenC conjugate vaccine provided at around 14 years of age was replaced with MenACWY conjugate vaccine.

Respiratory syncytial virus (RSV) is the most important cause of lower respiratory tract infection in infants and young children in the UK, in whom it causes bronchiolitis, tracheobronchitis and pneumonia. It is responsible for seasonal outbreaks of respiratory tract infection most commonly between October and April. The main burden of disease is borne by children younger than 2 years, and on average in England each year there are 30,000 RSV-associated hospital admissions in children younger than 5 years (Reeves et al., 2017). During the winter months, RSV is the single greatest cause of admission to hospital in children. Palivizumab provides passive immunity against RSV. The objective of the passive immunisation is to protect at-risk infants, for example, babies born with heart and lung disorders and premature babies, for whom RSV infection is likely to cause serious illness or death, and all children less than 24 months of age with severe combined immunodeficiency syndrome (SCID).

Mental health disorders

The emotional well-being of children is just as important as their physical health. Good mental health allows children and young people to develop resilience and grow into well-rounded, healthy adults. However, mental health disorders are another emerging concern in the child health arena. Mental health problems affect about 1 in 10 children and young people (Green et al., 2005). They include depression, anxiety and conduct disorder and are often a direct response to what is happening in children's lives. Alarming, however, 70% of children and young people who

experience a mental health problem have not had appropriate interventions at a sufficiently early age (Children's Society, 2008). Groups at particularly high risk of psychiatric disorder include children in the care system, young people who are homeless and young offenders. Biological, psychological and social factors all seem likely to contribute to the risk of psychiatric disorders and may act in combination.

Drugs, smoking and alcohol

The harm that drugs, smoking and drinking can do to the health of children and young people is recognised, and a number of targets have been set in an attempt to reduce prevalence. In 2014–15, 1% of school children aged 8–15 in England reported that they smoked regularly (at least once a week) (Scholes and Mindell, 2016). Similar proportions of boys and girls had tried smoking and smoked regularly, and the prevalence increased with age. The proportion of children who had ever smoked cigarettes declined from 19% in 1997 to 4% in 2015. In 2007, the minimum age for buying tobacco was increased from 16 years old to 18 years old.

The proportion of 11- to 15-year-old children in England who have tried alcohol has been decreasing since 2003 (NHS Digital, 2017). In a survey in 2014, 38% of 11- to 15-year-olds had tried alcohol at least once, the lowest proportion since the survey began. There was little difference between the prevalence of drinking between girls and boys; the prevalence of drinking alcohol also increased with age.

In England, between 2001 and 2010, the prevalence of drug use among 11- to 15-year-olds declined (Agalioti-Sgompou, 2015); since 2010, the decline has slowed. In 2014, 15% of pupils had ever taken drugs, 10% had taken drugs in the last year and 6% had taken drugs in the last month.

Nutrition and exercise

Health during childhood can affect well-being in later life. Good nutrition and physical exercise are vital both for growth and development and for preventing health complications in later life. In addition, dietary patterns in childhood and adolescence have an influence on dietary preferences and eating patterns in adulthood. The World Health Organization (WHO) regards childhood obesity as one of the most serious global public health challenges for the 21st century. Obese children and adolescents are at an increased risk of developing various health problems and are also more likely to become obese adults with an increased risk of developing diseases such as diabetes, heart disease, stroke and certain types of cancers.

The National Child Measurement Programme (NCMP) measures the height and weight of around 1 million school children in England every year, providing a detailed picture of the prevalence of child obesity. In England, 28% of children aged 2–15 were classified as overweight or obese (14% overweight, 14% obese) (Conolly and NatCen Social Research, 2016), with a slightly higher percentage of boys in the obese category compared with girls (15% vs. 13%). Childhood obesity increased with age, with 11% of children between 2 and 4 years of age being obese compared with 16% of those aged 13–15.

Obese children have a higher percentage of fat mass and a lower percentage of lean mass compared with normal-weight children. Drug-dose calculation and pharmacokinetics in obese children are poorly understood. The harmful consequences of inadvertent overdosing of obese children are of increasing concern to clinicians prescribing drugs with serious side effects, such as morphine and paracetamol. Ideal body weight (IBW) and lean body mass (LBM) are, depending on the drug, often recommended as safer alternatives to total body weight during weight-based dose calculation.

The normal child

Growth and development are important indicators of a child's general well-being, and paediatric practitioners should be aware of the normal developmental milestones in childhood. In the UK, development surveillance and screening of babies and children is well established through child health clinics and more recently the introduction of the NCMP, where children are weighed and measured by trained staff at school.

Weight is one of the most widely used and obvious indicators of growth, and progress is assessed by recording weights on a percentile chart. A weight curve for a child which deviates from the usual pattern requires further investigation. Separate recording charts are used for boys, girls and children with Down's syndrome, and because percentile charts are usually based on observations of the white British population, adjustments may be necessary for some ethnic groups. WHO has challenged the widely used growth charts, based on growth rates of infants fed on formula milk. In 2006, it published new growth standards based on a study of more than 8000 breast-fed babies from six countries around the world. The optimum size is now that of a breast-fed baby. Recently, new growth charts have been introduced for children from birth to 4 years of age, although specific 'neonatal and infant close monitoring charts' for infants from 0 to 2 years of age and 'childhood and puberty close monitoring charts' for children 2–20 years of age are also available. These combine the UK and WHO data. Copies are available from the Royal College of Paediatrics and Child Health (RCPCH) website (<http://www.rcpch.ac.uk/Research/UK-WHO-Growth-Charts>).

Height (or length in children <2 years of age) is another important tool in developmental assessment. In a similar way to weight, height or length should follow a percentile line. If this is not the case, or if growth stops completely, then further investigation is required. The normal rate of growth is taken to be 5 cm or more per year, and any alteration in this growth velocity should be investigated. In secondary care, height is not always measured routinely in practice, and this can lead to difficulties in assessing important factors such as body mass index (BMI), adjusted body weight and renal function.

Obesity is a growing concern in the paediatric population in the UK, as described previously. Available equations for adults may not give relevant BMI values in children; thus, BMI charts have been developed. These charts should be used rather than the popular BMI equation for adults to get accurate results. They are available from the RCPCH website. NHS Choices offers a useful

online 'healthy weight calculator' (<http://www.nhs.uk/tools/pages/healthyweightcalculator.aspx>) and offers advice and signposting to parents/carers and healthcare professionals dealing with an overweight or obese child.

For infants up to 2 years of age, head circumference is also a useful parameter to monitor. In addition to the previously described evaluations, assessments of hearing, vision, motor development and speech are undertaken at the child health clinics. A summary of age-related development is shown in Fig. 10.1.

Child health clinics play a vital role in the national childhood immunisation programme, which commences at 2 months of age. Immunisation is a major success story for preventive medicine, preventing diseases that have the potential to cause serious damage to a child's health or even death. An example of the impact that immunisation can have on the profile of infectious diseases is demonstrated by the meningitis C immunisation campaign, which began in November 1999. The UK was the first country to introduce the meningitis C conjugate (MenC) vaccine, and uptake levels have been close to 90%. The programme was targeted at under-20-year-olds and has been a huge success, with a 90% reduction in cases in that age group. A vaccine for the serotype B of the meningococcal microbe was developed in June 2013. Initially, the Joint Committee

on Vaccination and Immunisation (JCVI) deemed the vaccine not cost-effective. However, after months of pressure from parents, health professionals and charity groups, the JCVI reviewed the decision in 2014, and the vaccine is now available for infants younger than 1 year as part of the routine immunisation schedule.

The human papilloma virus vaccine has also recently been introduced to the immunisation programme in the UK for females aged 12–13 years of age, to reduce the risk of cervical cancer. More recently, the Rotavirus vaccine, an oral live attenuated vaccine, has been added to the UK immunisation schedule with the aim of reducing the number of annual deaths in young infants due to this viral infection and also of reducing the burden and spread of the disease in A&E or walk-in centres.

Advice on the current immunisation schedule can be found in the current online edition of the British National Formulary for Children and the government website <https://www.gov.uk/government/publications/the-complete-routine-immunisation-schedule>.

Drug disposition

Pharmacokinetic factors

An understanding of the variability in drug disposition is essential if children are to receive rational and appropriate drug therapy. However, when treating a patient, all the factors have a dynamic relationship, and none should be considered in isolation.

Absorption

Oral absorption. The absorption process of oral preparations may be influenced by factors such as gastric and intestinal transit time, gastric and intestinal pH and gastro-intestinal contents. Posture, disease state and therapeutic interventions such as nasogastric aspiration or drug therapy can also affect the absorption process. It is not until the second year of life that gastric acid output increases and is comparable on a per-kilogram basis with that observed in adults. In addition, gastric emptying time only approaches adult values at about 6 months of age.

The bioavailability of sulfonamides, digoxin and phenobarbital has been studied in infants and children of a wide age distribution. Despite the different physicochemical properties of the drugs, a similar bioavailability pattern was observed in each case. The rate of absorption was correlated with age, being much slower in neonates than in older infants and children. However, few studies have specifically reported on the absorption process in older infants or children. The available data suggest that in older infants and children, orally administered drugs will be absorbed at a rate and extent similar to those in healthy adults. Changes in the absorption rate would appear to be of minor importance when compared with the age-related differences of drug distribution and excretion.

Intramuscular absorption. Absorption in infants and children after intramuscular (i.m.) injection is noticeably faster than in the neonatal period because muscle blood flow is increased. On a practical note, intramuscular administration is very painful and should, where possible, be avoided. The route should not be used for the convenience of staff if alternative routes of administration are available.

Fig. 10.1 A summary of the various stages of development.

Intraosseous absorption. Intraosseous absorption is a useful route of administration in patients in whom intravenous access cannot be obtained. It is especially useful in paediatric cardio-respiratory arrests where rapid access is required. A specially designed needle is usually inserted into the flat tibial shaft until the marrow space is reached. This route is considered equivalent to the intravenous route for rate of drug absorption, and most drugs can be given by this route.

Topical absorption. Advances in transdermal drug delivery systems have led to an increased use of this route of administration. For example, patch formulations of hyoscine hydrobromide have been found to be very useful to dry up secretions in children with excess drooling; likewise, fentanyl patches can be useful in pain management. Percutaneous absorption, which is inversely related to the thickness of the stratum corneum and directly related to skin hydration, is generally much greater in the premature and term newborn than in the adult. This can lead to adverse drug reactions (ADRs). For example, the topical application of a preparation containing prilocaine and lidocaine (EMLA) should not be used in preterm infants (<37 weeks) because of concerns about significant absorption of prilocaine in this age group, which may lead to methaemoglobinaemia (Aspen, 2016). Another route of topical absorption is the ophthalmic route. Significant amounts of drugs may be absorbed from ophthalmic preparations through ophthalmic or nasolacrimal duct absorption; for example, administration of phenylephrine eye drops can lead to hypertensive episodes in children (Apt and Gaffney, 2016).

Subcutaneous absorption. The development of needle-free subcutaneous jet injection systems appears to bring many benefits as a method of drug administration. They have been shown to give comparable levels to standard subcutaneous injections and overcome the problems of needle phobia, with less pain on administration. This system has been used with growth hormone, insulin and sedative medicines given before procedures and vaccination in children. However, it should be borne in mind that the system is not completely painless, and it can be quite frightening to young children because it is very noisy.

Rectal absorption. The mechanism of rectal absorption is probably similar to that of the upper part of the gastro-intestinal tract, despite differences in pH, surface area and fluid content. Although some products are erratically absorbed from the rectum, the rapid onset of action can be invaluable.

Buccal absorption. The buccal cavity is a potentially useful route of administration in patients who cannot tolerate medications via the oral route, for example, postoperative patients or those with severe nausea. Highly lipophilic drugs such as fentanyl can rapidly cross the buccal mucosa.

There are a number of 'melt' and 'wafer' formulations available, such as ondansetron. These preparations have the advantage of palatability; however, they are not absorbed via the buccal mucosa but require swallowing and enteral absorption of the active constituent. Desmopressin melts, on the other hand, are designed for buccal absorption, and thus the buccal dose is smaller than the enteral dose.

Intranasal absorption. The intranasal route is another useful route of administration. Medicines can be administered intranasally for their local action, for example, sympathomimetics, or for their systemic effects, for example, desmopressin in the

treatment of diabetes insipidus. Highly lipophilic analgesics such as fentanyl and diamorphine are used via this route for the treatment of acute pain, particularly in situations where intravenous access is difficult, for example, reduction of fractures in the emergency department. Significant systemic absorption of medicines given intranasally for their local effect can also occur. For example, corticosteroids used in the treatment of allergic rhinitis could lead to cushingoid symptoms (Raveendran, 2014). Furthermore, administration may be difficult in the uncooperative child, and drugs administered may irritate the mucosa or be painful and unpleasant.

Distribution

Some of the factors that determine drug distribution within the body are subject to change with age. These include vascular perfusion, body composition, tissue-binding characteristics, and the extent of plasma protein binding.

As a percentage of total body weight, the total body water and extracellular fluid volume decrease with age (Table 10.1). Thus, for water-soluble drugs such as aminoglycosides, larger doses on the basis of a milligram per kilogram of body weight are required in the neonate than in the older child to achieve similar plasma concentrations.

Protein binding. Despite normal blood pH, free fatty acid and bilirubin levels in infants, binding to plasma proteins is reduced as a result of low concentrations of both globulins and albumin. It has been suggested that binding values comparable with those seen in adults are reached within the third year of life for acidic drugs, whereas for basic drugs, adult values are not reached until between 7 and 12 years of life. The clinical significance of this reduction in infants and older children is minimal. The influence of disease states, such as renal impairment, on plasma protein binding is more important. In the neonatal period these issues are complicated further by high circulating levels of endogenous agents such as bilirubin and immaturity of transporting proteins such as albumin. In this age range, care should be exercised when using drugs with an albumin binding affinity greater than 90% because they could displace bilirubin from its binding sites and lead to kernicterus. Ceftriaxone and phenytoin are two examples of drugs where use needs careful consideration in these situations.

Table 10.1 Extracellular fluid volume and total body water as a percentage of body weight at different life stages

Age	Total body water (%)	Extracellular fluid (%)
Preterm neonate	85	50
Term neonate	75	45
3 months	75	30
1 year	60	25
Adult	60	20

Drug metabolism

At birth, the majority of the enzyme systems responsible for drug metabolism are either absent or present in considerably reduced amounts compared with adult values, and evidence indicates that the various systems do not mature at the same time. This reduced capacity for metabolic degradation at birth is followed by a dramatic increase in the metabolic rate in the older infant and young child. In the age group of 1–9 years in particular, metabolic clearance of drugs is shown to be greater than in adults, as exemplified by theophylline, phenytoin and carbamazepine. Thus, to achieve plasma concentrations similar to those observed in adults, children in this age group may require a higher dosage than adults on a milligram-per-kilogram basis (Table 10.2).

Metabolic pathways that play only a minor role in adults may play a more significant role in children and compensate for any deficiencies in the normal adult metabolic pathway. For example, glucuronidation accounts for up to 70% of the metabolic pathway of paracetamol in adulthood; however, in the early newborn period, glucuronidation is deficient, accounting for less than 20% of paracetamol metabolism. This is compensated for by a more pronounced sulphate conjugation, and this leads to an apparently normal half-life in newborns. Paracetamol appears to be less toxic in children than in adults, and this may be in part explained by the compensatory routes of metabolism.

Metabolic differences may be further complicated by genetic polymorphism. The contribution of genetic factors to explain heterogeneity of drug response in infants and children is another important issue, with the ultimate goal for better treatment of children based on the individual genetic makeup. CYP2D6, the enzyme responsible for converting the prodrug codeine into the active compound morphine, is one example of an enzyme that displays genetic polymorphism. The enzyme production changes as the child grows (it is very low in the first weeks of life and in the teenage years, but it is highly available during infancy and childhood), and it has four genetic subtypes; a number of deaths in patients with the ultra-rapid metaboliser subtype led to the discontinuation of codeine use in infants and children.

Renal excretion

The anatomical and functional immaturity of the kidneys at birth limits renal excretory capacity. Younger than 3–6 months, the glomerular filtration rate is lower than that of adults but may be partially compensated for by a relatively greater reduction in tubular reabsorption. Tubular function matures later than the filtration process.

Age	Dosage (mg/kg/day)
1–9 years	24
9–12 years	20
12–16 years	18
Adult	13

Generally, the complete maturation of glomerular and tubular function is reached only towards 12–18 months of age. After 18 months, the renal excretion of drugs is comparable with that observed in older children and adults. Changes in renal clearance of gentamicin provide a good example of the maturation of renal function (Table 10.3).

Other factors

In addition to age-related changes in drug disposition, nutritional status and disease states can influence drug handling. High plasma clearance of antibiotics such as penicillins and aminoglycosides has been demonstrated in children with cystic fibrosis, increased elimination of furosemide has been reported in children with nephrotic syndrome and prolonged elimination of furosemide has been reported in infants with heart failure. Altered protein binding has been demonstrated in hepatic disease, nephrotic syndrome, malnutrition and heart failure.

Drug therapy in children

Dosage

Doses of medicines in children should be obtained from a paediatric dosage handbook and should not be extrapolated from the adult dose. There are a number of such texts available internationally. The information within them may be based on evidence from clinical studies in children or reflect the clinical experience of the contributors. In the UK, the British National Formulary for Children (BNFC) is a national formulary that includes prescribing guidelines and drug monographs. It contains information on licensed, unlicensed and off-label use of medicines. When consulting any dosage reference resource, care should be taken to identify the dosage convention being used. Most formularies use a single-dose convention and indicate the number of times the dose should be repeated in a 24-hour period. Other formularies indicate the total daily dose and the number of doses this is divided into. Some formularies combine both conventions. Confusing the total daily dose with the single dose to be repeated may have catastrophic consequences, and the single-dose convention has become the preferred convention.

Table 10.3 Renal clearance of gentamicin

	Plasma half-life (h)
Small premature infants weighing less than 1.5 kg	11.5
Small premature infants weighing 1.5–2 kg	8
Term infants and large premature infants less than 1 week of age	5.5
Infants 1 week to 6 months	3–3.5
Infants more than 6 months to adulthood	2–3

Although age, weight and height are the easiest parameters to measure, the changing requirement for drug dosage during childhood corresponds most closely with changes in body surface area (BSA). Nomograms which allow the surface area to be easily derived are available. There are practical problems in using the surface area method for prescribing; accurate height and weight may be difficult to obtain in a sick child, and manufacturers rarely provide dosage information on a surface-area basis. The surface-area formula for children has been used to produce the percentage method, giving the percentage of adult dose required at various ages and weights, although use should be reserved for exceptional circumstances (Table 10.4).

In selecting a method of dosage calculation, the therapeutic index of the drug should be considered. For agents with a narrow therapeutic index, such as cytotoxic agents, where recommendations are quoted per square metre, dosing must be based on the calculated surface area. However, there may be exceptions, for example, in children less than 1 year of age who have a proportionally larger surface area than other age groups, and where dosages of chemotherapeutic agents are often based on weight rather than surface area to prevent overestimation of the dose in this age group.

For drugs with a wide therapeutic index, such as penicillin, single doses may be quoted for a wide age range. Between these two extremes, doses are quoted in milligrams per kilogram, and this is the most widely used method of calculation. Whichever method is used, the resulting dosage should be rounded sensibly to facilitate dose measurement and administration and subsequently modified according to response or adverse effects.

It is important to note that none of the available methods of dosage calculation accounts for the change in dosage interval that may be required because of age-related changes in drug clearance. Where possible, the use of therapeutic drug monitoring to confirm the appropriateness of a dose is recommended.

Table 10.4 Percentage of adult dose required at various ages and body weights

	Mean weight for age (kg)	Percentage of adult dose
Newborn (full term)	3.5	12.5
2 months	4.5	15
4 months	6.5	20
1 year	10	25
3 years	15	33.3
7 years	23	50
10 years	30	60
12 years	39	75
14 years	50	80
16 years	58	90
Adult	68	100

Choice of preparation

The choice of preparation and its formulation will be influenced by the intended route of administration, the age of the child, availability of preparations, other concomitant therapy and, possibly, underlying disease states. The acceptability of a drug will vary with the type of formulation and age of the child. The problems of administering medicines to children were reviewed by the EMA, and guidelines on developing medicines for paediatric use were produced (EMA, 2005, 2013). It is common for health-care professionals to manipulate medicines to try to provide the required dose for children. Guidance on this is available at <http://www.medsiq.org/tool/manipulation-drugs-required-children-modric-%E2%80%93-guide-health-professionals>.

Buccal route

Drugs may be absorbed rapidly from the buccal cavity (the cheek pouch), or they may dissolve when administered and be swallowed and absorbed from the stomach. 'Melt' technology, in which the drug and flavourings are freeze-dried into a rapidly dissolving pellet, can be very useful. The 'melt' dissolves instantly into a very small volume which is difficult for the child to reject. Gels, sprays and liquids can also be administered into the buccal cavity, an example being midazolam to treat seizures.

Oral route

The oral route is usually the most convenient, but in an uncooperative child, it can be the least reliable. Safe and effective drug therapy requires accurate administration, yet the 5 mL spoon is a difficult means of administering liquid medicines. Use of an oral syringe can provide controlled administration and ensure accurate measurement of the calculated dose, and it avoids the need for dilution of preparations with syrup. Use of oral syringes (which will not fit an intravenous Luer connector) is mandatory in UK practice. Concentrated formulations may be administered as oral drops in a very small volume. Although convenient, there could be significant dosage errors if drops are not delivered accurately.

In general, liquid preparations are often considered to be more suitable for children younger than 7 years. However, there is a wide variability in the age at which children can swallow tablets and capsules, and some quite young children can cope with solid dose formulations, especially mini-tablets. Some commercially available products contain excipients such as alcohol, propylene glycol and dyes that may cause adverse effects or be inappropriate for use in children with particular disease states. The osmolality and tonicity of preparations may be important; necrotising enterocolitis (a disorder seen in the neonatal period) has been associated with many different factors, including high-osmolality infant feeding formulae and pharmaceutical preparations, although a causal relationship has not been established. Oral liquids with high-osmolality or extremes of pH may irritate the stomach and should be diluted for administration. Sugar-free preparations may be necessary for the diabetic child or be desirable in other children for the prevention of dental caries. It is, however, important to be aware of the potential problems associated with substitutes for sucrose. The artificial sweetening

agent aspartame, used in some preparations, should be used with caution in children with phenylketonuria because of its phenylalanine content. Other substitutes such as sorbitol and glycerol may not contribute to dental caries but produce diarrhoea if large doses are given. In these instances, a specially formulated preparation containing a higher amount of the active drug in a smaller volume may be preferable.

Injection solutions can sometimes be administered orally, although their concentration and pH must be considered together with the presence of unsuitable excipients. Powders or small capsules may be prepared and used as an alternative. However, lactose is a common diluent in powders and caution must be exercised in children with lactose intolerance.

Parents/carers are often discouraged from adding the dose of medicine to an infant's feed. On top of potential interactions which may arise with milk feeds, if the entire feed is not taken, a proportion of the dose will be lost. It is also important to advise parents/carers when it is not appropriate to crush solid dosage forms (e.g. sustained-release preparations). However, it should be recognised that addition of a medicine to a food or liquid may be the only way of rendering an unpalatable medicine acceptable. Whenever possible, evidence that this is pharmaceutically acceptable should be sought.

Manufacturers are increasingly recognising the difficulties associated with administration of medicines to children and are responding with novel formulations.

Mini tablets of just a few millimetres diameter may be useful to ease administration and allow flexibility of dosage. They may be presented in capsules or counted from bulk and can be individually coated for modified or sustained release. Increased surface area may present larger quantities of excipients to the child and requires careful control.

If an age-appropriate formulation is not available, for example, for a medicine used off-label, a liquid oral preparation may be prepared extemporaneously, often by crushing the 'adult' tablets and suspending the powder in commercial or locally produced suspending agents. Alternatively, the 'adult' dosage form may be manipulated, for example, by splitting tablets or dispersing it in water to take a proportion of the solution. Due consideration must be given to safety, solubility, accuracy and stability when modifying dosage forms.

Nasogastric, gastrostomy and jejunostomy administration

Medicines may be administered into the stomach via a nasogastric tube in the unconscious child or when swallowing is difficult. A gastrostomy tube may be placed into the stomach transcutaneously if the problem is long-term, for example, in some children with cerebral palsy. Enteral nutrition may also be administered through such tubes. Jejunostomies may be used when reflux persists despite use of a gastrostomy and/or fundoplication surgery. Drugs such as phenytoin may adsorb to the plastic of the tubes and interact with enteral feeds, requiring special administration techniques to ensure bioavailability. Crushed tablets may block thin-bore nasogastric tubes. Some drugs may be absorbed early in the duodenum, making administration via a jejunostomy inappropriate. Furthermore, the jejunum lacks the secretions to buffer drugs with certain pH or high osmolality, making the dilution of

these drugs with water or choosing a different formulation necessary. Suitability of drugs for nasogastric, gastrostomy and jejunostomy tube administration should always be checked.

Rectal route

The rectal route of administration is generally less favoured in the UK than in other European countries. It can be useful in patients who are vomiting or in infants or children reluctant or unable to take oral medication, but it is limited by the range of products available and the dosage inflexibility associated with rectal preparations. Some oral liquid preparations such as chloral hydrate and carbamazepine can be administered rectally. The route is useful in the unconscious child in the operating theatre or intensive care unit, and it is not uncommon to administer perioperative analgesics such as diclofenac and paracetamol and the antiemetic ondansetron using suppository formulations. Parents/carers and teachers may express concerns about using this route, fearing accusations of child abuse, but it is an important route of administration for diazepam or paraldehyde in the fitting child, although increasingly, buccal administration of midazolam may be preferred in this situation.

Parenteral route

When oral and rectal routes are inappropriate, the parenteral route may be necessary.

The problems associated with the administration of intramuscular injections in infants and children have been described earlier in this chapter. The route has a limited role in paediatric drug therapy and should not be used routinely. The intravenous route of administration is more widely used, but it is still associated with a number of potential problems that are outlined in the following sections.

Intravenous access. The practical difficulties of accessing small veins in the paediatric patient do not require explanation. However, these difficulties can often explain the sites of access that are chosen. Scalp veins, commonly used in newborn infants, are often very prominent in this age group, allowing easy access. It is also more difficult for the infant to dislodge a cannula from this site than from a site on the arm or foot. Likewise, the umbilical artery offers a useful route for monitoring the patient but can also be used for drug administration in some circumstances. Vasoconstrictive drugs, such as adrenaline (epinephrine), dopamine and isoprenaline, should not be given via this route.

Fluid overload. In infants and children, the direct administration of intravenous fluids from the main infusion container is associated with the risk of inadvertent fluid overload. This problem can be avoided by the use of a paediatric administration set and/or a volumetric infusion device to control the flow rate. A paediatric administration set incorporates a graduated volumetric chamber with a maximum capacity of 150 mL. Although this system is intended primarily as a safety device, the volume within the burette chamber can be readily adjusted, allowing its use for intermittent drug administration and avoiding the need for the 'piggyback system' commonly used in adult intravenous administration.

Dilution of parenteral preparations for infusion may also cause inadvertent fluid overload in children. In fluid-restricted or very young infants, it is possible that the volume of diluted drug can exceed the daily fluid requirement. To appreciate this problem, the paediatric practitioner should become familiar with the fluid volumes that children can tolerate. As a guide, these volumes can be calculated using the following formula: 100 mL/kg for the first 10 kg, plus 50 mL/kg for the next 10 kg, plus 20 mL/kg thereafter. Worked examples are given in [Table 10.5](#). It is important to remember that these volumes do not account for losses such as those caused by dehydration, diarrhoea or artificial ventilation. Although the use of more concentrated infusion solutions may overcome the problem of fluid overload, stability data on concentrated solutions are often lacking. It may, therefore, be necessary to manipulate other therapy to accommodate the treatment or even to consider alternative treatment options. Fluid overload may also result from excessive volumes of flushing solutions and is described later. Guidance on selecting appropriate intravenous fluids for administration to children to avoid fluid induced hyponatraemia was published by the National Patient Safety Agency (NPSA, 2007a). Additional guidance on intravenous fluid therapy in children and young people in hospital was published by the National Institute for Health and Care Excellence (NICE) in December 2015 (NICE, 2015).

Lack of suitable paediatric formulations. Many parenteral products are only available in adult dose sizes. The concentrations of these products can make it difficult to measure the small doses required in paediatrics. Dilution to achieve measurable concentrations, miscalculations and misinterpretation of decimal points may lead to errors. ‘Ten times’ errors are common particularly when drawing the dose from a single ampoule or vial that contains sufficient quantity for an adult patient.

Displacement volume. Reconstitution of powder injections in accordance with manufacturers’ directions usually makes no allowance for the displacement volume of the powder itself. Hence, the final volume may be greater than expected, and the concentration will, therefore, be less than expected. This can result in the paediatric patient receiving an underdose, which becomes even more significant in younger patients receiving smaller doses or more concentrated preparations. Paediatric units usually make available modified reconstitution directions which take account of displacement volumes.

Rates of infusion. The slow infusion rates often necessary in paediatrics may influence drug therapy. The greater the distance

between the administration port and the distal end of the delivery system, and the slower the flow rate, the longer the time required for the drug to be delivered to the patient. In very young infants and children, it may take several hours for the drug to reach the patient, depending on the point of injection. This is an important consideration if dosage adjustments are being made in response to plasma level monitoring. Bolus injections should always be given as close to the patient as possible.

Dead space. After administration via an injection port, a residual amount of drug solution can remain trapped at the port. If dose volumes are small, the trapped fluid may represent a considerable proportion of the intended dose. Similarly, the volume of solution required to prime the intravenous lines or the inline filters (i.e. the dead space) can be a significant proportion of the intended dose. This problem can be minimised by ensuring that drugs are flushed at an appropriate rate into the main infusion line after administration via an injection port or through a filter and by priming the lines initially with a compatible solution. The small volumes required to prime filters and tubing specifically designed for infants and children can be used to minimise the dead space. Modern filter materials can produce less adsorption of drugs so that more of the drug is delivered to the patient.

It is important to remember that flushing volumes can add a significant amount to the daily fluid and sodium intake, and it may be important to record the volume of flushing solutions used in patients susceptible to fluid overload.

Excipients. Analogous to oral preparations, excipients may be present in parenteral formulations and can be associated with adverse effects. Benzyl alcohol, polysorbates and propylene glycol are commonly used agents which may induce a range of adverse effects in children, including metabolic acidosis, altered plasma osmolality, central nervous system depression, respiratory depression, cardiac arrhythmias and seizures. Knowledge of the products that contain these ingredients may influence drug selection.

The National Patient Safety Agency highlighted the risks associated with the preparation of injectable preparations in 2007 (NPSA, 2007b). Many hospitals have established centralised intravenous additive services (CIVAS) that prepare single intravenous doses under aseptic conditions, thus avoiding the need for preparation at ward level. Such services have not only significantly decreased the risks associated with intravenous therapy, particularly in the paediatric population, but can also produce considerable cost savings because more than one dose may be drawn up from the one vial.

Pulmonary route

The use of aerosol inhalers for the prevention and treatment of asthma presents particular problems for children because of the coordination required. The availability of breath-activated devices and spacer devices and large-volume holding chambers has greatly improved the situation. Guidance has been published on the use of inhaler devices in children less than 5 years of age (NICE, 2000) and older children (NICE, 2002) and was updated in 2014 (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2014). Recent experience has shown that different types of large-volume holding chambers alter drug delivery and absorption and should not be considered as interchangeable.

Table 10.5 Calculation of standard daily fluid requirements in paediatric patients

15-kg patient	35-kg patient
100 mL/kg × 10 kg = 1000 mL	100 mL/kg × 10 kg = 1000 mL
Plus 50 mL/kg × 5 kg = 250 mL	Plus 50 mL/kg × 10 kg = 500 mL
Total = 1250 mL/day	Plus 20 mL/kg × 15 kg = 300 mL
	Total = 1800 mL/day

It must be remembered that drugs can be absorbed into the systemic circulation after pulmonary administration or may be absorbed via the enteral route when excess drug is swallowed. High-dose corticosteroid inhalation may suppress the adrenal cortical axis and growth by this mechanism.

Dose regimen selection

A summary of the factors to be considered when selecting a drug dosage regimen or route of administration for a paediatric patient is shown in [Table 10.6](#).

Medicines optimisation

Medicines optimisation is about ensuring that the right patients get the right choice of medicine, at the right time. By focusing on patients and their experiences, the goal is to help patients improve their outcomes, take their medicines correctly, avoid taking unnecessary medicines, reduce wastage of medicines and improve medicine safety. Ultimately, medicines optimisation can help encourage patients to take ownership of their treatment.

Parents or carers are often responsible for the administration of medicines to their children, and, therefore, basic principles of medicines optimisation such as concordance and adherence of both parties must be considered. The literature on nonadherence and concordance in children is limited, but the problem is considered to be widespread and similar to that reported in adults.

Nonadherence may be caused by several factors, such as patient resistance to taking the medicine, complicated dosage regimens, misunderstanding of instructions and apparent ineffectiveness or side effects of treatment. In older children and adolescents who may be responsible for their own medication, different factors may be responsible for nonadherence; for example, they may be unwilling to use their medication because of peer pressure.

Several general principles should be considered in an attempt to improve adherence. Adherence is usually better when fewer medicines are prescribed. Attention should be given to the formulation, taste, appearance and ease of administration of treatment. The regimen should be simple and tailored to the child's waking day. If possible, the child should be involved in choosing a suitable preparation when choice is available.

Many health professionals often counsel the parents/carers only, rather than involving the child in the counselling process. Where possible, treatment goals should be set in collaboration with the child.

Table 10.6 Factors to be considered when selecting a drug dosage regimen or route of administration for a paediatric patient

Factor	Comment
1. Age/weight/surface area	Is the weight appropriate for the stated age? If it is not, confirm the difference. Can the discrepancy be explained by the patient's underlying disease (e.g. patients with neurological disorders such as cerebral palsy may be significantly underweight for their age)? Is there a need to calculate dosage based on surface area, e.g. cytotoxic therapy? Remember heights and weights may change significantly in children in a very short space of time. It is essential to recheck the surface area at each treatment cycle using recent heights and weights.
2. Assess the appropriate dose	The age/weight of the child may have a significant influence on the pharmacokinetic profile of the drug and the manner in which it is handled. In addition, the underlying disease state may influence the dosage or dosage interval.
3. Assess the most appropriate interval	In addition to the influence of disease states and organ maturity on dosage interval, the significance of the child's waking day is often overlooked. A child's waking day is generally much shorter than that of an adult and may be as little as 12 h. Instructions given to parents particularly should take account of this; e.g. the instruction 'three times a day' will bear no resemblance to 'every 8 h' in a child's normal waking day. If a preparation must be administered at regular intervals, then the need to wake the child should be discussed with the parents, or preferably an alternative formulation, such as a sustained-release preparation, should be considered.
4. Assess the route of administration in the light of the disease state and the preparations and formulations available	Some preparations may require manipulation to ensure their suitability for administration by a specific route. Even preparations which appear to be available in a particular form may contain undesirable excipients that require alternatives to be found; e.g. patients with the inherited metabolic disorder phenylketonuria should avoid oral preparations containing the artificial sweetener aspartame because of its phenylalanine content.
5. Consider the expected response and monitoring parameters	Is the normal pharmacokinetic profile altered in children? Are there any age-specific or long-term adverse effects, such as on growth, that should be monitored?
6. Interactions	Drug interactions remain as important in reviewing paediatric prescriptions as they are in adult practice. However, drug–food interactions may be more significant, particularly drug–milk interactions in babies having 5–6 milk feeds per day.
7. Legal considerations	Is the drug licensed? If an unlicensed drug is to be used, the pharmacist should have sufficient information to support its use.

Parents consider the age group of 8–10 years the most appropriate at which to start including the child in the counselling process. As well as verbal instruction, parents often want written information. However, current patient information leaflets (PILs) must reflect the Summary of Product Characteristics and so are often inappropriate. If a drug is used in an ‘off-label’ manner, statements such as ‘not recommended for use in children’ may cause confusion and distress. Care needs to be taken, therefore, to ensure that the information provided, whether written or spoken, is appropriate for both the parents/carers and the child.

Information provided with medicines is often complex and may not always be relevant to children. The Royal College of Paediatrics and Child Health in conjunction with other bodies has launched a range of information leaflets on medicines for parents and carers. The leaflets cover off-label use of specific drugs and aim to provide appropriate, accurate and easily understandable information on dosage and side effects to those administering medicines to children. The leaflets can be downloaded from the website <http://www.medicinesforchildren.org.uk>.

Medicines in schools

Children with medical conditions should be properly supported at school so that they have full access to education, including school trips and physical education. Children who are acutely ill will be treated with medicines at home or in hospital, although it may be possible to return to school during their recovery phase. Children with chronic illness, such as asthma or epilepsy, and children recovering from acute illnesses may require medicines to be administered whilst at school. In addition, there are some medical emergencies that may occur at school or on school trips that require prompt drug administration before the arrival of the emergency services. These emergencies include anaphylaxis (associated with food allergy or insect stings), severe asthma attacks and seizures.

Policies and guidance

There is considerable controversy over the administration of medicines in schools. Whilst governing bodies must ensure that arrangements are in place to support pupils at school with medical conditions, there is no legal or contractual duty on school staff to administer medicine or supervise a pupil taking it. This is a voluntary role. Some support staff may have specific duties to provide medical assistance as part of their contract. Policies and procedures are required to ensure that prescribed medicines are labelled, stored and administered safely and appropriately and that teachers and care assistants are adequately trained and understand their responsibilities.

Advice has been provided for schools and their employers on how to manage medicines in schools in “Supporting pupils at school with medical conditions: Statutory guidance for governing bodies of maintained schools and proprietors of academies in England” (Department for Education, 2015). The roles and responsibilities of employers, parents and carers, governing bodies, head teachers, teachers and other staff and of local health services are all explained. The advice considers staffing issues such as employment of staff, insurance and training. Other issues

covered include drawing up a healthcare plan for a pupil; confidentiality; record keeping; the storage, access and disposal of medicines; home-to-school transport; and on-site and off-site activities. It also provides general information on four common conditions that may require management at school: asthma, diabetes, epilepsy and anaphylaxis.

Responsibility for common medicines

Responsible pupils should be allowed to administer their own medication. Children with asthma should carry their ‘reliever’ inhaler (e.g. salbutamol or terbutaline); a spare inhaler should be available in school, and easy access to it before and during sports should be assured. There should be no need to have ‘preventer’ inhalers at school because administration schedules of two or three times daily are appropriate and can avoid school hours. Medicines with an administration schedule of two or three times a day should be supplied wherever possible so that dosing during school hours is avoided. Sustained-release preparations or drugs with intrinsically long half-lives may be more expensive but avoid the difficulties of administration at school. Sustained-release methylphenidate and atomoxetine, both used in the management of attention-deficit/hyperactivity disorder (ADHD), are examples. When administration at school is unavoidable, the school time doses can be provided in a separate, labelled container.

Special schools

Some children with severe, chronic illness will go to special rather than mainstream schools where their condition can receive attention from teachers and carers who have undergone appropriate training. Some special schools will be residential. Pupils may also attend another institution for respite care. Particular attention to communication of changes to drug treatment between parents/carers, primary care doctors, hospital doctors and school staff is required if medication errors are to be avoided.

Monitoring parameters

Paediatric vital signs as specified in the Advanced Paediatric Life Support (APLS) guidelines are described in [Table 10.7](#). The figures presented in the tables are given as examples and may vary from hospital to hospital.

For standard paediatric haematological and biochemical parameters, local laboratory reference ranges should be consulted because these change throughout childhood.

Assessment of renal function

There are a number of methods of measuring renal function in children. These include the use of exogenous markers such as $^{51}\text{Cr-EDTA}$, $^{99\text{m}}\text{Tc-DTPA}$ and using endogenous serum and urine creatinine concentrations measured over a timed period. Exogenous markers methods are used when an exact determination of renal function is needed, for example, before commencing

Table 10.7 Paediatric vital signs (Advanced Life Support Group, 2016)

Age	Respiration rate at rest (breaths/min) 5th–95th centile	Heart rate (beats/min) 5th–95th centile	Blood pressure systolic		
			5th centile	50th centile	95th centile
Birth	25-50	120-170	65-75	80-90	105
1 month					
3 months					
6 months	20-40	110-160	70-75	85-95

12 years	12-24	65-115	90-105	100-120	125-140
14 years		60-110			
Adult					

complex chemotherapy. Despite some limitations, serum creatinine and estimated creatinine clearance are the most frequently used and most practical methods for 'bedside' assessment of renal function.

In adults, several formulae and nomograms are available for calculating and estimating renal function. However, these cannot be extrapolated to the paediatric population; the Cockcroft and Gault equation and the modification of diet in renal disease (MDRD) are validated only for patients aged 18 years and older.

Specific validated models are available for use in children. These equations use combinations of serum creatinine, height, weight, BSA, age and sex and, more recently, cystatin C (Cys-C) and blood urea nitrogen (BUN) to provide an estimate of creatinine clearance. Some of these equations have been further modified to better predict creatinine clearance; however, the advantage of simplicity is thereby lost. Several examples with their validated age ranges are shown here. The equations retain the limitations of the adult equations and tend to underperform in children with extreme weights or

rapidly changing creatinine levels, and they are affected by gender, ethnicity and concurrent illness and should be interpreted with care. Furthermore, the equations have been determined using different assays to measure parameters such as creatinine or Cys-C. An awareness of the method used by the local laboratory is needed to choose one equation or the other. Examples include the following:

- The most commonly used bedside equation (although more accurate ones are now available) is the original Schwartz equation:
 - $\text{GFR (mL/min/1.73 m}^2\text{)} = K \times \text{height/serum creatinine (SCr)}$
 - Height in cm
 - SCr in mmol/L
 - Age range validation: 1–21 years
 - GFR range validation: 3–220 mL/min
 - Jaffe assay method for creatinine determination
 - K is a constant dependent on analytical method used to measure SCr, body composition, age and gender

- $K = 40$; however, different K values are available for different ages/genders:
 - $K = 29$ in low-birth-weight (<2.5 kg) infants
 - $K = 49$ in girls 2–16 and boys 2–13 years old
 - $K = 62$ in boys 13–16 years old
- The most reliable paediatric equation using endogenous markers to date is the improved Schwartz equation from 2009 eGFR-CKiD2. This equation is complex but can be used if the BUN and Cys-C values are available; it will perform exceedingly well (close to exogenous methods) if the patient's GFR is 15–75 mL/min.
 - $eGFR = 39.8 \times [ht(m)/Scr]^{0.456} \times [1.8/Cys-C]^{0.418} \times [30/BUN]^{0.079} \times [ht(m)/1.4]^{0.179}$
 - SCr in mg/dL
 - Height in metres
 - SCys in mg/L
 - BUN in mg/dL
 - $\times 1.076$ if male
 - Age range: 1–17 years
 - Enzymatic method for creatinine determination
 - PENIA assay for cystatin C determination
 - NB: different units
- If Cys-C or BUN is not available, the most accurate endogenous markers equation is the 2008 Schwartz-Lyon equation:
 - $GFR (mL/min/1.73 m^2) = K \times height/SCr$
 - SCr in mmol/L
 - Height in cm
 - Age range: 1–18 years
 - GFR range: 18–150 mL/min
 - Jaffe method for creatinine, but converted to enzymatic result.
 - Calculates different K values for age and gender:
 - K in all girls and boys <13 years = 32.5
 - K in boys ≥ 13 years = 36.5
- If height is not available:
 - Use Schwartz-Lyon with average height.

Adverse drug reactions

Drug safety is an important issue in all medical disciplines, but in paediatrics, this is compounded by the fact that medicines are often not tested in children, and therefore at the time of licensing there is no indication for use in children. This leads to off-label and/or unlicensed (OLUL) prescribing, estimated to occur in 25% of paediatric in-patient prescriptions. It is clear that extrapolation of efficacy, dosing regimens and adverse drug reactions (ADRs) from adult data to children is inappropriate owing to size differences, developmental changes in physiology and drug handling. Taken together with the fact that the pattern of diseases in children is different from that in adults, this puts them at high risk of serious and unpredictable ADRs.

Studies have shown an incidence of ADRs in paediatric patients of between 0.4% and 17% of patients (Smyth et al., 2012), with the incidence of adverse drug reactions causing admission to hospital as 2.9%. The wide range reflects the limited number of formal prospective and retrospective studies examining the

incidence and characteristics of ADRs in the paediatric age group and the variations in study setting, patient group and definition of ADR used. Data can also be skewed by vaccination campaigns because adverse effects are common, and reporting is encouraged. One consistent finding is that the greater the number of medications the child is exposed to, the greater the risk of ADRs (Smyth et al., 2012).

ADRs in infants and older children typically occur at lower doses than in adults, and symptoms may be atypical. Examples include:

- enamel hypoplasia and permanent discolouration of the teeth with tetracyclines;
- growth suppression with long-term corticosteroids in prepubertal children;
- paradoxical hyperactivity in children treated with phenobarbital;
- hepatotoxicity associated with the use of sodium valproate; there are three major risk factors:
 - age under 3 years,
 - child receiving other anticonvulsants,
 - developmental delay;
- increased risk of Reye's syndrome with the use of salicylates in children with mild viral infection. Reye's syndrome is a life-threatening illness associated with drowsiness, coma, hypoglycaemia, seizures and liver failure. The mechanism of this toxicity remains unknown, but aspirin should generally be avoided in children younger than 16 years.

Many ADRs occur less frequently in the paediatric population, for example, gastro-intestinal bleeds with non-steroidal anti-inflammatory drugs (NSAIDs), hepatotoxicity with flucloxacillin and severe skin reactions with trimethoprim/sulfamethoxazole.

The reporting of ADRs is particularly important because the current system of drug development and authorisation not only deprives children of useful drugs because of the lack of clinical trials in children but may also exclude them from epidemiological studies of ADRs to prescribed drugs. The Medicines and Healthcare products Regulatory Agency (MHRA) and the Commission on Human Medicines (CHM) strongly encourage the reporting of serious ADRs in children, including those relating to unlicensed or off-label use of medicines, even if the intensive monitoring symbol (an inverted black triangle) has been removed. This reporting scheme has been extended in recent years to allow pharmacists, nurses and patients/carers to report suspected ADRs.

Medication errors

In contrast to ADRs, medication errors occur as a result of human mistakes or system flaws. Medication errors are now recognised as an important cause of adverse drug events in paediatric practice and should always be considered as a possible causative factor in any unexplained situation. They can produce a variety of problems ranging from minor discomfort to death. The National Patient Safety Agency (now the Patient Safety Agency within NHS England) reported that children aged up to 4 years were involved in 10% of medication incident reports where age was stated (NPSA, 2009). Further review of these reports highlighted issues with dose calculation, including 10-fold errors, and particular medicines (e.g. gentamicin).

Again, different reporting systems and criteria for errors make direct comparisons between studies difficult.

The incidence of medication errors and the risk of serious errors occurring in children are significantly greater than in adults. The causes are many and include:

- heterogeneous nature of the paediatric population and the corresponding lack of standard dosage;
- calculation errors by the prescriber, pharmacist, nurse or caregiver;
- lack of available dosage forms and concentrations appropriate for administration to children, necessitating additional calculations and manipulations of commercially available products or preparation of extemporaneous formulations from raw materials;
- lack of familiarity with paediatric dosing guidelines;
- confusion between adult and paediatric preparations;
- limited published information;
- need for precise dose measurement and appropriate drug delivery systems, the absence of which leads to administration errors and use of inappropriate measuring devices;
- 10-fold dosing errors, which are particularly important and potentially catastrophic, with reports still appearing regularly in the published literature.

The reporting and prevention of medication errors are important. The causes of medication errors are usually multifactorial, and it is essential that when investigating medication errors, particular focus should be placed on system changes and human factors.

Licensing medicines for children

Medicines licensing process

All medicines marketed in the UK must have been granted a product licence (PL) under the terms of the Medicines Act 1968 or a marketing authorisation (MA) following more recent European legislation on the authorisation of medicines. The aim of licensing is to ensure that medicines have been assessed for safety, quality and efficacy. In the UK, evidence submitted by a pharmaceutical company is assessed by the MHRA with independent advice from the CHM and its paediatric medicines expert group.

The licensed indications for a drug are published in the summary of product characteristics. Many medicines granted a product licence or MA for adult use have not been scrutinised by the licensing authorities for use in children. This is reflected by contraindications or cautionary wording in the summary of product characteristics. There has been a lack of commercial incentive to develop medicines for the relatively small paediatric market and perceived difficulties in carrying out clinical trials in this group. It is not illegal to use medicines for indications or ages not specified in the summary of product characteristics, but to ensure safe and effective treatment, health professionals should have adequate supporting information about the intended use before proceeding. Failure to ensure that the use of a medicine is reasonable could result in a suit for negligence if the patient comes to harm.

Unlicensed and 'off-label' medicines

Several reports on drug prescribing in the paediatric setting show that the use of 'off-label' (use of a medicine outside the terms of the licence) or unlicensed medicines is extensive both within hospital and in outpatient settings. In hospital and neonatal care studies the proportion of 'off-label' use varied between 10% and 65%. In outpatient settings the proportion of off-label use varied between 11% and 31% (Kimland and Odlind, 2012). Many 'off-label' medicines will have to be produced by using an 'adult' dose forms, such as tablets, and preparing an extemporaneous liquid preparation suitable for the child. This may be made from the licensed dose form, for example, by crushing tablets and adding suitable excipients, or from chemical ingredients. An appropriate formula with a validated expiry period and ingredients to approved standards should be used. Care must be taken to ensure accurate preparation, particularly when using formulae or ingredients which are unfamiliar.

On some occasions the drug to be used has no product licence or MA, perhaps because it is only just undergoing clinical trials in adults, has been imported from another country, has been prepared under a 'specials' manufacturing licence or is being used for a rare condition for which it has not previously been employed. As with 'off-label' use, there must always be information to support the quality, efficacy and safety of the medicine, as well as information on the intended use. There is always a risk in using such a medicine, which must be balanced against the seriousness of the child's illness and discussed with the parents/carers if practicable.

Many authorities require that the patient should always be informed if the medicine prescribed is unlicensed or 'off-label' and even that written informed consent be obtained before treatment begins. In many situations in paediatrics, this would be impractical, but if parents/carers are not informed, the PIL included with many medicines may cause confusion because it may state that it is 'not for use in children'. Patient or parent/carer information specific to the situation should be prepared and provided.

Legislation on medicines for children

The Paediatric Regulation came into force in the European Union (EU) in January 2007. Its objective was to improve the health of children in Europe by facilitating the development and availability of medicines for children aged 0–17 years. The regulation aims to ensure that medicines for use in children are of high quality, ethically researched and authorised appropriately and also improve the availability of information on the use of medicines for children. It aims to achieve this without subjecting children to unnecessary trials or delaying the authorisation of medicines for use in adults.

The regulation dramatically changed the regulatory environment for paediatric medicines in Europe. Its main impact was the establishment of the Paediatric Committee (PDCO) of the EMA, which is responsible for coordinating the agency's work on medicines for children. The PDCO's main role is to determine the studies that companies must carry out on children as part of paediatric investigation plans (PIPs). In return for such development, the company receives an additional 6 months of market exclusivity for its product.

In July 2012, the EMA published a report for the European Commission on the first 5 years of the regulation (EMA, 2012). This report concludes that paediatric development has become a more integral part of the overall development of medicinal products in the EU, with the regulation working as a major catalyst to improve the situation for young patients. The EMA and its PDOC have agreed to more than 600 PIPs with pharmaceutical companies, to provide data on the efficacy and safety of medicines for diseases of children. More paediatric clinical trials were done, around 350–400 clinical trials per year, that included children (0–18 years), and the proportion of clinical trials including children has increased in the last 6 years, to approximately 10%. Neonates are the most neglected group when it comes to medicines development, but medicines very often need to be used without any proper data on efficacy and safety. The EMA requested the inclusion of more neonates and infants in clinical trials to obtain these data in a safe way; currently 30% of the PIPs include studies with neonates, and more neonates and infants (26%) have been included in trials in recent years. The report also identifies some areas for improvement, such as the low uptake of paediatric-use marketing authorisations (PUMAs) by companies.

Several European governments have funded paediatric clinical trials networks to stimulate research and help undertake studies resulting from the paediatric medicines regulations. In the UK, the Clinical Research Network (Children Specialty) is part of the UK National Institute for Health Research (<https://www.crn.nihr.ac.uk/children/>).

WHO has a 'Make medicines child size' programme to stimulate the development of age-appropriate formulations of medicines for children, particularly for those which appear in the List of Essential Medicines for Children: <http://www.who.int/medicines/publications/essentialmedicines/en/>.

Case studies

Case 10.1

Name: PT	
Age: 7 years old	
Sex: Male	
Weight: 16 kg	
Presenting condition:	Presented in the emergency department with a 2-day history of worsening groin and hip pain. Could not bear weight. Patient was febrile with a temperature of 39.2 °C, vomiting and dehydrated. There was no history of injury.
Previous medical history:	Nil of note
Allergies:	No known drug allergies
Drug history:	Nil of note
Differential diagnosis:	Septic arthritis, osteomyelitis

Tests:	Urea and electrolytes Full blood count C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) Blood culture and sensitivities X-ray (hips and abdomen) Bone scan
Results:	Bone scan revealed right pubic osteomyelitis CRP = 56 mg/L (normal range 0–10 mg/L) ESR = 34 mm/h (normal range 1–10 mm/h) Blood culture revealed <i>Staphylococcus aureus</i> sensitive to flucloxacillin
Prescribed:	Flucloxacillin i.v. 800 mg four times a day for 2 weeks, to be followed by oral flucloxacillin 800 mg four times a day for 4 weeks
Progress:	Temperature settled and ESR/CRP decreased after initiation of antibiotic therapy

On the third day of treatment the patient developed a raised red rash which was suspected of being an allergic reaction to flucloxacillin. Treatment was changed to i.v. clindamycin 160 mg three times a day (10 mg/kg/dose) for 2 weeks followed by oral clindamycin 160 mg three times a day for a further 4 weeks.

Question

Comment on the drug therapy and any monitoring required.

Answer

There are a number of points to consider for PT:

- Body weight appears low for age; therefore, there is a need to check if the weight is correct (expected weight for a 7-year-old is approximately 23 kg). If incorrect, doses of medication will need to be recalculated.
- Recommended i.v. dose of flucloxacillin of 50 mg/kg/dose is correct. However, the usual maximum oral dose of flucloxacillin is 25 mg/kg/dose. This is because of the increased risk of gastric side effects with high oral doses of flucloxacillin.
- There is a need to consider adherence with oral flucloxacillin therapy due to poor palatability of the suspension formulation (if PT would not take capsules) and the frequent dosing regimen.
- Whilst the risk of flucloxacillin-induced hepatotoxicity is low in children, there is a need to consider measuring baseline and repeat liver function tests because of the prolonged course (>2 weeks) of flucloxacillin therapy.
- Clindamycin has good oral bioavailability, so i.v. therapy may be unnecessary. However, guidelines on the treatment of osteomyelitis suggest 1–2 weeks of i.v. therapy before switching to oral therapy.
- The recommended dose of clindamycin by i.v. infusion is up to 10 mg/kg dose 6 hourly in severe infection. The infusion should be diluted to 6 mg/mL with sodium chloride 0.9% or dextrose 5% (or a combination) and administered over 30–60 minutes at a maximum rate of 20 mg/kg/h. Consider 160 mg in 27 mL sodium chloride 0.9% over 30 minutes.
- The recommended standard oral dose of clindamycin is 3–6 mg/kg/dose four times a day. This may contribute to problems with adherence to long-term therapy. A three-times-daily dosing

regimen is to be preferred, particularly because PT may return to school, and four-times-daily dosing would require a dose to be administered at school, which may be problematic.

- Consideration should be given to how to administer clindamycin. Clindamycin palmitate suspension, which was palatable, is no longer available as a licensed preparation in the UK. Whilst extemporaneous formulations are available that use clindamycin hydrochloride capsules, the palatability of the resultant suspension is a major concern, particularly given the prolonged course of therapy. A 75 mg/5 mL suspension, licensed in Belgium, can be imported. From a safety and efficacy perspective, it is preferable to use such a product, which has been through a regulatory process similar to that of the UK, than to compound an extemporaneous preparation, which has not undergone appropriate pharmaceutical/pharmacokinetic evaluation.
- Consideration could be given to decreasing the dose of clindamycin to 150 mg three times a day to accommodate capsules, although PT may have difficulty taking these.
- The most serious adverse effect of clindamycin is antibiotic-associated colitis; however, this is often asymptomatic in children due to lack of receptors to the enterotoxin produced by *Clostridium difficile*. It is important to monitor for diarrhoea. If this arises, treatment should be discontinued.

Case 10.2

Name: CS

Age: 18 months old

Sex: Female

Weight: 10 kg

Presenting condition:

Severe right-sided abdominal pain

**Vomiting and loss of appetite
Increased temperature 38.2°C**

Previous medical history:

Nil of note

Allergies:

No known allergies

Drug history:

Nil of note

Tests:

Ultrasound

Provisional diagnosis:

Appendicitis

CS went to theatre where an appendicectomy was performed. The appendix was noted to be perforated.

The prescription reads:

Morphine i.v. 50 mg in 50 mL to run at 1–4 mL/h (10–40 micrograms/kg/h)

Paracetamol 200 mg four times a day as required orally or per rectum

Diclofenac 12.5 mg twice a day as required per rectum or

Ibuprofen 100 mg four times a day as required orally when tolerating milk

Five days of i.v. antibiotic therapy with:

- **Gentamicin 70 mg once daily**
- **Cefotaxime 500 mg four times a day**
- **Metronidazole 75 mg three times a day**

Question

Comment on CS's drug therapy.

Answer

- Consideration must be taken of the fact that CS is small for her age. Investigate if the weight has been recorded accurately in the drug chart.
- The morphine dose is incorrect. If the infusion is prepared as directed, 1 mL/h will actually provide 100 micrograms/kg/h (the dose of morphine is between 10 and 40 micrograms/kg/h). This is a 10-fold overdose, which is a medication error frequently seen in children.
- There is a need to consider how to administer the appropriate rectal dose of paracetamol to CS. Often, post-appendicectomy patients will need to be nil by mouth for a few days. Rectal bioavailability is lower than oral bioavailability, and there may be a need to consider giving a larger rather than smaller paracetamol dose, that is, possibly 250 mg/rectum 8 hourly rather than 125 mg 6 hourly, for up to 48 hours, but not exceeding 90 mg/kg/day.
- Regarding the use of the rectal route, i.v. paracetamol might be a better option for CS. The i.v. preparation is cost-effective compared with the suppositories, is more acceptable (in most cases) for the parents/carers and the child and is fast and effective. It has been shown to be morphine sparing postoperatively. This patient already has an i.v. cannula in situ, so i.v. paracetamol would be the drug of choice rather than rectal.
- Suggest that paracetamol and NSAID are administered regularly in addition to the morphine for at least the first few days post-surgery. Multimodal analgesic therapy is recommended. The NSAID should not be administered, even rectally, until CS is feeding. The gastro-intestinal side effects caused by NSAIDs are systemic, by affecting the prostaglandin pathways, not topical.
- There will be a need to monitor CS for side effects. Nausea, vomiting and pruritus all occur frequently with morphine but can be treated/prevented. It might be a good idea to get a laxative, anti-emetic and antihistamine prescribed so that the medication can be given in a timely manner should the need arise.
- Young children are particularly susceptible to developing myoclonic jerks with morphine. These are often worrying for parents/carers but resolve on withdrawal of the morphine.
- NSAIDs are well tolerated by children, and the risk of adverse events is much lower in children than the adult population. However, it is important to ensure adequate hydration status post-operatively, particularly when using NSAIDs. Acute renal failure has been reported in children who have been treated with NSAIDs and not adequately hydrated, especially bearing in mind that a second nephrotoxic agent, gentamicin, has been prescribed.
- The choice of antibiotics for CS offers adequate cover; however, it could be rationalised. High-dose (7 mg/kg) once-daily aminoglycoside (gentamicin/tobramycin) therapy is now routinely used in children. It is administered by short infusion over 20 minutes. Plasma drug levels should be monitored to achieve an 18- to 24-hour trough level of less than 1 mg/L to avoid toxicity. Monitor urea and electrolytes and serum creatinine. Cefotaxime can be given as a bolus injection over 3–5 minutes. Metronidazole can be given as a short bolus or as a short infusion over 20 minutes. Current practice is to use a broad-spectrum antibiotic such as co-amoxiclav that will offer cover against the most likely causative organisms, Gram-negative enterobacteria, anaerobes and Gram-positive bacteria potentially from surgical equipment. It will also avoid using three antibiotics, accessing the line multiple times, using cefotaxime (there is an increase of microorganisms showing resistances to cephalosporins) and using gentamicin (which is nephrotoxic and best avoided in the peri-operative period).

11 Geriatrics

Hamsaraj Shetty and Ken Woodhouse

Key points

- Older people form about 18% of the population and receive about one-third of health service prescriptions in the UK.
- Ageing results in physiological changes that affect the absorption, metabolism, distribution and elimination of drugs.
- Alzheimer's disease and vascular dementia are the most important diseases of cognitive dysfunction in the elderly. Donepezil, rivastigmine and galantamine are inhibitors of acetylcholinesterase and improve cognitive function in Alzheimer's disease.
- The elderly patient with Parkinson's disease is more susceptible to the adverse effects of levodopa such as postural hypotension, ventricular dysrhythmias and psychiatric effects.
- Aspirin, clopidogrel and anticoagulants (in patients with atrial fibrillation) reduce the reoccurrence of non-fatal strokes in the elderly.
- Calcium channel blockers (CCBs) are the first-line drugs for the treatment of hypertension in older people. In those intolerant to CCBs and in those who have contraindications, thiazide diuretics should be offered.
- Urinary incontinence can be classified as stress incontinence, overflow incontinence or due to detrusor instability. Commonly used drugs used in detrusor instability include oxybutynin, solifenacin, trospium and tolterodine.
- Non-steroidal anti-inflammatory drugs (NSAIDs) are more likely to cause gastroduodenal ulceration and bleeding in the elderly.

There has been a steady increase in the number of older people since the beginning of the 20th century. In addition, the 'oldest of the old' are getting older. People older than 65 years formed only 4.8% of the population in 1901, increasing to about 18% in 2014. Among people older than 65 years, those in their 80s accounted for 19% and those older than 90 years accounted for 2% in 1984. In 2014, 22% of those older than 65 years were in their 80s and 5% were older than 90 years. The number of centenarians has gone up by 6030, a 72% increase, over the past decade. It was estimated that there were 14,450 centenarians (aged older than 100 years) living in the UK in 2014 ([Office for National Statistics, 2015](#)). The number of centenarians is projected to increase to 80,000 in 2033. The significant increase in the number of very elderly people will have important social, financial and healthcare planning implications.

The elderly have multiple and often chronic diseases. It is not surprising, therefore, that they are the major consumers of drugs. Elderly people receive about one-third of National Health Service (NHS) prescriptions in the UK. In most developed countries, the elderly now account for 25–40% of drug expenditures.

A UK survey of drug usage in elderly people aged 65 and older identified that the prevalence of medication use was 75% in those aged 65–74 years and 84% in those aged 75 and older. The commonly used drugs were cardiovascular, followed by central nervous system (which included non-narcotic analgesics). A usage rate higher than 9% was identified in both age groups for gastrointestinal, musculoskeletal, haematological, dietetic, endocrine and respiratory medicines ([Chen et al., 2001](#)).

Institutionalised patients tend to be on larger numbers of drugs compared with patients in the community. Patients in long-term care facilities are likely to be receiving, on average, seven to eight drugs ([Centre for Policy on Ageing, 2012](#)). Many of nursing and residential home residents are prescribed psychotropic drugs for conditions including dementia and depression and therefore may be at risk of drug interactions and adverse drug reactions (ADRs). Much work is being undertaken in such homes on reducing the prescribing of inappropriate medicines, and the role of the pharmacist in undertaking such medication reviews has been highlighted ([Royal Pharmaceutical Society Wales, 2016](#)).

For optimal drug therapy in the elderly, a knowledge of age-related physiological and pathological changes that might affect the handling of and response to drugs is essential. This chapter discusses the age-related pharmacokinetic and pharmacodynamic changes ([Mangoni and Jackson, 2003](#)) which might affect drug therapy and the general principles of drug use in the elderly.

Pharmacokinetics

Ageing results in many physiological changes that could theoretically affect absorption, first-pass metabolism, protein binding, distribution and elimination of drugs. Age-related changes in the gastro-intestinal tract, liver and kidneys are:

- reduced gastric acid secretion
- decreased gastro-intestinal motility
- reduced total surface area of absorption
- reduced splanchnic blood flow
- reduced liver size
- reduced liver blood flow
- reduced glomerular filtration
- reduced renal tubular filtration

Absorption

There is a delay in gastric emptying and reduction in gastric acid output and splanchnic blood flow with ageing. These changes do not significantly affect the absorption of the majority of drugs. Although the absorption of some drugs such as digoxin may be slower, the overall absorption is similar to that in the young.

First-pass metabolism

After absorption, drugs are transported via the portal circulation to the liver, where many lipid-soluble agents are metabolised extensively (>90–95%). This results in a marked reduction in systemic bioavailability. Obviously, even minor reductions in first-pass metabolism can result in a significant increase in the bioavailability of such drugs.

Impaired first-pass metabolism has been demonstrated in the elderly for several drugs, including clomethiazole, labetalol, nifedipine, nitrates, propranolol and verapamil. The clinical effects of some of these, such as the hypotensive effect of nifedipine, may be significantly enhanced in the elderly. In frail hospitalised elderly patients, that is, those with chronic debilitating disease, the reduction in pre-systemic elimination is even more marked.

Distribution

The age-related physiological changes which may affect drug distribution are:

- reduced lean body mass
- reduced total body water
- increased total body fat
- lower serum albumin level
- α_1 -Acid glycoprotein level unchanged or slightly raised

Increased body fat in the elderly results in an increased volume of distribution for fat-soluble compounds such as clomethiazole, diazepam, desmethyl-diazepam and thiopental. On the other hand, reduction in body water results in a decrease in the distribution volume of water-soluble drugs such as cimetidine, digoxin and ethanol.

Acidic drugs tend to bind to plasma albumin, whereas basic drugs bind to α_1 -acid glycoprotein. Plasma albumin levels decrease with age, and therefore the free fraction of acidic drugs such as cimetidine, furosemide and warfarin will increase. Plasma α_1 -acid glycoprotein levels may remain unchanged or may rise slightly with ageing, and this may result in minimal reductions in free fractions of basic drugs such as lidocaine. Disease-related changes in the level of this glycoprotein are probably more important than age *per se*.

The age-related changes in distribution and protein binding are probably of significance only in the acute administration of drugs because, at steady state, the plasma concentration of a drug is determined primarily by free drug clearance by the liver and kidneys rather than by distribution volume or protein binding.

Renal clearance

Although there is a considerable interindividual variability in renal function in the elderly, in general the glomerular filtration

rate declines, as do the effective renal plasma flow and renal tubular function. Because of the marked variability in renal function in the elderly, the dosages of predominantly renally excreted drugs such as dabigatran should be individualised. Reduction in dosages of drugs with a low therapeutic index, such as digoxin and aminoglycosides, may be necessary. Dosage adjustments may not be necessary for drugs with a wide therapeutic index, for example, penicillins.

Hepatic clearance

The hepatic clearance (Cl_H) of a drug is dependent on hepatic blood flow (Q) and the steady-state extraction ratio (E), as can be seen in the following formula:

$$\begin{aligned} Cl_H &= Q \times \frac{C_a - C_v}{C_a} \\ &= Q \times E \end{aligned}$$

where C_a and C_v are arterial and venous concentrations of the drug, respectively. It is obvious from this formula that when E approaches unity, Cl_H will be proportional to and limited by Q . Drugs which are cleared by this mechanism have a rapid rate of metabolism, and the rate of extraction by the liver is very high. The rate-limiting step, as mentioned earlier, is hepatic blood flow, and therefore drugs cleared by this mechanism are called 'flow limited'. On the other hand, when E is small, Cl_H will vary according to the hepatic uptake and enzyme activity and will be relatively independent of hepatic blood flow. The drugs which are cleared by this mechanism are termed 'capacity limited'.

Hepatic extraction is dependent upon liver size, liver blood flow, uptake into hepatocytes, and the affinity and activity of hepatic enzymes. Liver size falls with ageing, and there is a 20–40% decrease in hepatic mass between the 3rd and 10th decade. Hepatic blood flow falls equally with declining liver size. Although it is recognised that the microsomal mono-oxygenase enzyme systems are significantly reduced in ageing male rodents, evidence suggests that this is not the case in ageing humans. Conjugation reactions have been reported to be unaffected in the elderly by some investigators, but a small decline with increasing age has been described by others.

Impaired clearance of many hepatically eliminated, particularly lipid-soluble, drugs has been demonstrated in the elderly. Morphological changes rather than impaired enzymatic activity appear to be the main cause of impaired elimination of these drugs. In frail debilitated elderly patients, however, the activities of drug-metabolising enzymes such as plasma esterases and hepatic glucuronyltransferases may well be impaired.

Pharmacodynamics

Molecular and cellular changes that occur with ageing may alter the response to drugs in the elderly. There is, however, limited information about these alterations because of the technical difficulties and ethical problems involved in measuring them. It is not surprising, therefore, that there is relatively little information about the effect of age on pharmacodynamics.

Changes in pharmacodynamics in the elderly may be considered under two headings:

- those due to a reduction in homeostatic reserve,
- those that are secondary to changes in specific receptor and target sites.

Reduced homeostatic reserve

Orthostatic circulatory responses

In normal elderly subjects, there is blunting of the reflex tachycardia that occurs in young subjects on standing or in response to vasodilatation. Structural changes in the vascular tree that occur with ageing are believed to contribute to this observation, although the exact mechanism is unclear. Antihypertensive drugs, drugs with α -receptor blocking effects (e.g. tricyclic antidepressants, phenothiazines and some butyrophenones), drugs which decrease sympathetic outflow from the central nervous system (e.g. barbiturates, benzodiazepines, antihistamines and morphine) and antiparkinsonian drugs (e.g. levodopa and pramipexole) are, therefore, more likely to produce hypotension in the elderly.

Postural control

Postural stability is normally achieved by static reflexes, which involve sustained contraction of the musculature, and phasic reflexes, which are dynamic, short-term and involve transient corrective movements. With ageing, the frequency and amplitude of corrective movements increase and an age-related reduction in dopamine (D_2) receptors in the striatum has been suggested as the probable cause. Drugs which increase postural sway, for example, hypnotics and tranquillisers, have been shown to be associated with the occurrence of falls in the elderly.

Thermoregulation

There is an increased prevalence of impaired thermoregulatory mechanisms in the elderly, although it is not universal. Accidental hypothermia can occur in the elderly with drugs that produce sedation, impaired subjective awareness of temperature, decreased mobility and muscular activity, and vasodilatation. Commonly implicated drugs include phenothiazines, benzodiazepines, tricyclic antidepressants, opioids and alcohol, either on their own or with other drugs.

Cognitive function

Ageing is associated with marked structural and neurochemical changes in the central nervous system. Cholinergic transmission is linked with normal cognitive function, and in the elderly the activity of choline acetyltransferase, a marker enzyme for acetylcholine, is reduced in some areas of the cortex and limbic system. Several drugs cause confusion in the elderly. Anticholinergics, hypnotics, H_2 antagonists and β -blockers are common examples.

Visceral muscle function

Constipation is a common problem in the elderly because there is a decline in gastro-intestinal motility with ageing. Anticholinergic drugs, opiates, tricyclic antidepressants and antihistamines are more likely to cause constipation or ileus in the elderly. Anticholinergic drugs may cause urinary retention in elderly men, especially those who have prostatic hypertrophy. Bladder instability is common in the elderly, and urethral dysfunction more prevalent in elderly women. Loop diuretics may cause incontinence in such patients.

Age-related changes in specific receptors and target sites

Many drugs exert their effect via specific receptors. Response to such drugs may be altered by the number (density) of receptors, the affinity of the receptor, postreceptor events within cells resulting in impaired enzyme activation and signal amplification, or altered response of the target tissue itself. Ageing is associated with some of these changes.

α -Adrenoceptors

α_2 -Adrenoceptor responsiveness appears to be reduced with ageing, whereas α_1 -adrenoceptor responsiveness appears to be unaffected.

β -Adrenoceptors

β -Adrenoceptor function declines with age. It is recognised that the chronotropic response to isoprenaline infusion is less marked in the elderly. Propranolol therapy in the elderly produces less β -adrenoceptor blocking effect than in the young. In isolated lymphocytes, studies of cyclic adenosine monophosphate (AMP) production have shown that on β -adrenoceptor stimulation, the dose-response curve is shifted to the right, and the maximal response is blunted.

An age-related reduction in β -adrenoceptor density has been shown in animal adipocytes, erythrocytes and brain, and also in human lymphocytes in one study, although this has not been confirmed by other investigators. Because maximal response occurs on stimulation of only 0.2% of β -adrenoceptors, a reduction in the number by itself is unlikely to account for age-related changes. Some studies have shown a reduction in high-affinity binding sites with ageing, in the absence of change in total receptor numbers, and others have suggested that there may be impairment of postreceptor transduction mechanisms with ageing that may account for reduced β -adrenoceptor function.

Cholinergic system

The effect of ageing on cholinergic mechanisms is less well known. Atropine produces less tachycardia in elderly humans than in the young. It has been shown in ageing rats that the hippocampal pyramidal cell sensitivity to acetylcholine is reduced. The clinical significance of this observation is unclear.

Benzodiazepines

The elderly are more sensitive to benzodiazepines than the young, and the mechanism of this increased sensitivity is not known. No difference in the affinity or number of benzodiazepine-binding sites has been observed in animal studies. Habituation to benzodiazepines occurs to the same extent in the elderly as in the young. A prospective population-based study did not support a causal association between benzodiazepine use and dementia (Gray et al., 2016).

Warfarin

The elderly are more sensitive to warfarin. This phenomenon may be due to age-related changes in pharmacodynamic factors. The exact mechanism is unknown.

Digoxin

The elderly appear to be more sensitive to the adverse effects of digoxin, but not to the cardiac effects.

Common clinical disorders

This section deals in detail only with the most important diseases affecting older people. Other conditions are mentioned primarily to highlight areas where the elderly differ from the young or where modifications of drug therapy are necessary.

Dementia

Dementia is an important cause of disability and dependence and is estimated to affect around 150 million people worldwide by 2050 (Public Health England, 2016). Caring for dementia is estimated to cost \$1 trillion by 2030.

Dementia is characterised by a gradual deterioration of intellectual capacity. Alzheimer's disease (AD), vascular dementia (VaD), dementia with Lewy bodies and frontotemporal dementia are the most important diseases of cognitive dysfunction in the elderly. The term mild cognitive impairment (MCI) is used to describe a decline in cognitive function without an associated difficulty in performing complex functional tasks such as shopping or social and occupational activities. Around 50% of patients with MCI develop AD within 4 years of diagnosis. AD has a gradual onset, and it progresses slowly. Forgetfulness is the major initial symptom followed by difficulty with occupational activities and the activities of daily living such as dressing and bathing. The individual with AD tends to get lost in his or her own environment. Eventually, the social graces are lost. Pathological examination of the brain characteristically reveals neuritic plaques containing amyloid beta (A β), neurofibrillary tangles which are composed of hyperphosphorylated tau filaments and accumulation of A β in cerebral blood vessel walls.

VaD is the second most important cause of dementia. It usually occurs in patients in their 60s and 70s and is more common in those with a previous history of hypertension or stroke. It is

Box 11.1 Drugs causing confusion in the elderly

- Antiparkinsonian drugs
- Barbiturates
- Benzodiazepines
- Diuretics
- Hypoglycaemic agents
- Monoamine oxidase inhibitors
- Opioids
- Steroids
- Tricyclic antidepressants

commonly associated with mood changes and emotional lability. Gait disorders, difficulties with executive function, dysarthria, dysphagia and incontinence become evident with advancing disease. Physical examination may reveal focal neurological deficits. A number of drugs and other conditions cause confusion in the elderly, and their effects may be mistaken for dementia. These are listed in Box 11.1.

In patients with AD, damage to the cholinergic neurones connecting subcortical nuclei to the cerebral cortex has been consistently observed. Postsynaptic muscarinic cholinergic receptors are usually not affected, but ascending noradrenergic and serotonergic pathways are damaged, especially in younger patients. Based on those abnormalities, several drugs have been investigated for the treatment of AD. Lecithin, which increases acetylcholine concentrations in the brain, 4-aminopyridine, piracetam, oxiracetam and pramiracetam, all of which stimulate acetylcholine release, have been tried but have produced no, or unimpressive, improvements in cognitive function. Anticholinesterases block the breakdown of acetylcholine and enhance cholinergic transmission. Donepezil, galantamine and rivastigmine are recommended for treatment of patients with AD of moderate severity only – that is, those with a Mini-Mental State Examination (MMSE) score of between 10 and 20 points (National Institute for Health and Care Excellence [NICE], 2016). Donepezil is a piperidine-based acetylcholinesterase inhibitor. It has been shown to improve cognitive function in patients with mild to moderately severe AD. However, it does not improve day-to-day functioning, quality-of-life measures or rating scores of overall dementia. Rivastigmine is a non-competitive cholinesterase inhibitor. It has been shown to slow the rate of decline in cognitive and global functioning in AD. Galantamine, a reversible and competitive inhibitor of acetylcholinesterase, has also been shown to improve cognitive function significantly and is well tolerated. Adverse effects of cholinesterase inhibitors include nausea, vomiting, diarrhoea, weight loss, agitation, confusion, insomnia, abnormal dreams, muscle cramps, bradycardia, syncope and fatigue. Treatment with these drugs should only be continued in people with dementia who show an improvement or no deterioration in their MMSE score, together with evidence of global (functional and behavioural) improvement after the first few months of treatment. The treatment effect should then be reviewed critically every 6 months, before a decision to continue drug therapy is made.

Memantine, an *N*-methyl-D-aspartate (NMDA) antagonist, has also been used for the treatment of moderate to severe AD. It acts

mainly on subtypes of glutamate receptors related to memory (i.e. NMDA), resulting in improvements in cognition. It has also been shown to have some beneficial effects on behaviour, and its use is recommended in patients with moderate to severe AD as part of well-designed clinical studies (NICE, 2016).

Deposition of amyloid (in particular, the peptide $\beta/A4$) derived from the Alzheimer amyloid precursor protein (APP) is an important pathological feature of the familial form of AD that accounts for about 20% of patients. Point mutation of the gene coding for APP (located in the long arm of chromosome 21) is thought to be associated with familial AD. So far, the anti-amyloid treatment strategy in AD has been disappointing. Vaccination against $A\beta_{42}$, which was very effective in clearing and accumulation brain amyloid in mouse models, was associated with serious adverse effects in human beings. Bapineuzumab, a monoclonal antibody that targets the N-terminus of $A\beta$, and solanezumab, a monoclonal antibody that binds to soluble $A\beta$, were both found to be ineffective in clinical trials. Tarenflurbil, avagacestat and semagacestat, all γ -secretase inhibitors which reduce $A\beta_{42}$ production, were found to be ineffective in placebo-controlled human trials, and the latter drug was associated with faster cognitive decline. β -Secretase inhibitors are also currently being investigated in phase 2 and 3 clinical trials for early AD. Tau neurofibrillary tangles found in AD patients are noted to be associated with synaptic loss and cognitive decline. Tau antibodies and drugs that modify Tau phosphorylation and aggregation are currently being investigated. Insulin signalling is thought to play a role in the pathogenesis of AD, and the benefit of insulin in mild AD is undergoing investigation (Scheltens et al., 2016).

A formulation containing caprylic triglyceride, fractionated coconut oil (Axona), is approved for treatment of AD in the USA. Souvenaid, which contains vitamins and supplements, is approved for early AD in some European countries, Australia, and China.

Depression is common in AD patients and is usually treated with a selective serotonin reuptake inhibitor (SSRI) drug. Agitation is also common, and whilst risperidone is the only antipsychotic licensed in the UK for treatment of severe aggression in AD, antipsychotic drugs such as quetiapine and olanzapine are now preferred in practice.

In some studies, donepezil and galantamine have been shown to improve cognition, behaviour and activities of daily living in patients with VaD, and in those with AD and coexistent cerebrovascular disease. Memantine has been reported to stabilise progression of VaD compared with placebo. However, acetylcholinesterase inhibitors and memantine should not be prescribed for the treatment of cognitive decline in patients with VaD, except as part of properly constructed clinical studies. Aspirin therapy has also been reported to slow the progression of VaD. The incidence of VaD is likely to decrease with other stroke-prevention strategies, such as smoking cessation, anticoagulation for atrial fibrillation and control of hypertension and hyperlipidemia.

Parkinsonism

Parkinsonism is a relatively common disease of the elderly, with a prevalence between 50 and 150 per 100,000. It is characterised by resting tremors, muscular rigidity and bradykinesia (slowness

of initiating and carrying out voluntary movements). The patient has a mask-like face and monotonous voice and walks with a stoop and a slow, shuffling gait.

The elderly are more susceptible than younger patients to some of the adverse effects of antiparkinsonian drugs. Age-related decline in orthostatic circulatory responses means that postural hypotension is more likely to occur in elderly patients with levodopa therapy. The elderly are more likely to have severe cardiac disease, and levodopa preparations should be used with caution in such patients because of the risk of serious ventricular dysrhythmias. Psychiatric adverse effects such as confusion, depression, hallucinations and paranoia occur with dopamine agonists and levodopa preparations. These adverse effects may persist for several months after discontinuation of the offending drug and may result in misdiagnosis (e.g. of AD) in the elderly. Bromocriptine and other ergot derivatives should be avoided in elderly patients with severe peripheral arterial disease because they may cause peripheral ischaemia. Antiparkinsonian drugs should be commenced in low doses and the dose increased gradually. 'Drug holidays', which involve discontinuation of drugs, for example, for 2 days per week, may reduce the incidence of adverse effects of antiparkinsonian drugs, but their role is questionable.

Stroke

In 2010, stroke was the second most common cause of death and the third most common cause of lost disability-adjusted life years (DALYs), with an estimated incidence of 16.9 million strokes worldwide. There were 33.0 million prevalent stroke cases, 5.9 million stroke deaths and 102.2 million DALYs lost. Over 38% of new strokes, 30% of prevalent strokes, 55% of stroke deaths and 28% of DALYs lost were in people aged older than 75 years. In developed countries, about 85% of strokes are ischaemic and 15% are due to haemorrhages. However, most stroke burden worldwide is due to haemorrhagic stroke.

Treatment of acute stroke

Thrombolytic agents. Intravenous alteplase increases the odds of a good stroke outcome if given within 4.5 hours of onset. The benefit is time dependent (odds ratio [OR] 1.75 if given within 3 hours and 1.26 if given between 3 and 4.5 hours). Odds of improved outcome are highest if it is given within 90 minutes, and it is not effective beyond 4.5 hours. The benefit occurs irrespective of stroke severity and age of patients. Alteplase compared with placebo significantly increased the odds of symptomatic intracranial haemorrhage (OR 5.55) and of fatal intracranial haemorrhage within 7 days (OR 7.140). Alteplase therapy was associated with higher 90-day mortality (hazard ratio 1.11). Although there was an absolute increase of about 2% in the risk of early death from intracranial haemorrhage, by 3–6 months, the risk was offset by absolute increase in disability-free survival of about 10% for patients treated in less than 3.0 hours and about 5% for patients treated after 3.0 hours, up to 4.5 hours (Embersson et al., 2014). Thrombolysis is a potentially dangerous treatment, especially in older people. Therefore, it should only be given to carefully selected patients after excluding patients

who have contraindications and those who are at very high risk of bleeding. Older people should not be denied this very effective treatment purely on the basis of chronological age. Careful adherence to thrombolysis protocol has been shown to reduce the risk of haemorrhagic complications after treatment with alteplase. Currently, alteplase is the only thrombolytic agent that is licensed for use in acute ischaemic stroke. Other thrombolytic agents such as tenecteplase are currently undergoing clinical trials. Endovascular therapy, especially with stent-based clot retrievers, in combination with alteplase therapy has been shown to be highly effective and is likely to become the standard therapy for acute stroke (NICE, 2016).

Antiplatelet therapy. Aspirin in doses of 150–300 mg commenced within 48 hours of onset of ischaemic stroke has been shown to reduce the relative risk of death or dependency by 2.7% up to 6 months after the event in two large studies (Chen et al., 2000).

Anticoagulation. Use of intravenous unfractionated heparin and low-molecular-weight heparin has not been shown to be beneficial and is associated with an increased risk of intracranial haemorrhage.

Neuroprotective agents. Many neuroprotective agents have been used for the treatment of acute ischaemic stroke, but none has been shown to have long-term beneficial effects.

Secondary prevention

Patients with ischaemic stroke, if they are in sinus rhythm, should receive aspirin 300 mg as soon as possible after the diagnosis. Aspirin should be discontinued after 2 weeks, and clopidogrel 75 mg daily should be started for secondary stroke prevention. If there is a history of allergy or intolerance to clopidogrel, the combination of aspirin 75 mg daily plus modified-release dipyridamole 200 mg twice daily or the latter drug on its own if the patient is allergic to aspirin, should be prescribed (NICE, 2010). Clopidogrel plus aspirin (75 mg each daily) compared with aspirin alone is associated with an absolute increase in the risk of life-threatening bleeding by 1.3%, and therefore this combination is not recommended for secondary stroke prevention (Diener et al., 2004).

In patients with atrial fibrillation who have had a previous stroke or transient ischaemic attack, anticoagulation with warfarin (international normalised ratio [INR] 1.5–2.7) has been shown to be significantly better than aspirin for secondary prevention (Hart et al., 2007). Anticoagulation has not been shown to be effective for secondary prevention in patients with sinus rhythm. The oral anti-factor Xa drugs apixaban, edoxaban and rivaroxaban and the antithrombin drug dabigatran are also approved by NICE for stroke prevention in patients who have had a transient ischaemic attack (TIA) or stroke if they are in atrial fibrillation. Compared with warfarin, they significantly reduce the risk of stroke or systemic embolism by 19% and significantly reduce all-cause mortality. They are associated with significantly lower risk of intracerebral haemorrhage, similar risk of major bleeding as warfarin, but slightly higher incidence of gastro-intestinal haemorrhage (Verheugt and Granger, 2015). They are very convenient to use because they are given once or twice daily and do not require routine monitoring. Because they have very short

half-lives (between 9 and 17 hours), adherence to treatment is absolutely essential if they are to be effective. Dabigatran is predominantly renally excreted and should be avoided in patients with severe renal impairment (creatinine clearance <30 mL/min). As with warfarin, older patients should be carefully counselled before commencing treatment with the direct oral anticoagulants (DOACs), and their full blood count, renal and liver function should be monitored at regular intervals.

Adequate control of hypertension (aiming for a blood pressure of <140/80 mmHg), hyperlipidaemia (ideally with a statin) and diabetes; stopping smoking; losing weight and reducing alcohol consumption are also important in secondary stroke prevention.

Primary prevention

Randomised controlled trials have shown that anticoagulation with warfarin compared with placebo reduces the risk of stroke in patients with atrial fibrillation (Hart et al., 2007). Control of risk factors such as hypertension, hyperlipidaemia, diabetes and smoking is likely to play an important role in primary prevention.

Osteoporosis

Osteoporosis is a progressive disease characterised by low bone mass and micro-architectural deterioration of bone tissue resulting in increased bone fragility and susceptibility to fracture. It is an important cause of morbidity in postmenopausal women. The most important complication of osteoporosis is fracture of the hip. Fractures of wrist, vertebrae and humerus also occur. Increasing age is associated with higher risk of fractures, which occur mostly in those aged older than 75 years. In the UK, more than 200,000 fractures occur each year, costing the NHS £1.8 billion per year, of which 87% is spent on hip fractures. In Europe, more than 3.7 million osteoporotic fractures occur annually, costing £22.5bn.

Prevention

Because complications of osteoporosis have enormous economic implications, preventive measures are extremely important. Regular exercise has been shown to halve the risk of hip fractures. Stopping smoking before menopause reduces the risk of hip fractures by 25%.

Treatment

Vitamin D and calcium. Vitamin D deficiency is common in elderly people. Treatment for 12–18 months with 800 IU of vitamin D plus 1.2 g of calcium given daily has been shown to reduce hip and non-vertebral fractures in elderly women (mean age 84 years) living in sheltered accommodation. Clinical trials have shown that vitamin D supplementation without co-administration of calcium do not prevent fracture. Recent evidence from clinical trials indicates that it is inappropriate to use vitamin D for osteoporosis prevention in community-dwelling adults who do not have specific risk factors for vitamin D deficiency. Calcium supplementation on its own also does not reduce fracture incidence and is no longer recommended for treatment of osteoporosis (Black and Rosen, 2016).

Calcitriol and alfacalcidol. Calcitriol (1,25-dihydroxyvitamin D), the active metabolite of vitamin D, and alfacalcidol, a synthetic analogue of calcitriol, reduce bone loss and have been shown to reduce vertebral fractures, but not consistently. Serum calcium should be monitored regularly in patients receiving these drugs.

Bisphosphonates. Bisphosphonates, synthetic analogues of pyrophosphate, bind strongly to the bone surface and inhibit bone resorption. Currently, five bisphosphonates are available for the prevention and treatment of osteoporosis: alendronate, etidronate, risedronate, ibandronate and zoledronate. Compared with placebo, alendronate, zoledronate and risedronate significantly reduce the risk of hip and vertebral fractures. Ibandronate significantly reduces the risk of vertebral fractures but not that of nonvertebral fractures. Ibandronate by intravenous route is approved only for treatment, but not the prevention, of postmenopausal osteoporosis. Alendronate, risedronate and zoledronate are approved for treatment of osteoporosis in men and steroid-induced osteoporosis. Risedronate and zoledronate are also approved for prevention of steroid-induced osteoporosis.

Alendronate can be given either daily (10 mg) or weekly (70 mg) with equal efficacy. It is effective in reducing vertebral fractures, wrist and hip fractures by about 50%. Etidronate is given cyclically with calcium supplements to reduce the risk of bone mineralisation defects. It reduces the risk of vertebral fractures by 50% in postmenopausal women. There is no evidence to support its effectiveness in preventing hip fractures. It is used less commonly now and is not approved for treatment of osteoporosis in the USA.

Risedronate can be administered once daily (5 mg), weekly (35 mg) or monthly (150 mg). It reduces vertebral fractures by 41% and non-vertebral fractures by 39%. It has been shown to reduce the risk of hip fractures by 40% in postmenopausal women.

Ibandronate can be given intravenously at a dose of 3 mg once every 3 months and by oral route either 150 mg once monthly or 2.5 mg daily. It reduces the incidence of clinical vertebral fractures by about 50% compared with placebo but does not reduce the risk of non-vertebral fractures.

Zoledronic acid significantly reduces the incidence of clinical vertebral fractures by 70%, hip fractures by 41% and non-vertebral fractures by 25% in patients with osteoporosis. It is administered intravenously at a dose of 5 mg, once a year.

All oral bisphosphonates cause gastro-intestinal side effects. Alendronate and risedronate are associated with severe oesophageal reactions including oesophageal stricture. Patients should not take these tablets at bedtime and should be advised to stay upright for at least 30 min after taking them. They should avoid food for at least 2 hours before and after taking etidronate. Alendronate and risedronate should be taken 30 min before the first food or drink of the day. Bisphosphonates should be avoided in patients with renal impairment. Serum calcium and vitamin D levels should be checked before commencing treatment with bisphosphonates because hypocalcaemia can occur, especially with zoledronate. Patients with vitamin D deficiency may develop severe and prolonged hypocalcaemia.

Rarely, atypical sub-trochanteric and femoral shaft fractures have been associated with prolonged (especially beyond 5 years) bisphosphonate therapy. The evidence for benefit with bisphosphonate therapy beyond 5 years is limited, and therefore the decision about long-term therapy should be carefully reviewed and individualised.

Osteonecrosis of the jaw can occur rarely (annual incidence: 0.067%) with bisphosphonate therapy, and it appears to depend on the potency of the drug used (highest risk with zoledronate), the indication for its use (more likely to occur when used for treatment of skeletal metastases than for osteoporosis or Paget's disease), the duration of therapy (more likely to occur with treatment beyond 3 years) and the route of administration (significantly higher with intravenous route). The risk factors for osteonecrosis include recent dental procedure with exposure of bone, dental disease, ill-fitting dental appliances, diabetes, smoking, concomitant treatment with steroids and comorbid conditions. Patients on bisphosphonates should be advised to maintain good dental hygiene and have regular dental checkups.

Strontium ranelate. Strontium ranelate, which both increases bone formation and reduces bone resorption, reduces vertebral (by 37%) and non-vertebral (including hip) fractures (by 14%) in postmenopausal women with osteoporosis. It is well tolerated. It can be used in those who are unable to tolerate bisphosphonates. It should be avoided in patients with severe renal disease (creatinine clearance less than 30 mL/min). It has been reported to cause severe drug rash with eosinophilia and systemic symptoms (DRESS), which causes skin rash, fever, lymphadenopathy and raised white cell count. It can involve the liver, kidneys and lungs and can cause death. Analysis of pooled data from randomised studies in around 7500 postmenopausal women with osteoporosis showed an increased risk of myocardial infarction with strontium ranelate compared with placebo, with a relative risk of 1.6 (95% confidence interval [CI], 1.07–2.38), and an increased risk of venous thrombotic and embolic events with a relative risk of 1.5 (95% CI, 1.04–2.19). Strontium ranelate is now restricted to the treatment of severe osteoporosis in postmenopausal women and adult men at high risk of fracture who cannot use other osteoporosis treatments.

Hormone replacement therapy. Oestrogens increase bone formation and reduce bone resorption. They also increase calcium absorption and decrease renal calcium loss. Hormone replacement therapy (HRT), if started soon after menopause, is effective in preventing vertebral fractures but has to be continued lifelong if protection against fractures is to be maintained. It is associated with increased risk of endometrial cancer, breast cancer and venous thromboembolism. One study has shown that HRT may increase the risk of death due to myocardial disease in elderly women with pre-existing ischaemic heart disease. It should be avoided in older patients.

Raloxifene. Raloxifene is an oral selective oestrogen receptor modulator (SERM) that has oestrogenic actions on bone and anti-oestrogenic actions on the uterus and breast. It reduces the risk of vertebral fractures, but not those at other sites. Adverse effects include hot flushes, leg cramps and risk of venous thromboembolism. It also protects against breast cancer. Its use is restricted, as a second-line drug, to younger postmenopausal women with vertebral osteoporosis.

Parathyroid hormone peptides. Teriparatide is the recombinant portion of human parathyroid hormone, amino acid sequence 1–34, of the complete molecule (which has 84 amino acids). It reduces vertebral and non-vertebral fractures in postmenopausal women. It does not reduce hip fractures. It is given

subcutaneously at a dose of 20 micrograms daily. The recombinant (full 1–84 amino acid sequence) parathyroid hormone peptide (Preotact) can also be used at a dose of 100 micrograms daily. It has similar efficacy as teriparatide. Both these drugs are expensive, and teriparatide is associated with an increased risk of osteosarcoma in animal studies. Teriparatide is recommended for secondary prevention of osteoporotic fractures in postmenopausal women who are unable to tolerate or have a contraindication for treatment with bisphosphonates or strontium.

Calcitonin. Calcitonin inhibits osteoclasts and decreases the rate of bone resorption, reduces bone blood flow and may have central analgesic actions. It is effective in all age groups in preventing vertebral bone loss. It is costly and has to be given parenterally or intranasally. Antibodies do develop against calcitonin, but they do not affect its efficacy. Calcitonin is useful in treating acute pain associated with osteoporotic vertebral fractures but is no longer recommended for treatment of osteoporosis because it is associated with malignancy with long-term use.

Denosumab. Denosumab is a fully human monoclonal antibody to RANKL (receptor activator of nuclear factor- κ B ligand). It acts as an antiresorptive agent by inhibiting the formation of mature osteoclasts by binding to RANKL, which regulates osteoclast formation, activity and survival. It reduces vertebral fractures by 68%, hip fractures by 40% and nonvertebral fractures by 20%. It has been approved for treatment of postmenopausal osteoporosis and also for osteoporosis in men. Atypical femoral fractures and osteonecrosis of the jaw have both been associated with denosumab. Atypical femoral fractures occur rarely after treatment for more than 2.5 years. Osteonecrosis of the jaw has mainly been reported in cancer patients receiving 120 mg of denosumab subcutaneously every 4 weeks. For treatment of postmenopausal osteoporosis, the dose used is 60 mg subcutaneously every 6 months. Risk factors for osteonecrosis and precautions for its prevention, discussed under bisphosphonates, should be considered in all patients before starting denosumab therapy. Severe hypocalcemia has been reported, usually in the first week of treatment with denosumab, especially in patients with renal impairment. Serum calcium level should be checked before starting, within 2 weeks of the first dose and in patients experiencing symptoms of hypocalcemia, such as muscle spasms, cramps or tingling of fingers/perioral region.

Arthritis

Osteoarthritis (also known as osteoarthritis), gout, pseudogout, rheumatoid arthritis and septic arthritis are the important joint diseases in the elderly. Treatment of these conditions is similar to that in the young. If possible, NSAIDs should be avoided in patients with osteoarthritis. Total hip and knee replacements should be considered in patients with severe arthritis affecting these joints.

Hypertension

Hypertension is an important risk factor for cardiovascular and cerebrovascular disease in the elderly. The incidence of myocardial infarction is 2.5 times higher, and that of cerebrovascular

accidents is twice as high, in elderly hypertensive patients compared with non-hypertensive subjects. Elevated systolic blood pressure is the single most important risk factor for cardiovascular disease and more predictive of stroke than diastolic blood pressure.

Blood pressure lowering has been shown to be beneficial in those patients younger and older than 65 years with no substantial variation in the reduction of major vascular events with different drug classes ([Blood Pressure Lowering Treatment Trialists' Collaboration, 2008](#)). There is evidence that treatment of both systolic and diastolic blood pressure in the elderly is beneficial. One large study has shown reductions in cardiovascular events, and mortality associated with cerebrovascular accidents in treated elderly patients with hypertension ([Amery et al., 1986](#)). The treatment did not reduce the total mortality significantly. Another study ([SHEP, 1991](#)), which used low-dose chlorthalidone to treat isolated systolic hypertension (systolic blood pressure 160 mmHg or more with diastolic blood pressure less than 95 mmHg), showed a 36% reduction in the incidence of stroke, with a 5-year benefit of 30 events per 1000 patients. It also showed a reduction in the incidence of major cardiovascular events, with a 5-year absolute benefit of 55 events per 1000 patients. In addition, this study reported that antihypertensive therapy was beneficial even in patients older than 80 years. Subgroup meta-analysis of seven randomised controlled trials, which included 1670 patients older than 80 years, showed that antihypertensive therapy for about 3.5 years reduces the risk of heart failure by 39%, strokes by 34% and major cardiovascular events by 22% ([Gueyffier, 1999](#)). In one placebo-controlled study which included 3845 patients who were 80 years of age or older and had a sustained systolic blood pressure of 160 mmHg or more, treatment with the diuretic indapamide (sustained release, 1.5 mg) plus perindopril (2 or 4 mg) to achieve the target blood pressure of 150/80 mmHg resulted in a 30% reduction in the rate of fatal or non-fatal stroke, a 39% reduction in the rate of death from stroke, a 21% reduction in the rate of death from any cause, a 23% reduction in the rate of death from cardiovascular causes and a 64% reduction in the rate of heart failure ([Beckett et al., 2008](#)). These studies demonstrate the increasing evidence that antihypertensive therapy in patients older than 80 years is beneficial.

Treatment of hypertension

Non-pharmacological. In patients with asymptomatic mild hypertension, non-pharmacological treatment is the method of choice. Weight reduction to within 15% of desirable weight, restriction of salt intake to 4–6 g/day, regular aerobic exercise such as walking, restriction of alcohol consumption and stopping smoking are the recommended modes of therapy.

Pharmacological. The current NICE guidance on the management of hypertension ([NICE, 2011](#)) states that for patients older than 55 years, calcium channel blockers (CCBs) are the first line. Step 2 adds an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin II receptor blocker to the CCB, whilst step 3 adds a thiazide-like diuretic.

Thiazide diuretics. Thiazides lower peripheral resistance and do not significantly affect cardiac output or renal blood flow.

They are effective, cheap and well tolerated and have also been shown to reduce the risk of hip fracture in elderly women. They can be used in combination with other antihypertensive drugs. Adverse effects include mild elevation of creatinine, glucose, uric acid and serum cholesterol levels, as well as hypokalaemia. They should be used in low doses because higher doses only increase the incidence of adverse effects without increasing their efficacy.

Calcium channel blockers. CCBs act as vasodilators. Amlodipine is the recommended first-line drug for treatment of hypertension in older people. It does not have significant negative inotropic or chronotropic effect and is generally well tolerated. Leg oedema is a common side effect. Verapamil and, to some extent, diltiazem decrease cardiac output and are generally not used first line. These drugs do not have a significant effect on lipids or the central nervous system. They may be more effective in the elderly, particularly in the treatment of isolated systolic hypertension. Adverse effects include headache, oedema and postural hypotension. Short-acting dihydropyridine, for example, nifedipine, should be avoided. Some studies indicate adverse outcomes with these agents, particularly in those patients with angina or myocardial infarction.

ACE inhibitors and angiotensin receptor blockers. ACE inhibitors and angiotensin receptor blockers (ARBs) used for the treatment of hypertension are discussed elsewhere (see [Chapter 19](#)). These drugs should be used with care in the elderly, who are more likely to have underlying atherosclerotic renovascular disease that could result in renal failure. Excessive hypotension is also more likely to occur in the elderly.

β -Adrenoceptor blockers. Although theoretically the β -blockers are expected to be less effective in the elderly, they have been shown to be as effective as diuretics in clinical studies. Water-soluble β -blockers such as atenolol may cause fewer adverse effects in the elderly. With the availability of better-tolerated and more effective alternative drugs, β -blockers are now mainly used in patients with coexistent ischaemic heart disease.

Myocardial infarction

The diagnosis of myocardial infarction in the elderly may be difficult in some patients because of an atypical presentation ([Bayer et al., 1986](#)). In the majority of patients, chest pain and dyspnoea are the common presenting symptoms. Confusion may be a presenting factor in up to 20% of patients older than 85 years. The diagnosis is made on the basis of history, serial electrocardiograms and cardiac enzyme estimations.

The principles of management of myocardial infarction in the elderly are similar to those in the young. Thrombolytic therapy has been shown to be safe and effective in elderly patients.

Cardiac failure

In addition to the typical features of cardiac failure, that is, exertional dyspnoea, oedema, orthopnoea and paroxysmal nocturnal dyspnoea (PND), elderly patients may present with atypical symptoms. These include confusion due to poor cerebral circulation, vomiting and abdominal pain due to gastrointestinal and hepatic congestion, or insomnia due to PND.

Dyspnoea may not be a predominant symptom in an elderly patient with arthritis and immobility. Treatment of cardiac failure depends on the underlying cause and is similar to that in the young. Loop diuretics, ACE inhibitors, and β -blockers are the important drugs used in the treatment of cardiac failure in the elderly.

Leg ulcers

Leg ulcers are common in the elderly. They are mainly of two types: venous or ischaemic. Other causes of leg ulcers are blood diseases, trauma, malignancy and infections ([Cornwall et al., 1986](#)), but these are less common in the elderly. Venous ulcers occur in patients with varicose veins who have valvular incompetence in deep veins due to venous hypertension ([Alavi et al., 2016](#)). They are usually located near the medial malleolus and are associated with varicose eczema and oedema. These ulcers are painless unless there is gross oedema or infection. Ischaemic ulcers, on the other hand, are due to poor peripheral circulation and occur on the toes, heels, foot and lateral aspect of the leg. They are painful and are associated with signs of lower limb ischaemia, such as absent pulse or cold lower limb. There may be a history of smoking, diabetes or hypertension.

Venous ulcers respond well to treatment, and more than 75% heal within 3 months. Elevation of the lower limbs, exercise, compression bandage, local antiseptic creams when there is evidence of infection, with or without steroid cream, are usually effective. Advanced wound dressings are needed for management of large, chronic, exudative ulcers. Hydrogels donate fluid, hydrocolloids maintain hydration, alginates and foams absorb the exudate present in wounds. Hydrogel, hydrocolloid and medical-grade honey dressings are useful to deslough wounds. Sterile maggots can also be used for removal of wound debris. Antiseptics should not be used when there is granulation tissue. Cotton or viscose tulle dressings impregnated with soft paraffin are useful as low-adherence dressings on granulating wounds and those with minimal exudation. They prevent the wound bed from coming into direct contact with secondary dressings. The type of dressing chosen should depend on the type of leg ulcer and comorbid conditions of the patient. Skin grafting may be necessary for large ulcers. Ischaemic ulcers do not respond well to medical treatment, and such patients should be assessed by vascular surgeons.

Urinary incontinence

Urinary incontinence in the elderly may be of three main types: stress incontinence, overflow incontinence and detrusor instability.

Stress incontinence

Stress incontinence is due to urethral sphincter incompetence. It occurs almost exclusively in women and is associated with weakening of pelvic musculature. It can occur in men after prostatic surgery. Involuntary loss of small amounts of urine occurs on performing activities which increase intra-abdominal pressure – for example, coughing, sneezing, bending and lifting. It does not cause significant nocturnal symptoms.

Overflow incontinence

Overflow incontinence is characterised by constant involuntary loss of urine in small amounts. Prostatic hypertrophy is a common cause and is often associated with symptoms of poor stream and incomplete emptying. Increased frequency of micturition at night is often a feature. Use of anticholinergic drugs and diabetic autonomic neuropathy are other causes.

Detrusor instability

This condition, also called overactive bladder (OAB), causes urge incontinence, where a strong desire to pass urine is followed by involuntary loss of large amounts of urine either during the day or night. It is often associated with neurological lesions or urinary outflow obstruction, for example, prostatic hypertrophy, but in many cases the cause is unknown. The prevalence of OAB has been reported to be around 11.8%. Around 19.1% of men and 18.3% of women older than 60 years were noted to have urgency of micturition in a multinational cross-sectional survey (Irwin et al., 2006).

Stress incontinence is not amenable to drug therapy. However, duloxetine is licensed for the treatment of moderate to severe stress incontinence in women along with pelvic floor exercises. In patients with prostatic hypertrophy α_1 -blockers such as prazosin, indoramin, alfuzosin, terazosin, and tamsulosin have all been shown to increase peak urine flow rate and improve symptoms in about 60% of patients. They reduce outflow obstruction by blocking α_1 -receptors and thereby relaxing prostate smooth muscle. Postural hypotension is an important adverse effect and occurs in between 2% and 5% of patients.

5 α -Reductase converts testosterone to dihydrotestosterone (DHT), which plays an important role in the growth of the prostate. The 5 α -reductase inhibitor finasteride reduces the prostate volume by 20% and improves peak urine flow rate. The clinical effects, however, might not become apparent until after 3–6 months of treatment. The main adverse effects are reductions in libido and erectile dysfunction in 3–5% of patients.

Several antimuscarinic drugs, including darifenacin, fesoterodine fumarate, oral and transdermal oxybutynin hydrochloride, modified-release propiverine hydrochloride, solifenacin succinate, trospium chloride, and modified-release tolterodine, have all been licensed for OAB (Wagg, 2012). The antimuscarinic drugs decrease detrusor contractions by inhibiting the M2 and M3 subtypes of muscarinic receptors in the urinary bladder. All these drugs are similar in efficacy and cause antimuscarinic side effects such as dry mouth, blurred vision and constipation. Transdermal and modified-release preparations are better tolerated but are more expensive.

Mirabegron, a β_3 -adrenoceptor agonist which relaxes the bladder, has been approved by NICE (2013) for the treatment of OAB, 'only for people in whom antimuscarinic drugs are contraindicated or clinically ineffective, or have unacceptable side effects'. The recommended dose is 50 mg daily. The lower dose of 25 mg daily should be used in patients with mild hepatic impairment or mild to moderate renal impairment if they are on strong inhibitors of cytochrome P450 3A, such as itraconazole, ketoconazole, ritonavir, or clarithromycin.

Mirabegron should not be used in patients with blood pressure higher than 160/100 mmHg and also in those with severe renal impairment. It is also contraindicated in those with moderate hepatic impairment, who are concurrently on strong inhibitors of cytochrome P450 3A.

A double-blind, double-placebo-controlled, randomised trial compared solifenacin, 5 mg initially (with possible escalation to 10 mg and, if necessary, subsequent switch to trospium XR, 60 mg) plus one intradetrusor injection of saline or one intradetrusor injection of 100 U of onabotulinum toxin A plus daily oral placebo showed that both interventions reduced the urge incontinence to a similar degree. Dry mouth was less common with onabotulinum toxin A, but it was more likely to result in complete resolution of urge incontinence. It was also associated with higher rates of transient urinary retention and urinary tract infections. A meta-analysis has concluded that onabotulinum toxin A is an effective treatment for idiopathic OAB symptoms, with side effects mainly confined to the urinary tract (Cui et al., 2015).

Drug therapy for OAB should be combined with pelvic floor exercises and bladder training. The need for continued drug therapy should be critically reviewed at regular intervals, and patients should be monitored for adverse effects.

Constipation

Chronic constipation accounts for around 8 million visits to doctors annually in the USA. The age-related decline in gastrointestinal motility and treatment with drugs (e.g. opiates, antimuscarinics, calcium-channel blockers, antidepressants) which decrease gastro-intestinal motility predispose the elderly to constipation. Decreased mobility, wasting of pelvic muscles and a low intake of solids and liquids are other contributory factors. Faecal impaction may occur with severe constipation, which in turn may cause subacute intestinal obstruction, abdominal pain, spurious diarrhoea and faecal incontinence. Adequate intake of dietary fibre, regular bowel habit and use of bulking agents such as bran or ispaghula husk may help prevent constipation. When constipation is associated with a loaded rectum, a stimulant laxative such as senna or bisacodyl may be given. Frail, ill elderly patients with a full rectum may have atonic bowels that will not respond to bulking agents or softening agents, and in such cases, a stimulant is more effective. A stool-softening agent such as docusate sodium is effective when stools are hard and dry. For severe faecal impaction, a phosphate enema may be needed. Long-term use of stimulant laxatives may lead to abuse and atonic bowel musculature.

Linaclotide acts on guanylate cyclase C receptor to increase intestinal fluid secretion and transit. It is licensed for use in moderate to severe irritable bowel syndrome associated with constipation. Lubiprostone, a bicyclic fatty acid derived from prostaglandin E, which activates chloride channel, increases intestinal water secretion and motility. It has been approved for use in chronic severe constipation and irritable bowel syndrome. Prucalopride, a prokinetic agent, which is a selective 5 HT4-receptor agonist, is licensed for chronic severe constipation in women. However, because of its comparable efficacy with less expensive laxatives, further studies are probably needed to establish the cost effectiveness of this drug.

Gastro-intestinal ulceration and bleeding

Gastro-intestinal bleeding associated with peptic ulcer is less well tolerated by the elderly. The clinical presentation may sometimes be atypical, with, for example, patients presenting with confusion. *Helicobacter pylori* infection is common, and its treatment is similar to that in younger patients. NSAIDs are more likely to cause gastroduodenal ulceration and bleeding in the elderly.

Principles and goals of drug therapy in older people

A thorough knowledge of the pharmacokinetic and pharmacodynamic factors discussed is essential for optimal drug therapy in older people. In addition, some general principles based on common sense, if followed, may result in even better use of drugs.

Avoid unnecessary drug therapy

Before commencing drug therapy, it is important to ask the following questions:

- Is it really necessary?
- Is there an alternative method of treatment?

In patients with mild hypertension, non-drug therapies which are of proven efficacy should be considered in the first instance. Similarly, unnecessary use of hypnotics should be avoided. Simple measures such as emptying the bladder before going to bed to avoid having to get up, avoidance of stimulant drugs in the evenings or at night or moving the patient to a dark, quiet room may be all that is needed.

Effect of treatment on quality of life

The aim of treatment in elderly patients is not just to prolong life but also to improve the quality of life. To achieve this, the correct choice of treatment is essential. In a 70-year-old lady with severe osteoarthritis of the hip, for example, total hip replacement is the treatment of choice rather than prescribing NSAIDs with all their associated adverse effects.

Treat the cause rather than the symptom

Symptomatic treatment without specific diagnosis is not only bad practice but can also be potentially dangerous. A patient presenting with 'indigestion' may in fact be suffering from angina, and therefore treatment with proton pump inhibitors or antacids is clearly inappropriate. When a patient presents with a symptom, every attempt should be made to establish the cause of the symptom and specific treatment, if available, should then be given.

Drug history

A drug history should be obtained in all elderly patients. This will ensure that patients are not prescribed a drug or drugs to which they may be allergic or the same drug or group of drugs to which they have previously not responded. It will also help avoid potentially serious drug interactions.

Concomitant medical illness

Concurrent medical disorders must always be taken into account. Cardiac failure, renal impairment and hepatic dysfunction are particularly common in the elderly and may increase the risk of adverse effects of drugs.

Choosing the drug

Once it is decided that a patient requires drug therapy, it is important to choose the drug likely to be the most efficacious and least likely to produce adverse effects. It is also necessary to take into consideration coexisting medical conditions. For example, it is inappropriate to commence diuretic therapy to treat mild hypertension in an elderly male with prostatic hypertrophy.

Dose titration

In general, older people require relatively smaller doses of all drugs compared with young adults. It is recognised that the majority of adverse drug reactions occurring in them are dose related and potentially preventable. It is, therefore, rational to start with the smallest possible dose of a given drug in the least number of doses and then gradually increase both, if necessary. Dose titration should obviously take into consideration age-related pharmacokinetic and pharmacodynamic alterations that may affect the response to the chosen drug.

Choosing the right dosage form

Many older people find it easy to swallow syrups, suspensions or effervescent tablets rather than large tablets or capsules.

Packaging and labelling

Many elderly patients with arthritis find it difficult to open child-resistant containers and blister packs. Medicines should be dispensed in easy-to-open containers that are clearly labelled using large print.

Good record keeping

Information about a patient's current and previous drug therapy, alcohol consumption, smoking and driving habits may help in choosing appropriate drug therapy and when the treatment needs to be altered. It will help reduce costly duplications and will also identify and help avoid dangerous drug interactions.

Regular supervision and review of treatment

A UK survey showed that 59% of prescriptions to the elderly had been given for more than 2 years, 32% for more than 5 years and 16% for more than 10 years. Of all prescriptions given to the elderly, 88% were repeat prescriptions; 40% had not been discussed with the doctor for at least 6 months, especially prescriptions for hypnotics and anxiolytics. It also showed that 31% of prescriptions were considered pharmacologically questionable, and 4% showed duplication of drugs.

It is obvious that there is a need for regular and critical review of all prescriptions, especially when long-term therapy is required.

Adverse drug reactions

It is recognised that ADRs occur more frequently in the elderly. A UK multicentre study in the UK showed that ADRs were the only cause of admission in 2.8% of 1998 admissions to 42 units of geriatric medicine (Williamson and Chopin, 1980). It also showed that ADRs were contributory to a further 7.7% of admissions. On the basis of this study, it was estimated that up to 15,000 geriatric admissions per annum in the UK are at least partly due to an ADR. Obviously, this has enormous economic implications.

The elderly are more susceptible to ADRs for a number of reasons. They are usually on multiple drugs, which in itself can account for the increased incidence of ADRs. It is, however, recognised that ADRs tend to be more severe in the elderly, and gastrointestinal and haematological ADRs are more common than would be expected from prescribing figures alone. Age-related pharmacokinetic and pharmacodynamic alterations and impaired homeostatic mechanisms are the other factors which predispose the elderly to ADRs, by making them more sensitive to the pharmacological effects of the drugs. Not surprisingly, up to 80% of ADRs in the elderly are dose-dependent and therefore predictable.

Adherence

Although it is commonly believed that the elderly have poor adherence with their drug therapy, there is no clear evidence to support this. Studies in Northern Ireland and continental Europe have shown that the elderly are as adherent with their drug therapy as the young, provided that they do not have confounding disease. Cognitive impairment, which is common in old age, multiple drug therapy and complicated drug regimens may impair adherence in the elderly. Poor adherence may result in treatment failure. The degree of adherence required varies depending on the disease being treated. For treatment of a simple urinary tract infection, a single dose of an antibiotic may be all that is required, and therefore adherence is not important. On the other hand, adherence of 90% or more is required for successful treatment of epilepsy or difficult hypertension. Various methods have been used to improve adherence. These include prescription diaries, special packaging, training by pharmacists and counselling.

Conclusion

The number of elderly patients, especially those older than 75 years, is steadily increasing, and they are accounting for an ever-increasing proportion of healthcare expenditure in the West. Understanding age-related changes in pharmacodynamic factors, avoiding polypharmacy and regular and critical review of all drug treatments will help in the rationalisation of drug prescribing, reduction in drug-related morbidity and cost of drug therapy for this important subgroup of patients.

Case studies

Case 11.1

An 80-year-old man with Parkinson's disease, Mr JB, was admitted to hospital with increasing confusion and recurrent falls. He had a past history of ischaemic heart disease. Mr JB's primary care doctor had recently commenced him on antihypertensive therapy. His drug therapy included co-careldopa 12.5/50 mg three times a day, amlodipine 10 mg once a day, simvastatin 40 mg once a day, clopidogrel 75 mg once a day and isosorbide mononitrate 10 mg twice a day.

Question

Which drugs could have contributed to Mr JB's symptoms?

Answer

Co-careldopa, amlodipine and isosorbide mononitrate all cause postural hypotension. Recent addition of amlodipine is likely to have caused symptomatic postural hypotension. Significant postural hypotension could lead to falls and decreased cerebral blood flow, which in turn may cause confusion.

Case 11.2

An 85-year-old lady, Mrs FW, presented to hospital with sudden onset of right-sided weakness and loss of speech. She had a previous history of hypertension, ischemic heart disease, hyperlipidemia and atrial fibrillation (AF). Mrs FW was on bisoprolol 2.5 mg once a day, rivaroxaban 15 mg once a day, simvastatin 20 mg once a day and amlodipine 5 mg once a day. A computed tomography (CT) head scan revealed an intracerebral haemorrhage involving the left frontal lobe.

Question

How should Mrs FW be managed?

Answer

It is very likely that rivaroxaban, a DOAC, has contributed to the intracerebral haemorrhage. Patients who develop intracerebral haemorrhage whilst on anticoagulants (both warfarin and DOACs) continue to bleed as long as they are anticoagulated. The larger the haematoma, the worse is the outcome. Therefore, the priority is to reverse the anticoagulation with a specific antidote (in this case, an anti-Xa antidote) as soon as possible. Surgical evacuation of the haematoma is not routinely performed at present because there is no evidence for its efficacy.

Case 11.3

An 80-year-old woman with a previous history of hypothyroidism presented with a history of abdominal pain and vomiting. She had not moved her bowels for the previous 7 days. Two weeks earlier her primary care doctor had prescribed a combination of paracetamol and codeine to control pain in her osteoarthritic hips.

Question

What are the likely underlying causes of this patient's bowel dysfunction?

Answer

This patient developed severe constipation after taking a codeine-containing analgesic. Ageing is associated with decreased gastro-intestinal motility. Hypothyroidism, which is common in the elderly, is also associated with reduced gastro-intestinal motility. Whenever possible, drugs that are known to reduce gastro-intestinal motility should be avoided in the elderly.

Case 11.4

A 75-year-old lady who suffered from osteoarthritis of the hip and knee joints presented with a history of passing black stools. Her drug therapy included naproxen 500 mg twice daily and paracetamol 1 g as required.

Question

What is the likely cause of this patient's symptoms?

Answer

The likely cause is upper gastro-intestinal bleeding due to naproxen, which is an NSAID. Elderly people are more prone to develop ulceration in the stomach and duodenum with NSAIDs compared with young patients. Pain in osteoarthritis is not inflammatory in origin. If

at all possible, NSAIDs should be avoided in such patients. If a mild NSAID is indicated, ibuprofen is preferred in older people because it is better tolerated. A yellow card should be submitted to the Medicines and Healthcare Products Regulatory Agency (MHRA) if a serious adverse event occurs with NSAID treatment. The MHRA is particularly interested in receiving reports of ADRs in patients older than 65 years.

Case 11.5

A 75-year-old man, Mr AJ, presented to his primary care physician with exertional dyspnoea and increasing leg oedema for 4 weeks. He had a previous history of hypertension, ischaemic heart disease and hyperlipidemia. Mr AJ smoked 30 cigarettes per day. He was on amlodipine 10 mg once a day, atorvastatin 40 mg once a day and clopidogrel 75 mg once a day. The primary care doctor diagnosed heart failure and commenced him on ramipril 2.5 mg once a day. Four weeks later, Mr AJ returned to his primary care doctor with anorexia, nausea and vomiting.

Question

What may have caused Mr AJ's new symptoms?

Answer

Mr AJ has probably gone into renal failure causing anorexia, nausea and vomiting due to the resultant uraemia. Patients with atherosclerotic vascular disease, which Mr AJ is likely to have, sometimes develop bilateral renal artery stenosis (as a result of atherosclerosis). Prescribing ACE inhibitors in such patients may result in acute renal failure due to the significant reduction in renal blood flow.

SECTION **3**

THERAPEUTICS

12 Dyspepsia, Peptic Ulcer Disease and Gastro-Oesophageal Reflux Disease

Dan Greer

Key points

- Symptoms of dyspepsia lack specificity and are poor predictors of underlying causes; therefore, undiagnosed dyspepsia without ALARM symptoms should be treated empirically without an endoscopic diagnosis.
- For patients without ALARM symptoms, lifestyle advice on healthy eating, weight reduction and smoking cessation should be offered together with a review of medication for potential causes of dyspepsia. If these fail to control symptoms, treatment options are 1 month of proton pump inhibitor (PPI) or to test and treat for *Helicobacter pylori* (*H. pylori*).
- A diagnosis of peptic ulcer disease, gastro-oesophageal reflux disease (GORD) or functional dyspepsia can only be confirmed by endoscopy.
- Treatment of peptic ulcer disease centres on removal of the underlying cause, most commonly non-steroidal anti-inflammatory drugs (NSAIDs) or *H. pylori*. In some cases further acid suppression is required for 1–2 months.
- For *H. pylori* eradication, a 1-week course of twice-daily triple therapy with a PPI, clarithromycin and amoxicillin or metronidazole remains first-line therapy, but a recent history of antibiotic exposure may affect choice because resistance to clarithromycin and metronidazole is increasingly common.
- Gastroprotection should be offered to all patients on chronic NSAID therapy to reduce the risk of ulcer disease. The highest-risk groups are older people and those with previous ulcer disease or gastro-intestinal bleeding, and NSAIDs should be avoided where possible in these groups.
- Dual antiplatelet therapy carries a similar risk of gastro-intestinal bleeding to NSAIDs, and therefore gastroprotection is warranted.
- Treatment for endoscopically confirmed GORD consists of 1–2 months of PPI therapy. Some patients with recurrent symptoms may require maintenance therapy; those with severe oesophagitis should remain on full dose PPI. There is no role for *H. pylori* eradication therapy in GORD.
- Functional dyspepsia is difficult to treat; initial treatment options are to eradicate *H. pylori* if present or to offer 1 month of low-dose PPI or an H₂ antagonist.
- The association of long-term PPI treatment with *Clostridium difficile* and osteoporosis means that PPIs should only be continued where there is a clear indication. Long-term PPI treatment is indicated for NSAID gastroprotection and severe oesophagitis only. Patients receiving PPIs for other indications should receive short courses of 1–2 months, with maintenance offered at the lowest effective dose only for those with resistant or recurrent symptoms.

Dyspepsia is an umbrella term used to describe a range of symptoms associated with the upper gastro-intestinal tract and includes upper abdominal pain or discomfort, heartburn, acid reflux, nausea and vomiting. The underlying causes of dyspepsia symptoms include gastric and duodenal ulcers, gastro-oesophageal reflux disease (GORD) and oesophageal or gastric cancers; however, the cause is often unknown, which is classified as functional dyspepsia. The key challenge in managing dyspepsia is to differentiate the majority of patients who can be managed symptomatically from those who may have more serious underlying pathology that requires further investigation before treatment.

Epidemiology

In the UK, dyspepsia occurs in 40% of the population annually and leads to a primary care doctor consultation in 5% and referral for endoscopy in 1%. In those patients with signs or symptoms severe enough to merit endoscopy, 40% have functional dyspepsia, 40% have GORD and 13% have peptic ulcer disease, whereas gastric and oesophageal cancers are very rare, occurring in only 3% of endoscopies ([National Institute for Health and Care Excellence \[NICE\], 2014a](#)).

The incidence of peptic ulcer disease in the Western world is declining, probably driven by the declining prevalence of *Helicobacter pylori* (*H. pylori*) infection, reduction in non-steroidal anti-inflammatory drugs (NSAIDs) use and increased use of gastroprotective agents.

Pathophysiology

The pathophysiology of dyspepsia depends on the underlying cause.

Peptic ulcer disease

An ulcer is defined as a breach in the gastric or duodenal mucosa down to the submucosa ([Fig. 12.1](#)). The two main causes of peptic ulcer disease are *H. pylori* infection and the use of aspirin and NSAIDs. Less common is ulcer disease associated with massive hypersecretion of acid, which occurs in the rare gastrinoma

Fig. 12.1 Duodenal ulcer seen at endoscopy. Note also a visible blood vessel that is a stigma of recent haemorrhage.

(Zollinger–Ellison) syndrome. Stress ulcers are ulcers that form due severe physiological stress, such as head injury, spinal cord injury, burns, multiple trauma or sepsis. Mechanical ventilation and the presence of coagulopathies place patients at particular risk of stress-related mucosal bleeding and may warrant prophylactic treatment (Quenot et al., 2009).

Helicobacter pylori

H. pylori is a Gram-negative microaerophilic bacterium found primarily in the gastric antrum of the human stomach (Fig. 12.2). Ninety-five percent or more of duodenal ulcers and 80–85% of gastric ulcers are associated with *H. pylori*. *H. pylori* infection is thought to occur in infancy or early childhood, and infection is associated with poor socioeconomic conditions. Transmission most likely occurs via the oral-oral and faeco-oral route. In developed countries, the prevalence among middle-aged adults is falling, whereas in many developing countries, the prevalence in the same age group is much greater. Only about 15% of infected individuals develop ulcers (Kuipers, 1997). This is likely to be due to variation in virulence between strains of *H. pylori*, differences in host response to infection and other environmental factors.

The underlying pathophysiology associated with *H. pylori* infection involves the production of cytotoxin-associated gene A (*CagA*) proteins and vacuolating cytotoxins, such as vac A, which activate the inflammatory cascade. *CagA* status and one genotype of the vac A gene are also predictors of the ulcerogenic capacity of a strain. In addition, a number of enzymes produced by *H. pylori* may be involved in causing tissue damage and include urease, haemolysins, neuraminidase and fucosidase.

There appear to be two patterns of infection with *H. pylori*. Infection in infancy is thought to lead to pan gastritis and gastric ulcers, whereas acquisition in later childhood may lead to a predominantly antral gastritis only, causing duodenal ulcers.

Fig. 12.2 *Helicobacter pylori*. The Gram-negative spiral bacterium *H. pylori*, formerly known as *Campylobacter pylori*, was isolated serendipitously from patients with gastritis by Barry Marshall and Robin Warren in 1982. Seven years later, it was conceded that *H. pylori* is responsible for most cases of gastric and duodenal ulcer.

In antral gastritis, a bacterially mediated decrease of antral D cells that normally secrete somatostatin leads to a loss of the negative-feedback action of somatostatin on gastrin, which is the main hormone involved in stimulating gastric acid secretion. The resulting hypergastrinaemia and high acid content in the proximal duodenum leads to metaplastic gastric-type mucosa, which provides a niche for *H. pylori* infection followed by inflammation and ulcer formation.

In pan gastritis, there is a more generalised inflammatory response to infection in the gastric mucosa, leading to mucosal damage and ulceration.

Non-steroidal anti-inflammatory drugs

The major systemic action of NSAIDs that contributes to the formation of ulcers is the reduction of mucosal prostaglandin production via COX-1 (Fig. 12.3). This leads to a reduction in the mucosal protective mechanisms of mucous, bicarbonate production and mucosal repair. Patients taking NSAIDs have a fourfold increase in the risk of ulcer complications compared with nonusers (Hernandez-Diaz and Rodriguez, 2000). The absolute risk of ulcer complications in patients on NSAIDs is approximately 1% per year.

Ulcers have been found to be more common in patients who have taken NSAIDs for less than 3 months, with the highest risk observed during the first month of treatment. The risk of ulcer complications (Box 12.1) is progressive depending on the number of risk factors present (Lanza et al., 2009). The most important risk factors are a history of ulcer complications and advancing age, particularly older than 75 years. Corticosteroids alone are an insignificant ulcer risk but potentiate the ulcer risk when added to NSAIDs, particularly in daily doses of at least 10 mg of prednisolone (Lanza et al., 2009).

Low-dose aspirin (75 mg/day) alone increases the risk of ulcer bleeding by approximately twofold, and dual antiplatelet use increases this risk to fourfold. This effect may be due to the antiplatelet action, independent of other risk factors. Concomitant use of aspirin with NSAIDs further increases the risk. There is no evidence that anticoagulants increase the risk of NSAID ulcers,

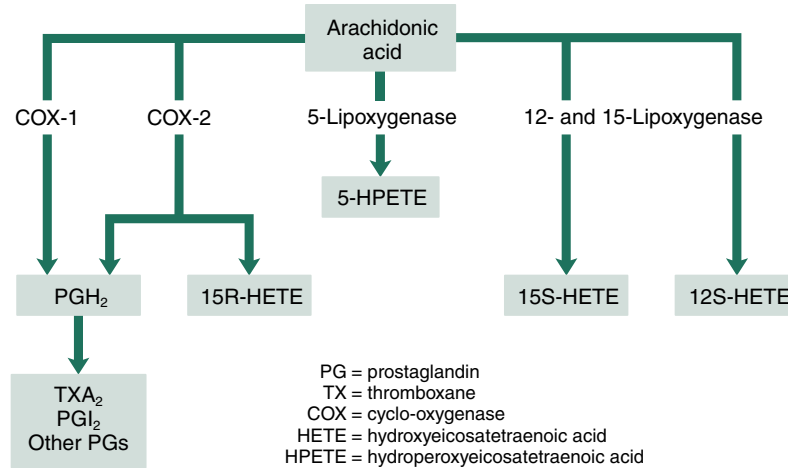

Fig. 12.3 Arachidonic acid pathway.

Box 12.1 Risk factors for non-steroidal anti-inflammatory drug ulcers

- Age >65 years
- Previous peptic ulceration/bleeding
- High dose of NSAID or more than one NSAID (including aspirin)
- Short-term history of NSAID use (<1 month)
- Concomitant corticosteroid or anticoagulant use
- Cardiovascular disease

NSAID, Non-steroidal anti-inflammatory drug.

Box 12.2 Odds ratio of peptic ulcer bleeding with different non-steroidal anti-inflammatory drugs (Langman et al., 1994)

Ibuprofen	2.0
Diclofenac	4.2
Naproxen	9.1
Indometacin	11.3
Piroxicam	13.7
Ketoprofen	23.7
Azapropazone	31.5

but they are associated with an increase in the risk of haemorrhage (García Rodríguez et al., 2011). Use of selective serotonin reuptake inhibitors (SSRIs) also increases the risk of bleeding, due to the antiplatelet effect of serotonin. The presence of cardiovascular disease is also considered as an independent risk factor.

NSAIDs differ in their propensity to cause ulceration (Box 12.2), with ibuprofen and diclofenac considered lowest risk, and ketoprofen and azapropazone considered highest. The risk also increases with higher doses of NSAIDs (García Rodríguez and Jick, 1994).

Selective cyclo-oxygenase-2 inhibitors

The gastro-intestinal side effects of conventional NSAIDs are mediated through the inhibition of COX-1 (see Fig. 12.3). COX-1

stimulates synthesis of homeostatic prostaglandins, whereas COX-2 is predominantly induced in response to inflammation. Selective COX-2 inhibitors tend not to reduce the mucosal production of protective prostaglandins to the same extent as NSAIDs. COX-2 inhibitors are, therefore, considered to be safer than nonselective NSAIDs in patients at high risk of developing gastro-intestinal mucosal damage. Although studies have confirmed the reduction of endoscopic and symptomatic ulcers (Hooper et al., 2004), an increase in cardiovascular risk, including heart attack and stroke, has resulted in the withdrawal of some COX-2 inhibitors from the market. Additional contraindications are now in place for those COX-2 inhibitors that remain; these include the recommendation that they should not be taken by patients with established heart or cerebrovascular disease or taken in combination with low-dose aspirin because this negates any gastro-intestinal protective effects. More recently, a European safety review concluded that diclofenac also has a similar thrombotic risk to COX-2 inhibitors (European Medicines Agency [EMA], 2013). The need for and choice of anti-inflammatory agent should therefore take into account gastro-intestinal, cardiovascular and other risks such as potential cardio-renal effects. For all agents, the lowest effective dose should be used for the shortest duration.

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux disease (GORD) is caused by reflux of acid or bile from the stomach into the oesophagus, or beyond, causing symptoms and/or complications (Katz et al., 2013). The pathophysiology of reflux is multifactorial and involves increased transient lower oesophageal sphincter relaxations, reduced tone of the lower oesophageal sphincter, hiatus hernia, abnormal oesophageal acid clearance and delayed gastric emptying. Risk factors include obesity, pregnancy and certain medications.

Drug-related causes of gastro-oesophageal reflux disease

Some drug classes cause relaxation of the lower oesophageal sphincter, increasing the risk of GORD. These include calcium channel blockers, nitrates and theophylline. Bisphosphonates are

Box 12.3 ALARM features

- Dysphagia
- Unintentional weight loss
- Melaena or haematemesis
- Anaemia
- Persistent vomiting
- Epigastric mass

thought to be directly toxic to oesophageal mucosa, hence the need to swallow with a glass of water and remain upright after administration. Smoking is also thought to reduce oesophageal sphincter pressure, although a direct association has not been proven.

Functional dyspepsia

The pathophysiology of functional dyspepsia is unclear and likely to be multifactorial. Dysmotility and visceral hypersensitivity have been proposed as possible causes, and there are also changes in brain activity, suggesting that central processing may be altered (Ford and Moayyedi, 2013). *H. pylori* may be implicated, as eradication results in symptom improvement in some patients.

Patient assessment and clinical manifestations

Typical symptoms for the underlying causes of dyspepsia are described herein; however, it should be emphasised that symptoms lack specificity and, alone, are poor indicators of the underlying cause. It is for this reason that UK guidelines (NICE, 2014a) recommend a single treatment pathway for those with 'undiagnosed' dyspepsia, with the emphasis on assessing patients at any age for ALARM features (Box 12.3) and referring them for endoscopic investigation. These groups of patients are at a higher risk of underlying serious disease, such as cancer, peptic ulcer disease or severe oesophagitis. Referral is also recommended for patients over the age of 55 if symptoms are unexplained or persistent despite initial management (NICE, 2014a). Malignant disease is rare in young people and in those without ALARM features. Medication should also be reviewed for potential causes of dyspepsia (Box 12.4). The possibility of cardiac or biliary disease should be considered as part of the differential diagnosis.

Peptic ulcer disease

Peptic ulcers classically present with epigastric pain, described as a gnawing or burning sensation, although some ulcers (particularly NSAID-induced ulcers) are asymptomatic. Duodenal ulcers typically cause pain occurring 1–3 hours after meals, which is relieved by food, whereas gastric ulcer pain is typically triggered by food. Complications of peptic ulcer disease may occur with or without previous dyspeptic symptoms. These are haemorrhage (haematemesis or melaena), chronic iron-deficiency anaemia,

Box 12.4 Drugs causing dyspepsia

- Antibiotics
- Bisphosphonates
- Calcium channel blockers
- Corticosteroids
- Drugs with antimuscarinic effects (e.g. tricyclic antidepressants)
- Iron
- Nitrates
- Non-steroidal anti-inflammatory drugs, including aspirin
- Potassium chloride
- Theophylline

pyloric stenosis and perforation. In the setting of acute gastrointestinal bleeding with significant blood loss, patients may present with tachycardia and hypotension.

Gastro-oesophageal reflux disease

Classical symptoms of GORD are heartburn, regurgitation, volume reflux, odynophagia (painful swallowing) or dysphagia. Complications include oesophageal stricture, oesophageal ulceration and Barrett's oesophagus, a metaplasia where squamous cells are replaced by columnar epithelium. Barrett's oesophagus can be a precursor to oesophageal cancer, with 0.5–1% of patients progressing to cancer per year (Shaheen and Richter, 2009).

Investigations

Endoscopy

Endoscopy is generally the investigation of choice for diagnosing the underlying cause of dyspepsia, although the investigation is invasive and expensive. Routine endoscopy in patients presenting with dyspepsia without ALARM features (see Box 12.3) is not necessary but should be undertaken in patients with ALARM features and in those patients older than 55 years who present with unexplained or persistent symptoms of dyspepsia. Biopsies may be taken to exclude malignancy and uncommon lesions such as in Crohn's disease.

Patients presenting with severe upper gastro-intestinal bleeding should undergo endoscopy immediately after resuscitation, whereas others should undergo endoscopy within 24 hours (NICE, 2012). Risk assessment scores such as the Blatchford score (Blatchford et al., 2000) pre-endoscopy can be used to identify low-risk patients who can be managed safely without endoscopy or admission to hospital (Table 12.1). The Rockall score (Rockall et al., 1996) post-endoscopy includes endoscopic findings to predict those with high mortality (Table 12.2). Where gastric ulcer is found, endoscopy should be repeated to confirm ulcer healing because gastric ulcers can be malignant.

Patients with iron-deficiency anaemia who have a normal endoscopy are likely to undergo a colonoscopy to look for a lower gastro-intestinal source of blood loss. In such cases iron therapy should be withheld until after this investigation because the dark stools resultant from iron therapy can impair views of the mucosa despite bowel preparation.

Radiology

Double-contrast barium radiography should detect 80% of peptic ulcers but is only done where endoscopy has failed or the patient declines endoscopy. Endoscopy is preferred because of the ability to take biopsies and administer endoscopic therapy if required for bleeding lesions.

Table 12.1 Blatchford score (Blatchford et al., 2000)

Risk factor	Score ^a
Urea (mmol/L)	
6.5–8.0	2
8.0–10.0	3
10.0–25	4

Diagnosis	Mallory–Weiss tear	All other diagnoses	GI malignancy	
Evidence of bleeding	None		Blood, adherent clot, spurting vessel	

^aAdd score for each risk factor to give total score.

CHF, Chronic heart failure; GI, gastro-intestinal; IHD, ischaemic heart disease; SBP, systolic blood pressure.

Helicobacter pylori detection

There are several methods of detecting *H. pylori* infection. They include noninvasive tests such as serological tests to detect antibodies, [¹³C] urea breath tests and stool antigen tests. Urea breath tests have a sensitivity and specificity over 90% and are accurate for both initial diagnosis and confirmation of eradication. The breath test is based on the principle that urease activity in the stomach of infected individuals hydrolyses urea to form ammonia and carbon dioxide. The test contains carbon-labelled urea which, when hydrolysed, results in the production of labelled carbon dioxide that appears in the patient's breath. The stool antigen test uses an enzyme immunoassay to detect *H. pylori* antigen in stool. This test also has a sensitivity and specificity over 90% and can be used in the initial diagnosis and also to confirm eradication. However, the breath test is preferred for confirming eradication because there is currently insufficient evidence for the stool test as a test of eradication. Serological tests are based on the detection of anti-*H. pylori* immunoglobulin G (IgG) antibodies but are not able to distinguish between active or previous exposure to infection. Near-patient serology tests are not recommended because they are inaccurate (NICE, 2014a).

Invasive tests requiring gastric antral biopsies include urease tests, histology and culture. Of these, the biopsy urease test is widely used. Agar-based biopsy urease tests are designed to be read at 24 hours, whereas the strip-based biopsy urease tests can be read at 2 hours following incubation with the biopsy material. Increasing the number of biopsy samples increases the sensitivity of the test because infection can be patchy. The accuracy of the urea breath test, biopsy urease test and stool test can be reduced by drug therapy; therefore, it is recommended patients discontinue PPIs at least 2 weeks before testing and discontinue antibiotics at least 4 weeks before testing to reduce the risk of false-negative results.

Treatment

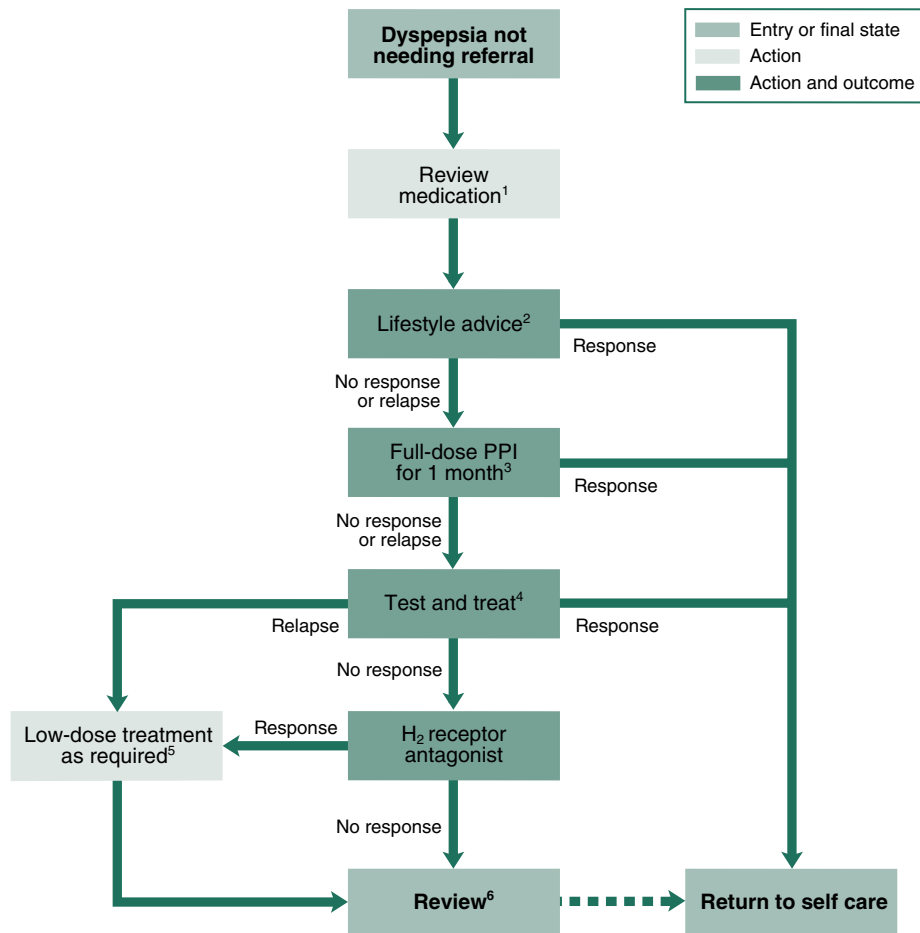

Undiagnosed dyspepsia

National guidelines (NICE, 2014a) provide algorithms to guide practitioners through the management of patients presenting

with dyspepsia (Fig. 12.4) who do not need referral for endoscopy. Medicines should be reviewed for potential causes of dyspepsia (see Box 12.4), and lifestyle advice should be offered on healthy eating, weight reduction and smoking cessation. Patients should be advised to avoid known precipitants where possible, such as smoking, alcohol, coffee, chocolate, fatty foods and being overweight. Raising the head of the bed and having a main meal well before going to bed may help some.

There is, however, little evidence that these measures improve symptoms.

If these initial steps fail, options are either to test and treat for *H. pylori* or to offer 1 month of full-dose PPI. No difference has been found between efficacy or costs of the two options (Ford et al., 2008), but if the prevalence of *H. pylori* in the population being considered is known to be low, it probably makes more sense to give acid suppression first line. Retesting

- 1 Review medications for possible causes of dyspepsia, for example, calcium antagonists, nitrates, theophyllines, bisphosphonates, steroids and NSAIDs.
- 2 Offer lifestyle advice, including advice on healthy eating, weight reduction and smoking cessation, promoting continued use of antacid/alginates.
- 3 There is currently inadequate evidence to guide whether full-dose PPI (proton pump inhibitor) for 1 month or *H. pylori* test and treat should be offered first. Either treatment may be tried first with the other offered if symptoms persist or return.
- 4 Detection: use carbon-13 urea breath test, stool antigen test or, when performance has been validated, laboratory-based serology.
- 5 Offer low-dose treatment with a limited number of repeat prescriptions. Discuss the use of treatment on an as-required basis to help patients manage their own symptoms.
- 6 In some patients with an inadequate response to therapy it may become appropriate to refer to a specialist for a second opinion. Emphasise the benign nature of dyspepsia. Review long-term patient care at least annually to discuss medication and symptoms.

Fig. 12.4 Decision algorithm for management of uninvestigated dyspepsia. (With permission from NICE.)

for *H. pylori* to confirm eradication is not considered worthwhile in this scenario. H₂ receptor antagonists are considered second line because they are less effective. If symptoms recur, PPI therapy should be tailored to the lowest dose needed to control symptoms, including discussing with patients the possibility of using them on an 'as-needed' basis to manage their own symptoms.

Peptic ulcer disease

Acute bleeding peptic ulcer

Peptic ulcer is the most common cause of nonvariceal upper gastro-intestinal bleeding. In major bleeding, the priority is to resuscitate initially with fluids, with or without blood, to stabilise before endoscopy. NSAIDs should be stopped, and if patients are actively bleeding, anticoagulants should be reversed. For warfarin this should be with a combination of prothrombin complex concentrate (PCC) and 5 mg vitamin K. Vitamin K alone in this scenario is insufficient because it can take up to 12 hours for full reversal (Keeling et al., 2011). Endoscopy allows identification of the severity of disease as well as endoscopic haemostatic therapy, which is successful in reducing mortality. Endoscopic therapy is necessary only in patients who exhibit high-risk stigmata (active bleeding, nonbleeding visible vessel, adherent clot) on endoscopy.

Pharmacological agents used for endoscopic injection therapy include 1:10,000 adrenaline (epinephrine), human thrombin and fibrin glue. Mechanical endoscopic treatment options include thermocoagulation using a heater probe or endoscopic clipping. Combination therapies are superior to monotherapy and so are recommended (Barkun et al., 2010; NICE, 2012). The need for surgery, re-bleeding rates and mortality are reduced with endoscopic therapy, but bleeding recurs in about 10% of patients and can cause death (Hearnshaw et al., 2011). Patients with uncontrolled bleeding should receive repeat endoscopic treatment, arterial embolisation or surgery.

The use of intravenous PPI therapy before endoscopy in patients with upper gastro-intestinal bleeding may reduce the need for endoscopic therapy but does not affect relevant clinical outcomes such as re-bleeding, need for surgery or mortality (Sreedharan et al., 2010). Therefore, it is not recommended before endoscopy (NICE, 2012).

Acid suppression reduces the re-bleeding rate and should be given to those patients at high risk of re-bleeding following endoscopic haemostatic therapy. The rationale for this is that gastric acid inhibits clot formation, and if intragastric pH is maintained above 6 during the first 3 days after the initial bleed, there is opportunity for clot stabilisation and haemostasis. Results from a meta-analysis suggest that PPIs significantly reduce re-bleeding rates compared with H₂-receptor antagonists and are the preferred choice of treatment (Leontiadis et al., 2010). In similar dosage regimens, there are no data to suggest any PPI is more efficacious than another. The optimal dose and route of PPI are unknown in this indication, although reduction in mortality is observed in high-risk patients when high-dose PPI therapy is given (e.g. 80 mg bolus omeprazole, pantoprazole or esomeprazole followed by 8 mg/h for 72 hours) following endoscopic haemostasis (Barkun

et al., 2010; Scottish Intercollegiate Guidelines Network [SIGN], 2008).

Successful eradication of *H. pylori* reduces the rate of re-bleeding to a greater extent than antisecretory non-eradicating therapy (Gisbert et al., 2004). Following successful *H. pylori* eradication and healing of the ulcer, there is no need to continue maintenance antisecretory therapy beyond 4 weeks unless required for prophylaxis of ulcer complications in those continuing to take aspirin or NSAIDs (SIGN, 2008).

Patients receiving aspirin monotherapy for secondary prevention of vascular events should continue aspirin once bleeding is controlled because although the risk of rebleeding is increased by restarting aspirin early, the overall risk of mortality is lower (Sung et al., 2010), and the addition of a PPI is of benefit in the prevention of recurrent bleeding (Lai et al., 2002). If aspirin is being taken for primary prevention, the risk of bleeding may outweigh benefits, and stopping aspirin permanently should be considered. Clopidogrel alone is not a safer alternative than aspirin and PPI in terms of prevention of recurrent ulcer bleeding. For patients on other antiplatelets or dual antiplatelet therapy, the balance of risk and benefit is less clear and is likely to depend on the indication (e.g. acute coronary syndrome or for cardiac stent) and how long ago the procedure or event occurred. Generally, non-aspirin antiplatelets are stopped acutely, and then advice should be taken from the appropriate specialist.

Uncomplicated peptic ulcer disease

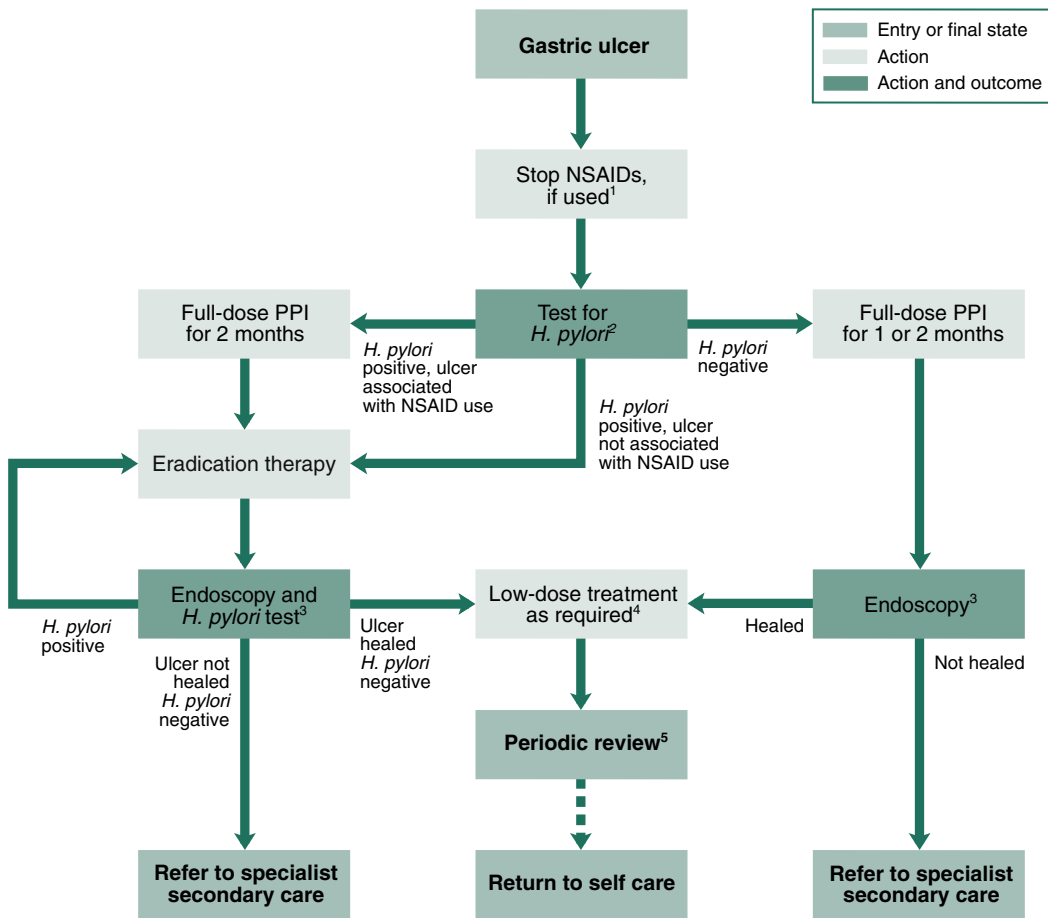

Treatment of endoscopically proven uncomplicated peptic ulcer disease centres on removal of the principal underlying causes, namely, eradication of *H. pylori* infection and discontinuation of NSAIDs. Algorithms for treatment are available from the National Institute for Health and Care Excellence (NICE, 2014a) (Fig. 12.5A and B).

***Helicobacter pylori* eradication.** Eradication of *H. pylori* speeds healing of ulcers, but the major benefit is in reduction of recurrence and avoidance of the need for long-term acid-suppression therapy. Eradication reduces recurrence from 64 per 100 patients to 13 per 100 patients in duodenal ulcer, and from 52 per 100 patients to 16 in 100 patients for gastric ulcer (Ford et al., 2016). Antibiotics alone, or acid-suppressing agents alone, do not eradicate *H. pylori*. Both therapies act synergistically because growth of the organism occurs at elevated pH, and antibiotic efficacy is enhanced during growth. Additionally, increasing intragastric pH may enhance antibiotic absorption.

The standard regimen is a triple therapy consisting of a PPI, clarithromycin and amoxicillin or metronidazole in a twice-daily simultaneous course. However, there are concerns that this regimen is losing efficacy in some areas of the world, principally driven by an increase in *H. pylori* resistance to clarithromycin. In Central, Western and Southern Europe resistance is now greater than 20%, though in Northern Europe resistance rates are still less than 10%, so clarithromycin-based therapies are still considered appropriate (Megraud et al., 2013). The current NICE (2014a) recommendation is 1 week of therapy, whereas more recent European guidelines recommend 2 weeks of therapy, which is thought to increase eradication by approximately 10% (Malfertheiner et al., 2017). A significant factor in driving

resistance is individual exposure to antibiotics; therefore, previous exposure to clarithromycin and metronidazole or quinolone should be checked. Amoxicillin resistance is rare. Data reflecting current recommendations by NICE (2014a) are shown in Tables 12.3 and 12.4. However, the discontinued manufacture of the bismuth containing tripotassium dicitratobismuthate in early 2016 in the UK means that bismuth-based therapies may be difficult to source. An unlicensed alternative is to use bismuth subsalicylate (Pepto-Bismol) (Public Health England, 2016). *H. pylori* eradication for peptic ulcer disease should be confirmed 6–8 weeks after beginning treatment by retesting. If first- and second-line regimens fail, gastric biopsy and sensitivity testing are recommended.

Successful eradication relies on patient adherence to the medication regimen. It is, therefore, important to educate patients about the principles of eradication therapy and also about coping with common adverse effects associated with the regimen. Diarrhoea is the most common adverse effect and should subside after treatment is complete. In rare cases, this can be severe and continue after treatment. If this happens, patients should be advised to return to their doctor because rare cases of antibiotic-associated colitis have been reported. If drugs are not taken as intended, then nonadherence may result in antibiotic resistance. If eradication is successful, uncomplicated active peptic ulcers heal without the need to continue ulcer-healing drugs beyond the duration of eradication therapy (Gisbert et al., 2004).

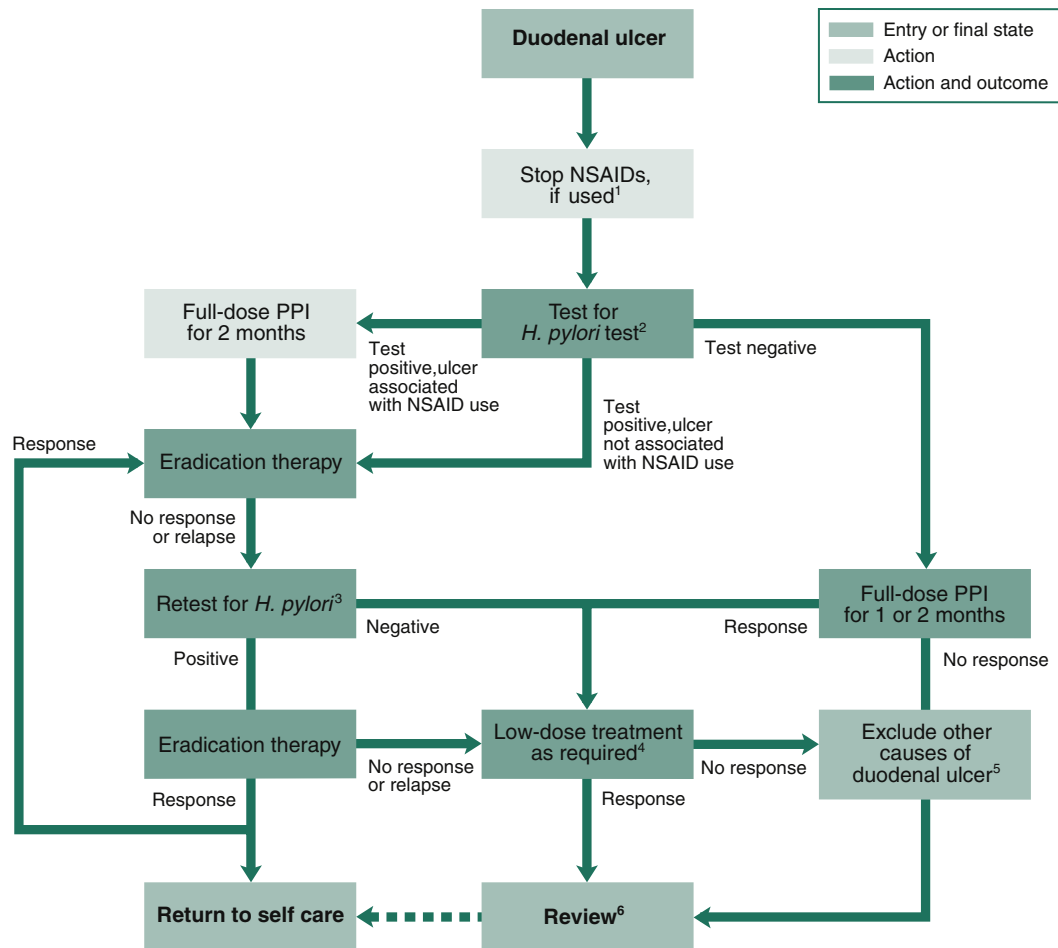

A

- 1 If NSAID continuation is necessary, after ulcer healing offer long-term gastric protection or consider substitution to a newer COX-2-selective NSAID.
- 2 Use a carbon-13 urea breath test, stool antigen test or, when performance has been validated, laboratory-based serology.
- 3 Perform endoscopy 6 to 8 weeks after treatment. If re-testing for *H. pylori* use a carbon-13 urea breath test.
- 4 Offer low-dose treatment, possibly used on an as-required basis, with a limited number of repeat prescriptions.
- 5 Review care annually, to discuss symptoms, promote stepwise withdrawal of therapy when appropriate and provide lifestyle advice. In some patients with an inadequate response to therapy it may become appropriate to refer to a specialist.

Table 12.4 *Helicobacter pylori* eradication second-line regimens

Standard (use whichever was not used first line)	PPI twice a day, amoxicillin 1 g twice a day, clarithromycin 500 mg twice a day Or PPI twice a day, amoxicillin 1g twice a day, metronidazole 400 mg twice a day
Previous clarithromycin and metronidazole exposure	PPI twice a day, quinolone twice a day, tetracycline 500 mg twice a day
Penicillin allergy with no previous quinolone exposure	PPI twice a day, metronidazole 400 mg twice a day, levofloxacin 500 mg twice a day
Penicillin allergy with previous quinolone exposure	PPI twice a day, tripotassium dicitratobismuthate (De-nol) 240 mg four times a day, ^a tetracycline 500 mg four times a day, metronidazole 400 mg twice a day

^aAlternatively, bismuth subsalicylate 525 mg four times a day (Pepto-Bismol).
PPI, Proton pump inhibitor.
PPI doses for *H. pylori* eradication: esomeprazole 20 mg, lansoprazole 30 mg, omeprazole 20–40 mg, pantoprazole 40 mg, rabeprazole 20 mg.
See also NICE (2014a).

Other accepted indications for *H. pylori* eradication include mucosal-associated lymphoid tissue (MALT) lymphoma of the stomach, severe gastritis, and in patients with a high risk of gastric cancer, such as those with a family history of the disease.

Treatment of non-steroidal anti-inflammatory drug-associated ulcers

When NSAIDs are discontinued, most uncomplicated ulcers heal using standard doses of a PPI, H₂-receptor antagonist, misoprostol or sucralfate, although in practice, PPIs are used first line. Healing is impaired if NSAID use is continued. Studies have demonstrated conflicting results for comparative healing rates between PPIs and H₂-receptor antagonists in this situation (Goldstein et al., 2007; Yeomans et al., 2006). PPIs demonstrate higher healing rates at 4 weeks but similar healing rates to H₂-receptor antagonists at 8 weeks. There is no evidence that high-dose PPI is better than treatment with the standard dose. Although effective, misoprostol use is limited by treatment-related adverse events, principally diarrhoea.

Patients should be advised to avoid over-the-counter aspirin and NSAIDs and to use paracetamol-based products. This is probably best facilitated by advising patients to seek pharmacy advice when purchasing over-the-counter analgesic preparations.

Prophylaxis of non-steroidal anti-inflammatory drug ulceration

The most effective way to reduce NSAID-related ulcers is to avoid their use in patients who are at highest risk of gastro-intestinal toxicity (see Box 12.1). However, some patients with chronic rheumatological conditions may require long-term NSAID treatment, in which case the lowest effective dose should be used.

Treatment for ulcer prophylaxis is now considered cost-effective for all patients who require NSAIDs for any period of time, not just in those at high risk (NICE, 2014b). Options include co-therapy with acid-suppressing agents or a synthetic prostaglandin analogue, or substitution of a selective COX-2 inhibitor for

Table 12.5 Drugs for prophylaxis for non-steroidal anti-inflammatory drug-induced ulceration

Drug	Licensed indication	Prophylaxis dose
Omeprazole	Prophylaxis of further DU or GU	20 mg every day
Esomeprazole	Prophylaxis of DU or GU	20 mg every day
Lansoprazole	Prophylaxis of DU or GU	15–30 mg every day
Pantoprazole	Prophylaxis of DU or GU	20 mg daily
Misoprostol	Prophylaxis of DU or GU	200 micrograms 2–4 times a day
Ranitidine	Prophylaxis of DU	150 mg twice a day
Ranitidine	Prophylaxis of DU (unlicensed)	300 mg twice day

DU, Duodenal ulcer; GU, gastric ulcer.

a nonselective NSAID. The prostaglandin analogue misoprostol at a dose of 800 micrograms daily has the strongest evidence of being effective at reducing NSAID-associated ulcer complications and symptomatic ulcers (Rostom et al., 2002). However, it is rarely used in practice because adverse effects, primarily diarrhoea, abdominal pain and nausea, limit its use, and lower doses are less effective. PPIs are effective in reducing endoscopically diagnosed ulcers and symptomatic ulcers. Studies have not demonstrated any advantage in using higher-than-standard doses of PPIs to reduce the risk of ulcers. Standard doses of H₂-receptor antagonists (e.g. ranitidine 150 mg twice a day) are effective in reducing the risk of endoscopic duodenal ulcers. However, reduction in the risk of gastric ulcers requires double this dose, and therefore standard-dose ranitidine is not recommended. Gastroprotective agents licensed for prophylaxis of NSAID ulceration are listed in Table 12.5.

In patients with no history of peptic ulcer bleeding but with risk factors, a combination of COX-2 inhibitor with a PPI was found to be similar in efficacy to a combination of nonselective NSAID with a PPI (Scheiman et al., 2006). In patients with a history of ulcer bleeding, a combination of selective COX-2 inhibitor with a PPI reduced recurrent ulcer bleeding compared with COX-2 inhibitor alone (Chan et al., 2007); however, this was not compared with a combination of a nonselective NSAID and a PPI. An earlier study suggested COX-2 inhibitors alone offered similar protection to that offered by a combination of nonselective NSAID with PPI (Lai et al., 2005). However, overall results suggest that in high-risk patients with a history of gastro-intestinal bleeding in whom an NSAID is indicated where alternative analgesic therapies have failed and in whom there are no contraindications to selective COX-2 inhibitors, a combination of PPI with a selective COX-2 inhibitor may be the safest strategy.

Helicobacter pylori and prevention of non-steroidal anti-inflammatory drug-related ulcers

Trials on eradication of *H. pylori* for prevention of NSAID-related ulcers are not consistent in their outcomes, with benefits shown in those patients about to start NSAIDs but not in those already receiving long-term NSAIDs (Malfertheiner et al., 2017). The value of eradication of *H. pylori* in chronic NSAID users is, therefore, unclear. It would be considered mandatory in patients with a prior history of peptic ulcer disease, but the cost-effectiveness of such a strategy is unknown in those patients at low risk of peptic ulcer.

Prophylaxis of gastro-intestinal bleeding during anti-platelet therapy

In low-dose aspirin users, standard-dose PPIs are more effective than high dose H₂-receptor antagonists in preventing recurrent ulcer bleeding following ulcer healing and eradication of *H. pylori* (Ng et al., 2010). However, in those patients who do not have a history of peptic ulcer bleeding, high-dose H₂-receptor antagonists might be an alternative to PPIs (Taha et al., 2009). When the combination of aspirin and clopidogrel is indicated, concomitant PPI therapy has been shown to reduce the risk of ulcer complications (Bhatt et al., 2010).

There is no UK guidance available regarding who should receive prophylaxis with antiplatelet therapy. However, American guidelines suggest a pragmatic approach (Fig. 12.6) by offering prophylaxis to those at highest risk, which includes those on single antiplatelet therapy with a history of gastro-intestinal bleeding or peptic ulcer disease, and all patients with either dual antiplatelet therapy or antiplatelet and anticoagulant (Bhatt et al., 2008).

Helicobacter pylori-negative, non-steroidal anti-inflammatory drug-negative ulcers

Ulceration in the absence of *H. pylori* infection or NSAID or aspirin use is rare, and validation of a negative medication history and *H. pylori* status should be confirmed using biopsy samples and a careful medication history that includes over-the-counter preparations. Many analgesics contain aspirin or NSAIDs, and some patients purchase low-dose aspirin. If both of these are excluded, standard therapy is 4 weeks of a PPI.

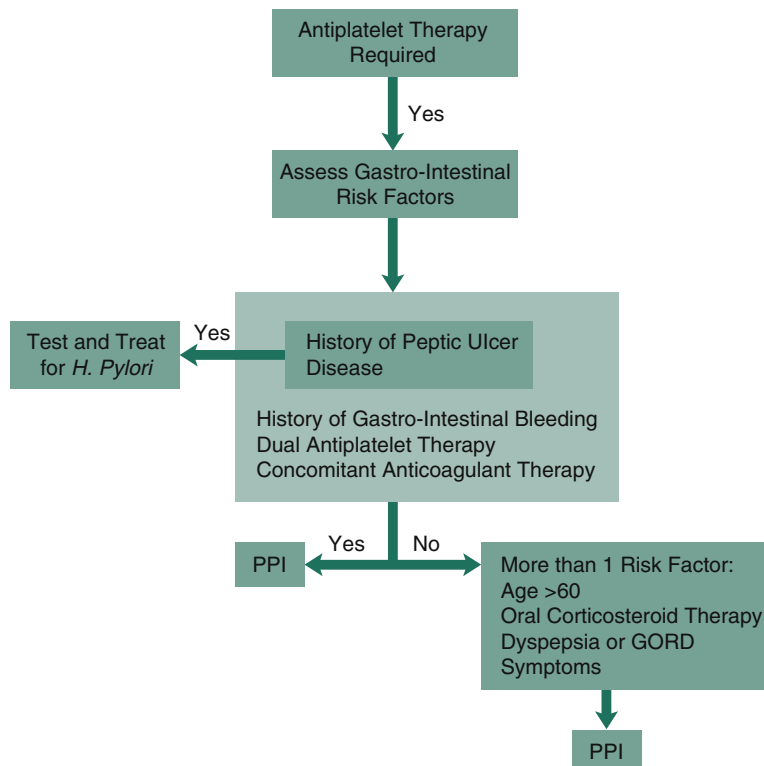

Fig. 12.6 Decision algorithm for gastroprophylaxis with antiplatelet therapy. (Adapted from Bhatt et al., 2008.)

Table 12.6 The Los Angeles classification of severity of reflux oesophagitis (Lundell et al., 1999)

Grade A	One or more mucosal breaks <5 mm in maximal length
Grade B	One or more mucosal breaks >5 mm but without continuity across mucosal folds
Grade C	Mucosal breaks continuous between >2 mucosal folds but involving <75% of the oesophageal circumference
Grade D	Mucosal breaks involving >75% of oesophageal circumference

Gastro-oesophageal reflux disease

Table 12.6 describes the classification of oesophagitis severity (Lundell et al., 1999). Reflux disease should be diagnosed on the basis of endoscopy, classifying into those with oesophagitis and those with endoscopy-negative reflux disease (ENRD), no oesophagitis but predominant reflux-like symptoms. A treatment algorithm as described by NICE (2014a) is shown in Fig.12.7. Patients with predominant reflux symptoms but with no prior endoscopy should be managed as undiagnosed dyspepsia. NICE (2014a) defines standard- and high-dose PPI differently when treating severe oesophagitis. Definitions of standard, high and maintenance doses of PPIs are given in Tables 12.7 and 12.8.

¹ GORD refers to endoscopically determined oesophagitis or endoscopy-negative reflux disease. Patients with uninvestigated 'reflux-like' symptoms should be managed as patients with uninvestigated dyspepsia. There is currently no evidence that *H. pylori* should be investigated in patients with GORD.
² Offer low-dose treatment, possibly used on an as-required basis, with a limited number of repeat prescriptions.
³ Review long-term patient care at least annually to discuss medication and symptoms. In some patients with an inadequate response to therapy or new emergent symptoms it may become appropriate to refer to a specialist for a second opinion. A minority of patients have persistent symptoms despite PPI therapy and this group remains a challenge to treat. Therapeutic options include adding an H₂ receptor antagonist at bedtime.
⁴ Consider a high dose of the initial PP, switching to another full-dose PPI or switching to another high-dose PPI.

Fig. 12.7 Management algorithm for gastro-oesophageal reflux disease (NICE, 2014a). (With permission from NICE.)
 GORD, Gastro-oesophageal reflux disease; PPI, proton pump inhibitor.

Table 12.7 Definitions of maintenance-, standard- and high-dose proton pump inhibitors for dyspepsia, peptic ulcer disease and gastro-oesophageal reflux disease

PPI	Full/standard dose	Low dose (on-demand dose)	Double dose
Esomeprazole	20 mg ^a once a day	Not available	40 mg ^c once a day
Lansoprazole	30 mg once a day	15 mg once a day	30 mg ^b twice a day
Omeprazole	20 mg once a day	10 mg ^b once a day	40 mg once a day
Pantoprazole	40 mg once a day	20 mg once a day	40 mg ^b twice a day
Rabeprazole	20 mg once a day	10 mg once a day	20 mg ^b twice a day

^aLower than the licensed starting dose for esomeprazole in gastro-oesophageal reflux disease (GORD), which is 40 mg, but considered to be dose-equivalent to other proton pump inhibitors (PPIs). When undertaking meta-analysis of dose-related effects, NICE (2014a) classed esomeprazole 20 mg as a full-dose equivalent to omeprazole 20 mg.

^bOff-label dose for GORD.

^c40 mg is recommended as a double dose of esomeprazole because the 20 mg dose is considered equivalent to omeprazole 20 mg.

See also NICE, 2014a.

Table 12.8 Definitions of maintenance-, standard- and high-dose proton pump inhibitors for dyspepsia, peptic ulcer disease and gastro-oesophageal reflux disease – severe oesophagitis only

PPI	Full/standard dose	Low dose (on-demand dose)	High/double dose
Esomeprazole	40 mg ^a once a day	20 mg ^a once a day	40 mg ^a twice a day
Lansoprazole	30 mg once a day	15 mg once a day	30 mg ^b twice a day
Omeprazole	40 mg ^a once a day	20 mg ^a once a day	40 mg ^a twice a day
Pantoprazole	40 mg once a day	20 mg once a day	40 mg ^b twice a day
Rabeprazole	20 mg once a day	10 mg once a day	20 mg ^b twice a day

^aChange from the NICE 2004 dose, specifically for severe oesophagitis, agreed by the guideline development group during the NICE 2014 update.

^bOff-label dose for gastro-oesophageal reflux disease (GORD).

See also NICE, 2014a.

A 4- to 8-week course of standard-dose PPI therapy is most effective for healing of oesophagitis and in ENRD, being more effective than H₂ antagonists (Moayyedi et al., 2011; Sigterman et al., 2013). Extending the course from 4 to 8 weeks increases healing by 14% (NICE, 2014a), and therefore an 8-week course is recommended for endoscopically severe oesophagitis (Los Angeles class C or D; Lundell et al., 1999). If initial courses fail, high-dose PPI, switching PPI, or adding an H₂ antagonist at night are options.

For maintenance therapy if symptoms return, intermittent courses can be given or, alternatively, on-demand single doses can be taken immediately as symptoms occur. Patients who relapse frequently may require continuous maintenance therapy using the lowest dose that provides effective symptom relief, although in milder disease, on-demand therapy has been shown to be as effective and as acceptable to patients as continuous maintenance therapy (Pace et al., 2007).

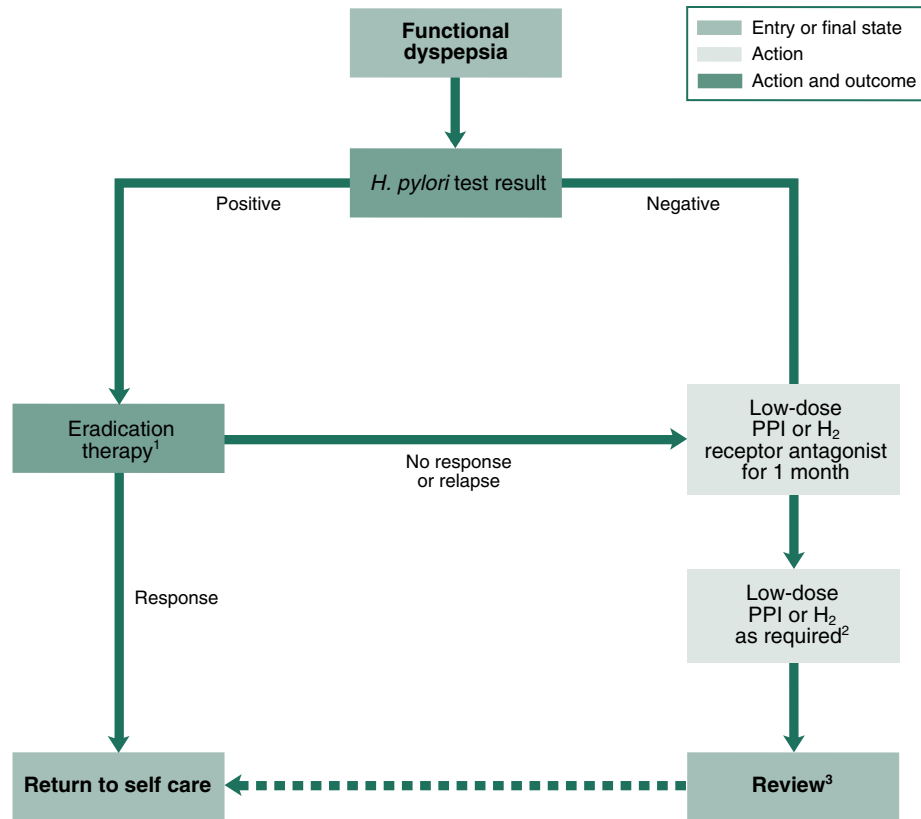

An exception to this is patients with endoscopically severe oesophagitis (Los Angeles class C or D) or oesophageal stricture, who should remain on standard-dose PPI as maintenance. Because uncontrolled acid reflux is thought to be an underlying cause of

progression of Barrett's oesophagus to oesophageal adenocarcinoma, patients with Barrett's oesophagus should also continue on standard-dose PPI. *H. pylori* eradication is not recommended in the management of GORD (Malfertheiner et al., 2017).

Prokinetics are no longer licensed for GORD because their evidence of efficacy is poor, and following a safety review, licensed use of domperidone and metoclopramide is now restricted to short-term use in nausea and vomiting only (Medicines and Healthcare Products Regulatory Agency [MHRA], 2013, 2014a). If patients have severe symptoms that are uncontrolled by medical therapy or if there are refractory complications such as recurrent strictures, anti-reflux surgery can be performed after appropriate confirmatory pH and manometry tests.

Functional dyspepsia

Patients with dyspeptic symptoms but with a normal endoscopy are classified as having functional dyspepsia. A treatment algorithm is given in Fig. 12.8. Eradication of *H. pylori*, if present, may improve symptoms and is recommended as

¹ Do not retest unless there is a strong clinical need.

² Offer low-dose treatment, possibly on an as-required basis, with a limited number of repeat prescriptions.

³ In some patients with an inadequate response to therapy or new emergent symptoms it may become appropriate to refer to a specialist for a second option. Emphasise the benign nature of dyspepsia. Review long-term patient care at least annually to discuss medication and symptoms.

Fig. 12.8 Decision algorithm for management of functional dyspepsia. (With permission from NICE.)

first-line therapy by [NICE \(2014a\)](#). Second-line therapy is low-dose PPI or an H₂ antagonist for 4 weeks, for which there is little difference in efficacy for this indication. As for undiagnosed dyspepsia, if symptoms recur therapy should be tailored to the lowest dose needed to control symptoms. This should include discussing with patients the possibility of using therapy on an ‘as-needed’ basis to manage their own symptoms.

Pyloric stenosis

Malignancy is the most common cause of gastric outlet obstruction. Peptic ulcer disease is the underlying cause in about 10% of cases. There is limited anecdotal evidence that incomplete gastric outlet obstruction may improve within several months of successful *H. pylori* eradication. Conventional treatment with acid-suppressive therapy may also help. If medical therapy fails to relieve the obstruction, endoscopic balloon dilation or surgery may be required.

Zollinger–Ellison syndrome

Zollinger–Ellison syndrome is a rare syndrome that consists of a triad of non-β islet cell tumours of the pancreas that contain and release gastrin, leading to gastric acid hypersecretion and severe ulcer disease. Extrapancratic gastrinomas are also common and may be found frequently in the duodenal wall. A proportion of these patients have tumours of the pituitary gland and parathyroid gland (multiple endocrine neoplasia type I). Surgical resection of the gastrinoma may be curative. Medical management consists of greater-than-standard doses of PPIs. The somatostatin analogue octreotide inhibits secretion of gastrin and can be used as a second-line agent.

Stress ulcers

Histamine H₂-receptor antagonists, PPIs, and sucralfate (4–6 g daily in divided doses) have been used to prevent stress ulceration in the intensive care unit until the patient tolerates enteral

feeding. UK guidelines recommend the use of either H_2 antagonists or PPIs (orally or intravenously) for acutely ill patients admitted to critical care (NICE, 2012). These agents have been shown to reduce the risk of gastro-intestinal bleeding but not mortality. It is important that the ongoing need for these agents is reviewed when patients recover or are discharged from critical care. Sucralfate is rarely used in practice because of the risk of bezoar formation and the need to administer at different times from other medicines.

Drugs for dyspepsia

Proton pump inhibitors

The PPIs are all benzimidazole derivatives that control gastric acid secretion by inhibition of gastric H^+ , K^+ -ATPase, the enzyme responsible for the final step in gastric acid secretion from the parietal cell (Fig. 12.9).

The PPIs are inactive prodrugs that are carried in the bloodstream to the parietal cells in the gastric mucosa. The prodrugs readily cross the parietal cell membrane into the cytosol. These drugs are weak bases and therefore have a high affinity for acidic environments. They diffuse across the secretory membrane of the parietal cell into the extracellular secretory canaliculus, the site of the active proton pump (see Fig. 12.9). Under these acidic conditions the prodrugs are converted to their active form, which irreversibly binds the proton pump, inhibiting acid secretion. Because the 'active principle' forms at a low pH, it concentrates selectively in the acidic environment of the proton pump and results in extremely effective inhibition of acid secretion. The different PPIs (omeprazole, esomeprazole, lansoprazole, pantoprazole and rabeprazole) bind to different sites on the proton pump, which may explain their differences in potency on a milligram-per-milligram basis.

Fig. 12.9 Receptor stimulation of acid secretion.

PPIs require an enteric coating to protect them from degradation in the acidic environment of the stomach. This delays absorption, and a maximum plasma concentration is reached after 2–3 hours. Because these drugs irreversibly bind to the proton pump, they have a sustained duration of acid inhibition that does not correlate with the plasma elimination half-life of 1–2 hours. The apparent half-life is approximately 48 hours. This prolonged duration of action allows once-daily dosing of PPIs, although twice-daily dosing is recommended in some cases of severe oesophagitis or in *H. pylori* eradication. All PPIs are most effective if taken about 30 minutes before a meal because they inhibit only actively secreting proton pumps, and meals are the main stimulus for proton pump activity.

Intravenous PPIs are most frequently used to prevent recurrent ulcer bleeding in high-risk patients. Intravenous preparations are therapeutically equivalent to oral preparations. In the UK, omeprazole, pantoprazole and esomeprazole can be given intravenously.

PPIs are metabolised in the liver to various sulphate conjugates that are extensively eliminated by the kidneys (80%). With the exception of severe hepatic dysfunction, no dose adjustments are necessary in liver disease or in renal disease. The clinical effect of PPIs is similar among all agents when administered chronically in equivalent standard doses. Their efficacy and relative safety has led them to be first-line agents for treating dyspepsia, GORD and peptic ulcer disease.

Adverse drug reactions

Experience suggests that PPIs are a remarkably safe group of drugs. The most commonly reported side effects are diarrhoea, headaches, abdominal pain, nausea, fatigue and dizziness which resolve on drug discontinuation (Table 12.9). Possible mechanisms for diarrhoea include bacterial overgrowth, changes in intestinal pH and bile salt abnormalities. Some cases of persistent chronic watery diarrhoea associated with lansoprazole have been diagnosed as microscopic colitis, although this may be a class effect.

Although PPIs are very safe on an individual patient basis, the extensive use of PPIs on a population basis has led to some public health concerns. PPIs are associated with an approximately twofold increased risk of *Clostridium difficile*. The absolute risk is low in the general population, with a number needed to harm (NNH) of 3900 at 1 year, but is much greater in high-risk patients such as hospitalised patients receiving antibiotics, where

Table 12.9 Common adverse reactions to ulcer-healing drugs

Fatigue		
Dizziness		

the NNH may be as high as 50 at 2 weeks (Tleyjeh et al., 2012). Long-term use is also associated with an increased risk of hip fractures, although the association is not strong (hazard ratio of fracture 1.28 at 1 year), and the absolute risk is also low, with an NNH of 2000 at 1 year (Khalili et al., 2012).

Drug interactions

The cytochrome P450 isoenzyme CYP2C19 is the main route of metabolism of esomeprazole, lansoprazole, omeprazole and pantoprazole and is also involved in the metabolism of rabeprazole. Omeprazole and esomeprazole are potent inhibitors of CYP2C19, and therefore they may increase the levels of drugs that are metabolised by this isoenzyme. There are, however, relatively few drug interactions of clinical significance. Omeprazole partially inhibits the metabolism of R-warfarin via CYP2C19, and there are isolated case reports of increases in INR with other PPIs.

Omeprazole and esomeprazole at a dose of 40 mg may inhibit the metabolism of phenytoin, but this is unlikely to be clinically relevant.

Absorption of ketoconazole, posaconazole and itraconazole is reduced by omeprazole due to a reduction in acidity required for absorption. This is likely to be a class effect of PPIs, and concomitant use should be avoided. A similar interaction with PPIs reduces absorption of the HIV-protease inhibitors indinavir, nelfinavir and atazanavir, and so concomitant use should be avoided. Conversely, exposure to saquinavir appears to be increased, although the mechanism for this is unknown.

The conversion of clopidogrel to its active form is reliant on CYP2C19, and the inhibition of this activity by omeprazole and esomeprazole may be of concern, although the clinical relevance of this is unclear. The most recent MHRA guidance advises avoidance of concurrent use of esomeprazole and omeprazole, but not other PPIs, acknowledging the lack of clear evidence to support an interaction and the potential benefits of concurrent use in reducing the risk of gastro-intestinal bleeding (MHRA, 2010).

H₂-receptor antagonists

The H₂-antagonists are all structural analogues of histamine. They competitively block the histamine receptors in gastric parietal cells, thereby preventing acid secretion. Pepsinogen requires acid for conversion to pepsin, and so when acid output is reduced, pepsin generation is, in turn, also reduced.

All the available drugs (cimetidine, ranitidine, famotidine, nizatidine) have similar properties. Maximum plasma concentration is reached within 1–3 hours after administration. First-pass hepatic metabolism varies; ranitidine is most extensively metabolised, which explains the difference between the intravenous and oral dose. All H₂-antagonists are eliminated to a variable and significant extent via the kidneys, and all require dosage reduction in moderate to severe renal impairment. They are equally effective at suppressing daytime and nocturnal acid secretion, and they do not cause total achlorhydria. The evening dose of an H₂-antagonist is particularly important because during the daytime, gastric acid is buffered for long periods by food; however, during the night this does not occur, and the intragastric pH may fall below 2.0 for several hours. For healing oesophagitis, intragastric pH must

remain above 4.0 for 18 hours or more per day. H₂-receptor antagonists are, therefore, less effective in healing oesophagitis. Adding a bedtime dose of H₂-receptor antagonist to PPI therapy may enhance nocturnal gastric pH control in patients in whom nocturnal gastric acid breakthrough is problematic.

The role of H₂-receptor antagonists in the management of dyspepsia has diminished because PPIs are more effective and generally recommended as first line. They do provide an alternative or addition in those unresponsive to PPIs, and their availability for purchase means they still have a role to play in self-management of dyspepsia.

Adverse drug reactions

H₂-receptor antagonists are a safe group of drugs. The risk of any adverse reaction is below 3%, and serious adverse reactions account for less than 1%. Diarrhoea and headache are the most common, and occasionally mental confusion and rashes have been reported (see Table 12.9). Hepatotoxicity is a rare adverse effect. Cimetidine, due to its antiandrogenic effects, has been associated with gynaecomastia and impotence when used in high doses.

Drug interactions

Cimetidine is a nonspecific, weak inhibitor of a number of the cytochrome P450 isoenzymes and therefore inhibits the metabolism of many drugs, which is potentially important for drugs with a narrow therapeutic index. Clinically relevant interactions are established for theophylline, warfarin, and phenytoin. The other H₂ antagonists do not inhibit cytochrome P450 to a clinically relevant extent, and for this reason, cimetidine is now rarely used in practice.

The absorption of some drugs may be affected by the changes in gastric pH that can be produced by any of the H₂-receptor antagonists. Clinically relevant examples include reduction of posaconazole and atazanavir absorption.

Bismuth chelate

Bismuth has been included in antacid mixtures for many decades but fell from favour because of its neurotoxicity. Bismuth chelate is a relatively safe form of bismuth that has ulcer-healing properties comparable to those of H₂-antagonists. Its mode of action is not clearly understood, but it is thought to have cytoprotective properties. Bismuth is toxic to *H. pylori* and was one of the first agents to be used to eradicate the organism and reduce ulcer recurrence. Tripotassium dicitratobismuthate in combination with tetracycline, metronidazole and a PPI has been used in quadruple-therapy regimens in patients resistant to triple therapy, although manufacture of this agent in the UK ceased in early 2016. An alternative is to use bismuth subsalicylate (Pepto-Bismol) (Public Health England, 2016).

Adverse drug reactions

Small amounts of bismuth are absorbed from bismuth chelate, and urinary bismuth excretion may be raised for several weeks

after a course of treatment. The risk of bismuth intoxication is small if these products are used at the recommended dose and for short courses of treatment. Bismuth may accumulate in patients with impaired renal function. The most commonly reported events are nausea, vomiting, blackened tongue and dark faeces.

Sucralfate

Sucralfate is the aluminium salt of sucrose octasulphate. Although it is a weak antacid, this is not its principal mode of action in peptic ulcer disease. It has mucosal protective effects, including stimulation of bicarbonate and mucus secretion and stimulation of mucosal prostanoids. At a pH less than 4.0, it forms a sticky, viscid gel that adheres to the ulcer surface and may afford some physical protection. It is capable of adsorbing bile salts. These activities appear to reside in the entire molecular complex and are not due to the aluminium ions alone. Sucralfate has no acid-suppressing activity. Sucralfate is now less commonly used in practice due to the practicalities of managing other medicines and because of the risk of bezoar formation (an undigested mass trapped in the gastro-intestinal tract). When prescribed, the liquid formulation is often used because the tablets are large and difficult to swallow.

Adverse drug reactions

Constipation appears to be the most common problem with sucralfate, and this is thought to be related to the aluminium content (see Table 12.9). About 3–5% of a dose is absorbed, and therefore there is a risk of aluminium toxicity with long-term treatment. This risk is correspondingly greater in patients with renal impairment. Caution is required to avoid oesophageal bezoar formation around a nasogastric tube in patients managed in the intensive care unit.

Drug interactions

Sucralfate may bind to other agents in the gastro-intestinal tract and reduce the absorption of other drugs. Therefore, it should be taken at least 2 hours following other medicines.

Antacids

Antacids have a place in symptomatic relief of dyspepsia, in particular, self-management. The choice of antacid lies between aluminium-based and magnesium-based products, although many proprietary products combine both. Calcium-based products are less suitable because calcium stimulates acid secretion. Antacids containing sodium bicarbonate are unsuitable for regular use because they deliver a high sodium load and generate large quantities of carbon dioxide. It should be noted that magnesium trisilicate mixtures contain a large amount of sodium bicarbonate. Some products contain other agents, such as dimethicone or alginates. Products containing sodium alginate with a mixture of antacids are effective in relief of symptoms in GORD but are not particularly effective antacids.

Antacids provide immediate symptom relief, and a more rapid response is achieved with liquid preparations. They have

a limited duration of action and need to be taken several times a day, usually after meals (to coincide with peak acid production) and at bedtime.

Adverse drug reactions

Aluminium-based antacids cause constipation, and magnesium-based products cause diarrhoea. When combination products are used, diarrhoea tends to predominate as a side effect. Although these are termed ‘non-absorbable’, a proportion of aluminium and magnesium is absorbed and the potential for toxicity exists, particularly with coexistent renal failure.

Drug interactions

Administration should be separate from drugs with potential for chelation, such as tetracycline and ciprofloxacin, and also pH-dependent controlled-release products.

Case studies

Case 12.1

A 62-year-old man, Mr BD, presented to the emergency department following haematemesis and melaena. He was suffering no pain. His past medical history included non-ST-elevated myocardial infarction (NSTEMI) for which he had undergone percutaneous coronary intervention (PCI) and bare metal stent insertion 4 months previously. Mr BD stopped smoking 2 years ago, drinks alcohol in moderation and is not obese. He is prescribed the following prescribed medicines:

- aspirin (dispersible) 75 mg daily,
- clopidogrel 75 mg daily,
- ramipril 2.5 mg twice daily,
- atorvastatin 80 mg daily,
- bisoprolol 5 mg daily,
- GTN spray prn.

On investigation, Mr BD's blood pressure was 98/60 mmHg with a heart rate of 120 beats/min and respiratory rate of 20 beats/min. There was no jaundice or stigmata of liver disease. Mr BD's blood results were as follows:

	Value	Reference range
Urea	18 mmol/L	3.1–7.9 mmol/L
Creatinine	87 mmol/L	75–155 mmol/L
INR	1.0	
Sodium	142 mmol/L	135–145 mmol/L
Potassium	4.3 mmol/L	3.4–5.0 mmol/L
Haemoglobin	8 g/dL	13.5–18 g/dL
MCV	90 fL	78–100 fL

Endoscopy revealed an actively bleeding gastric ulcer.

Questions

1. What immediate treatment should Mr BD have received before endoscopy?
2. What treatment should he receive at the time of endoscopy?
3. Why should biopsies be taken at the time of endoscopy?
4. What pharmacological treatment should be given to Mr BD to reduce the risk of re-bleeding following endoscopic haemostatic therapy?

5. What was the likely cause of Mr BD's bleeding ulcer?
6. When should antiplatelet therapy be restarted, and which agent(s) should be prescribed?
7. Should Mr BD receive gastroprotection following ulcer healing?
8. Identify what aspects of Mr BD's medicines you would want to discuss with him.

Answers

1. Mr BD's age, comorbidity and clinical signs of shock place him at risk of death and in need of emergency hospital admission for aggressive resuscitation with intravenous fluids and red blood cell transfusion. Crystalloid solutions should be used for volume restoration before administering blood products. Sodium chloride 0.9% is appropriate fluid replacement. There is no evidence to support the use of intravenous PPIs before diagnosis by endoscopy.
2. Patients who are in shock and have active peptic ulcer bleeding are at high risk of continuing to bleed and should receive haemostatic endoscopic therapy. Endoscopic treatment is indicated only for those with high-risk lesions (active bleeding, nonbleeding visible vessels or adherent blood clot). Endoscopic injection of large volume (at least 13 mL) 1:10,000 adrenaline achieves haemostasis through vasoconstriction, and haemostasis is sustained if this is combined with thermal coagulation or mechanical endoscopic clipping. The patient should receive combination endoscopic therapy.
3. The presence of *H. pylori* should be sought at the time of endoscopy. Biopsies should be taken from the antrum and the body of the stomach. Samples are sent for testing for the presence of malignant cells, and samples are used for the rapid urease test for *H. pylori*. The presence of bleeding may reduce the sensitivity of the rapid urease test, and if negative results are obtained, a urea breath test or stool sample can be undertaken once oral intake is established.
4. In patients who have received endoscopic haemostatic therapy, high-dose intravenous PPI therapy reduces the risk of re-bleeding. The optimum dose and route are unclear, but improved mortality is observed in high-risk patients when a dose of 80 mg bolus followed by 8 mg/h infusion for 72 hours is given. Maintaining intragastric pH above 6 is considered to stabilise clot formation and prevent re-bleeding. Because a positive test for *H. pylori* was obtained, oral eradication therapy should be given, although there is no evidence to suggest this must be given in the acute phase; therefore, the usual practice is to wait until oral intake is established. *H. pylori* eradication therapy is effective in the prevention of re-bleeding from peptic ulcer. Ulcer healing can be achieved with an additional 3-week treatment with standard-dose PPI.
5. Mr BD was taking dual antiplatelet therapy to reduce the risk of myocardial infarction and cardiovascular death. Both of these agents carry an increased risk of bleeding events, the risk being additive with dual therapy. Mr BD did not have any additional risk factors for peptic ulcer disease, but it is important to take a careful medication history to identify if he had been taking NSAID analgesics and ensure he avoids such medicines in the future. The bleeding peptic ulcer was likely caused by the combination of aspirin and clopidogrel.
6. In patients with NSTEMI, most benefit is gained from the addition of clopidogrel to aspirin therapy in the first 3 months (CURE Study Investigators, 2001). Prolonged treatment for 12 months is indicated if a drug-eluting stent is inserted, but because this patient had a bare metal stent inserted 4 months previously, the benefit from the addition of clopidogrel probably does not outweigh the gastro-intestinal bleeding risk, and consideration should be given to discontinuation of clopidogrel. Aspirin should be continued at a dose of 75 mg daily. There is no evidence to suggest enteric coating is of any benefit, so the dispersible formulation should be continued. It is suggested that aspirin should be restarted within 7 days of discontinuation to maintain cardiovascular secondary prevention.
7. Mr BD should be prescribed the standard dose of PPI as maintenance therapy to reduce the risk of further aspirin-induced gastro-intestinal bleeding.
8. Mr BD needs to be aware of both his cardiovascular and gastro-intestinal risks. He does need to continue aspirin, but he should be aware of the need to discontinue clopidogrel now because it is 4 months following his NSTEMI, and the benefit does not outweigh the risk. He should be advised not to take any other aspirin or NSAID-containing medicines. If the test for *H. pylori* is positive, Mr BD should be prescribed 7 days of treatment with a twice-daily PPI, such as omeprazole 20 mg, amoxicillin 1 g and clarithromycin 500 mg, after ascertaining he is not penicillin sensitive and checking for recent antibiotic use. The importance of this treatment in prevention of re-bleeding should be emphasised to encourage adherence to the prescribed course, which he may complete after discharge from hospital. Aspirin will be restarted, and the dose of omeprazole will be reduced to 20 mg daily long-term for gastroprotection after any *H. pylori* eradication.

Case 12.2

A 68-year-old male, Mr MF, presents with melaena. He has a past medical history of atrial fibrillation and hypertension. On examination, Mr MF is pale and clammy, with a blood pressure of 95/60 mmHg and a pulse of 110 beats/min with a Blatchford score of 11. His drug history is recorded as follows:

- warfarin 4 mg daily,
- amlodipine 5 mg daily,
- simvastatin 40 mg daily.

Mr MF's blood results were as follows:

	Value	Reference range
Sodium	140 mmol/L	135–145 mmol/L
Potassium	3.9 mmol/L	3.4–5.0 mmol/L
Urea	11.5 mmol/L	3.1–7.9 mmol/L
Creatinine	90 mmol/L	75–155 mmol/L
WCC	$7.6 \times 10^9/L$	$3.5\text{--}11 \times 10^9/L$
MCV	90 fL	78–100 fL
INR	2.8	
Haemoglobin	10.5 g/dL	13.5–18 g/dL

The impression is that Mr MF has had an upper gastro-intestinal bleed. The plan is for Mr MF to undergo reversal of anticoagulation, resuscitation with intravenous fluids and then an urgent endoscopy.

Questions

1. If you were confirming Mr MF's medication history, what particular aspects should be checked?
2. How should warfarin be reversed?
3. An endoscopy reveals Mr MF has a bleeding duodenal ulcer for which he receives a 72-hour PPI infusion. A *H. pylori* test is negative. How should Mr MF's anticoagulation be managed?

Answers

1. Mr MF should be asked about potential over-the-counter use of aspirin or NSAIDs; this is often missed because they have not been prescribed. If Mr MF has been using these medicines, then he should be advised to avoid future use.

- For active bleeding, warfarin should be reversed even though Mr MF'S INR is within the therapeutic range. This is undertaken by administration of 5 mg intravenous vitamin K and prothrombin complex 25–50 units/kg.
- As the risk of re-bleeding is highest within the first 72 hours following endoscopy, in this case, it would be advisable to withhold anticoagulation at least until this point. When the risk of thrombus is higher, for example, in metallic valve or recent pulmonary embolism (PE), anticoagulation may be restarted once the patient is stable using heparin or low-molecular-weight heparin. With regard to restarting warfarin in this patient with atrial fibrillation, the risk of stroke can be calculated using the CHA₂DS₂-VASC score, and the risk of bleeding can be calculated using the HAS-BLED score. These figures can be used to help Mr MF make an informed decision about his preferences for restarting anticoagulation. If warfarin is to be restarted, it would be reasonable to continue a PPI long-term for gastroprotection.

Case 12.3

A 57-year-old woman, Mrs MG, presents to her primary care doctor with symptoms of epigastric pain that have interfered with her normal activities over the previous few weeks. Medication history reveals that Mrs MG takes no prescribed medicines and only occasional paracetamol as an analgesic for minor ailments. Although she has occasional heartburn, this is not the predominant symptom. Mrs MG has not vomited and does not have difficulty or pain on swallowing. She has not lost weight recently and has normal stools with no evidence of bleeding. The pain is not precipitated by exercise and does not radiate to the arms and neck. Mrs MG is a nonsmoker and only drinks a small quantity of alcohol on social occasions. She is not overweight. She has an allergy to penicillin.

Questions

- How should Mrs MG be treated?
- Which *H. pylori* test should be used in primary care?

Answers

- It is important to ascertain if Mrs MG has ALARM features (see Box 12.3), which should be investigated particularly because her age places her at higher risk of gastro-intestinal cancer. It is also important to consider differential diagnoses such as cardiac pain, although the lack of radiation and lack of link with exertion suggests a cardiac cause is unlikely. Because she has no ALARM features, she can be treated following the pathway for uninvestigated dyspepsia. Because there are no obvious medication-related causes or lifestyle-related factors to address, an initial strategy of testing and treating for *H. pylori* or a month of PPI would be appropriate. If her *H. pylori* test is positive, a 7-day course of twice-daily eradication therapy of omeprazole 20 mg, metronidazole 400 mg and clarithromycin 250 or 500 mg can be prescribed. Mrs MG should be advised to complete the course of therapy to avoid eradication failure and/or resistance to antibiotics. The potential interaction between metronidazole and alcohol should be explained to the patient in terms of the risk of nausea, vomiting, flushing and breathlessness, which may occur during and for a few days after discontinuing metronidazole. Mrs MG should also be alerted to the common adverse effect of diarrhoea associated with triple therapy. Patients should be encouraged to cope with the inconvenience but report symptoms to their doctor if they continue after the course of treatment is finished. If neither *H. pylori*

eradication nor a month of PPI is successful, Mrs MG should be offered H₂ antagonist therapy.

- The most accurate noninvasive *H. pylori* test is the carbon-13 urea breath test. Alternative tests are the stool antigen test and a laboratory-based serology test. Local facilities and costs determine the choice of tests. Serology tests based on measurement of serum antibody are commonly used for initial detection of *H. pylori* but cannot be used to confirm eradication because circulating antibody remains after removal of the antigen.

Case 12.4

A 68-year-old woman, Ms WR, presents for review of her medication. Her medical history includes hypertension and osteoarthritis of the knees. Ms WR receives a regular prescription for the following:

- bendroflumethiazide 2.5 mg daily,
- naproxen 500 mg twice daily.

Ms WR stopped smoking 4 years ago and drinks no more than 10 units of alcohol per week. She is overweight, with a body mass index (BMI) of 30 kg/m². Ms WR occasionally purchases an antacid to treat symptoms of heartburn if she's eaten a large meal at night. Her blood pressure is 148/92 mmHg with a pulse of 82 beats/min. The results of Ms WR's routine blood tests are as follows:

	Value	Reference range
Sodium	138 mmol/L	135–145 mmol/L
Potassium	3.9 mmol/L	3.4–5.0 mmol/L
Creatinine	110 mmol/L	75–155 mmol/L
Blood glucose	6.8 mmol/L	<11.1 mmol/L
Total cholesterol	4.5 mmol/L	<4.0 mmol/L
Haemoglobin	12.0 g/dL	11.5–16.5 g/dL

Questions

- What is the mechanism for NSAID-induced peptic ulcer disease?
- What are the risks associated with NSAID use in this patient?
- What are the options for treating Ms WR's pain and minimising the risk of peptic ulceration?

Answers

- NSAIDs cause superficial erosions, but the main mechanism for causing ulcers is through their systemic inhibition of mucosal prostaglandin production. COX-1 is the enzyme responsible for the synthesis of prostaglandins responsible for gastro-intestinal mucosal protection through maintenance of blood flow and production of mucus and bicarbonate. Another isoform of COX, COX-2 is involved in the inflammatory response, and the prostaglandins produced are associated with pain and inflammation. The anti-inflammatory action of NSAIDs is thought to be as a result of inhibition of COX-2. Inhibition of COX-1 is thought to be responsible for the gastro-intestinal and renal adverse effects of NSAIDs.
- Patients older than 60 years of age are at higher risk of peptic ulcer complications than their younger counterparts, and the risk is much higher in those above 75 years of age (Hernandez-Diaz and Rodriguez, 2000). Other risk factors include a previous history of peptic ulcer disease, in particular, peptic ulcer bleeding. Dyspepsia symptoms do not correlate with those who develop peptic ulcer disease and are, therefore, not a risk factor and can be treated symptomatically. Concomitant drug therapy, such as aspirin, corticosteroids and anticoagulants, increases the risk of peptic ulcer complications. In this case, the patient's age places Ms WR

at risk, and therefore the benefits of the NSAID should be weighed against the risks and potential options for risk management considered. Age is also a risk factor for NSAID-induced decrease in renal perfusion caused by inhibition of prostaglandin-stimulated renal blood flow, a compensatory mechanism that is activated when renal perfusion is impaired. Withdrawal of NSAID therapy can improve renal perfusion and associated haemodynamic effects such as hypertension.

3. The safest option for Ms WR is to manage the pain with regular use of a paracetamol-based product and to withdraw the NSAID, thus removing the risk of peptic ulcer disease but also removing the potential detrimental effect the NSAID may have on blood pressure because the patient is just above the target for blood pressure control. Weight loss may also help reduce the burden on her knees and may also have some positive effect on Ms WR's blood pressure. The relative risk of ulcer complications has been compared among groups of NSAIDs, with naproxen being of intermediate risk (García Rodríguez and Jick, 1994). Different NSAIDs vary in their selectivity for COX isoenzymes and may account for the relative toxicities observed. Selective COX-2 inhibitors are associated with low risk but are contraindicated in patients with cardiovascular disease because they have been associated with an increased incidence of myocardial infarction. However, some other nonselective NSAIDs have also been associated with thrombotic risk, although naproxen seems to have the lowest risk and so is an appropriate choice of NSAID if indicated in this patient (Trelle et al., 2011). There is no clear evidence to test for and eradicate *H. pylori* in chronic NSAID users. An assessment of Ms WR's pain should be undertaken, and the risks associated with naproxen use should be explained. Ms WR may be willing to change to regular paracetamol with the addition of codeine if necessary. Otherwise adding a standard dose of PPI to naproxen reduces the gastrointestinal risks but not the renal risks.

Case 12.5

Mr LP, aged 64 years, is attending a medication review clinic. While discussing any concerns Mr LP has about his medication, he mentions that he suffers from heartburn. On further questioning, Mr LP explains that his heartburn has been recently getting worse, and that food occasionally "gets stuck" when he is eating. Mr LP has a past medical history of hypertension, angina and heart failure. He lives alone and smokes 30–40 cigarettes per day. Mr LP's medication history is as follows:

- aspirin 75 mg daily,
- ramipril 5 mg twice a day,
- furosemide 40 mg each morning,
- amlodipine 5 mg each morning,
- isosorbide mononitrate MR 30 mg each morning,
- simvastatin 40 mg at night,
- GTN spray 1–2 sprays when required.

Despite changing his angina medication to a β -blocker, Mr LP's symptoms did not resolve, and in view of his dysphagia, he was admitted for endoscopy. It has been 4 weeks since Mr LP's hospital admission (2 months since you last saw him). His current medication is as follows:

- bisoprolol 5 mg each morning,
- furosemide 40 mg each morning,
- ramipril 5 mg twice a day,
- lansoprazole 30 mg each morning.

The interim discharge note states that the endoscopy found a grade B oesophagitis. However, there is no information as to the course length required for Mr LP's PPI.

Questions

1. What nonmedication advice can you offer Mr LP?
2. What recommendations could you make regarding Mr LP's drug therapy?
3. Does Mr LP require any further investigation at this stage?
4. How long should the PPI be continued at the treatment dose?
5. Will Mr LP require any further treatment once he has finished the course of treatment-dose PPI?

Answers

1. Lifestyle advice can be offered. Smoking cessation may help symptoms of dyspepsia. If Mr LP is overweight, weight reduction may also help. Other options include exploring dietary intake for potential triggers. Avoiding eating late at night and using extra pillows to prop up his head at night may potentially help Mr LP's reflux-like symptoms, although there is no evidence to support this strategy.
2. Calcium channel blockers and nitrates can lower oesophageal sphincter pressure and could, therefore, be contributing to his heartburn. Alternatives, such as a β -blocker, for his angina could be explored.
3. Mr LP describes symptoms of dysphagia, which is an ALARM symptom. Therefore, although the previous options could be explored, he should be referred as soon as possible for an endoscopy. Dysphagia could represent an underlying oesophageal stricture or tumour.
4. Because Mr LP has confirmed oesophagitis, 1–2 months of treatment-dose PPI should be offered. Because Mr LP has now had a month of treatment, you should discuss with him whether he has any continuing symptoms. If he does, it would be appropriate for the PPI to be continued at the treatment dose for a further month.
5. Initially, treatment could be stopped, although GORD is a chronic disease, with approximately two-thirds of patients requiring further treatment. If Mr LP's symptoms recur, treatment should be offered at the lowest dose that controls symptoms. The option of Mr LP taking the PPI on an on-demand basis (i.e. taking PPI only when symptoms occur) could be considered.

13 Inflammatory Bowel Disease

Sarah Cripps

Key points

- Ulcerative colitis and Crohn's disease are the two most common types of inflammatory bowel disease (IBD) of the gut. Both are chronic relapsing conditions with a high ongoing morbidity and remain largely incurable.
- Ulcerative colitis and Crohn's disease are related diseases, but there are contrasting features which relate to the clinical presentation, the site of involvement and extent of inflammation across the bowel wall. Ulcerative colitis is limited to the large bowel and the mucosa, whereas Crohn's disease frequently involves the small intestine, with inflammation extending through the bowel wall to the serosal surface.
- The aims of treatment are to control acute attacks promptly and effectively and to induce and maintain remission. Successful treatment also aims to prevent inflammatory damage and/or dysplasia which leads to surgical intervention.
- Choice and route of therapy will depend on the site and the extent and severity of the disease, together with knowledge of current or previous treatment.
- A reduction in inflammation with corticosteroids and aminosalicylates is the mainstay of treatment, with immunosuppressants (e.g. azathioprine, methotrexate, ciclosporin) and biologic agents (e.g. infliximab, adalimumab and vedolizumab) reserved for more severe and refractory cases.
- The management of IBD poses a challenge to the multidisciplinary team both clinically and economically.
- The biggest cost for commissioners relates to hospital care and biological treatments.
- National standards and management guidelines for IBD aim to ensure patients receive consistent, high-quality, evidence-based care and IBD services throughout the UK.

Introduction

Inflammatory bowel disease (IBD) can be divided into two chronic inflammatory disorders of the gastro-intestinal tract, namely, Crohn's disease and ulcerative colitis. Crohn's disease can affect any part of the gastro-intestinal tract, whereas ulcerative colitis affects only the large bowel.

IBD follows a relapsing and remitting course that is unpredictable and causes disruption to a patient's lifestyle and places a burden on the workplace and healthcare setting.

The management of IBD patients poses a challenge to the multidisciplinary team both clinically and economically. Current available treatment for IBD is not curative. In practice, complex cases

and those prescribed biologics are increasingly managed by specialist hospital centres. Patients whose disease is less severe are still managed predominantly by gastroenterologists and IBD specialist nurses with support from primary care doctors. Situations when primary care doctors should refer patients to secondary care include failure to respond to oral treatment for acute exacerbations and toxicity to immunomodulators. It is essential that primary care doctors and pharmacists recognise signs of an acute severe exacerbation and refer patients to hospital promptly for intensive treatment. National standards and management guidelines for IBD aim to ensure patients receive consistent, high-quality care and IBD services throughout the UK that are evidence based; engaged in local, national and international networking; and meet specific minimum standards.

Epidemiology

The incidence of IBD is greater in North America, Europe, Australia and New Zealand, although the incidence in Africa, Asia and South America is rising steadily. This increase in developing countries may be due to improved sanitation and vaccination programmes along with a decreased exposure to enteric infections. Jewish and Asian people living in USA and UK are more commonly affected by IBD than those living in Israel and Asia. There appears to be no association between IBD and social class.

Up to 260,000 people are affected by IBD in the UK ([National Institute for Health and Care Excellence \[NICE\], 2012](#)). Around 146,000 of these have a diagnosis of ulcerative colitis compared with 115,000 who are diagnosed with Crohn's disease. These figures differ from those published by the [National IBD Standards Group \(2013\)](#), which estimated around 620,000 people had IBD in 2012. The incidence of ulcerative colitis is stable, whereas the incidence of Crohn's disease appears to be increasing.

The peak incidence of IBD occurs between 10 and 40 years, although it can occur at any age, with 15% of cases diagnosed in individuals over the age of 60 years. Up to one-third of patients with Crohn's disease are diagnosed before the age of 21 ([NICE, 2012](#)). The incidence appears equal between males and females, although some studies in Crohn's disease suggest it is more common in females. The incidence of new cases of ulcerative colitis in Europe and USA is 2–8 per 100,000 per year with a prevalence of 40–80 per 100,000 per year. The incidence has remained fairly

static over the last 40 years. In the UK, Crohn's disease occurs with a similar frequency to ulcerative colitis, with around 4 per 100,000 per year and a prevalence of 50 per 100,000. The rates in Central and Southern Europe are lower. In South America, Asia and Africa, Crohn's disease is uncommon but appears to be on the rise (Mpofo and Ireland, 2006).

Aetiology

The precise aetiology of IBD is unclear, although its development and progression are multifactorial.

Environmental

Diet

Evidence that dietary intake is involved in the aetiology of IBD is inconclusive. Breastfeeding may reduce the risk of developing IBD (Mpofo and Ireland, 2006). Some other dietary factors have been associated with IBD, including fat intake, fast-food ingestion, milk and fibre consumption and total protein and energy intake. A large number of case-control studies have reported a causal link between the intake of refined carbohydrates and Crohn's disease (Gibson and Shepherd, 2005). The mechanism for diet as a trigger is poorly understood but is likely to involve dietary effects on the microbiome.

There is limited evidence that altering diet reduces inflammation or the risk of flare-ups. Patients with Crohn's disease may improve if they take an exclusive elemental (amino acid based), oligomeric (peptides) and polymeric (whole protein) feeds, although symptoms typically return when their normal diet is reintroduced. Other dietary modifications have not been proved to be effective, although patients are often able to identify foods that aggravate or exacerbate their coexistent irritable bowel syndrome (IBS).

Smoking

There is a higher rate of smoking amongst patients with Crohn's disease than in the general population, with up to 40% of patients with the disease being smokers. Smoking worsens the clinical course of the disease and increases the risk of relapse and the need for surgery. Fewer patients with ulcerative colitis smoke (approximately 10%). Former smokers are at the highest risk of developing ulcerative colitis, whereas current smokers have the lowest risk. Stopping smoking can provoke the emergence of ulcerative colitis, indicating that smoking may help to prevent the onset of the disease. In part this effect may be caused by nicotine (Guslandi, 1999).

Infection

Exposure to *Mycobacterium paratuberculosis* has been considered a causative agent of Crohn's disease, although current evidence indicates it is not an aetiological factor.

Ulcerative colitis may present after an episode of infective diarrhoea, but overall, there is little evidence to support the role of a single infective agent.

Enteric microflora

Enteric microflora plays an important role in the pathogenesis of IBD because the gut acts as a sensitising organ that contributes to the systemic immune response. Patients with IBD show a loss of immunological tolerance to intestinal microflora, and consequently, antibiotics often play a role in the treatment of IBD, particularly Crohn's disease. Although there is inconclusive evidence for a specific pathogen causing IBD, evidence suggests that there is a reduced diversity of luminal microbiota in IBD, with a decrease in *Firmicutes* such as bifidobacteria, lactobacillus and *Faecalibacterium prausnitzii* and an increase in mucosal-adherent bacteria.

Manipulating the intestinal flora using probiotics, prebiotics and symbiotics is an attractive therapeutic aim, but there is currently limited evidence of efficacy or clinical use. Probiotics such as *Bifidobacteria* and *Lactobacilli* favourably alter the intestinal microflora balance. More trials are needed to support the use of probiotics as therapy in IBD.

Drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) such as diclofenac have been reported to exacerbate IBD (Felder et al., 2000). It is thought this may result from direct inhibition of the synthesis of cytoprotective prostaglandins. Antibiotics may also precipitate a relapse in disease due to a change in the enteric microflora. The risk of developing Crohn's disease is marginally increased in women taking the oral contraceptive pill, possibly caused by vascular changes.

Measles, mumps and rubella vaccine. There has been much debate about the link between bowel disease and measles, measles vaccine or combined measles, mumps and rubella (MMR) immunisation. However, current evidence has indicated no proven correlation.

Appendicectomy

Appendicectomy has an inverted association with Crohn's disease and ulcerative colitis. For ulcerative colitis, it is protective against disease development, whereas appendicectomy for appendicitis appears to marginally increase one's risk of Crohn's disease (Radford-Smith et al., 2002). It is unclear whether this protective effect is immunologically based or whether individuals who develop appendicitis and consequently have an appendicectomy are physiologically, genetically or immunologically distinct from the general population.

Stress

Some patients find that stress triggers a relapse in their IBD, and this has been reproduced in animal models. It is thought that stress activates inflammatory mediators at enteric nerve endings in the gut wall. In addition to stress as a trigger factor, living with IBD can also be stressful. Its chronic nature, lack of curative

treatment, distressing symptoms and impact on lifestyle can make it difficult for patients to cope.

Genetic

A genetic predisposition to IBD is well established. Evidence for this predominantly comes from an observed high concordance rate for Crohn's disease amongst monozygotic twins and a 3- to 20-fold increased risk of IBD in first-degree relatives. Disease location (e.g. colonic versus ileal) and type of clinical presentation (e.g. fibrostenotic) appear to have a heritable pattern, and an earlier onset and increased severity at presentation also appear to occur in the offspring of affected parents in subsequent generations. Studies have implicated over 200 distinct susceptibility loci for IBD. Variants within these loci further increase the overall genetic variation associated with IBD risk. Genetic studies have enabled us to identify specific pathways that are important in the pathogenesis of the disease. The colitis phenotype results from interactions among multiple genetic loci, but actual disease is more likely to be dependent upon enteric microflora (Snapper and Podolsky, 2016).

Ethnic and familial

Jews are more prone to IBD than non-Jews, with Ashkenazi Jews having a higher risk than Sephardic Jews. In North America, IBD is more common in whites than blacks.

Pathophysiology

In individuals with IBD, trigger factors typically cause a severe, prolonged and inappropriate inflammatory response in the gastrointestinal tract, and the ongoing inflammatory reaction leads to an alteration in the normal architecture of the digestive tract. Genetically susceptible individuals seem unable to downregulate immune or antigen-nonspecific inflammatory responses. It is thought that chronic inflammation is characterised by increased activity of effector lymphocytes and proinflammatory cytokines that override normal control mechanisms. Others, however, have suggested that IBD may result from a primary failure of regulatory lymphocytes and cytokines, such as interleukin-10 and

transforming growth factor- β , to control inflammation and effector pathways. In Crohn's disease, it is also thought that T cells are resistant to apoptosis after inactivation. The presence of non-pathogenic bowel flora appears to be an essential factor.

Disease location

The character and distribution, both macroscopic and microscopic, of chronic inflammation define and distinguish ulcerative colitis and Crohn's disease. Table 13.1 shows the differences in location and distribution of ulcerative colitis and Crohn's disease. Fig. 13.1 details the histological differences.

Table 13.1 Location and distribution of ulcerative colitis and Crohn's disease		
	Ulcerative colitis	Crohn's disease
Location	Colon and rectum 40% proctitis 20% pancolitis 10–15% backwash ileitis	Entire gut (mouth to anus, rectal sparing) 45% ileocaecal disease 25% colitis only 20% terminal ileal disease 5% small bowel disease 5% anorectal, gastroduodenal, oral disease
Distribution	Continuous, diffuse	Often discontinuous and segmental 'skip lesions' Full thickness (transmural)
	No granulomas	Granulomatous inflammation
	Inflammation of mucosa	
	Ulceration is fine and superficial	Deep ulceration with mucosal extension
Fissures, fistulae and stricture	Absent	Common
Perianal disease	Absent	Present

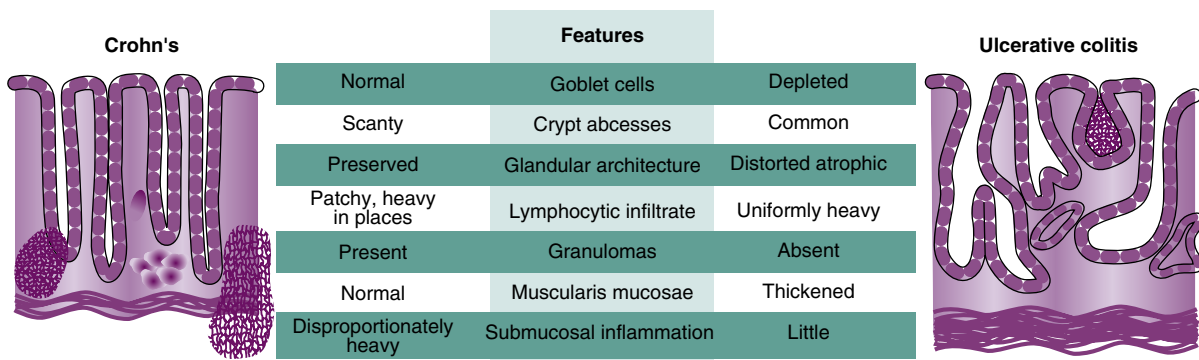

Fig. 13.1 Histological features in the rectal biopsy that help to distinguish between ulcerative colitis and Crohn's disease. (From Misiewicz et al., 1994, with kind permission from Blackwell Scientific Publications, Oxford.)

Crohn's disease

Crohn's disease can affect any part of the gut from the mouth to the anus. Approximately 45% of patients have ileocaecal disease, 25% colitis only, 20% terminal ileal disease, 5% small bowel disease and 5% anorectal, gastroduodenal or oral disease. Crohn's disease can involve one area of the gut or multiple areas, with unaffected areas in between being known as 'skip lesions'. The areas of the small bowel affected are typically thickened and narrow. A 'red ring' is often the first visible abnormality seen on colonoscopy. This is a lymphoid follicular enlargement with a surrounding ring of erythema, which develops into aphthoid ulceration and may progress to deep fissuring ulcers with a cobblestone appearance, fibrosis and strictures. Intestinal strictures arise from chronic and extensive inflammation and fibrosis, and bowel obstruction may arise. Local gut perforation may cause abscesses, which may also lead to fistulae.

Microscopically, inflammation and ulceration are transmural (i.e. extend through all layers of the bowel wall). Inflammatory cells are seen throughout, resulting in ulceration and microabscess formation. Non-caseating epithelioid cells, sometimes with Langhans's giant cells, are seen in about 25% of colonic biopsies and in 60% of surgically resected bowels. Chronic inflammation in the small intestine, colon, rectum and anus leads to an increased risk of carcinoma.

Ulcerative colitis

At first presentation, ulcerative colitis is confined to the rectum (proctitis) in 40% of cases, the sigmoid and descending colon (left-sided colitis) in 40% and the whole colon (total ulcerative colitis or pancolitis) in 20% of cases. Proctitis extends to involve more of the colon in a minority, with 15–30% of patients developing more extensive disease over 10 years. Fig. 13.2 highlights the location of colonic disease. The reason why some patients have extensive disease and some have limited disease is unknown. In severe total ulcerative colitis, there may also be inflammation of the terminal ileum. This is known as 'backwash ileitis' but is not clinically significant. The colon appears mucopurulent, erythematous and granular with superficial ulceration that in severe cases leads to ulceration. As the colon heals by granulation, post-inflammatory polyps may form.

Microscopically, superficial inflammation is seen with inflammatory cells infiltrating the lamina propria and crypts. Crypt abscesses occur, the crypt structure is lost and goblet cell depletion

arises as mucin is lost. Dysplasia, which can potentially progress to carcinoma, may be seen in biopsies taken from patients with long-standing total colitis.

Colitis not yet classified

Colitis not yet classified (sometimes referred to as indeterminate colitis) is when the clinical, biochemical, endoscopic and histologic features of the disease do not allow a distinction between Crohn's colitis or ulcerative colitis. This occurs in approximately 10% of IBD colitis.

Other types of colitis

Another type of chronic colitis is microscopic colitis (which can be differentiated into lymphocytic colitis or collagenous colitis). The main feature is watery diarrhoea in the presence of a normal colonoscopy and chronic inflammation in the absence of crypt architectural distortion on mucosal biopsies. Drugs such as NSAIDs and proton pump inhibitors (PPIs) are implicated as the cause in up to 50% of cases of microscopic colitis. Diversion colitis is when inflammation occurs in the defunctioned colon, causing a mucous discharge. Pseudomembranous colitis is caused by *Clostridium difficile*, usually after prolonged or multiple antibiotics. The use of PPIs predisposes patients to *C. difficile* infection. It is diagnosed by sigmoidoscopy and detection of *C. difficile* toxin in the stool.

Clinical manifestation

The clinical differences between Crohn's disease and ulcerative colitis are described in Table 13.2.

Crohn's disease

The clinical features of Crohn's disease depend in part on the site of the bowel affected, the extent, severity and the pathological process in each patient. Crohn's disease tends to be more disabling than ulcerative colitis, with 25% of patients unable to work 1 year after diagnosis. The predominant symptoms in Crohn's disease are diarrhoea (which may contain some blood and mucus), abdominal pain and weight loss. Weight loss occurs in most patients, irrespective of disease location. Ten to twenty

Fig. 13.2 Location of colonic disease in ulcerative colitis. (A) Proctitis involves only the rectum. (B) Proctosigmoiditis involves the rectum and sigmoid colon. (C) Distal colitis involves only the left side of the colon. (D) Pancolitis involves the entire colon.

Table 13.2 Clinical differences between ulcerative colitis and Crohn's disease

	Ulcerative colitis	Crohn's disease
Symptoms of active disease		
Prominent symptom	Bloody diarrhoea, urgency to pass stool	Diarrhoea, abdominal pain, weight loss 30% no gross bleeding
Fever	Implies acute severe colitis or infection	Common
Abdominal pain	Varies	Common
Diarrhoea	Very common	Fairly common
Rectal bleeding	Very common	Fairly common
Weight loss	Fairly common	Common
Signs of malnutrition	Fairly common	Common
Abdominal mass	Absent	Common
Dehydration	Very common	Common
Autoantibodies	Common	Rare
Electrolyte disturbances, iron deficiency anaemia raised inflammatory markers (CRP/ESR), hypoalbuminaemia	Common	Common
Pattern of disease	Both characterised by unpredictable periods of remission and relapse	
Occurrence	Occurs more in people of Caucasian and Ashkenazic Jewish origin than in other racial and ethnic subgroups Incidence fairly static 146,000 patients in UK	Occurs more in people of Caucasian and Ashkenazic Jewish origin than in other racial and ethnic subgroups 5-fold increase in incidence at all ages since 1950s 115,000 patients in UK Can occur at any age – up to one-third diagnosed before 21 years old peak 20–40 years
Occurrence in smokers	Uncommon in smokers	3–4 times more common in smokers
Occurrence in breastfeeding and appendectomy	Breastfeeding and appendectomy protective	Breastfeeding protective Appendectomy may increase risk
Fissures, fistulae and strictures	Absent	Common
Perianal disease	Absent	Present
Extra-intestinal manifestations	Present	Present
CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.		

percent of patients will have weight loss greater than 20%. The main cause is decreased oral intake, although malnutrition is also common. As a result, patients sometimes have a low body mass index (BMI). Growth retardation is common in young Crohn's patients. There is a slight increase in mortality in patients with extensive Crohn's disease.

It is estimated that only 10% patients have prolonged remission, with 20% requiring hospital admission each year and 50% requiring surgery within 10 years of diagnosis. This is unlike

ulcerative colitis, where mortality appears to be slightly increased compared with the general population.

Small bowel, ileocaecal and terminal ileal disease

Patients present with pain and/or a tender palpable mass in the right iliac fossa with weight loss and diarrhoea, which usually contains no blood. Diarrhoea is caused by mucosal inflammation, bile salt malabsorption or bacterial overgrowth proximal to

a stricture. Small bowel obstruction may also occur as a consequence of inflammation, fibrosis and stricture formation. Patients often describe a more generalised intermittent pain which is colicky, with loud gurgling bowel sounds (borborygmi), abdominal distension, vomiting and constipation. When inflammation or abscesses are the predominant pathology, patients then present with constant pain and fever. Enteric fistulae occur and may involve the skin, bladder or vagina. Although rare, perforation of the gut may present with an acute abdomen and peritonitis. Vitamin B₁₂ and iron deficiencies are common, predisposing patients to anaemia, while bile acid malabsorption also occurs in such patients and predisposes them to cholesterol gallstones and oxalate renal stones.

Crohn's colitis

The main symptoms are abdominal pain, profuse and frequent diarrhoea usually without blood, and weight loss. Patients also complain of lethargy, anorexia and nausea and may appear thin, tachycardic, anaemic, malnourished and febrile. Colitis may present insidiously with minimal discomfort. Patients with severe involvement of the colon or the terminal ileum often have electrolyte abnormalities, hypoalbuminaemia and iron-deficiency anaemia. Extra-intestinal complications are more common in those patients with large bowel disease.

Perianal disease

Patients may present with an anal fissure, fistula or a perirectal abscess. These symptoms can have a significant impact on the patient's lifestyle. Fistulae are abnormal channels lined with granulation tissue that can form between the intestine and the skin as well as organs such as the bladder, vagina, or other parts of the intestine.

Gastroduodenal and oral disease

Gastroduodenal and oral disease are both rare manifestations. Gastroduodenal Crohn's disease presents as dyspepsia, pain, weight loss, anorexia, nausea and vomiting. Oral disease is very painful and may cause chronic ulceration, resulting in anorexia.

Stricturing Crohn's disease

Strictures, narrowed segments of bowel, are common and can lead to blockages, acute dilatation and perforation if not surgically treated. Patients usually present with pain, vomiting and constipation (see Fig. 13.3).

Ulcerative colitis

Typical symptoms of ulcerative colitis include bloody diarrhoea (the most predominant symptom) with mucus, urgency and frequency. Abdominal pain usually is of cramps associated with (and relieved by) the urge to defaecate. Weight loss occurs in severe cases. Frank blood loss is more common in ulcerative colitis than Crohn's disease. Approximately 50% of patients with ulcerative colitis have some form of relapse each year,

Fig. 13.3 Stricture formation in Crohn's disease.

and severe attacks can be life-threatening. Up until the 1960s, one-third of ulcerative colitis patients died from the condition; with advances in medical and surgical treatment, death is now extremely rare.

Most patients diagnosed with ulcerative colitis will have mild disease at first presentation, and only 10% will have severe disease. Up to 30% will undergo colectomy within 10 years of diagnosis (Mowat et al., 2011).

Acute severe disease

In addition to the typical symptoms of ulcerative colitis, patients with acute severe disease present with more than six bloody stools per day (10–20 liquid stools per day is not unusual), with one or more of the following: a fever (>37.8 °C), tachycardia (>90 bpm), anaemia (Hb <10.5 g/dL) or elevated inflammatory markers (erythrocyte sedimentation rate [ESR] >30 mm/h; C-reactive protein [CRP] >8 mg/L). Severity is commonly assessed using the Truelove and Witts's criteria (see investigations).

Moderately active disease

Stool frequency is less than six motions each day with diarrhoea, mucus and rectal bleeding. Moderately active disease is more common in 'left-sided' disease. Toxic megacolon is rare in patients with rectosigmoidal involvement, and the incidence of colon cancer is much lower in these patients than those with total colitis.

Proctitis

The manifestations of active proctitis are less severe. These are tenesmus, pruritus ani, rectal bleeding and mucous discharge. Patients are often constipated and may require an osmotic laxative such as a macrogol.

Toxic dilatation

This can occur in untreated severe ulcerative colitis. There is a high risk of perforation, with a historical mortality of 50%.

Fig. 13.4 Some of the extra-intestinal illnesses and features of malnutrition found in patients with inflammatory bowel disease. (From Misiewicz et al., 1994, with kind permission from Blackwell Scientific Publications, Oxford.)

Extra-intestinal complications

Around 20–30% of patients with IBD will present with extra-intestinal manifestations. They are more commonly seen in patients when IBD affects the colon. Complications affect the joints, skin, bone, eyes, liver and biliary tree and are mostly (but not exclusively) associated with active disease. Fig. 13.4 highlights some of the extra-intestinal features of IBD.

Joints and bones

Arthropathies occur in 10% of patients with IBD, are more common in women and are a well-recognised complication of IBD. Patients with pauciarticular disease, characterised by arthritis limited to five or fewer joints, often experience a flare in the arthropathy when there is an exacerbation of the IBD symptoms. When the IBD relapse is treated, the arthropathy improves. This is in contrast to polyarticular arthropathy, a chronic condition which affects more than five joints; a flare of the IBD appears not to be temporally related to the activity of the arthropathy. About 5% of patients with IBD also have ankylosing spondylitis. This is thought to be immunologically mediated and not associated with IBD activity. Osteopenia, potentially leading to osteoporosis, is often seen in patients with IBD because of chronic steroid use (particularly when the cumulative dose of prednisolone exceeds 10 g) and/or malabsorption.

Skin

Both erythema nodosum and pyoderma gangrenosum are associated with IBD. Erythema nodosum appears as tender, hot, red

nodules usually on the shins that subside over a few days to leave a brown skin discolouration. The onset is normally directly related to IBD activity in the 8% of patients affected.

Pyoderma gangrenosum presents as a discrete pustule that develops into an ulcer. In the 2% of patients affected, IBD activity does not appear to be directly related to the pyoderma gangrenosum, which may begin or worsen when the IBD is quiescent.

Sweet's syndrome (an acute febrile neutrophilic dermatosis), which has some similarity to erythema nodosum, may also be associated with IBD.

Eye

Ocular complications are infrequent, occurring in less than 10% of cases. Episcleritis (intense burning and itching with localised area of blood vessels) is the most common complication of IBD. Scleritis may impair vision. Uveitis (headache, burning red eye, blurred vision) is often associated with joint and skin manifestations of IBD. Conjunctivitis is frequently seen in IBD patients but is not specific, and no true association has been demonstrated.

Hepatobiliary

Biliary complications of IBD are gallstones and primary sclerosing cholangitis (PSC). The latter occurs in 5% of patients with ulcerative colitis but less frequently in those with Crohn's disease. Conversely, the prevalence of IBD (mostly ulcerative colitis) in patients with PSC is 70–80%. PSC, found predominantly in males, is a chronic cholestatic condition characterised by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. Patients present with obstructive jaundice, cholangitis

and raised cholestatic liver enzymes. Magnetic resonance cholangiopancreatography (MRCP) is the diagnostic test of choice, with endoscopic retrograde cholangiopancreatography (ERCP) restricted to when intervention is required (e.g. for removal of obstructing gallstones). There is an increased risk of cholangiocarcinoma, cirrhosis and hepatocellular carcinoma (HCC) with a liver transplant being the only effective treatment.

Thromboembolic

Thromboembolic complications occur in around 1–2% of IBD patients. The most common cause of death in hospitalised IBD patients was once pulmonary embolism (Solem et al., 2004). However, the risk of this is now reduced because of the routine use of venous thromboembolism prophylaxis in hospitalised patients.

Anaemia

Anaemia is the most common systemic complication of IBD. In the majority of cases, IBD-associated anaemia is a unique example of the combination of chronic iron deficiency and anaemia of chronic disease (ACD). Other causes of anaemia in IBD include vitamin B₁₂ and folate deficiency and the toxic effects of medications such as azathioprine and methotrexate.

All patients with IBD should be regularly assessed for the presence of anaemia because of its impact on quality of life and comorbidity. About two-thirds of IBD patients have anaemia at diagnosis.

The cause of iron-deficiency anaemia includes continuous blood loss from the ulcerated surface of the bowel or malnutrition with reduced iron intake. Diagnostic criteria depend on the level of inflammation. In patients without clinical, endoscopic or biochemical evidence of active disease, serum ferritin less than 30 micrograms/L is indicative. However, in the presence of inflammation, a serum ferritin up to 100 micrograms/L may still be consistent with iron deficiency and warrant active treatment. In comparison the diagnostic criteria for ACD in the presence of biochemical or clinical evidence of inflammation are a serum ferritin greater than 100 micrograms/L and transferrin saturation less than 20%. If the serum ferritin level is between 30 and 100 micrograms/L, a combination of true iron deficiency and ACD is likely.

Patients with IBD should be monitored for recurrent iron deficiency every 3 months for at least a year after correction and between 6 and 12 months thereafter. After effective iron replenishment, anaemia recurs rapidly, and patients with IBD should be monitored for iron deficiency every 3 months using a combination of haemoglobin, ferritin, transferrin saturation, and CRP (Dignass et al., 2015).

Other complications of inflammatory bowel disease

Complications of ulcerative colitis include toxic dilatation of the colon (>5.5 cm identified by abdominal X-ray) and the risk of perforation. Repeated resections can lead to short bowel in Crohn's disease and the need for lifelong total parenteral nutrition and medication to control a high-output stoma. There is a risk of colorectal cancer in patients with colonic disease,

and routine colonoscopic surveillance is recommended for patients at increased risk (NICE, 2011).

Investigations

A full patient history should include recent travel, medication (such as recent use of antibiotics or NSAIDs), sexual and vaccination history as appropriate and identifying potential risk factors such as smoking, family history and recent infection, such as gastroenteritis. A combination of clinical signs and symptoms and endoscopic, radiological, histological and haematological investigations will help to confirm diagnosis, disease recurrence and response to treatment (Dignass et al., 2015). Differential diagnoses of IBD include carcinoma, infection, drug-induced colitis, ischaemia, radiation damage, irritable bowel syndrome and diverticulitis.

Endoscopy

The key diagnostic investigation in IBD is lower gastro-intestinal tract endoscopy (sigmoidoscopy and colonoscopy), which allows direct visualisation of the large bowel and histopathological assessment from biopsies. Treatment response to biologics can be assessed via mucosal healing seen at colonoscopy. In patients with severe symptoms, it is sometimes necessary to delay a full colonoscopy because of the increased risk of perforation.

To enable a good view of the mucosa, bowel-cleansing agents (e.g. Citramag, Picolax or Moviprep) are taken prior to the procedure. Phosphate enemas are given prior to sigmoidoscopy and are considered safe in acute severe colitis provided there is no colonic dilatation.

The Ulcerative Colitis Endoscopic Index of Severity (UCEIS) predicts overall assessment of endoscopic severity of disease (Travis et al., 2012). Three descriptors are graded as vascular pattern, bleeding and ulceration to give a score out of 8. A higher score is more predictive of likely colectomy. The use of the UCEIS has reduced variance in endoscopic reporting from 73% to 14% (Travis et al., 2012).

Wireless capsule endoscopy allows the small bowel to be viewed and can be useful in patients with non-stricturing Crohn's disease. The patient swallows a small single-use capsule, usually after an overnight fast. This capsule consists of a camera, a light source and a wireless circuit for the acquisition and transmission of signals. As the capsule moves through the gastro-intestinal tract, images are transmitted to a data recorder, worn on a belt outside the body. These data are transferred to a computer for interpretation. The capsule is then passed in the patient's stool (NICE, 2004).

Radiology

Radiological imaging is used in the initial evaluation or diagnosis, preoperative review, to highlight the presence of complications during exacerbations and to evaluate extra-intestinal manifestations. Radiological examination still plays a key role in IBD affecting the small bowel, although endoscopy has generally

replaced conventional X-ray examinations of the colon. There are various types of radiological tests, and the most appropriate imaging technique is ideally discussed with a radiologist to minimise unnecessary ionising radiation.

Abdominal X-ray is essential in severe indeterminate colitis to exclude colonic dilatation and may help assess disease extent of ulcerative colitis or identify proximal constipation. In Crohn's disease, abdominal radiography may identify a potential mass in the right iliac fossa or highlight evidence of small bowel dilatation.

Computed tomography (CT scan) and magnetic resonance imaging (MRI) are the best radiological methods for locating and defining fistulae and abscesses in active Crohn's disease. MRI has the advantage over CT in that there is no radiation, which is advantageous in a young population, and with Crohn's disease, where repeat imaging is likely.

Radiolabelled leucocyte scans that utilise autologous leucocytes labelled with ⁹⁹technetium-hexamethylenamine oxime are very rarely used because modern imaging provides superior information about disease severity and complications.

Laboratory findings

Although not diagnostic, active disease is suggested in patients with raised inflammatory markers that include erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in addition to a low haemoglobin, raised ferritin and raised platelet count. Vitamin B₁₂ may be low in patients with chronic terminal ileal disease. Low red cell folate and serum albumin, magnesium, calcium, zinc and essential fatty acids also indicate chronic inflammation and malabsorption. Anti-*Saccharomyces cerevisiae* antibodies (ASCAs) are more likely to be present in Crohn's disease. Serology is used by some clinicians but is not sensitive or specific enough to be a commonly used diagnostic tool.

Malabsorption, indicated by low serum trace elements (e.g. magnesium and zinc), is not seen in ulcerative colitis. Low albumin may indicate relapse in active disease. Patients with sclerosing cholangitis often present with altered liver function tests (LFTs).

Cytomegalovirus (CMV) should be considered in severe or refractory colitis, particularly in the presence of high fevers and/or deranged LFTs. Reactivation is common in patients taking immunosuppressants.

Stool tests

Stool tests do not diagnose IBD but contribute to excluding alternative diagnoses, such as infection and identifying a potential precipitant for a flare in symptoms. Red and white blood cells can be seen on microscopic examination of fresh stools. Microscopic identification of infective cells such as amoeba may also be visualised. *C. difficile* toxin can be assessed through culture and toxin assay. *C. difficile* has a higher prevalence in IBD patients and is associated with increased mortality.

Faecal calprotectin is often used as indicator for IBD. It is a useful diagnostic marker for predicting relapses or flares and can help assess the efficacy of treatment. Increased levels of faecal calprotectin correlate with endoscopic disease activity and can

Table 13.3 Truelove and Witts's criteria for assessing severity of ulcerative colitis (NICE, 2013)

Feature	Mild	Moderate	Severe
Motions per day	<4	4–6	>6
Rectal bleeding	Little	Moderate	Large amounts
Temperature	Apyrexial	Intermediate	>37.8 °C on 2 of 4 days
Pulse rate	Normal	Intermediate	>90 bpm
Haemoglobin	Normal	Intermediate	<10.5 g/dL
ESR	Normal	Intermediate	>30 mm/h

bpm, Beats per minute; ESR, erythrocyte sedimentation rate.

help distinguish between a diagnosis of IBD and irritable bowel syndrome (IBS) in which faecal calprotectin levels are normal. Proton pump inhibitors (e.g. omeprazole) may be associated with elevated calprotectin values so this should be taken into account when interpreting results.

Clinical assessment tools

The Crohn's Disease Activity Index (CDAI) (Best et al., 1976) or the Harvey–Bradshaw Index (HBI) (Harvey and Bradshaw, 1980) are used in most clinical trials to define remission in Crohn's disease. However, in clinical practice the CDAI is rarely used because it needs to be measured prospectively and is complex. The HBI is a simple measure of stool frequency, pain and other clinical features that is increasingly used to document selection for and response to biologic therapy. A CDAI of <150 or an HBI of 3 or below suggests the patient is in remission (NICE, 2010). When using these scores, consideration should be made for any physical, sensory or learning disabilities or communication difficulties that could affect the scores and make any adjustments as appropriate. The Truelove and Witts's criteria (NICE, 2013) comprise a useful tool in defining the severity of ulcerative colitis in adults (see Table 13.3). A severe attack is defined as more than six bloody stools a day plus one or more of the following: pulse greater than 90 beats/min, temperature greater than 37.8 °C, haemoglobin less than 10.5 g/dL or ESR greater than 30 mm/h. In this case, the patient should be admitted to hospital. The Paediatric Ulcerative Colitis Activity Index (PUCAI) is used with children (Turner et al., 2007a).

The Simple Clinical Colitis Activity Index (SCCAI) (Walmsley et al., 1998) allows initial evaluation of exacerbations of ulcerative colitis using scores for five clinical criteria. These are ESR, bowel frequency per day and at night/day, urgency of defaecation, presence of blood in stool, general well-being and extra-colonic features.

Predicting the outcome of severe ulcerative colitis (resistance to steroids and likelihood of requiring colectomy) should be assessed on day 3 of intensive treatment with intravenous corticosteroids. Those patients with frequent stools (>8/day) or raised CRP (>45 mg/L) predicts the need for surgery in 85% cases (Travis et al., 1996). Remission in ulcerative colitis is defined

Fig. 13.5 Treatment options in inflammatory bowel disease from mild to moderate and severe disease.

as complete resolution of symptoms with a normal bowel pattern (<3 stools/day), no urgency and no visible bleeding. Mucosal healing is confirmed by endoscopy.

Treatment of inflammatory bowel disease

At present there is no cure for IBD because the exact cause of the condition is unknown. Widely ranging drugs and nutritional supplements are available to maintain the patient in long periods of remission in both Crohn's disease and ulcerative colitis. However, surgical intervention often becomes necessary if a complication occurs or if the patient fails to respond to medical therapy. Because the majority of people with IBD are diagnosed under the age of 30, effective treatment and avoidance of relapses are of paramount importance in this chronic, long-term condition. Steroid-free remission remains one of the main goals of therapy.

The available treatments for inflammatory bowel disease are not curative. They are largely aimed at:

- treating acute attacks promptly and inducing remission,
- maintenance of remission,
- minimising toxicity related to drug treatment,
- optimising nutrition and/or growth,
- encouraging smoking cessation in patients with Crohn's disease,
- minimising psychological concerns,
- detecting cases of colorectal cancer,
- managing disease complications,
- maintaining or improving quality of life.

In addition, identification and selection of patients who would benefit from surgery and/or endoscopic treatment are also undertaken.

Nutritional therapy

Nutritional therapy can be considered as an adjunctive or primary treatment. Although a potential problem for all patients with IBD, patients with Crohn's disease are at particular risk of becoming malnourished and developing a variety of nutritional deficiencies.

Although of benefit in Crohn's disease, there is no indication for enteral feeding in the treatment of ulcerative colitis. In

Crohn's disease, there is evidence that enteral liquid feed favourably alters the inflammatory response and may be useful in inducing remission. However, there is little evidence to support its use as maintenance treatment. Exclusive enteral nutrition for 3–6 weeks is an alternative to corticosteroids to induce remission. This is commonly used in paediatrics, where avoidance of corticosteroids because of their side effects, such as growth retardation, is desirable. Up to 80% of paediatric patients achieve remission with exclusive elemental nutrition. The efficacy in adults is lower, primarily as a result of tolerability and adherence. There does not appear to be a difference in efficacy between elemental and polymeric diets (Mowat et al., 2011).

Patients who have extensive small bowel resection may experience many nutritional deficiencies because of malabsorption. Iron depletion, hypoproteinaemia, deficiencies in water- and fat-soluble vitamins, trace elements and electrolytes may all occur and must be corrected using a suitable replacement regimen.

Where appropriate, and when enteral nutrition is not indicated or adequate, a total parenteral nutrition (TPN) regimen may be prescribed. Some patients receive concurrent enteral and parenteral feeding.

Drug treatment

Drug treatments are often required for many years, and patient preference, acceptability and potential side effects affect both choice and potential medication adherence. A therapeutic strategy and consistency in the management of patients with IBD are essential. Strategies for the management of induction of remission and maintenance of remission for both conditions are set out in the respective NICE (2012, 2013) management guidelines and other international guidelines such as those from the European Crohn's and Colitis Organisation (Dignass et al., 2012a, 2012b; Gionchetti et al., 2016; Gomollon et al., 2016). Patients are likely to receive several different treatments during the course of their illness as a result of intolerance or lack of response, and medicine optimisation is key to ensure patients get the most out of their medicines.

The mainstays of drugs used in the treatment of IBD are corticosteroids, aminosalicylates, immunomodulators and biologics. Fig. 13.5 illustrates the stepwise approach to drug treatment options.

The choice of drug treatment and route of administration depends on the site, extent and severity of disease and whether it is being used for the induction or maintenance of remission. Consideration of the treatment history is also an important factor. Maintenance treatment is advised for the majority of patients (except those ulcerative colitis patients who have undergone colectomy). The majority of IBD patients are managed successfully as hospital outpatients or by their primary care doctor. Only severe extensive or fulminant disease requires hospitalisation and the use of parenteral therapy and/or surgical intervention. Oral medication can be given to most patients for maintenance of mild to moderate disease. Immunomodulators and biologics, which are reserved for more severe disease, should only be initiated by/on the advice of a specialist gastroenterologist. The use of immunomodulators, biologics or surgery is invariably required if steroid treatment alone fails to induce remission or cannot be withdrawn. An algorithm for drug treatment in IBD is shown in Fig. 13.6.

Although commonly used and accepted practice in the UK, many of the drugs recommended in the treatment of IBD, such as the immunomodulators (azathioprine, mercaptopurine, methotrexate, ciclosporin, and tacrolimus), are used outside of their UK marketing authorisation. In addition, many drugs do not have a UK licence for use in children. This includes some oral and topical aminosalicylates, and therefore reference should be made to the British National Formulary for Children (BNFC). Informed consent for the use of these drugs should therefore be obtained and documented because the prescriber must take full responsibility for their use.

The route of administration is a particularly important factor in IBD. In contrast to most other conditions, minimal systemic absorption and maximal intestinal wall drug levels are required with oral therapy. Several delivery strategies have been used to achieve this, including the chemical modification of drug molecules, delayed and controlled-release formulations and the use of bioadhesive particles.

Rectal route

Disease confined to the anus, rectum or left side of the colon is more appropriately treated with rectally administered topical preparations where the drug is applied directly to the site of inflammation (Table 13.4). Rectally administered topical preparations of aminosalicylates and corticosteroids are recommended in mild to moderate ulcerative colitis (NICE, 2013).

Drugs administered rectally have reduced systemic absorption and fewer side effects than those administered orally or intravenously. The choice of formulation (suppository, foam or liquid enema) depends on the site of inflammation, product presentation, acceptability, patient preference and cost. Adherence to topical therapy is generally poor, and good patient education is required for effective benefit. Patients with poor dexterity may find the use of rectal products difficult, and these preparations may therefore be poorly tolerated and consequently have a limited advantage.

Proctitis is best treated with suppositories. Where inflammation affects the rectum and sigmoid colon (up to 15–20 cm), foam enemas are preferred. In more extensive disease extending

to the splenic flexure (30–60 cm), liquid enemas are the agents of choice. However, patients often require a combination of different rectal preparations because, for example, over 90% of liquid enemas bypass the rectum and thereby exert no therapeutic benefit at that site. As a consequence, a suppository may also be required to treat rectal inflammation. The propellant action of foam applicators also results in some preparations bypassing the rectal mucosa. Enemas or suppositories should be administered just before bedtime in a supine position because this allows a much longer retention time. Liquid enemas can be warmed and should be inserted while lying in the left lateral position.

Corticosteroids

The glucocorticoid properties of hydrocortisone and prednisolone are the mainstay of treatment in active ulcerative colitis and Crohn's disease to induce remission. Prednisolone administered orally or rectally (if colonic or rectal disease) is the steroid of choice, although in emergency situations, hydrocortisone or methylprednisolone is used when the parenteral route is required. Corticosteroids have direct anti-inflammatory and immunosuppressive actions which rapidly control symptoms. They can be used either alone or in combination, with a suitable mesalazine (5-aminosalicylic acid, 5-ASA) formulation or immunosuppressant, to induce remission. Rectal corticosteroids are recommended for use in mild to moderate proctitis/sigmoiditis but are not as effective as rectal aminosalicylates.

Corticosteroids are ineffective in preventing relapse once remission has occurred. If disease symptoms recur during the withdrawal period, the dose should be increased and a slower taper schedule commenced. The addition of an immunomodulator should be considered. Oral corticosteroids should not be used for maintenance treatment because of serious long-term side effects, such as osteoporosis, and abrupt withdrawal should be avoided. Patients should be maintained on aminosalicylates, immunosuppressants or biologics or a combination of these, as appropriate, or referred for surgery.

Oral corticosteroids. Oral prednisolone will control mild and moderate IBD, and 70% of patients improve after 2–4 weeks of 40 mg/day. This is gradually reduced over the next 4–6 weeks to prevent acute adrenal insufficiency and early relapse. Prednisolone at doses higher than 40 mg/day increases the incidence of adverse effects and has little therapeutic advantage. Initial doses below 20 mg/day, faster reduction regimens or short pulses of corticosteroids are generally ineffective in active disease (St Clair Jones, 2014). An example of a reducing oral prednisolone regimen is detailed in Box 13.1.

Oral corticosteroids should be taken in the morning to mimic the diurnal rhythm of the body's cortisol secretion and prevent sleep disturbance. Uncoated steroid tablets are suitable for most patients, whereas enteric-coated preparations do not offer any proven advantage and should be avoided in patients with short bowel or strictures because of poor absorption and bolus release at stricture sites.

Short-term side effects of corticosteroids include moon face, acne, sleep and mood disturbance, dyspepsia, hypokalaemia,

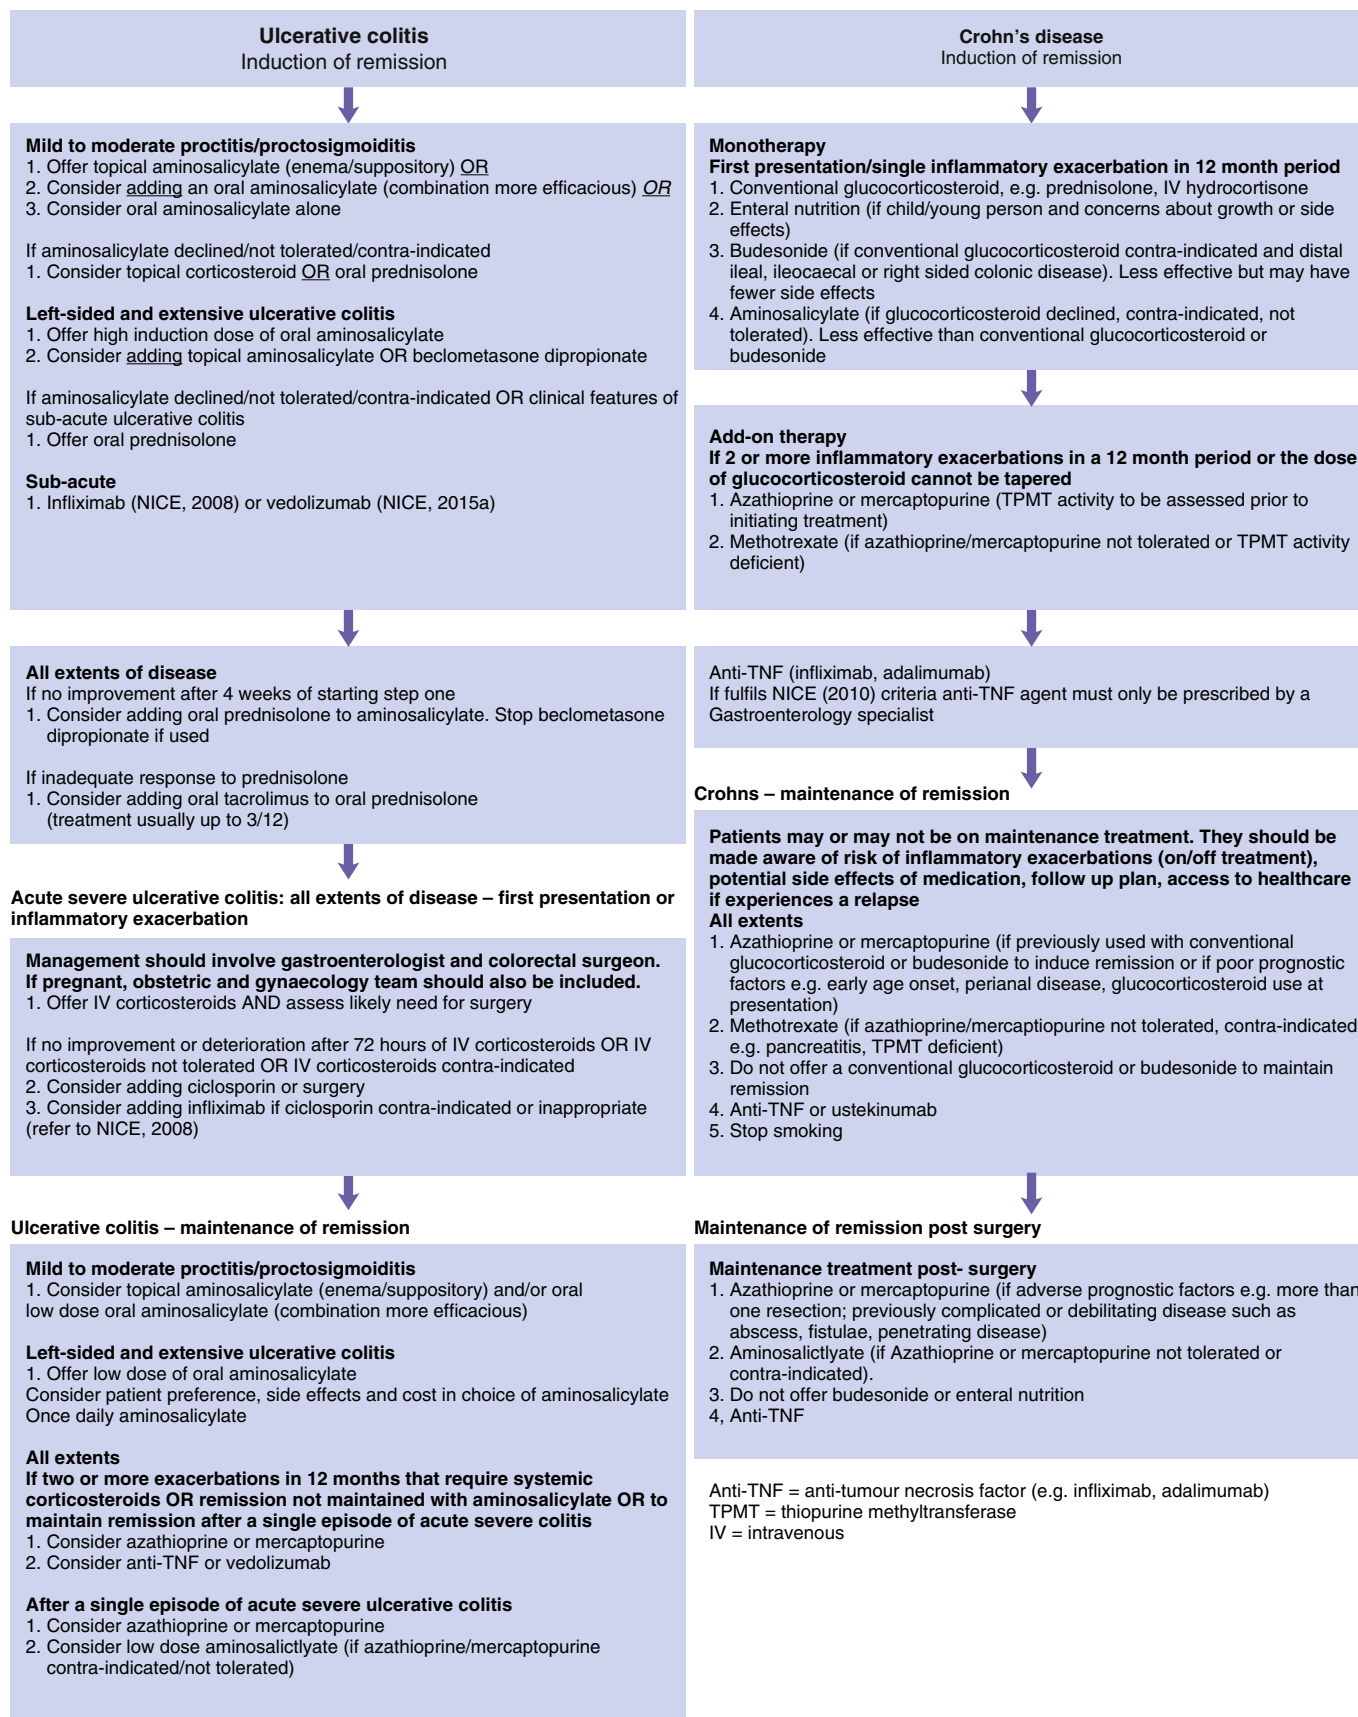

Fig. 13.6 Drug treatment algorithm for inflammatory bowel disease. (Adapted from NICE, 2012, 2013.)

Table 13.4 Comparison of commercially available preparations for rectal administration in inflammatory bowel disease

Generic name (proprietary name)	Formulation	Site of release
Budesonide (Entocort)	Retention enema	Rectum and rectosigmoid colon
Budesonide (Budenofalk)	Foam enema	Rectum and rectosigmoid colon
Hydrocortisone acetate (Colifoam)	Foam enema	Rectum and rectosigmoid colon
Mesalazine (Pentasa, Salofalk)	Retention enema	Transverse and descending colon and rectum
Mesalazine (Asacol, Salofalk)	Foam enema	Rectum and rectosigmoid colon
Mesalazine (Asacol, Pentasa, Salofalk)	Suppositories	Rectum
Prednisolone sodium metasulfobenzoate (nonproprietary)	Foam enema	Rectum and rectosigmoid colon
Prednisolone sodium phosphate (Predsol)	Retention enema	Transverse and descending colon
Prednisolone sodium phosphate (nonproprietary)	Suppositories	Rectum
Sulfasalazine (Salazopyrin)	Suppositories	Rectum

hypernatraemia and glucose intolerance. Prolonged use can cause cataracts, osteoporosis and increased risk of infection. All patients taking corticosteroids must be issued with a steroid card and counselled on potential side effects.

Rectal corticosteroids. The distribution and absorption characteristics of rectally administered steroids vary greatly. Hydrocortisone (e.g. Colifoam) is readily absorbed from the rectal mucosa, with high peak concentrations compared with prednisolone sodium metasulphobenzoate. Topical preparations may play a role either alone or in combination with oral steroids.

Intravenous corticosteroids. Intravenous corticosteroids remain the mainstay of therapy in severe ulcerative colitis. The landmark article by [Truelove and Witts \(1955\)](#) showed a reduction in mortality from 24% in the placebo group to 7% in the steroid-treated group. Severe extensive or fulminant disease (often referred to as acute severe colitis [ASC]) or disease that is not responding to oral corticosteroids requires hospital admission with parenteral corticosteroids. Patients are given either hydrocortisone sodium succinate, administered intramuscularly or intravenously at doses of 100 mg three or four times a day, or methylprednisolone 15–20 mg three or four times a day, for 5 days. No additional benefit is gained after 7–10 days.

Additional therapy used in severe disease (ulcerative colitis or Crohn's) may include intravenous fluid and electrolyte replacement (especially potassium), blood transfusion and/or intravenous iron replacement, topical therapy for rectal and/or colonic involvement, thromboprophylaxis with prophylactic heparin (IBD is associated with increased coagulopathy), antibiotics and nutritional support. Aminosalicylates should be stopped during an acute severe exacerbation because of poor absorption and the side effect of diarrhoea, which could exacerbate or be misleading. Care should also be taken with the use of anti-motility drugs such as codeine and loperamide and antispasmodic drugs in an acute exacerbation of colitis because they can precipitate a paralytic ileus and toxic megacolon in active disease. Treatment with corticosteroids should not be delayed whilst awaiting microbiological results for possible infective causes.

If improvement is seen with intravenous corticosteroids, oral prednisolone treatment is normally introduced as soon as possible and withdrawn over the following 6–8 weeks. Too-rapid reduction is associated with relapse. Corticosteroids are ineffective in preventing relapse once remission has occurred. The use of immunomodulators or biologics should be considered to induce and maintain remission as the steroids are withdrawn. The use of these drugs (plus surgery) is invariably required if steroid treatment alone fails to induce remission or cannot be withdrawn.

A typical treatment algorithm for the management of an acute attack of ulcerative colitis is presented in [Fig. 13.7](#).

Other steroids. In the UK, oral budesonide (Budenofalk or Entocort) is licensed for the induction of remission in patients with mild to moderate active Crohn's disease affecting the ileum and/or the ascending colon. Budenofalk is also licensed for microscopic colitis. Cortiment is licensed for induction of remission in adults with mild to moderate active ulcerative colitis where aminosalicylates are not sufficient. Rectal budesonide (Entocort enemas) are licensed for ulcerative colitis.

Budesonide is less effective than conventional corticosteroids in inducing remission in active disease, but it has fewer side effects than prednisolone because of its rapid and extensive first-pass metabolism. However, the absorbed drug has a higher affinity for glucocorticoid receptors, 50–100 times that of prednisolone, and so long-term or maintenance treatment is not advocated. Budesonide is useful for moderate terminal ileal Crohn's disease or for patients intolerant to prednisolone, as it is more expensive. A standard dose for induction of remission would be 9 mg/day orally for up to 8 weeks reducing the dose for the last 2 weeks of treatment. Budesonide should not be used in severe active disease.

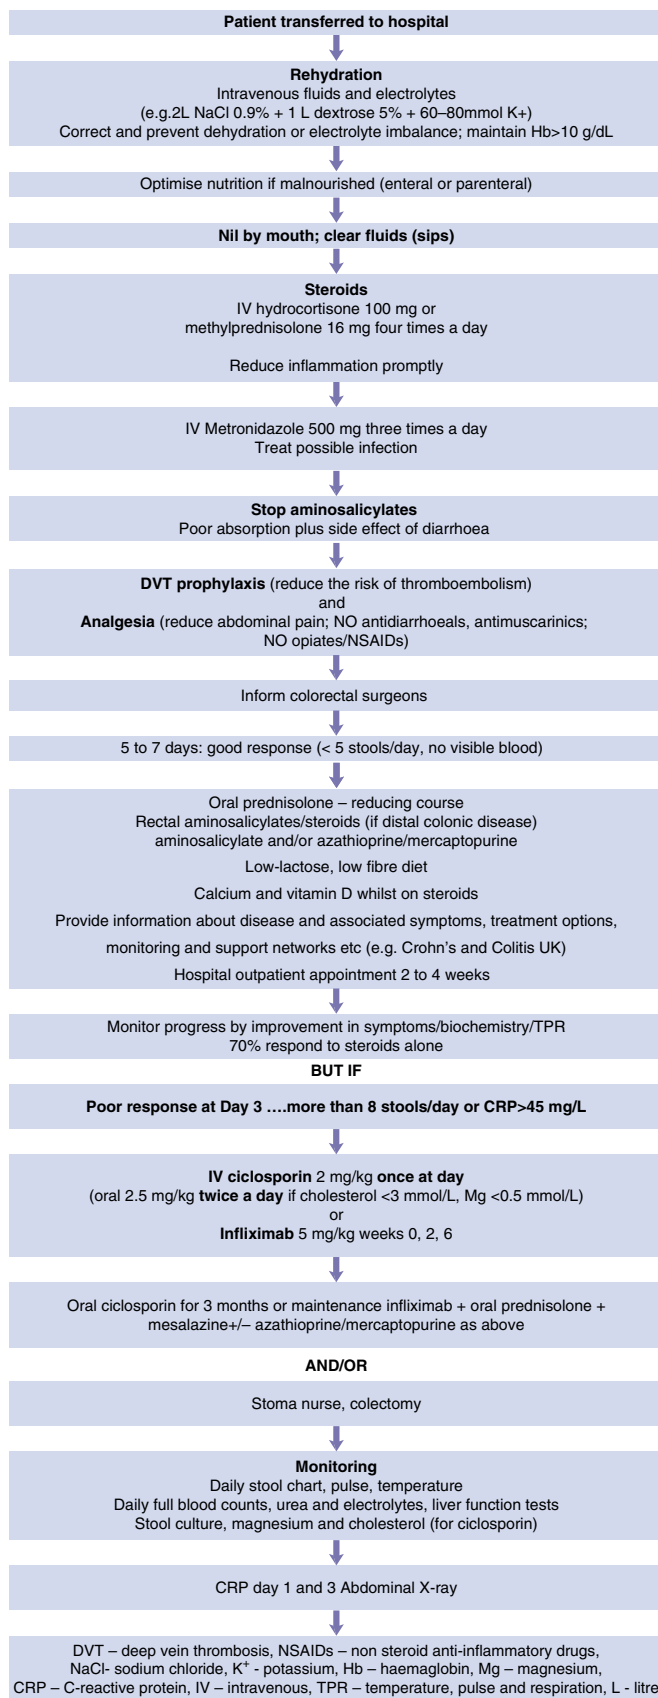

Fig. 13.7 Treatment algorithm for an acute severe attack of ulcerative colitis.

Oral beclometasone dipropionate (Clipper) is licensed as adjunct therapy with aminosalicylates for a maximum duration of 4 weeks in ulcerative colitis. It should not be used with other corticosteroids.

Aminosalicylates

The aminosalicylates currently licensed for the treatment of IBD include sulfasalazine, mesalazine, olsalazine and balsalazide. Their mode of action is unclear, but a local effect on epithelial cells by a variety of mechanisms to moderate the release of lipid mediators, cytokines and reactive oxygen species is proposed. Different formulations deliver variable amounts of the active component, mesalazine (5-ASA), to the gut lumen, where it exerts a predominantly local action independent of blood levels. The dissolution profile and site of ulceration determine the effectiveness of different preparations. Diagnosis, disease location, activity, side-effect profile, efficacy and cost all affect the choice of aminosalicylate. Available as oral or rectal preparations, aminosalicylates can be used in combination with steroids to induce and maintain remission in mild to moderate ulcerative colitis. Sulfasalazine is cheaper, but the newer aminosalicylates are generally used in practice. Mesalazine also reduces the risk of colorectal cancer by 75% (St Clair Jones, 2014).

The use of aminosalicylates in Crohn's disease is less well established. They should only be considered for the induction of remission in patients who decline or cannot tolerate glucocorticosteroids and/or for maintenance postoperatively (dose >2 g/day) if an immunosuppressant or biologic is unsuitable (NICE, 2012). Fig. 13.6 highlights the place in therapy of aminosalicylates in the management of ulcerative colitis.

Sulfasalazine consists of sulfapyridine diazotised to mesalazine. It is broken down by bacterial azoreductase in the colon to mesalazine and sulfapyridine. Sulfapyridine is absorbed in the colon, metabolised by hepatic acetylation or hydroxylation followed by glucuronidation and excreted in urine. Mesalazine is partly absorbed, metabolised by the liver and excreted via the kidneys as *n*-acetyl 5-ASA. However, the majority is acetylated as it passes through the intestinal mucosa. Sulfasalazine itself is poorly absorbed, and that which is absorbed is recycled back into the gut, via the bile, either unchanged or as the *n*-acetyl metabolite.

Elimination of sulfapyridine depends on the patient's acetylator phenotype. Those who inherit the 'slow' acetylator phenotype experience more side effects. The dissolution profile of the drug and the site of ulceration determine effectiveness (Fig. 13.8). The optimal dose of sulfasalazine to achieve and maintain remission is usually in the range of 2–4 g/day in 2–4 divided doses. Acute attacks require 4–8 g/day in divided doses until remission occurs, but at these doses, associated side effects are often observed.

About 30% of patients taking sulfasalazine experience adverse effects, which are either dose related and dependent on acetylator phenotype or idiosyncratic and not dose related. Dose-related side effects include nausea, vomiting, abdominal pain, diarrhoea, headache, metallic taste, haemolytic anaemia, reticulocytosis and methaemoglobinaemia. Side effects which are not dose related include rashes, aplastic anaemia, agranulocytosis,

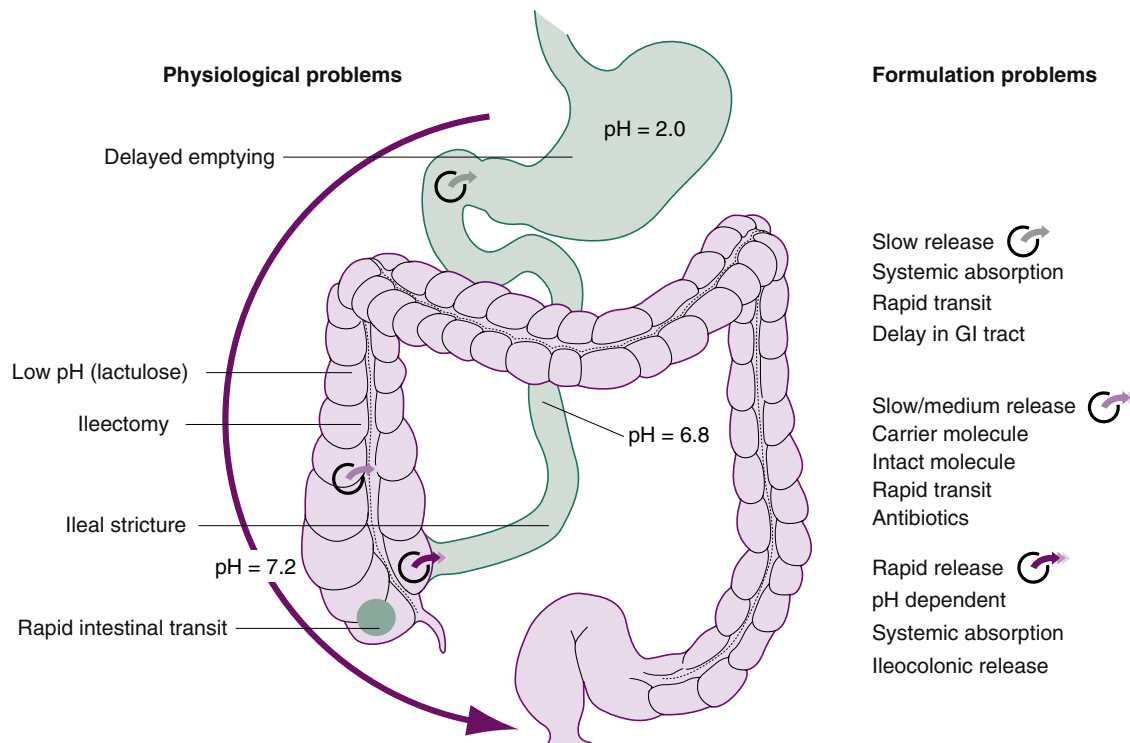

Fig. 13.8 Physiological and formulation problems encountered with mesalazine and delivery systems.

pancreatitis, hepatic and pulmonary dysfunction, renal impairment, peripheral neuropathy and oligospermia. In 3% of patients, acute intolerance may be seen. The most frequent manifestation is diarrhoea. Adverse effects usually occur during the first 2 weeks of therapy, the majority being related to plasma sulfapyridine levels. Sulfasalazine metabolites are responsible for the yellow colouration of bodily fluids and staining of soft contact lenses.

Sulfasalazine is now only used in favour of mesalazine in those patients who have enteropathy (colitis-associated arthropathy). Mesalazine is tolerated by 80% of patients who are intolerant of sulfasalazine. Many of the sulfonamide-related adverse effects of sulfasalazine are avoided by using one of the newer aminosalicylate formulations. However, mesalazine alone can still cause side effects, including blood disorders, pancreatitis, renal dysfunction and lupoid phenomenon. Patients should be counselled on how to recognise and report blood dyscrasias, and if they occur, treatment should be stopped. Olsalazine-induced diarrhoea may help patients with distal disease and proximal constipation, and in these cases, olsalazine is often the 5-ASA of choice.

Formulations of mesalazine. Mesalazine is unstable in acid medium and rapidly absorbed from the gastro-intestinal tract. To increase the stability and/or alter the site of release of active drug in oral formulations, 5-ASA is modified by different delivery systems:

- acrylic resin-coat that releases 5-ASA pH-dependently (Asacol, Salofalk, Octasa);
- ethyl cellulose mesalazine granules that release 5-ASA in a timely manner throughout the gastro-intestinal tract irrespective of pH (Pentasa);

- diazotisation of mesalazine to itself or inert carrier with release of drug in colon by splitting by bacterial enzymes (sulfasalazine, olsalazine, balsalazide);
- multimatrix (Mezavant XL).

Initial choice of preparation should take into account the dose frequency, cost, availability and patient preference. Table 13.5 compares the oral aminosalicylate preparations currently available.

Although once considered not interchangeable, the British National Formulary (BNF) now advises that patients prescribed oral mesalazine should be closely monitored if the preparation needs to be changed (e.g. because of a local formulary). Although there is no evidence to show that any one oral preparation of mesalazine is more effective than the other, delivery characteristics do vary, so patients who are switched to a different brand should be advised to report any changes in their symptoms.

High dose oral aminosalicylate (≥ 4 g/day) should be given for the induction of remission in mild-moderate ulcerative colitis with or without a rectal aminosalicylate and often in combination with a corticosteroid. For maintenance of remission in ulcerative colitis, doses of ≥ 2 g/day should be used.

For remission doses, NICE (2013) guidance recommends that a once-daily dosing regimen of aminosalicylate should be considered based on evidence that it can be more effective than multiple dosing and may even be superior. However, it may result in more side effects. It should be noted that not all oral aminosalicylates currently have a UK licence for once-daily dosing, and therefore the prescriber should follow relevant professional guidance and take full responsibility for the decision. Informed consent should be obtained and documented.

Table 13.5 Comparison of available oral aminosalicylate preparations for patients with inflammatory bowel disorder

Drug	Formulation	Optimal drug release pH	Site of drug release
Mesalazine			
Asacol MR	Tablets: 400 mg: Enteric coated with Eudragit S 800 mg: Enteric coated with layer of Eudragit S followed by Eudragit S+L	pH-dependent Delayed release (pH >7)	Terminal ileum and large bowel (colon and rectum)
Octasa MR	Tablets: Enteric coated with Eudragit S	pH >7	Terminal ileum and colon
Mezavant XL	Tablets: Film coated with methacrylate copolymers Type A, Type B	Gastroresistant coating with lipophilic and hydrophilic matrix (pH >7)	Terminal ileum and colon
Pentasa	Tablets and granules: Ethylcellulose-coated microgranules to allow slow, continuous release	Diffusion through semipermeable membrane (any enteral pH ^a)	Duodenum to rectum
Salofalk	Tablets: Enteric coated with Eudragit L Granules: Eudragit L and matrix granule structure (slow, continuous release)	pH-dependent Delayed release (pH >6) and matrix	Terminal ileum and colon
Azo-bonded preparations			
Salazopyrin (Sulfasalazine)	5-ASA + SA	Cleavage by intestinal bacteria azoreductase (pH >7)	Colon
Colazide (Balsalazide)	Prodrug		
Dipentum (Olsalazine)	Dimer		
^a Released at all gastro-intestinal tract pH conditions. 5-ASA, 5-Aminosalicylic acid; SA, sulfasalazine.			

Renal function should be monitored before starting an oral aminosalicylate, at 3 months of treatment and then annually during treatment (more frequently in renal impairment), Blood disorders can also occur, and patients should be advised to report any unexplained bruising, bleeding, purpura, sore throat, fever or malaise. The drug should be stopped if there is a suspicion of blood dyscrasias.

In the UK, all mesalazine preparations are licensed for ulcerative colitis; however, only Octasa MR and Asacol MR are licensed for Crohn's disease. Mesalazine has limited efficacy for the treatment of Crohn's disease and in general is not recommended. Mesalazine enemas (1 g), foam enemas (1 g per application) or suppositories (250 mg, 500 mg and 1 g) are effective alternatives for treating distal ulcerative colitis and proctitis. The optimum rectal dose is 1 g. Rectal administrations of 5-ASA formulations are significantly better than rectal corticosteroids in inducing remission in ulcerative colitis, but steroids are cheaper, although availability is now limited. In severe ulcerative colitis, oral and topical formulations should be combined to give prompt symptom relief. Topical and oral 5-ASA is better than either alone (NICE, 2013).

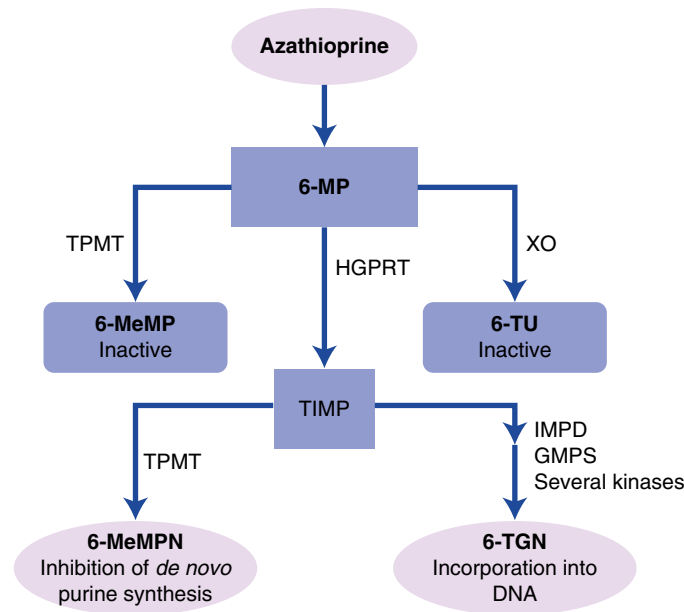

Immunosuppressants

Azathioprine, 6-mercaptopurine, methotrexate, ciclosporin and mycophenolate are immunosuppressants used in patients unresponsive to steroids and aminosalicylates or who relapse when

steroids are withdrawn. They are used to induce and maintain remission. They can take several weeks to work and require regular monitoring. They are often referred to as steroid-sparing agents or immunomodulators.

Thiopurines (azathioprine, mercaptopurine). The thiopurines remain the first-line immunomodulators used for the treatment of IBD. Azathioprine is metabolised to 6-mercaptopurine by the liver. Mercaptopurine is further metabolised to pharmacologically active 6-thioguanine nucleotides (TGN). Mercaptopurine is also metabolised by the enzyme thiopurine methyltransferase (TPMT), which produces methylmercaptopurine (MeMP), and xanthine oxidase (XO), which produces thiouric acid. Neither of these metabolites are pharmacologically active. Patients who have high levels of TPMT can produce high levels of MeMP, which can cause hepatotoxicity. High levels of TGN can cause dose-related adverse effects, such as myelosuppression. Fig. 13.9 shows the metabolic pathway of azathioprine. Competing pathways result in inactivation by TPMT or XO or incorporation of cytotoxic nucleotides into DNA.

TPMT activity should be assessed before initiating azathioprine or mercaptopurine to inform the initial starting dose and identify patients at increased risk of myelosuppression or liver dysfunction. TPMT measurements are not used in dose optimisation. In patients where the TPMT activity is deficient (very low or absent), azathioprine or mercaptopurine should not be used. Lower treatment doses (half recommended initiation doses) can be considered if TPMT activity is below normal but not deficient.

6-MP = mercaptopurine; TPMT = thiopurine methyltransferase; 6-MeMP = methylmercaptopurine; XO = xanthine oxidase; TIMP = thioisoinic acid; 6-TGN = thioguanine nucleotides; 6-MeMPN = methylmercaptopurine nucleotide; 6-TU = thiouric acid; GMPS = guanosine monophosphate synthetase; HGPRT = hypoxanthine-guanosine-phosphoribosyl-transferase; IMPD = inosine monophosphate dehydrogenase

Fig. 13.9 Metabolic pathway of azathioprine. (Adapted from Dervieux et al., 2001; McLeod and Siva, 2002.)

Box 13.2 Thiopurine methyltransferase levels

<10 mU/L	Deficient
20–67 mU/L	Low
68–150 mU/L	Normal
>150 mU/L	High

One in 300 people have no functional TPMT activity, and most patients who develop leucopenia will have a normal TPMT. TPMT levels are used for predicting early events rather than long-term control (see Box 13.2).

Both azathioprine and 6-mercaptopurine have steroid-sparing properties. Although the action in IBD is unclear, their active metabolites inhibit purine ribonucleotide synthesis, which may in turn inhibit lymphocyte function, primarily T cells.

Azathioprine and mercaptopurine are recommended for the induction and maintenance of remission in IBD, although they have a much slower onset of action than steroids in active disease. They should be considered in patients who:

- require two or more steroid courses in 1 year;
- continue to have chronic active disease when prednisolone is reduced below 15 mg/day or within 6 weeks of stopping;
- are intolerant of aminosalicylate therapy;
- are post-op for prophylaxis of complex Crohn's disease (fistulising/extensive disease);
- fail to maintain remission with 5-ASA in ulcerative colitis;
- have suffered a single episode of acute severe ulcerative colitis;

- require thiopurine to maintain remission in Crohn's disease if used to induce remission with steroids and/or have poor prognostic signs.

Oral maintenance doses for azathioprine are usually 2–2.5 mg/kg/day (typically 100–250 mg/day) and for mercaptopurine, 1–1.5 mg/kg/day (typically 50–150 mg/day). Doses are adjusted to patient response, tolerance, white blood cell and platelet counts and 6-thioguanine levels. Patients are usually prescribed a reducing dose of corticosteroid, in addition, to induce remission because mercaptopurine and azathioprine can take several weeks to show a therapeutic benefit.

Seventy percent of patients will tolerate azathioprine. Of the remaining 30%, a further 70% will tolerate mercaptopurine. The most common side effects occur within 2–3 weeks of starting treatment and rapidly stop on withdrawal. These include flu-like symptoms (myalgia, headache), nausea and diarrhoea. Nausea is reduced by taking the medicine with food. Although rare (<3%), leucopenia can develop suddenly and unpredictably. Hepatotoxicity and pancreatitis have also been reported in less than 5% of patients. Thioguanine has been used but is associated with a greater risk of hepatotoxicity.

There is ongoing debate as to how long thiopurines can safely be used for, particularly because the patient is likely to be young when treatment is initiated. One of the main concerns is the increased risk of developing lymphoproliferative disorders (lymphoma, non-melanoma skin cancers and cervical dysplasia) (Gomollon et al., 2016). This risk remains very small (<1%) after 10 years of use (Mowat et al., 2011). There is currently insufficient data to suggest that anti-tumour necrosis factor (anti-TNF) agents alone increase the risk of lymphoproliferative disorders

Table 13.6 Therapeutic drug monitoring of thiopurines and actions required

Metabolite level	Reason	Action
MeMP and TGN low/absent	Not adhering to treatment	Patient education
TGN and MeMP low/absent but adhering to treatment	Subtherapeutic dosing	Increase dose. Recheck levels after 4 weeks (when reach steady state).
TGN low, MeMP high	May be unresponsive to treatment and at risk of hepatotoxicity	Consider co-prescribing allopurinol, which, by inhibiting XO and possibly methylating pathways, results in higher ratio of thiopurine converted to TGN. In this case, the dose of azathioprine needs to be reduced to 25–50% of the standard dose to avoid excessive TGN levels.
TGN and MeMP high with patient not responding to treatment	Nonresponder to treatment	Stop thiopurine and consider alternative treatment.

The recommended range is 200–400 pmol/8x10⁸ red blood cells for TGN and <5700 pmol/8x10⁸ red blood cells for MeMP.
MeMP, methylmercaptopurine; TGN, thioguanine nucleotides; XO, xanthine oxidase.

or solid tumors. In contrast, their combination with thiopurines significantly increases the risk of lymphoproliferative disorders, and there have been rare cases of fatal hepatosplenic T-cell lymphoma reported. Cases have been predominantly young males (≤ 35 years) (NICE, 2012). Although the absolute risk of malignancy is low, the risks should always be balanced carefully against the substantial benefits associated with these treatments and discussed with the patient.

Therapeutic drug monitoring of thiopurine metabolites (TGN and MeMP) is increasingly used to assess adherence and dose optimisation and to allow patients who were previously considered intolerant of or not responding to thiopurines to remain on this treatment. The recommended therapeutic range is of TGN is 200–400 pmol/8 × 10⁸ red blood cells and <5700 pmol/8 × 10⁸ red blood cells for MeMP. Table 13.6 highlights how these results should be interpreted and action to take. Low white blood cell counts or abnormal LFTs may be caused by high TGN or MeMP levels, respectively.

Methotrexate. A low-dose regimen of methotrexate is effective in inducing and maintaining remission in patients with chronically active Crohn's disease. The evidence for use in ulcerative colitis is less convincing, although use is common in practice.

Patients receive once-weekly doses of methotrexate ranging from 15 to 25 mg on the same day each week. These can be given orally or by subcutaneous or intramuscular injection. Oral medication is more practical, although parenteral administration

may be more effective and better tolerated. Methotrexate is reserved for patients intolerant or unresponsive to thiopurines. Methotrexate can take between 6 weeks to 3 months to have a full effect.

Methotrexate metabolites inhibit dihydrofolate reductase, although this cytotoxic action does not explain the drug's anti-inflammatory effect. Inhibition of cytokine and eicosanoid synthesis and modification of adenosine levels probably contribute.

Adverse effects associated with methotrexate are essentially gastro-intestinal (nausea, vomiting, diarrhoea and stomatitis). These may also be reduced by prescribing weekly doses of folic acid 5 mg. Folic acid should not be taken on the same day as the methotrexate. Monitoring is undertaken because of the serious side effects of hepatotoxicity, bone marrow suppression and pneumonitis.

Methotrexate is teratogenic, and all male and female patients should be counselled about using contraception while taking the medication and also for 3 months after therapy is withdrawn. Guidance to improve the safety of methotrexate use and minimise the potential risk of overdose has been issued (National Patient Safety Agency [NPSA], 2007). Measures include the issue of patient handheld monitoring cards detailing dose and blood test results, comprehensive written and verbal medication information, dispensing one strength of tablet (2.5 mg) and ensuring in-patient medication charts clearly state once-weekly dosing and the number and strength of tablets routinely used. A memory aid commonly recommended to patients to remember dose frequency is to take methotrexate on Mondays and folic acid on Fridays. Tablets disperse in water, which may help adherence because there are typically large numbers of tablets per dose.

Calcineurin inhibitors (ciclosporin, tacrolimus). Ciclosporin is a calcineurin inhibitor that acts at an early stage on precursors of helper T cells by interfering with the release of interleukin-2. This inhibits the formation of the cytotoxic lymphocytes which cause tissue damage. Both controlled and uncontrolled studies suggest that ciclosporin is effective rescue therapy for severe ulcerative colitis failing to respond to intravenous steroids (Campbell et al., 2005). Its use in Crohn's disease is unproven.

Doses of 2–5 mg/kg/day in treating acute severe colitis have been shown to be effective. A dose of 2 mg/kg/day intravenously has been shown to be as effective as 4 mg/kg/day, and because of dose-related toxicity, 2 mg/kg/day should be used. Patient response to ciclosporin has varied, with adverse effects causing withdrawal of treatment in some cases. However, some patients have stopped concurrent steroid therapy and have remained in remission for some time.

When patients with severe colitis fail to show little or no improvement within 72 hours of starting parenteral steroids, or their symptoms worsen at any time despite corticosteroid treatment, then ciclosporin at an intravenous dose of 2 mg/kg/day/i.v. is indicated.

If patients respond to parenteral ciclosporin, they can subsequently be maintained on an oral dose (5 mg/kg in two divided doses) for 3–6 months. If patients have a low plasma magnesium (<0.5 mmol/L) or low cholesterol (<3 mmol/L), they are at an increased risk of ciclosporin-induced seizures when given intravenously. In these circumstances, treatment with

an oral ciclosporin preparation from the outset at a dose of 5 mg/kg/day in two divided doses (to account for variation in bioavailability), is preferred. Ciclosporin therapy is used for many patients but normally as a bridge to colectomy or starting maintenance treatment with azathioprine or mercaptopurine. When used to bridge to azathioprine maintenance therapy, it is estimated that 30–50% of patients with steroid-refractory ulcerative colitis remain in clinical remission at the end of 1 year (Turner et al., 2007b). Treatment with ciclosporin should not be longer than 3–6 months because significant toxicity precludes long-term use.

Infliximab is an alternative ‘rescue therapy’ for acute severe colitis (NICE, 2008) if ciclosporin is contraindicated or clinically inappropriate. The result of a multi-centre randomised controlled trial (CONSTRUCT) that compared the clinical and cost-effectiveness of infliximab and ciclosporin in the treatment of steroid-resistant acute severe colitis showed similar efficacy in prevention of short- and long-term colectomy rates (Duijvis et al., 2016). Forty percent of patients who receive ciclosporin develop minor side effects, such as tremor, paraesthesia, headache, gum hyperplasia, burning sensations of the hands and feet and hirsutism. Major complications include nephrotoxicity, neurotoxicity, hepatotoxicity and hypertension with low mortality reported. In severe proctitis, refractory to standard treatments, ciclosporin enemas have been used with some success at a dose of 250 mg at night for 1 month. No commercial preparation is available, which prohibits routine use in practice.

Tacrolimus is an alternative calcineurin inhibitor to ciclosporin that has shown some benefit in inducing remission in ulcerative colitis. It can be considered as a treatment option if there is an inadequate response to oral prednisolone after 2–4 weeks in mild to moderate ulcerative colitis (NICE, 2013) at a dose of 0.025 mg/kg twice daily. Tacrolimus has limited value in Crohn’s disease.

Tacrolimus is also associated with bone marrow suppression, hypertension and renal dysfunction. It may also induce diabetes.

The main concern with calcineurin inhibitors is opportunistic infection, such as *Pneumocystis carinii* pneumonia (PCP) and *Aspergillus fumigatus* pneumonia. Routine use of PCP prophylaxis may be considered, particularly if patients are on dual or triple immunosuppression.

Trough drug levels, taken before a dose, should be monitored for both ciclosporin and tacrolimus. For ciclosporin, the target level is within the range of 100–200 ng/mL; for tacrolimus, the target level is within the range of 5–15 ng/mL. Both drugs take 2–3 days to reach steady state. Grapefruit juice, macrolide antibiotics (mainly erythromycin and clarithromycin), ketoconazole, fluconazole, itraconazole, diltiazem, verapamil, oral contraceptives and protease inhibitors are just some of the drugs that increase both ciclosporin and tacrolimus levels and can cause toxicity. Both ciclosporin and tacrolimus should be prescribed by brand because of variations in absorption and subsequent effects on efficacy and toxicity.

Mycophenolate. Mycophenolate (MMF) has shown to be of some benefit in the management of IBD in patients intolerant to thiopurines. It appears to be safe, well tolerated and efficacious for both short- and long-term therapy, without the

need for dose escalation. Further evaluation of mycophenolate comparing it to conventional immunosuppressants is required (Gomollon et al., 2016).

Monitoring of aminosalicylates and immunosuppressants. It is essential that patients who are receiving aminosalicylates and immunomodulators have regular blood monitoring to ensure they avoid toxicity associated with these drugs as a result of bone marrow suppression and hepatotoxicity. The effects of these drugs should be monitored as advised. Documented local safety monitoring policies and procedures (including audit) for people receiving drugs that need monitoring is strongly recommended. Shared care policies are developed where care of a patient is the joint responsibility of both secondary and primary care doctors. These policies should clearly highlight the responsibilities of primary and secondary care healthcare staff and the patient with ulcerative colitis or Crohn’s disease or the patient’s parent/carer as appropriate. A member of the staff within the multidisciplinary team should be nominated to act on abnormal results and communicate with primary care or secondary care doctors and patients with ulcerative colitis and/or their parents or carers, as appropriate.

Blood tests should include full blood counts and LFTs, including plasma bilirubin and alkaline phosphatase. These should be undertaken weekly for the first month and then every 2 to 3 months unless there is a dose change, when bloods should be repeated more frequently. Although often advised, there is no evidence that more frequent monitoring is more effective. Patients should be taught to recognise the signs of bone marrow suppression and liver toxicity (e.g. jaundice) and educated about the need for earlier blood tests and the increased risk of infection because of immunosuppression. It is recommended that all patients initiated or maintained on immunosuppressants are provided with a record card detailing current dose and blood test results. Guidance on appropriate action following abnormal blood results is provided in [Box 13.3](#).

All patients taking immunomodulators should be vaccinated against seasonal influenza and pneumococcal pneumonia. Patients should be advised to avoid live vaccines such as polio and yellow fever while taking immunosuppressants, including corticosteroids. Sunscreens and protective covering should be encouraged to reduce sunlight exposure to patients taking immunosuppressants to reduce the risk of skin cancers.

Biologic agents

Monoclonal antibodies are a significant treatment development in recent years for IBD. They are used to induce and maintain remission in severe disease. If effective, they can reduce corticosteroid requirements, help to drain fistulae, achieve mucosal healing and reduce the need for major abdominal surgery or hospitalisation. The main licensed monoclonal antibodies currently used are anti-tumour necrosis factor α (anti-TNF- α) antagonists (infliximab, adalimumab, golimumab), the $\alpha 4\beta 7$ integrin antagonist (vedolizumab) and the IL-12, IL-23 antagonist (utekinumab).

Biologics should only be started by doctors with experience in their use in IBD, and their clinical benefit should be reviewed regularly. They are generally indicated for patients who have

Box 13.3 Guidance on dealing with abnormal blood results for patients on immunosuppressant therapy

Baseline U & Es, LFTs and FBC should be carried out prior to initiation of therapy. These should be repeated weekly for 4 weeks then every 2–3 months. If there is a dose change, blood should be rechecked after 2 weeks.

Methotrexate should be withheld and the relevant expert advice obtained if any of the following occur:

WBC	$<3.5 \times 10^9/L$
Neutrophils	$<2 \times 10^9/L$
Platelets	$<150 \times 10^9/L$
AST/ALT	$>3 \times$ normal range

- Unexplained respiratory symptoms, e.g. dyspnoea, dry cough, especially if accompanied by fever and sweats
- Renal impairment
- Mouth or throat ulceration/rash/unexplained bleeding/fever/alopecia/recurrent sore throats, infections, fever or chills/nausea/vomiting/diarrhoea

Azathioprine or **mercaptopurine** should be withheld and the relevant expert advice obtained if any of the following occur:

WBC	$<3.5 \times 10^9/L$
Neutrophils	$<2 \times 10^9/L$
Platelets	$<150 \times 10^9/L$
AST/ALT	$>3 \times$ normal range

- Significant reduction in renal function
- Mouth or throat ulceration/rash/unexplained bleeding/fever/upper abdominal or back pain/alopecia/recurrent sore throats, infections, fever or chills/nausea/vomiting/diarrhoea
- Nausea may be relieved by taking the dose with/after food or in divided doses

Ciclosporin should be withheld and the relevant expert advice obtained if any of the following occur:

- High blood levels (will require dose adjustment)
- Significant reduction in renal function
- Uncontrolled hypertension

Drug blood levels should be done at similar intervals to FBC. A 12-h trough level should be taken (i.e. before a dose). Target level within the range of 100–200 ng/mL. It takes 2–3 days to reach steady state after dose change.

ALT, Alanine transaminase; AST, aspartate transaminase; FBC, full blood count; LFTs, liver function tests; U & Es, urea and electrolytes; WBC, white blood cell.

failed, are intolerant or have contraindications to conventional therapy including corticosteroids and immunomodulators.

Study design and patient populations are sufficiently different between studies of different biological agents used in IBD. Therefore, direct comparisons of efficacy should be viewed with caution.

In Crohn's disease, those patients with a high disease activity and features indicating a poor prognosis may derive greater benefit from earlier use – for example, patients diagnosed younger than 40 years old and patients with stricturing disease, steroid dependency, perianal disease, greater than 5 kg weight loss and complex fistulae (Gomollon et al., 2016).

Not all patients will require biological therapy, which is expensive. Currently, only infliximab is commercially available as a biosimilar, with a biosimilar of adalimumab anticipated in 2018.

The use of biosimilars has made a significant impact on the financial costs of treating IBD with these agents; costs are now up to 40% cheaper than the originator biologic. The licence of the biosimilar was based on extrapolated data from a rheumatology population. However, studies in the IBD population have demonstrated comparable efficacy and safety in patients who were switched to an infliximab biosimilar compared to naïve anti-TNF- α users and also patients who had been previously exposed to one or more biologics (Fiorino et al., 2016). Table 13.7 summarises the biological agents currently used in IBD. The choice should take into account drug licensing, funding, access and cost.

There is currently no specific guidance regarding how long biologics should be continued. Many patients in clinical remission for greater than 1 year, with a normal CRP and complete mucosal healing on endoscopy, will remain in remission during the following year after stopping treatment with an anti-TNF agent. All biologics should be reviewed regularly to assess appropriate use. If patients clinically respond to induction doses, maintenance should be given until treatment failure (including the need for surgery) or until 12 months after initiation of treatment, whichever is shorter. Patients should then have their disease reassessed and continue treatment if there is clear evidence of ongoing active disease and treatment is still clinically appropriate. Treatment can be restarted if patients subsequently relapse. The STORI trial (Louis et al., 2012) identified that infliximab withdrawal was associated with a high risk of relapse. Patients in the study were on combination therapy with infliximab and thiopurine. Treatment was stopped after 6 months of remission (clinical and endoscopic). The average relapse rate was 58% at 1 year, which suggested that if well tolerated, treatment should not be interrupted. Patients with two or fewer identified risk factors had a relapse risk of only 14–16%. Risk factors were identified as male sex, no previous surgical resection, WCC $>6 \times 10^9/L$, haemoglobin <145 g/L, CRP >5 mg/L, faecal calprotectin >300 micrograms/g. The study also found that restarting treatment with infliximab following symptoms relapse was successful in 98% of patients if restarted within 6 months of stopping treatment.

Monoclonal antibodies are contraindicated in patients with tuberculosis (TB); therefore, all patients should have a chest X-ray prior to administration to exclude active or latent TB. Other contraindications include moderate to severe cardiac failure, history of malignancy (excluding non-melanoma skin cancer), sepsis (including pelvic or perianal) and optic neuritis. Intestinal stricturing is a relative contraindication because obstruction may be exacerbated through rapid healing at the stricture site. Chronic hepatitis B/C carriers, primary failure or absence of inflammatory activity (normal CRP) are also contraindications.

Infliximab and vedolizumab are given via an intravenous infusion, whereas adalimumab, golimumab, certolizumab and ustekinumab can be given subcutaneously, enabling patients to self-administer at home. Infliximab must be administered in a setting where there are adequate resuscitation facilities available and patients can be closely monitored because of the potential risk of an acute infusion-related reaction, including anaphylactic shock, and delayed hypersensitivity reactions. As yet, there have been no reported anaphylactic or severe infusion reactions reported for vedolizumab.

Infection is the main concern with all anti-TNF agents. Patients self-administering adalimumab, golimumab or certolizumab at

Table 13.7 Summary of biological agents used in inflammatory bowel disease (adults only)

Agent	Mode of action	Indication	Criteria	Licensed in UK	Standard dose	UK National funding/ access decisions NICE TA
Infliximab	Anti-TNF- α antagonist	Crohn's disease	Moderately to severely active disease in patients who have not responded despite a full and adequate course of therapy with a corticosteroid and/or an immunosuppressant or who are intolerant to or have medical contraindications for such therapies	Yes	5 mg/kg at weeks 0, 2 and 6; if responds, maintenance 5 mg/kg every 8 weeks	TA187 (NICE, 2010) Infliximab and adalimumab for the treatment of Crohn's disease
			Fistulising active disease, in patients who have not responded despite a full and adequate course of therapy with conventional treatment (including antibiotics, drainage and immunosuppressive therapy)	Yes	5 mg/kg at weeks 0, 2 and 6, then refer to product literature	TA187 (NICE, 2010) Infliximab and adalimumab for the treatment of Crohn's disease
			Ulcerative colitis	Induction and maintenance of remission of moderate to severe active disease in patients who have had an inadequate response to conventional therapy including corticosteroids and or who are intolerant to or have medical contraindications for such therapies	Yes	5 mg/kg at weeks 0, 2 and 6; if responds, maintenance 5 mg/kg every 8 weeks
Adalimumab	Anti-TNF- α antagonist	Crohn's disease	Option for treatment of acute exacerbation of severe ulcerative colitis when treatment with ciclosporin is contraindicated or inappropriate	Yes	5 mg/kg at weeks 0, 2 and 6; if responds maintenance 5 mg/kg every 8 weeks	TA163 (NICE, 2008) Infliximab for acute exacerbation of ulcerative colitis
			Moderately to severely active disease unresponsive to full and adequate course of therapy with a corticosteroid and/or an immunosuppressant or who are intolerant to or have medical contraindications for such therapies	Yes	160 mg subcutaneously on week 1, 80 mg week 2 then 40 mg subcutaneously on alternate weeks; can increase to weekly if loss of response. Review treatment if no response within 12 weeks of initial dose.	TA187 (NICE, 2010) Infliximab and adalimumab for the treatment of Crohn's disease
			Ulcerative colitis	Moderately to severely active disease unresponsive to full and adequate course of therapy with a corticosteroid and/or an immunosuppressant or who are intolerant to or have medical contraindications for such therapies	Yes	160 mg subcutaneously on week 1, 80 mg week 2 then 40 mg subcutaneously on alternate weeks
Golimumab	Anti-TNF- α antagonist	Ulcerative colitis	Moderate to severely active disease who have not responded adequately to conventional therapy or who are intolerant to it	Yes	200 mg week 0, 100 mg week 2, then 50 mg every 4 weeks (100 mg if >90 kg)	TA329 (NICE, 2015b) Infliximab, adalimumab and golimumab for treating moderately to severely active ulcerative colitis after the failure of conventional therapy

Table 13.7 Summary of biological agents used in inflammatory bowel disease (adults only)—cont'd

Agent	Mode of action	Indication	Criteria	Licensed in UK	Standard dose	UK National funding/access decisions NICE TA
Certolizumab pegol	Anti-TNF- α antagonist	Crohn's disease	Moderate to severely active disease when patients have lost response to or are intolerant of alternative licensed anti-TNF antagonist	No	400 mg subcutaneously at weeks 0, 2, 4 and then 400 mg every 4 weeks	No NICE TA undertaken Individual funding request required
Vedolizumab	α 4 β 7 antagonist	Crohn's disease	Moderately to severely active disease who have had an inadequate response with, lost response to or were intolerant to either conventional therapy or a TNF- α antagonist	Yes	300 mg intravenously at weeks 0, 2, 6 and then maintenance every 8 weeks. Review treatment if no response after 10 weeks. Can increase to every 4 weeks if loss of response.	TA352 (NICE, 2015c) Vedolizumab for treating moderately to severely active Crohn's disease after prior therapy
Vedolizumab	α 4 β 7 antagonist	Ulcerative colitis	Moderately to severely active disease who have had an inadequate response with, lost response to, or were intolerant to either conventional therapy or a TNF- α antagonist	Yes	300 mg at weeks 0, 2, 6 and then maintenance every 8 weeks. Review treatment if no response after 10 weeks. Can increase to every 4 weeks if loss of response.	TA342 (NICE, 2015a) Vedolizumab for treating moderately to severely active ulcerative colitis
Ustekinumab	IL-12, IL-23 antagonist	Crohn's disease	Moderately to severely active Crohn's disease who have had an inadequate response with, lost response to or were intolerant to either conventional therapy or a TNF- α antagonist or have medical contraindications to such therapies	Yes	Intravenous induction treatment (dose depends on body weight and is approximately 6 mg/kg). Maintenance subcutaneous treatment at week 8 (90 mg), then every 12 weeks	TA456 (NICE, 2017) Ustekinumab for moderately to severely active Crohn's disease after previous treatment

6-MP, 6-Mercaptopurine; AZA, azathioprine; IL, interleukin; TA, technology appraisal; TNF, tumour necrosis factor.

home should be educated on how to recognise signs of infection, for example, fever, productive cough, toothache, stinging on passing urine or if neurological symptoms develop and therefore delay their dose.

Anti-TNF- α antagonists (infliximab, adalimumab, golimumab, certolizumab) are monoclonal antibodies which inhibit the functional activity of the proinflammatory cytokine TNF- α , which damages cells lining the gut, causing pain, cramping and diarrhoea. Colonic biopsies post-treatment with these agents show a substantial reduction in TNF- α and a reduction in the commonly elevated plasma inflammatory marker CRP.

Around 40% of patients with Crohn's disease do not respond to treatment with anti-TNF agents, 30% to 50% achieve complete remission after 6 months and 30% of patients maintain the response for 12 months with continual treatment (Mowat et al., 2011).

Infliximab. Infliximab is a chimeric human murine monoclonal antibody licensed for treating patients who have moderate to severely active Crohn's disease (with or without fistulae) or ulcerative colitis, who are unresponsive/intolerant or who have contraindications to conventional therapy such as corticosteroids and/or immunosuppressants or antibiotics. NICE (2010) defines

appropriate use of infliximab in Crohn's disease as a CDAI score of 300 or more or a Harvey–Bradshaw score of 8 or 9 or above. For ulcerative colitis, moderate disease is defined as more than 4 daily bowel movements but the patient is not systemically ill; and severe ulcerative colitis as more than 6 bowel movements daily and the patient is also systemically unwell (with tachycardia, fever, anaemia or a raised ESR) (NICE, 2015b).

Infliximab is administered by intravenous infusion at a standard dose of 5 mg/kg, which in practice is often rounded up or down to the nearest 100 mg vial. The induction dosing is at weeks 0 and 2 and if a clinical response is seen, and then a maintenance dose of 5 mg/kg every 8 weeks should be given. Fixed dosing is superior to intermittent dosing because of the reduced risk of immunogenicity (NICE, 2010). The effectiveness of infliximab for maintenance of Crohn's disease was demonstrated in the ACCENT 1 study (Hanauer et al., 2002) and, the ACCENT II for fistulising disease (Sands et al., 2004) and confirmed in the SONIC study (Colombel et al., 2010). The effectiveness of infliximab in maintaining clinical remission and mucosal healing in ulcerative colitis was observed in ACT 1 and 2 studies (Gomollon et al., 2016).

In some patients, infliximab has been associated with either infusion (during or shortly after infusion) or delayed hypersensitivity reactions. It may also affect the normal body immune responses in a significant number of patients. Anaphylactic reactions have been reported. All doses should be preceded with intravenous corticosteroid (hydrocortisone 100 mg) unless the patient has been taking an immunosuppressant for more than 3 months, to reduce the risk of a hypersensitivity reaction. Other side effects include headache, dizziness, nausea, rash, raised LFTs, abdominal pain and fatigue.

Adalimumab. Adalimumab is a fully humanised anti-TNF monoclonal antibody which is licensed for the treatment of moderate to severely active Crohn's disease and ulcerative colitis where patients are refractory or intolerant to corticosteroids and/or conventional immunomodulators. It may also be used in those patients who have primary or secondary nonresponse to infliximab or developed a hypersensitivity reaction. Because adalimumab is fully humanised, it is less immunogenic than infliximab. It also has the advantage of being given as a subcutaneous injection, which enables patients to self-administer at home, therefore reducing nursing time and hospital bed occupancy. This also lends itself to being supplied by home delivery services. The licensed dose is an initial induction of 80 mg followed by 40 mg at week 2 and then 40 mg on alternate weeks thereafter as maintenance. An accelerated dose of 160 mg followed by 80 mg and then 40 mg on alternate weeks maintenance is more commonly used in practice, particularly in those patients who have previously been on infliximab. The maintenance dose can be increased to 40 mg weekly if a diminished or suboptimal response is seen. Treatment should be stopped if no response is seen within 12 weeks of the initial dose in Crohn's disease or within 8 weeks in ulcerative colitis.

Adalimumab effectiveness in maintaining clinical remission in Crohn's disease was proven in the CHARM study (Colombel et al., 2007). The ULTRA 2 study supported the benefit versus placebo for maintaining remission in ulcerative colitis (Sandborn et al., 2012).

Certolizumab. Certolizumab is a PEGylated monoclonal antibody fragment TNF- α antibody. It was given a negative opinion by the European Medicines Agency Committee for Medicinal Products for Human use in IBD and is not approved by NICE. It is therefore rarely used and only in difficult cases where a TNF antagonist may be justified but other drugs within the class have exhibited secondary loss of response or are not tolerated. It is administered by subcutaneous injection.

Golimumab. Golimumab is only licensed for ulcerative colitis. It is administered by subcutaneous injection. Efficacy was demonstrated in the PUSUIT studies (Sandborn et al., 2014). The standard dosing regimen is 200 mg at initial induction, 100 mg at week 2, then 50 mg every 4 weeks (100 mg if >90 kg); treatment should be reviewed if no response after 4 doses.

Vedolizumab. Vedolizumab is a humanised monoclonal antibody and is a highly gut-selective immunosuppressive biologic. It works by exclusively binding to $\alpha 4\beta 7$ integrin, which is a protein preferentially expressed on a subset of lymphocytes. These lymphocytes migrate to the gastro-intestinal tract and cause inflammation characteristic of IBD. Vedolizumab binds to the $\alpha 4\beta 7$ integrin and subsequently inhibits the ability of the lymphocytes

to interact with gut endothelial cells (via the mucosal address in cell adhesion molecule-1 [MAdCAM-1]) and thus inhibits their ability to cross the endothelium and cause inflammation.

Clinical studies suggest it is more effective in ulcerative colitis than Crohn's disease. Efficacy in achieving significant rates of clinical remission compared to placebo was demonstrated in the GEMINI 1 and II studies (Feagan et al., 2013; Sandborn et al., 2013).

Vedolizumab can take up to 10 weeks to show clinical benefit. This relatively slow onset of action makes it inappropriate for acute severe colitis. If no therapeutic benefit is observed by week 10, treatment should be stopped. Longer-term remission data appear to be more favourable compared to anti-TNF- α antagonists. The standard dosing regimen is 300 mg at initiation, weeks 2 and 6 and then every 8 weeks. Vedolizumab is administered by intravenous infusion over 30 minutes. Current advice states it should only be used during pregnancy if the benefits clearly outweigh any potential risk to both the mother and foetus.

The gut-specific mode of action appears to result in minimal systemic immunosuppressive effects when compared with anti-TNF- α antagonists. The most common reported side effects are nasopharyngitis, headache and arthralgia. Malignancy has been reported in less than 1% of cases (colon cancer and melanoma). This safety profile suggests vedolizumab can be prescribed long-term to young and elderly patients (Bryant et al., 2015).

Ustekinumab. Ustekinumab is a human monoclonal antibody that targets the p40 subunit of the interleukins (IL)-12 and IL-23, thereby preventing their binding to receptors of T-cells and natural killer cells. It was licensed in early 2017 for patients with moderately to severely active Crohn's disease who have had an inadequate response with, lost response to, or are intolerant of either conventional therapy or a TNF- α antagonist or who have medical contraindications to such therapies. Maintenance dosing is administered subcutaneously every 8–12 weeks. Clinical efficacy has been demonstrated in the UNITI-1, UNITI-2 and IM-UNITI studies (Feagan et al., 2016).

Other biologics. There are several trials in IBD looking at other biologics which target different molecules in the inflammatory process to modulate the immune response. These include Janus kinase (JAK) inhibitors.

Combination of biologics with immunomodulators. Concomitant immunosuppressant therapy (e.g. thiopurines, methotrexate) with anti-TNF agents is not associated with better clinical efficacy in patients who have already failed these drugs. However, in the SONIC study, a combination of infliximab plus azathioprine was shown to be more efficacious in achieving and maintaining steroid-free remission than infliximab monotherapy or azathioprine monotherapy in patients naïve to both therapies (Colombel et al., 2010). The rate of infusion-related infliximab reactions was also less with combination treatment, with no significant difference in the rate of serious infection. Immunomodulators are thought to reduce the risk of anti-drug antibody formation and potentiate efficacy. In practice, the results of this study have been extrapolated to other biologics and immunomodulator combinations. At present there is no clear evidence that this is required for vedolizumab, but theoretically, anti-drug antibodies could lead to loss of response. This is counterbalanced by one of the benefits of vedolizumab monotherapy, which

is the avoidance of systemic immunosuppression. Until further evidence is available, it is usually recommended by most gastroenterologists that immunomodulators do not need to be routinely started alongside vedolizumab. However, if a patient is already on and tolerating an immunomodulator, it is reasonable to continue this pending further information.

A recent review of the clinical management of Crohn's disease by NICE states that there is uncertainty regarding the comparative effectiveness and long-term adverse effects of immunosuppressants when combined with biologics (infliximab and adalimumab), and the use of monotherapy or combination therapy should be discussed with patients when initiating treatment with an anti-TNF antagonist and regularly throughout treatment (NICE, 2016).

Medication optimisation of biologics. Current strategies to overcome a loss of response or concerns regarding adherence of biologics include increasing the dose, decreasing the interval between administrations or switching to a different agent (same class or one with a different mode of action). Optimising the use of a concurrent immunomodulator may also be indicated.

The ability to measure drug levels (trough) and anti-drug antibodies for infliximab and adalimumab provides an alternative strategy to optimise the use of these treatment options. Assays to measure levels of other biologics are under development. The benefit of therapeutic drug monitoring was highlighted in the TAXIT trial, which investigated the value of optimising infliximab by measuring trough levels and anti-drug antibodies in patients in clinical remission (Vande Castele et al., 2012).

The main indications for requesting trough anti-TNF and antibody levels in IBD are if there is a loss of response, annual review of stable disease and following dose alteration. Assessment of levels and anti-drug antibodies serum concentrations after induction may also be a predictive tool for estimating the long-term clinical response to biological therapy.

The timing of testing is important. Levels must be taken just prior to a dose (up to maximum of 24–48 hours). The results must be considered in context with symptoms, disease activity (e.g. C-reactive protein [CRP], full blood count [FBC], ferritin, Harvey–Bradshaw index), patient history (e.g. previous surgery, disease severity, current life events) and endoscopic, histological and radiological findings before dose adjustments are made. NICE has developed guidance on the use of therapeutic drug monitoring of anti-TNF inhibitors in Crohn's disease (NICE, 2016).

Antibiotics

The gut microbiota plays a role in promoting and maintaining inflammation in inflammatory bowel diseases, hence the rationale for the use of antibiotics in the treatment of those disorders. Antibiotics, however, may induce undesirable side effects and resistance, especially during long-term therapy. Most of the evidence for benefit is in Crohn's disease associated with perianal disease, sepsis associated with abscesses, fistulae, perforation and bacterial overgrowth in the small bowel. There is little benefit demonstrated for their use in ulcerative colitis, except for in pouchitis.

Different antibiotics, including ciprofloxacin, metronidazole, and the combination of both rifaximin and anti-tuberculous regimens, have been evaluated in clinical trials for the treatment of inflammatory bowel disease, although more studies are needed to define their exact role. Rifaximin is virtually unabsorbed after oral administration and is devoid of systemic side effects. Rifaximin has provided promising results in inducing remission of Crohn's disease and ulcerative colitis. It may also have a role in maintaining remission of ulcerative colitis and pouchitis. The potential therapeutic activity of rifaximin in IBD requires further research.

Pseudomembranous colitis caused by *C. difficile* usually occurs after prolonged or multiple antibiotics. This can be distinguished from other causes of colitis by biopsy and stool culture. If it is unclear whether a patient has pseudomembranous or acute colitis, empirical treatment with metronidazole or vancomycin and steroids is advised. A colonoscopy can be performed once symptoms resolve.

Cytomegalovirus (CMV) affects more than 40% of the population. When it occurs, CMV colitis usually affects IBD patients who are significantly immunosuppressed. It occurs more frequently with ulcerative colitis than with Crohn's disease. The most common clinical presentation mimics a flare or relapse, with bloody diarrhoea, fever and abdominal pain. Poor response to corticosteroids should prompt investigation of CMV as a cause for symptoms. There is a high mortality associated with CMV (up to 30%), and therefore prompt treatment with ganciclovir or valganciclovir is indicated (Filizzola et al., 2004).

Other treatments

Thalidomide. Thalidomide has been used, under specialist supervision, in refractory cases of Crohn's disease. Thalidomide acts as a TNF- α inhibitor and probably stabilises lysosomal membranes. At therapeutic doses, it also inhibits the formation of superoxide and hydroxyl radicals, both potent oxidants capable of causing tissue damage. Daily doses in the range of 50–400 mg have proved beneficial when used for periods of 1 week to several months. Side effects during treatment include sedation, dry skin and reduced libido. Thalidomide is teratogenic and should never be used in women of childbearing age.

Antidiarrhoeals. Codeine and loperamide should be used with caution to treat diarrhoea and abdominal cramping in IBD. Their use may mask inflammation, infection, obstruction or colonic dilation, thereby delaying correct diagnosis.

Bile salt sequestrants. Diarrhoea resulting from the loss of bile salt absorption such as bowel resection of terminal ileal disease, may improve with a bile sequestrant such as cholestyramine. Doses of up to 4 g three times a day inhibit the secretion of water and electrolytes stimulated by bile acids. Colestipol and colestevlam are alternatives. Patients may undergo a ⁷⁵Se tauroselcholic acid (SeHCAT) scan to formally diagnose bile salt malabsorption.

Fish oils (omega-3 fatty acids). Fish liver oils containing eicosapentaenoic and docosahexaenoic acids have been used with some success in the treatment of both ulcerative colitis and Crohn's disease. These products cause unpleasant regurgitation, which renders them unpalatable in long-term use. Enteric-coated

preparations have reduced this problem. It is thought that fish oils work by diverting fatty acid metabolism from leukotriene B4 to the formation of the less inflammatory leukotriene B5.

Miscellaneous treatments. There are many limited trials, studies and case series in the literature evaluating other therapies for ulcerative colitis and Crohn's disease. These include sodium cromoglicate, bismuth and arsenic salts, sucralfate, nicotine, oxygen-derived free radical scavengers, somatostatin analogues, lidocaine, chloroquine, D-penicillamine, carbomers, antituberculous agents, heparin, aloe vera and worm therapy (helminths). In general, these treatments are not recommended, although the variety illustrates the limitations of current therapy. When a patient is not responding to conventional agents, consideration should be given to referral to a specialist centre for a review of current therapy and a plan for future management. Complementary treatments, for example, acupuncture and aromatherapy, may have a role in improving quality of life, but if used, this use should be concomitant with standard medical and surgical care.

Leukapheresis has been shown to have some benefit in patients with IBD. It involves removal of leucocytes from the blood, either through an adsorptive system or by centrifugation. In each system, venous blood is removed in a continuous flow, anticoagulated, processed to deplete the leucocytes and returned to the circulation (NICE, 2005).

There is some evidence that faecal microbiota transplantation (FMT) may have a therapeutic role in IBD (Lopez and Grinspan, 2016). FMT is the administration of a solution of faecal matter from a donor into the intestinal tract of a recipient to directly change the recipient's gut microbial composition and confer a health benefit. Faecal microbiota transplantation has the potential to be an effective and safe treatment for IBD, although well-designed randomised controlled trials are required in this area (Anderson et al., 2012). FMT has been used to successfully treat recurrent *C. difficile* infection (NICE, 2014).

Autologous hematopoietic stem cell transplantation has been used in a small number of patients with severe refractory Crohn's disease, with encouraging results (Gomollen et al., 2016). Further studies are required to define its place in therapy.

VSL#3, a probiotic, has efficacy in the maintenance treatment of pouchitis, although real-world remission rates, palatability, availability and cost all limit its use. Another probiotic, Mutaflor (*Escherichia coli* Nissle), is as effective as 5-ASA in the maintenance of ulcerative colitis and is utilised in occasional cases. Prebiotics stimulate the growth of specific, beneficial microorganisms in the colon, whilst symbiotics are a combination of both prebiotics and probiotics.

Surgical treatment

Of Crohn's disease patients, 50–80% will require surgery within 5–10 years of diagnosis. In contrast, 20–30% of ulcerative colitis patients will usually undergo colectomy over long-term follow-up (20 years).

In ulcerative colitis, proctocolectomy is curative. Most patients elect to subsequently have an ileoanal pouch formed, although this is a quality-of-life decision, and some decide to continue with a permanent ileostomy. Up to 30% of patients will ultimately require surgical intervention. In those who

undergo ileal pouch surgery, half will suffer from pouchitis, in which antibiotics are commonly required to treat and prevent symptoms.

All patients admitted to hospital with acute severe colitis should be assessed daily for the likelihood of requiring surgery. Acute severe colitis is typically defined using the Truelove and Witts's criteria. These are met if the patient is passing 6 or more bloody stools in 24 hours plus has at least one of the following: a tachycardia (pulse >90 bpm), a fever (>37.8 °C), raised ESR >30 mm/h (CRP often used as a surrogate), and/or anaemia (Hb <10.5g/dL). The severity of the colitis is related to the additional number of Truelove and Witts's criteria met, with other markers including endoscopic severity (as defined by the ulcerative colitis endoscopic index of severity), a low albumin and adverse features on an abdominal X-ray (colonic dilatation, mucosal oedema, mucosal islands). The need for rescue therapy (failure of i.v. steroids) is usually determined by stool frequency of >8 on day 3 or a CRP >45 mg/L on day 3 of steroid treatment. Ciclosporin or infliximab can be used as rescue therapy (NICE, 2013).

Curative surgery is not possible in Crohn's disease because recurrence is normal. Complications (stenosis, abscess, fistula) in the course of their illness result in about 70% of patients with Crohn's disease requiring at least one surgical procedure. Surgical techniques vary and include resection and anastomosis, and strictureplasty. The choice of surgical procedure will depend on type and extent of disease, presence of complications and previous response to medical treatment. If a significant length of gut is removed, this can result in short gut syndrome, which may require long-term parenteral nutrition and medication to control a high-output stoma.

Control of a high-output stoma either because of short gut or following colectomy should be carefully managed to prevent dehydration and metabolic disturbance, for example, hyponatraemia and hypomagnesaemia. Drinking more non-isotonic solutions can make the situation worse because this flushes the contents of the small intestine through and exacerbates dehydration. Food and drink can promote secretion and increase volume. The causes of high-output stomas need to be considered and may include high lactose intake, partial obstruction, intraabdominal sepsis, gastric hypersecretion, inappropriate diet, laxatives and diuretics. Treatment options should include a high-dose proton pump inhibitor (PPI) to reduce gastric acid hypersecretion and codeine phosphate (180–240 mg/day) and/or loperamide (doses up to 100 mg/day are common) to reduce gut motility. In the absence of a colon, a dose of loperamide that exceeds 16 mg/day can be used without adverse effect. Octreotide has been used as an alternative to the antimotility drugs but would appear to offer limited benefit and is best reserved for when other measures have been tried. Intake of isotonic fluids with a sodium concentration greater than 90 mmol/L, to allow the jejunum to absorb water, is also indicated. Care should be taken with medication that could be affected by rapid transit through the gastro-intestinal tract, leading to reduced or erratic absorption (e.g. modified-release preparations) or medication that could alter fluid and electrolytes or be affected by changes caused by dehydration (e.g. digoxin).

Prophylactic treatment should be considered to maintain remission after surgery for Crohn's disease. The choice of therapy will depend on the presence of adverse prognostic factors for disease

recurrence, the most reliable of which are active smoking and perforating disease. Smoking cessation in patients who smoke significantly reduces postoperative relapse (Gionchetti et al., 2016). Other factors such as disease location, previous response to therapy, and disease recurrence after previous operations should be considered. The choice of postoperative therapy is currently as for standard maintenance (immunomodulators and/or anti-TNF therapy). The role of vedolizumab has yet to be established. Whatever strategy is initially used, it is now good practice to reassess disease activity at colonoscopy with or without small bowel imaging at 6–12 months postoperatively and adjust management accordingly. Because ulcerative colitis is confined to the colon, prophylactic treatment in ulcerative colitis is unnecessary following colectomy.

Patient care

The impact of a diagnosis of IBD should not be underestimated. In general, most patients are diagnosed when they are relatively young, and the disease can have a significant effect on the rest of their lives. In addition to managing symptoms, the condition can result in loss of education and difficulty in gaining employment or insurance. In young patients, it can cause psychological problems and growth failure or retarded sexual development. Anxiety and loss of self-esteem are commonly described. In addition to pharmacological treatments, psychological support is also important. It is important to counsel patients on the importance of medication adherence during periods of remission. Medical treatment with corticosteroids and immunosuppressants may cause secondary health problems such as infection, and surgery may result in complications such as intestinal failure. The care of patients with IBD is therefore a challenge for the multidisciplinary team.

NICE management guidelines for ulcerative colitis (NICE, 2013) and Crohn's disease (NICE, 2016) highlighted patient information and support as key priorities for implementation (i.e. having the biggest impact on patient care and outcomes) in the management of induction and maintenance of remission. All information and advice should be appropriate for the patient's age, cognitive/literacy levels and cultural/linguistic needs and in an understandable format. Discussions with patients should include treatment options, monitoring, side effects, diet and nutrition, fertility, prognosis and cancer risk. Patients and/or their parents or carers should be informed of contact details for support groups (e.g. Crohn's and Colitis UK), which can provide leaflets on such issues as the disease itself, treatments, insurance, employment and pregnancy. Patients and/or parents and carers should be aware of whom to contact when symptoms of active disease develop. Primary care doctors and community pharmacists should be aware of the contact details for their local IBD nurse specialist, if available, and how to get rapid access to secondary care services when necessary. As with any condition, patients should be warned about unreliable information sources. Pharmacists have a key role in providing information to patients about their medication and have an integral role within the multidisciplinary team in caring for this patient group.

All patients should be educated about their illness and medication and reminded that even in periods of remission, it is important to continue taking prescribed therapy. This should take the form of verbal and written information. Drug use is invariably lifelong, and patients are likely to receive several different treatments during the course of their illness as a result of intolerance or lack of response. Certain patients, such as females or newly diagnosed patients, may require more tailored information about the condition or treatment. Patients with poor dexterity may find the use of rectal preparations difficult, and these preparations may therefore be poorly tolerated.

Patients and primary care doctors may require additional reassurance because several of the treatments used, for example, azathioprine, are unlicensed for IBD. Regular blood monitoring of aminosalicylates and immunosuppressants is essential to ensure patients avoid the toxicity associated with these drugs. All patients taking steroids must be issued a steroid card. Shared care policies between primary care doctors, gastroenterologists and patients should be in place.

Optimising pharmacological treatments in inflammatory bowel disease

Table 13.8 summarises the pharmacological profile of drugs used in adults with IBD. Medicine optimisation is important in IBD patients to maximise the beneficial clinical outcomes, particularly because medication is associated with toxic side effects and in the case of biologics, high financial costs. Adherence to medication, even in periods of remission, is very important. Treatments can be optimised by the following strategies:

- Provide tailored information on the condition, its complications and the medication used to individuals and/or their carers.
- Ensure good communication within the multidisciplinary team and across primary and secondary care interfaces.
- Encourage adherence even during periods of remission; studies have shown non-adherence to be one of the main factors contributing to relapse (Robinson et al., 2013).
- Provide good education for patients on how to take medication, especially administration of topical therapy, which is essential to ensure effectiveness and adherence.
- Use an appropriate dose and reduction regimen of corticosteroids during an acute flare.
- Advise patients taking aminosalicylates on how to increase their dose during a flare and how to reduce to an appropriate maintenance dose when in remission.
- Prescribe the most appropriate rectal formulation therapy for the site of disease (e.g. enema for descending colon, foam for sigmoid colon, suppositories for rectum), with the patient's dexterity and the cost of the formulation also taken into account.
- Review medication choice in patients who are in clinical remission.
- Develop rescue strategies in patients who have stopped treatment and subsequently relapsed.
- Use therapeutic drug monitoring to optimise treatment with thiopurines and biologics.

Table 13.8 Pharmacological profile of drugs used in adults with inflammatory bowel disease

Pharmacological group	Daily dose	t _{1/2}	Metabolism
Steroids			
Hydrocortisone	125–250 mg as foam enema	1.5 h	Hepatic metabolism 70% and 30% unchanged
	100–400 mg in 0.9% w/v in sodium chloride intravenous injection	1.5 h	Hepatic metabolism 70% and 30% unchanged
Prednisolone	20–40 mg orally	3 h	Hepatic metabolism 70% and 30% unchanged
	20 mg as foam or liquid enema	3 h	Hepatic metabolism 70% and 30% unchanged
	5–10 mg as suppositories	3 h	Hepatic metabolism 70% and 30% unchanged
Budesonide	3–9 mg orally 2mg/dose as foam or liquid enema	2.8 h	90% Hepatic metabolism
Aminosalicylates			
Mesalazine	500 mg to 1.5 g as suppositories	0.7–2.4 h	Local and systemic hepatic acetylation, glucuronidation
	1 g as enema	0.7–2.4 h	Local and systemic hepatic acetylation, glucuronidation
	1.2–4.8 g orally	0.7–2.4 h	Local and systemic hepatic acetylation, glucuronidation
Olsalazine	1–3 g orally	1.0 h	Local and systemic hepatic acetylation, glucuronidation
Sulfasalazine	3 g as enema	5–8 h	Colonic azo-reduction Local and systemic acetylation Hepatic glucuronidation
	1–2 g as suppositories	5–8 h	Colonic azo-reduction Local and systemic acetylation Hepatic glucuronidation
	4–8 g orally	5–8 h	Colonic azo-reduction Local and systemic acetylation Hepatic glucuronidation
Balsalazide	3–6.75 g orally	1.0 h	Local and systemic hepatic acetylation
Antibiotics			
Metronidazole	600 mg–1.2 g orally	6–24 h	Hepatic metabolism
	1.5 g intravenously	6–24 h	Hepatic metabolism
Immunosuppressants			
Azathioprine	2–2.5 mg/kg/day orally	3 h	Hepatic metabolism to 6-mercaptopurine
Mercaptopurine	1–1.5 mg/kg/day orally	1.5 h	Hepatic metabolism to inactive metabolite
Methotrexate	15–25 mg orally/intramuscular/subcutaneous injection once weekly	3–10 h	Insignificant metabolism at low doses
Ciclosporin	2 mg/kg intravenously	19–27 h	Mainly hepatic metabolism
	2.5 mg/kg twice daily orally	19–27 h	Mainly hepatic metabolism
Mycophenolate	1–2 g/day orally	11–24 h	Hepatic metabolism
Tacrolimus	0.025 mg/kg twice daily orally	43 h	Hepatic metabolism

Table 13.8 Pharmacological profile of drugs used in adults with inflammatory bowel disease—cont'd

Pharmacological group	Daily dose	t _{1/2}	Metabolism
Monoclonal antibodies			
Infliximab	5 mg/kg intravenous infusion every 8 weeks (maintenance)	8–9 days	Unknown
Adalimumab	40 mg subcutaneous injection every 2 weeks (maintenance)	10–19 days	Unknown
Certolizumab	400 mg subcutaneous injection every 4 weeks (maintenance)	14 days	Unknown
Golimumab	50 mg subcutaneous injection every 4 weeks (maintenance)	9–15 days	Unknown
Vedolizumab	300 mg intravenous infusion every 8 weeks (maintenance)	25 days	Unknown
Ustekinumab	90 mg subcutaneous injection every 8–12 weeks (maintenance)	3 weeks	unknown
Miscellaneous			
Arsenic salts	250 mg to 1 g rectally	72 h	Tissue deposition excreted unchanged
Bismuth salts	200 mg to 1.2 g rectally	60–80 h	Tissue deposition excreted unchanged
Fish oils	3–4 g	None	Used in the arachidonic acid cycle
Sodium cromoglicate	200–800 mg orally 100–400 mg rectally	Unknown	Poorly absorbed, excreted unchanged in urine and bile
Nicotine	5–15 mg transdermally	0.5–2.0 h	Hepatic oxidation to cotinine 5% excreted unchanged
Lidocaine	200–800 mg rectally	1–2 h	Hepatic de-ethylation and hydrolysis 3% excreted unchanged Largely excreted unchanged
Human growth hormone	1.5–5 mg daily by subcutaneous injection	0.5–4 h	Unknown
Thalidomide	100–400 mg orally	7–16 h	Hydrolysis
Cholestyramine	4–12 g orally		Not absorbed
Probiotics, e.g. VSL#3	1–2 sachets daily orally		Poorly absorbed

Pregnancy

IBD affects young adults, so pregnancy is not uncommon. Patients are strongly advised to discuss any plans for pregnancy with their gastroenterologist. Information should be provided on the effects of disease on pregnancy and the potential risks and benefits of medical treatment. There needs to be good communication across specialties involved in the joint care of pregnant women (e.g. primary care doctors, obstetrics, gastroenterology and colorectal surgeons). Good nutrition, stopping smoking and adherence to medication are important.

Most women with IBD have a normal pregnancy and deliver a healthy baby. Active disease is more of a risk to a normal pregnancy

than medication. Disease control prior to conception and throughout the pregnancy is associated with the best outcomes for both mother and baby. Conception occurring at a time of active disease increases the risk of persistent activity during pregnancy. Women who continue maintenance treatment throughout pregnancy reduce the risk of a flare in the postpartum period, when the risk is more likely.

There is no evidence that inactive Crohn's disease and ulcerative colitis affect fertility, although active Crohn's disease or previous pelvic or pouch surgery can reduce it. There is no evidence that medication affects fertility in females. In males, sulfasalazine causes reversible oligospermia. In such cases, an alternative aminosalicilate should be used as appropriate.

Children of parents with IBD have an increased risk of developing IBD, although the overall risk remains low. The risk is higher for Crohn's disease and also if both parents are affected. Although most babies born are normal and healthy, caesarean delivery is more frequent in women with IBD. There is also an increased risk of low birthweight and preterm birth, which is linked to disease activity at conception or during the pregnancy (van der Woude et al., 2015).

With the exception of methotrexate, mycophenolate and thalidomide, which are contraindicated in pregnancy, most drugs used in the treatment of IBD do not present a significant hazard. There is currently little information for the use in vedolizumab in pregnancy. Despite most patient information leaflets cautioning use in pregnancy or breastfeeding, most specialists agree that maintenance treatment should continue to keep disease under control (van der Woude et al., 2015). The risk of infection with anti-TNF agents alone or in combination with immunomodulators is controversial.

Infliximab and adalimumab are generally considered low risk. Because both drugs cross the placenta and can stay in the circulation of the baby for several months, consideration to discontinue at around 32 weeks of pregnancy should be discussed. Because these drugs remain in the baby's circulation, live vaccines such as the rotavirus vaccine and Bacillus Calmette–Guérin vaccine (BCG) should be avoided in the first 6 months after birth. Table 13.9 summarises the risks associated with the use of IBD medications during pregnancy and lactation.

Vaginal delivery or caesarean section should be discussed because the pelvic floor muscles used to deliver naturally are also important for bowel function. This is particularly important if surgery (such as a pouch formation) may be required in the future. A caesarean section is almost always recommended when there is active perianal Crohn's disease or when there is an ileo-anal pouch or ileorectal anastomosis. It is worth considering a caesarian section in those with ulcerative colitis who have higher risk factors for future surgery, such as those with more than one admission for acute severe ulcerative colitis.

Smoking

Encouraging patients to stop smoking, especially those with Crohn's disease, can have a significant impact on the course of the disease as well as other health benefits. Smoking increases the risk of flare and postoperative relapse and increases the risk of blood clots. In pregnant women with IBD who smoke, there is a higher chance of a low-birth-weight baby and a higher risk of deformity and miscarriage.

Osteoporosis

Long-term steroid use and underlying IBD both contribute to a higher risk of developing osteoporosis. This is prevalent in up to 50% of the patient population with IBD. Patients with Crohn's disease appear more susceptible to osteoporosis than those with ulcerative colitis. Regular DEXA-scanning should be considered, and preventive treatment with bisphosphonate and/or calcium and vitamin D supplements may be necessary.

Table 13.9 Risks of inflammatory bowel disease medications used during pregnancy and lactation

Drug	During pregnancy	During lactation
Mesalazine	Low risk	Low risk
Sulfasalazine	Low risk	Low risk
Corticosteroids	Low risk	Low risk, 4 h delay before breastfeeding is advised
Azathioprine, mercaptopurine	Low risk	Low risk
Anti-TNF agents	Low risk; consider stopping around third trimester in patients with sustained remission	Probably low risk, limited data
Vedolizumab	Limited data	Avoid
Methotrexate	Contraindicated	Contraindicated
Thalidomide	Contraindicated	Contraindicated
Ciclosporin, tacrolimus	Low risk	Avoid
Mycophenolate	Contraindicated	Avoid
Metronidazole	Avoid first trimester	Avoid
Ciprofloxacin	Avoid first trimester	Avoid

TNF, Tumour necrosis factor.

Guidance for the treatment of osteoporosis in IBD has been published by NICE (2013).

Anaemia

Iron supplementation is recommended in all IBD patients with iron-deficiency anaemia. Although there is evidence of benefit in treating iron deficiency without anaemia in other conditions, such as chronic fatigue and heart failure, such evidence is not yet available in the context of IBD.

The aim of iron supplementation is to normalise haemoglobin levels and iron stores. An increase in haemoglobin of at least 2 g/dL within 4 weeks of treatment is an acceptable speed of response.

Intravenous iron should be considered as first-line treatment in patients with clinically active IBD, with previous intolerance to oral iron, with haemoglobin below 10 g/dL, and in patients who need erythropoiesis-stimulating agents. The usual treatment of iron-deficiency anaemia with oral iron has relevant limitations in IBD patients such as malabsorption and gastro-intestinal irritation. Intravenous iron is more effective, shows a faster response and is better tolerated than oral iron. It is, however, more expensive. There is no difference in efficacy between the available licensed intravenous preparations.

Opportunistic infections and vaccination

IBD patients at most risk of opportunistic infections are those treated with immunomodulators and biologics, especially in combination, and those with malnutrition. The European Crohn's and Colitis Organisation has published evidence-based consensus guidelines on the prevention, diagnosis and management of opportunistic infections in IBD (Rahier et al., 2014). UK practice currently recommends influenza (annually), pneumococcal and human papilloma virus (HPV) (female) vaccinations if age appropriate. Hepatitis B vaccinations should be considered prior to starting immunosuppressants (including steroids and biologics) in the non-immune high-risk patient. Patients taking immunosuppressants, including biologics, should avoid live vaccines such as MMR, oral polio, yellow fever, live typhoid, varicella and BCG.

Immunosuppressants should be withheld and specialists informed in those patients suffering from chickenpox or active skin lesions in shingles. For those with exposure to chickenpox or shingles and no history of infection/vaccination, passive immunisation with varicella zoster immune globulin (VZIG) should be carried out.

Colonoscopic surveillance

Adults with IBD may have a higher risk of developing colorectal cancer than the general population. The increased risk is typically associated with the extent, severity and longevity of inflammation and other factors, such as the presence of coexistent primary sclerosing cholangitis (PSC), an inflammatory disease of the bile ducts. Colorectal cancer is the third most common cancer in the UK. Colonoscopic surveillance in people with IBD can detect any problems early and potentially prevent progression to colorectal cancer. In the UK, for people who are not already in surveillance programmes, the [NHS Bowel Cancer Screening Programme](#) offers screening using faecal occult blood testing every 2 years to all men and women aged 60–74 years. People undergoing colonoscopic surveillance are not generally offered screening as part of the Bowel Cancer Screening Programme. Colonoscopic surveillance in the UK should be offered in line with [NICE \(2011\)](#) guidelines.

Since the original Quality Care: Service Standards for the Healthcare of People Who Have Inflammatory Bowel Disease (IBD) was published ([IBD Standards Group UK, 2009](#)), there have been marked improvements in the delivery of IBD services, as shown by the findings of the UK-wide IBD audits. Care should be delivered by a multidisciplinary team comprising a medical gastroenterologist, nurse specialist, pharmacist, dietician, psychologist, colorectal surgeon, primary care doctor, radiologist and histopathologist. The aim of these standards is to ensure patients receive consistent, high-quality care and that IBD services throughout the UK are evidence based, engaged in local and national networking, based on modern information technology (IT) and audited to meet specific minimum standards. A quality standard for IBD was published by [NICE \(2015d\)](#) to improve services across the UK. There are several published guidelines for the management of IBD ([Mowat et al., 2011](#); [Dignass et al., 2012a, 2012b](#); [NICE, 2012, 2013](#); [Gomollen et al., 2016](#)) that aim

to provide a consistent, evidence-based and cost-effective strategy for treating this challenging group of patients.

Case studies

Case 13.1

Miss AT presents with weight loss, fluctuating symptoms of abdominal pain and occasional blood in stool. On examination she appears thin and pale and complains of angular stomatitis and mouth ulcers causing problems with eating. Her abdomen is tender. On imaging and colonoscopy there is ileocaecal and perianal distribution of Crohn's disease. She is a social drinker and smokes 10 cigarettes/day.

Miss AT has been on adalimumab (40 mg on alternate weeks) for the last 6 months, and a recent serum trough level came back as 1.2 micrograms/mL (reference range of assay 4.9–6.5 micrograms/mL). She started a reducing course of steroids 2 weeks ago.

Other blood results included Hb 8.9 g/dL, CRP 21 mg/L, platelets $400 \times 10^9/L$, temperature 37 °C.

Questions

1. What action should be taken with a subtherapeutic level of adalimumab?
2. What advice, if any, would you give regarding Miss AT smoking?

Answers

1. The reason for a suboptimal therapeutic level may be poor adherence, suboptimal dosing or the presence of anti-drug antibodies. Adherence should be questioned, but if Miss AT is taking her adalimumab as prescribed, the dose should be increased to 40 mg weekly. Another trough level should be performed after a couple of months.

If there were high levels of anti-drug antibodies detected, then it would be appropriate to switch to a different anti-TNF agent, such as infliximab. If Miss AT has previously had infliximab, and had secondary loss of response or it was not tolerated, then consider different target, for example, usteknumab.

Miss AT is not currently on an immunomodulator. Provided there are no contraindications or previous reports of intolerance, azathioprine should be added at a dose of 2–2.5 mg/kg/day. The TPMT level should be checked prior to starting azathioprine. If the TPMT activity is deficient (very low or absent), azathioprine should not be used. Lower treatment doses (half recommended initiation doses) can be considered if TPMT activity is below normal but not deficient. Alternatively, methotrexate could be considered.

2. Encouraging patients to stop smoking, especially those with Crohn's disease, can have a significant impact on the course of the disease as well as other health benefits. Smoking increases the risk of disease flare and postoperative relapse and increases the risk of blood clots.

Case 13.2

Mr BG is newly diagnosed with mild ulcerative colitis. His abdominal X-ray suggests predominantly disease of the rectum and sigmoid colon. His past medical history includes joint stiffness as a result of rheumatoid arthritis. He presents at the pharmacy with a prescription for Asacol MR tablets 800 mg three times a day and Salofalk 1 g rectal foam enemas, two administrations at bedtime.

Questions

1. What advice would you give Mr BG about the administration of Salofalk enemas?
2. The community pharmacist substitutes Asacol MR tablets for Octasa MR tablets 800 mg three times a day. Does the change of mesalazine brand matter?
3. Can Octasa MR be taken in a single daily dose?
4. What are the side effects of 5-ASA treatments?

Answers

1. Rectal therapy is appropriate for mild left-sided disease. Enemas are best administered just before bedtime when the supine position allows longer retention times. Salofalk rectal foam comes in a canister that is first fitted with an applicator and then shaken for about 20 seconds before the applicator is inserted into the rectum as far as is comfortable. To administer a dose of Salofalk, the pump dome is fully pushed down and released. The spray will only work properly when held with the pump dome pointing down. Following the first or second activation, depending on need, the applicator should be held in position for 10–15 seconds before being withdrawn from the rectum. If the patient has difficulty in holding this amount of foam, the foam can also be administered in divided doses: one at bedtime and one in the morning. The best results are obtained after the bowels have been emptied. A new applicator is used for each dose. Patients with rheumatoid arthritis may have difficulty in using enemas, and this may affect adherence and treatment success. Mr BG should be shown how to use the product. The aerosol canister is flammable, and care should be taken in sunlight and temperatures over 30 °C.
2. To increase the stability and/or alter the site of release of active drug in oral formulations, 5-ASA is modified by different delivery systems. Both Asacol MR and Octasa MR tablets have an acrylic resin-coat that releases 5-ASA pH-dependently. Although once considered not interchangeable, the British National Formulary (BNF) now advises that patients prescribed oral mesalazine should be closely monitored if the preparation needs to be changed (e.g., because of the local drug formulary). Although there is no evidence to show that any one oral preparation of mesalazine is more effective than the other, patients who are switched to a different brand should be advised to report any changes in their symptom control. The dose, frequency and patient acceptability are more important than the product.
3. For maintenance of remission [NICE \(2013\)](#) recommends that a once-daily dosing regimen of aminosalicylate should be considered based on evidence that it can be more effective than multiple dosing and may even be superior. However, it may result in more side effects. The licensed dose of Octasa MR tablets for induction of remission of mild acute ulcerative colitis is 2.4 g (three tablets) once daily or in divided doses. For moderate disease, this can be increased to six tablets. Maintenance doses are in the range of 1.6 g to 2.4 g (two to three tablets) taken once daily or in divided doses. The maximum adult dose should not exceed six tablets a day and not exceed three tablets taken together at any one time.
4. The side effects of aminosalicylates include diarrhoea, nausea, vomiting, abdominal pain, headache, exacerbation of colitis. Renal function should be monitored before starting an oral aminosalicylate, at 3 months of treatment and then annually during treatment. More frequent monitoring is required for patients with renal impairment. Blood disorders can also occur, and patients should be advised to report any unexplained bruising, bleeding, purpura, sore throat, fever or malaise. The drug should be stopped if there is a suspicion of blood dyscrasias. Aminosalicylates should be avoided in patients with salicylate hypersensitivity.

Case 13.3

Miss CP presents with a 3-week history of acute, foul-smelling, bloody diarrhoea accompanied by mild to severe lower abdominal discomfort. Frequency of bowel movements is eight per day for the last week. She has had two previous attacks in the past year requiring steroids. On examination Miss CP is thin and pale, tender in left iliac fossa, abdomen distended, active bowel sounds. She is currently taking Pentasa 2 g twice a day.

Her ulcerative colitis endoscopic index score (UCEIS) on colonoscopy is 7/8, in keeping with acute severe colitis. On admission, her results were Hb 10.7 g/dL, CRP 84 mg/L, albumin 29 g/dL, platelets $624 \times 10^9/L$, potassium 3.0 mmol/L, creatinine 79 mmol/L, pulse >90 beats/min, temperature >37.8 °C.

Intravenous corticosteroids, fluid and electrolyte replacement and subcutaneous unfractionated heparin are prescribed. However, at day 3, her CRP is still elevated at 70 mg/L, and bowel frequency remains at more than 6 motions/day.

Questions

1. What action should be taken if there is little response to intravenous corticosteroids at day 3 in the management of acute severe colitis?
2. What assessments should be done before and during treatment with intravenous ciclosporin?
3. If Miss CP responds to i.v. ciclosporin, on what maintenance treatment should she be discharged?
4. What counselling would you offer Miss CP about her ciclosporin treatment?

Answers

1. Predicting the outcome of acute severe colitis (resistance to steroids and likelihood of requiring colectomy) should be assessed on day 3 of intensive treatment with intravenous corticosteroids. Those patients with frequent stools (>8/day), or stool frequency of 3–8 and raised CRP (>45 mg/L) should have treatment escalation with the addition of ciclosporin or infliximab because they are most likely to require colectomy. After 7 days of treatment, patients with >3 stools/day with visible blood have a 60% chance of continuous symptoms and 40% chance of colectomy in the following months ([Travis et al., 1996](#)).
2. The use of ciclosporin for acute severe colitis is an unlicensed indication but approved by [NICE \(2013\)](#). The i.v. dose is 2 mg/kg/day. Provided cholesterol >3.0 mmol/L, then i.v. route is safe. There is an increased risk of fitting if the patient has low cholesterol. Hypomagnesaemia can also lead to an increase risk of fitting, so this should be corrected if necessary. Ensure there is no infection, and if so, consider antibiotics. The patient should also be informed of potential need for a colectomy if medical treatment fails. The patient could also have an appointment with a stoma nurse specialist and surgeon in case of emergency surgery, in which the risks and benefits of surgery are discussed. Signs of ciclosporin toxicity include hypertension, renal dysfunction and tremor. A trough level should be done after 48 hours of treatment, aiming for therapeutic range of 100–200 ng/mL.
3. The hydrocortisone should be switched to oral steroids (prednisolone) and tapered over 8 weeks because steroids are not indicated for long-term maintenance treatment. Intravenous ciclosporin should be converted to oral at a dose of 2.5 mg/kg twice a day for 3–6 months. As Miss CP has experienced a severe acute exacerbation, then 5-ASA may no longer be sufficient for maintenance treatment. Therefore, Miss CP should be considered for azathioprine when

the dose of prednisolone is reduced. NICE (2013) states that after a single episode of acute severe colitis or if two or more exacerbations have occurred within 12 months that require systemic corticosteroids, or remission is not maintained with aminosalicylate, then azathioprine or mercaptopurine can be considered.

Miss CP should start calcium/vitamin D supplements when on oral steroids. Miss CP should have a DEXA scan to see if bisphosphonate therapy is required because she has had several steroid courses over the last year. Miss CP should be encouraged to get mild exercise. Her bone mineral density should be monitored, particularly because of her low body mass index (BMI) and steroid use.

- Miss CP should be counselled on the importance of remaining on the same brand of ciclosporin because there are different release characteristics between brands. She should have bloods tests (FBC, renal, ciclosporin trough levels) weekly for the first month, then every month or after a change in dose. Miss CP should be educated on how to recognise signs of over immunosuppression, such as a sore throat, fever or bruising. Miss CP should avoid grapefruit juice. In the UK, there should be a shared care protocol in place if primary care doctors are to continue prescribing and monitoring the ciclosporin.

Case 13.4

Mr DS has been admitted for his first dose of vedolizumab. He was diagnosed with ulcerative colitis 5 years ago and recently received infliximab for an acute exacerbation of this disease. Unfortunately, Mr DS experienced an adverse reaction to infliximab. He is currently taking azathioprine 100 mg once a day.

Questions

- Is vedolizumab an appropriate treatment option for Mr DS?
- What dose would you recommend?
- What are the potential side effects which Mr DS might develop?
- Because Mr DS is already prescribed azathioprine, should this be continued if he is prescribed vedolizumab as maintenance treatment?

Answers

- Vedolizumab is licensed for patients with moderately or severely active inflammatory bowel disease (ulcerative colitis or Crohn's disease) who have had an inadequate response with, lost response to or become intolerant of either standard therapy for these conditions or a TNF- α inhibitor (e.g., infliximab or adalimumab). Mr DS has had a reaction to infliximab, so vedolizumab is appropriate.
- The licensed dose of vedolizumab in moderate/severe ulcerative colitis is 300 mg by i.v. infusion to be given at initiation and then weeks 2 and 6. Further doses can be given every 8 weeks, following a review of continued therapeutic benefit at week 10. Patients established on therapy who begin to lose response may benefit from a 4-week interval between doses.
- Vedolizumab is given as an infusion over 30 minutes. Mr DS should be observed continuously throughout and after his infusion for signs of acute hypersensitivity reactions. If a severe anaphylactic reaction occurs during the infusion, it should be immediately

stopped. If Mr DS has a mild or moderate infusion-related reaction, then a slower infusion rate or temporary interruption of therapy may be considered. Pre-treatment with hydrocortisone can be useful. The most common reported side effects are nasopharyngitis, headache and arthralgia.

- Immunomodulators are thought to reduce the risk of anti-drug antibody formation and potentiate efficacy (Colombel et al., 2010). In practice, the results of this study on infliximab and azathioprine are extrapolated to other biologics and immunomodulator combinations. Currently, there is no clear evidence that this is required for vedolizumab, but theoretically, anti-drug antibodies could lead to loss of response, so until additional evidence is available, it is common practice to continue immunomodulators in those patients already taking and tolerating them.

Case 13.5

Mrs EW was diagnosed with Crohn's disease 4 years ago and is prescribed mercaptopurine 75 mg once a day and infliximab every 8 weeks as maintenance therapy. She would like to become pregnant and wants to know if she should stop her mercaptopurine and infliximab treatment to avoid any congenital defects.

Questions

- What advice would you give Mrs EW?
- What advice should Mrs EW be given regarding vaccinations both for herself and her baby?

Answers

- Most women with IBD have a normal pregnancy and deliver a healthy baby. Active disease is more of a risk to a normal pregnancy than medication. Mrs EW therefore needs to keep well and continue current treatment to ensure her disease is well controlled prior to conception and throughout the pregnancy. Mercaptopurine and infliximab are considered safe during pregnancy and breastfeeding. However, because infliximab crosses the placenta and can stay in the circulation of the baby for several months, consideration to discontinue at around 32 weeks of pregnancy should be discussed with Mrs EW.
There needs to be good communication across specialties involved in the joint care of Mrs EW (e.g., primary care, obstetrics, gastroenterology and colorectal surgeons).
Mrs EW should be advised on nutrition and the avoidance of smoking and alcohol consumption. A higher dose of folic acid (5 mg/day) is recommended in IBD patients such as Mrs EW to prevent neural tube defects.
- Patients taking immunosuppressants, including biologics, should avoid live vaccines. The seasonal flu jab and pneumococcal vaccine is safe during pregnancy and should be given to anyone prescribed an immunosuppressant.
Because infliximab remains in the baby's circulation, live vaccines such as the MMR vaccine, rotavirus or BCG against tuberculosis should be avoided in the first 6 months after birth.

Acknowledgments

The author would like to thank Dr Oliver Brain, Consultant Gastroenterologist, Oxford University Hospitals NHS Foundation Trust, for his support and contribution to this chapter.

14 Constipation and Diarrhoea

Ian Smith and Jonathan Berry

Key points

Constipation

- Constipation is most commonly considered as less frequent evacuation of the bowels with difficulty in passing a stool.
- Constipation can affect all age groups.
- When assessing the patient, it is important to understand what they mean by the term constipation and why they believe they are constipated.
- The evidence for the safety and efficacy of laxatives is limited, which means the process of managing constipation is based more on expert opinion than on evidence.

Diarrhoea

- Diarrhoea is a symptom and can be due to many causes and conditions.
- Diarrhoea can be considered to be acute (<14 days), persistent (>14 days but <4 months) or chronic (>4 months).
- Hydration and nutrition are the interventions with the greatest impact on the course of acute diarrhoea.

Constipation and diarrhoea are two of the most common disorders of the gastro-intestinal (GI) tract. They can both be considered to be either a symptom or a disorder, usually depending on how long they last. The majority of cases of both constipation and diarrhoea are not life-threatening but will cause varying degrees of morbidity. When assessing patients with these conditions, it should be considered that they may be a symptom of another, more serious disorder. For example, constipation may be secondary to hypothyroidism, hypokalaemia, diabetes, multiple sclerosis or GI obstruction. Likewise, diarrhoea may be secondary to ulcerative colitis, Crohn's disease, malabsorption or bowel carcinoma. Both constipation and diarrhoea can also be drug-induced which should also be considered when assessing a patient.

Constipation

Constipation is most commonly considered as less frequent evacuation of the bowels with difficulty in passing a stool. Abnormal, in terms of frequency, would be considered to be fewer than three bowel actions a week (Connell et al., 1965), and this has been incorporated into the Rome III diagnostic criteria for functional constipation (Longstreth et al., 2006). As well as frequency, other criteria can be added into the definition of constipation,

such as stool hardness, straining and the feeling of incomplete evacuation. This all leads to the subjectivity of a true definition. Constipation, it can be said, is defined by the sufferer. If, after a discussion with a patient when normal and abnormal bowel habits are described, the patient says he or she is constipated, then the patient should be considered to require help with his or her constipation (National Institute of Health and Care Excellence [NICE], 2015a).

Incidence

Constipation can affect all age groups. The prevalence of the condition is difficult to measure due to the subjectivity of the definition, but a review article indicated that the prevalence rate worldwide ranged from 2.5% to 79% in adults and from 0.7% to 29.6% in children. The prevalence of self-reported constipation was stated to be about 20% (Mugie et al., 2011). This review indicated that constipation is more common in women than in men, and that the incidence increases with age, particularly after 65 years. There is a higher incidence in elderly patients in nursing homes (Rao and Go, 2010). In the elderly, contributing factors have been identified such as poor diet, insufficient intake of fluids, lack of exercise, concurrent disease states and the use of medicines that can cause constipation. Increased prevalence has also been found in people of high body mass index and low socioeconomic status.

Changes in hormones and mechanical factors during pregnancy lead to an increase in prevalence of constipation compared with the general population. The prevalence rate is higher during the second trimester, and about 40% are affected at some stage during pregnancy (Cullen and O'Donoghue, 2007).

Aetiology

The digestive system can be divided into the upper and lower GI tracts. The upper GI tract starts at the mouth, includes the oesophagus and stomach, and is responsible for the ingestion and digestion of food. The lower GI tract consists of the small intestine, large intestine (colon), rectum and anus (Fig. 14.1), and is responsible for the absorption of nutrients, conserving body water and electrolytes, drying the faeces and elimination. Normally there is a net absorption of water during transit to the rectum. If too much water is reabsorbed, this will, generally, lead to constipation, whereas too much water in the faeces will result in diarrhoea.

The contents of the intestine are swept along the GI tract by waves of muscular contractions called peristalsis. These

Fig. 14.1 The lower gastro-intestinal tract.

peristaltic waves eventually move the faeces from the colon to the rectum, and this then induces the urge to defaecate. This process is under the influence of the autonomic nervous system (sympathetic and parasympathetic).

Agents that alter intestinal motility, either directly or by acting on the autonomic nervous system, affect the transit time of substances along the GI tract. Because the extent of absorption and secretion of fluid from the GI tract generally parallels transit time, a slower transit time will lead to the formation of hard stools and constipation. Transit times are faster in males than in females (Degen and Phillips, 1996) and can be affected by the type of food that is ingested and the amount of fluid that is drunk.

Motility is largely under parasympathetic (cholinergic) control, with stimulation bringing about an increase in motility, whereas antagonists such as antimuscarinics, or drugs with antimuscarinic side effects, decrease motility and induce constipation. This mechanism is distinct from that of the other major group of drugs that induce constipation, the opioids. Opioids cause constipation by maintaining or increasing the tone of smooth muscle, suppressing forward peristalsis, raising sphincter tone at the ileocaecal valve and anal sphincter, and reducing sensitivity to rectal distension. This delays the passage of faeces through the gut, with a resultant increase in absorption of electrolytes and water in the small intestine and colon.

Constipation can be classed as primary or secondary (Rao and Meduri, 2011). Chronic primary constipation can be subclassified into five categories:

- normal transit
- slow transit
- dyssynergic defecation, which is the difficulty in expelling stools
- slow transit–dyssynergic combination
- irritable bowel syndrome (IBS) with constipation

Secondary constipation can be caused by many different factors including diet, drugs and behaviour. These and other factors are highlighted in Table 14.1.

Differential diagnosis

When assessing patients, it is important to understand what patients mean by the term constipation and why they believe they are constipated. The onset, duration and severity of the condition will need to be assessed. This will require information about the

frequency and consistency of their stools and any other issues which affect defaecation, such as straining or incomplete evacuation. An assessment of the action the person has taken to manage his or her condition and how effective it has been will be required. Predisposing factors will also require investigation to identify any possible causes. Current medication will need investigation with particular regard to medicines known to cause constipation (Table 14.2). In the UK, more than 700 medicinal products, including ophthalmic preparations, have constipation listed as a possible side effect.

The Rome III diagnostic criteria identify patients with functional constipation when 25% of bowel movements are associated with at least two of the following symptoms: straining; hard or lumpy stools; a sense of incomplete evacuation; a sense of anorectal obstruction; the need for manual manoeuvres; or fewer than three defaecations per week in the previous 3 months with an onset of symptoms longer than 6 months (Longstreth et al., 2006). The Bristol Stool Chart (see Useful Websites) provides practitioners and patients with a practical guide to stool consistency (Lewis and Heaton, 1997).

Patients will require referral and further investigation if they are passing blood or mucus in their stools, have unintentional and unexplained weight loss, experience fever or have nocturnal symptoms which disturb their sleep. The longer the constipation has lasted the more likely it is to need further investigation, in particular if it is unresponsive to treatment. A person older than 50 years who has started to complain about constipation without a previous history may require referral. Recurrent abdominal pain or discomfort with constipation is more associated with IBS (Lui, 2011).

Rao and Meduri (2011) gave an outline of the methods which can be used to investigate chronic constipation. These include clinical evaluation and diagnostic tests. The diagnostic tests are further broken down as follows:

- radiographic studies including plain abdominal radiography, barium enema, magnetic resonance imaging (MRI), endoscopy, and defecography;
- tests for colonic function including colonic transit study, colonic transit scintigraphy, wireless motility capsule and colonic manometry;
- tests for anorectal function including anorectal manometry, high-resolution manometry, balloon expulsion test and rectal barostat test.

General management

The aim, when managing constipation, should be to restore normal bowel function. This aim may not be realistic in some patients. The general approach to treating constipation is first to clear faecal loading or impaction before starting to treat chronic constipation. When treating the condition it is recommended that individual preference and the response to treatment are considered. A stepped approach is recommended, which will involve adjusting the dose, frequency and combination of laxatives (NICE, 2015a). Little evidence is available about the most effective treatments for constipation, and what evidence does exist concentrates on the treatment of chronic constipation. Non-drug advice is widely accepted as the first-line treatment,

Table 14.1 Causes of constipation

Cause	Comments
Poor diet	Diets high in animal fats (e.g. meats, dairy products, eggs) and refined sugar (e.g. sweets), but low in fibre predispose to constipation
Irritable bowel syndrome	Spasm of colon delays transit of intestinal contents; patients have a history of alternating constipation and diarrhoea
Poor bowel habit	Ignoring and suppressing the urge to have a bowel movement will contribute to constipation
Laxative abuse	Habitual consumption of laxatives necessitates increase in dose over time until intestine becomes atonic and unable to function without laxative stimulation
Travel	Changes in lifestyle, daily routine, diet and drinking water may all contribute to constipation
Hormone disturbances	For example, hypothyroidism and diabetes
Pregnancy	Mechanical pressure of womb on intestine and hormonal changes (e.g. high levels of progesterone)
Fissures and haemorrhoids	Painful disorders of the anus often lead patients to suppress defaecation, leading to constipation
Diseases	Many disease states may have constipation as a symptom (e.g. scleroderma, lupus, multiple sclerosis, Parkinson's disease, stroke and dementia)
Mechanical compression	Scarring, inflammation around diverticula and tumours can produce mechanical compression of intestine
Nerve damage	Spinal cord injuries and tumours pressing on the spinal cord affect nerves that lead to intestine
Colonic motility disorders	Peristaltic activity of intestine may be ineffective, resulting in colonic inertia
Medication	See Table 14.2
Dehydration	Insufficient fluid intake or excessive fluid loss; water and other fluids add bulk to stools, making bowel movements soft and easier to pass
Immobility	Prolonged bedrest after an accident, during an illness or general lack of exercise
Electrolyte abnormalities	Hypercalcaemia or hypokalaemia
Anxiety and depression	The psychological symptoms can be a result of the distress associated with constipation, or constipation can be an expression of the depressive or anxiety disorder

although there is a lack of evidence that it is effective (Lui, 2011). Laxatives can be used if the patient does not respond to non-drug advice or if they need relief while the non-drug advice is taking effect. If there is a medicine which is causing or contributing to the problem, this should be withdrawn or adjusted if possible.

Patients with opioid-induced constipation will require treatment with an osmotic or stimulant laxative alone or in combination. Methylnaltrexone bromide injection can also be added to their treatment if required. This is an opioid-receptor antagonist which does not alter the central analgesic effect of opioids.

Non-drug advice

Non-drug advice is advocated for all patient groups, except those who are terminally ill. Education and discussion about their current bowel habits may be required because some people believe that if they do not have a bowel movement each day they are constipated, and this may lead to laxative overuse. All advice given should incorporate

any of the predisposing factors identified. General advice about the patient not ignoring the urge to have a bowel movement, as well as increasing fluid intake, dietary fibre and activity, may help the patient, particularly if any of these have been identified as a possible predisposing factor. This will require understanding the fluid intake, exercise activity and diet of the patient, to give effective advice.

It is generally recommended that fibre intake in the form of fruit, vegetables, cereals, grain foods, wholemeal bread and so on be increased to between 18 and 30 g/day. Studies have shown that low-fibre diets can lead to constipation. High-fibre diets can lead to a decrease in transit time and an increase in stool weight (Rao and Go, 2010). Fibre intake should be increased gradually to prevent flatulence and bloating. The effect of increasing fibre could be seen within a few days but may take up to 4 weeks to have an effect (NICE, 2015a). Advice on adequate fluid intake could be appropriate, and this will be important in patients who are consuming a high-fibre diet. A high-fibre diet is not recommended in those with megacolon or hypotonic colon/rectum because they do

Table 14.2 Examples of medicines known to cause constipation [frequency defined as very common (>10%) or common (1–10%)]

Class	Examples
α -Blocker	Prazosin
Antacid	Aluminium and calcium salts
Antimuscarinic	Trihexyphenidyl, hyoscine, oxybutynin, procyclidine, tolterodine
Antidepressant	Tricyclics, selective serotonin reuptake inhibitors, reboxetine, venlafaxine, duloxetine, mirtazapine
Antiemetic	Palonosetron, dolasetron, aprepitant
Antiepileptic	Carbamazepine, oxcarbazepine
Antipsychotic	Phenothiazines, haloperidol, pimozide and atypical antipsychotics such as amisulpride, aripiprazole, olanzapine, quetiapine, risperidone, zotepine, clozapine
Antiviral	Foscarnet
β -Blocker	Oxprenolol, bisoprolol, nebivolol; other β -blockers cause constipation more rarely
Bisphosphonate	Alendronic acid
Central nervous system stimulant	Atomoxetine
Calcium channel blocker	Diltiazem, verapamil
Cytotoxic	Bortezomib, buserelin, cladribine, docetaxel, doxorubicin, exemestane, gemcitabine, irinotecan, mitoxantrone, pentostatin, temozolomide, topotecan, vinblastine, vincristine, vindesine, vinorelbine
Dopaminergic	Amantadine, bromocriptine, carbegolide, entacapone, tolcapone, levodopa, pergolide, pramipexole, quinagolide
Growth hormone antagonist	Pegvisomant
Immunosuppressant	Basiliximab, mycophenolate, tacrolimus
Lipid-lowering agent	Colestyramine, colestipol, rosuvastatin, atorvastatin (other statins uncommon), gemfibrozil
Iron	Ferrous sulphate
Metabolic disorder	Miglustat
Muscle relaxant	Baclofen
NSAID	Meloxicam; other NSAIDs, e.g. aceclofenac, and cyclo-oxygenase-2 inhibitors reported as uncommon
Smoking cessation	Bupropion
Opioid analgesic	All opioid analgesics and derivatives
Ulcer healing	All proton pump inhibitors, sucralfate

NSAID, Non-steroidal anti-inflammatory drug.

not respond to bulk in the colon. Similarly, a high-fibre diet may not be appropriate in those with opioid-induced constipation.

An increased level of exercise could also be advised. Although it has not been associated with improvement in constipation, it has been associated with an increase in quality of life and decreased bowel symptoms (Rao and Meduri, 2011).

Drug treatment

Evidence for the safety and efficacy of laxatives is limited, which means the process of managing constipation is based more upon expert opinion than on evidence. If non-drug advice is unsuccessful, or there is a clinical need, a short course of treatment with laxatives would be appropriate. Bulk-forming agents are seen as

the first-line treatment. Osmotic and stimulant laxatives are used as second-line treatments. Where the constipation is believed to be due to opioid medication, the recommendation is not to use a bulk-forming agent but to use an osmotic or stimulant laxative instead.

In pregnancy there is very little evidence to support the use of laxatives. It is generally accepted that a bulk-forming laxative would be the first choice if non-drug advice is unsuccessful followed by lactulose (Rungsiprakarn et al., 2015).

Laxatives are subcategorised into groups related to their mechanism of action; however, some laxatives have more than one mechanism of action; that is, bulk-forming agents also have softening properties. Docusate sodium can be considered as a stimulant laxative and faecal softener. Glycerol suppositories have a lubricant effect, in addition to a stimulant effect.

Bulk-forming agents. Ispaghula formulated as powder, granules and effervescent granules, methylcellulose tablets and sterculia granules are all bulk-forming agents. Their use is most appropriate in situations where the patient has small, hard stools and the dietary intake of fibre cannot be increased.

The mechanism of action for bulk-forming agents is that they are polysaccharides which are not digested. There is some evidence to indicate that ispaghula can cause an increase in frequency, weight and consistency of stools (Ashraf et al., 1995). Following ingestion it usually takes 12–36 hours before any effect is seen but may be longer. An adequate volume of fluid should be ingested to avoid intestinal obstruction. Bulk-forming agents can be used safely long-term during pregnancy or when breast-feeding, but many users will experience problems with flatulence and distension. The use of bulk-forming agents is not recommended in patients with colonic atony, intestinal obstruction or faecal impaction. They are less effective, or may even exacerbate constipation, in those who lack mobility.

Stimulant laxatives. Medicines in the stimulant laxative group include bisacodyl, sodium picosulfate, senna and dantron. They directly stimulate colonic nerves that cause movement of the faecal mass, reduce transit time and result in the passage of stool within 6–12 hours. As a consequence of their time to onset, oral dosing at bedtime is generally recommended. Suppositories that contain laxatives have a more immediate effect, causing defaecation within 20–60 minutes. Abdominal cramps are a common side effect of stimulant laxatives. Chronic use of stimulant laxatives should be avoided and discouraged because this can lead to electrolyte disturbances and an atonic colon. In the elderly atonic colon is of less concern, and prolonged use may be required in a few cases. Stimulant laxatives should be avoided in patients with intestinal obstruction.

Co-danthramer and co-danthrusate are stimulant laxatives with limited use. Their carcinogenic effects, identified from rodent studies, have limited their use to those patients who are terminally ill.

Osmotic laxatives. Osmotic laxatives include magnesium salts, phosphate enemas, sodium citrate enemas, lactulose and macrogols. These agents retain fluid in the bowel by osmosis and change the water distribution in faeces to produce a softer, bulkier stool. Their ingestion should be accompanied by an appropriate fluid intake. Bowel-cleansing preparations of phosphates

and sodium citrate in the form of enemas are mainly used before bowel surgery, colonoscopy or radiological examination.

Lactulose is a semisynthetic disaccharide, which is not absorbed from the gut. It may take 48 hours or longer to work. It is also useful in the treatment of hepatic encephalopathy because it produces an osmotic diarrhoea of low faecal pH that discourages the growth of ammonia-producing organisms.

Macrogols are inert polymers of ethylene oxide. They are formulated in enemas, powders or liquid with salts such as sodium chloride and potassium chloride. Macrogol-containing enemas are mainly used as bowel-cleansing preparations. Macrogol powders and liquid are used for chronic constipation or faecal impaction.

Faecal softeners. Docusate sodium is a non-ionic surfactant that has stool-softening properties. It reduces surface tension, increases the penetration of intestinal fluids into the faecal mass and has weak stimulant properties. Oral preparations, like lactulose, can take up to 48 hours to act. Enemas have a rapid onset of action (within 20 minutes) but should not be used in individuals with haemorrhoids or an anal fissure.

Liquid paraffin, a traditionally used laxative, has very limited use because of the problems it may cause, including anal irritation and seepage, granulomatous reactions and lipoid pneumonia. It can also reduce the absorption of fat-soluble vitamins.

Other drugs used in constipation. Linaclotide, lubiprostone and prucalopride have very limited use. For example, within the UK, linaclotide is licensed for the treatment of moderate-to-severe IBS associated with constipation; lubiprostone is licensed for the treatment of chronic idiopathic constipation in adults whose condition has not responded adequately to lifestyle changes; prucalopride is licensed for the treatment of chronic constipation in women, when other laxatives have failed to provide an adequate response.

Diarrhoea

Diarrhoea, as a symptom, can be due to many causes and conditions. A definition of diarrhoea is the abnormal passing of loose or liquid stools, with increased frequency and/or increased volume (NICE, 2013). Increased frequency is defined as the presence of three or more abnormally loose or watery stools in the preceding 24 hours (World Gastroenterology Organisation, 2012).

Diarrhoea can be considered acute (<14 days), persistent (>14 days but <4 months) or chronic (>4 months). The usual cause of acute diarrhoea, in all age groups, is viral or bacterial infection (Tam et al., 2012). Other causes of acute diarrhoea include food allergies, anxiety or alcohol misuse. Chronic diarrhoea can be associated with conditions such as IBS, inflammatory bowel disease, colorectal cancer and malabsorption syndromes. Certain medicines can also cause diarrhoea as a side effect. This section will consider acute diarrhoea caused by infection or drugs.

Incidence

As with constipation, prevalence rates of diarrhoea are difficult to estimate. Worldwide there are an estimated 1.7 billion cases

Table 14.3 Types of diarrhoea

Type	Cause
Osmotic diarrhoea	Solutes in the intestinal lumen increasing the osmotic gradient
Secretory diarrhoea	Water being secreted in the intestinal lumen
Inflammatory and infectious diarrhoea	Infection or inflammation affecting the lining of the intestine
Accelerated transit time diarrhoea	An increase in transit time through the intestine, which is then too fast to allow absorption of enough water

of diarrhoeal disease every year. Each year 760,000 children younger than 5 years die of diarrhoea, mostly in developing countries (World Health Organisation [WHO], 2013a). This means that more than 2000 children are dying every day as a result of diarrhoeal diseases. Chronic diarrhoea in the Western population is said to be about 4–5% (Thomas et al., 2003). The incidence of diarrhoea among adults in Great Britain is stated as, on average, just under one episode per person each year (Feldman and Banatvala, 1994). It has been estimated that there are just less than 17 million cases per year of infectious intestinal disease (IID), and this leads to just greater than 1 million primary care doctor consultations per year in the UK (Tam et al., 2012). Of these cases, viral causes are more common than bacterial causes. Norovirus is the most common cause, being responsible for nearly 3 million cases. The most common bacterial cause is *Campylobacter*, with just more than half a million cases. Since the mid-1990s it would appear that the incidence of IID has increased by about 40%. Over the same period the number of primary care doctor consultations for IID has halved, which is believed to be because of changes in healthcare usage. *Clostridium difficile*, which is an important cause of IID in hospital and other healthcare settings, appears to be a rare cause of community IID. Worldwide, rotavirus is the most common cause of severe debilitating diarrhoea in children younger than 5 years (WHO, 2013b).

Aetiology

There are four types of diarrhoea. These are described in Table 14.3. Pathogens produce secretory diarrhoea and inflammatory and infectious diarrhoea via a number of methods.

They can cause a secretory diarrhoea by producing enterotoxins which have a dual action of activating adenyl cyclase and directly acting on the nerves in the intestine to release water (e.g. *Vibrio cholerae*, *Staphylococcus aureus* and *Clostridium* species).

Inflammatory and infectious diarrhoea is caused by the pathogen disrupting or destroying the epithelium of the intestine. Bacteria such as *Salmonella*, *Escherichia coli* O157, *Shigella* and *Campylobacter* and protozoa such as *Cryptosporidium* and *Giardia* cause this type of infectious diarrhoea. Norovirus and rotavirus also cause this type of diarrhoea, although the mechanism of action may be more complicated (Shetty and Tang, 2009).

Many medicines (Table 14.4), particularly broad-spectrum antibiotics such as ampicillin, erythromycin and neomycin, induce diarrhoea secondary to therapy. With antibiotics, the mechanism involves the overgrowth of antibiotic-resistant bacteria and fungi in the large bowel after several days of therapy. The diarrhoea is generally self-limiting; however, when the overgrowth involves *C. difficile*, it can be life-threatening. *C. difficile*-associated diarrhoea is a major concern in the hospital setting. Pathogenic strains produce two enterotoxins: toxin A, which causes fluid accumulation in the lumen of the large intestine; and toxin B, which is responsible for ulceration of the bowel wall. These are responsible for the severe diarrhoea, and consequential pseudo-membranous colitis and toxic megacolon which characterise the *C. difficile* infection (Shetty, 2009).

Signs and symptoms

Diarrhoea, like constipation, is a change from the normal bowel function. In diarrhoea there is an increase in frequency or an increase in weight of the stools, or both. Acute diarrhoea is associated with loose or watery stools that may be accompanied by anorexia, nausea, vomiting, abdominal cramps, flatulence or bloating.

Getting a complete history of the patient is important. The duration of the diarrhoea, along with its severity and symptoms, will need to be ascertained to establish whether referral is warranted. Warning signs that warrant further investigation include blood in the stools, persistent vomiting, unintentional and unexplained weight loss, or nocturnal symptoms which disturb sleep.

Patients should be questioned about whether other members of the family or other people they have been in contact with are ill. They should also be questioned about the food they have eaten, any medicines they have taken and if they have recently travelled abroad, because all of these factors are important in assessing the condition.

Dehydration can be a consequence of diarrhoea, and this can be exacerbated if the patient is also vomiting. Signs and symptoms of dehydration should be reviewed when assessing a patient, and particularly if the patient is very young or very old.

In mild dehydration there are usually no signs, but symptoms such as lassitude, anorexia, nausea, light-headedness and postural hypotension may be described. Symptoms such as apathy, tiredness, dizziness, headache and muscle cramps together with signs such as pinched face, dry tongue or sunken eyes, reduced skin elasticity, postural hypotension, tachycardia and oliguria could indicate moderate dehydration. In severe dehydration, the above symptoms are more marked and may also include profound apathy, weakness and confusion, leading to coma with signs of shock, tachycardia, marked peripheral vasoconstriction, systolic blood pressure less than 90 mmHg, uraemia, oliguria or anuria (NICE, 2015b).

Investigations

Before any investigations are undertaken, a medication history is required to eliminate drug-induced diarrhoea. Testing for *C. difficile*-induced pseudomembranous colitis is indicated in those with severe symptoms or where hospitalisation or antibiotic

Table 14.4 Examples of medicines known to cause diarrhoea (defined as very common [$>10\%$] or common [$1-10\%$])

Class	Examples
α -Blocker	Prazosin
Angiotensin-converting enzyme inhibitor	Lisinopril, perindopril
Angiotensin receptor blocker	Telmisartan
Acetylcholinesterase inhibitor	Donepezil, galantamine, rivastigmine
Antacid	Magnesium salts
Antibacterial	All
Antidiabetic	Metformin, acarbose
Antidepressant	Selective serotonin reuptake inhibitors, clomipramine, venlafaxine
Antiemetic	Aprepitant, dolasetron
Antiepileptic	Carbamazepine, oxcarbazepine, tiagabine, zonisamide, pregabalin, levetiracetam
Antifungal	Caspofungin, fluconazole, flucytosine, nystatin (in large doses), terbinafine, voriconazole
Antimalarial	Mefloquine
Antiprotozoal	Metronidazole, sodium stibogluconate
Antipsychotic	Aripiprazole
Antiviral	Abacavir, emtricitabine, stavudine, tenofovir, zalcitabine, zidovudine, atazanavir, indinavir, lopinavir, nelfinavir, saquinavir, efavirenz, ganciclovir, valganciclovir, adefovir, oseltamivir, ribavirin, fosamprenavir
β -Blocker	Bisoprolol, carvedilol, nebivolol
Bisphosphonate	Alendronic acid, disodium etidronate, ibandronic acid, risedronate, sodium clodronate, disodium pamidronate, tiludronic acid
Cytokine inhibitor	Adalimumab, infliximab
Cytotoxic	All classes of cytotoxics
Dopaminergic	Levodopa, entacapone
Growth hormone antagonist	Pegvisomant
Immunosuppressant	Ciclosporin, mycophenolate, leflunomide
Non-steroidal anti-inflammatory drug	All
Ulcer healing	All proton pump inhibitors
Vaccine	Pediacel (5 vaccines in 1), haemophilus, meningococcal
Miscellaneous	Calcitonin, strontium ranelate, colchicine, dantrolene, olsalazine, anagrelide, nicotinic acid, pancreatin, eplerenone, acamprosate

therapy with lincomycin, broad-spectrum β -lactams or cephalosporins has occurred within the preceding 6 weeks.

In general, stool culture is required in patients who are unwell (fever or dehydration), immunocompromised, with blood or pus in the stool, or where there is no improvement within a week. Stool culture is also required when there is a history of recent overseas travel other than to Europe, North America, Australia or New Zealand.

Further tests that may be required in chronic diarrhoea are listed in [Table 14.5](#).

Treatment

Acute infective diarrhoea, including traveller's diarrhoea, is usually a self-limiting disorder. However, depending on the causative agent, a number of complications may have to be addressed. Dehydration and electrolyte disturbance can be readily treated but may, if severe, progress to acidosis and circulatory failure with hypoperfusion of vital organs, renal failure and death.

General measures

Patients should be advised on handwashing and other hygiene-related issues to prevent transmission to other family members.

Table 14.5 Blood tests in patients with chronic diarrhoea

Test	Comments
Full blood count	Detection of anaemia or raised platelet count suggesting inflammation
Liver function tests	Including albumin level
Tests for malabsorption	Calcium; vitamin B ₁₂ and red blood cell folate; iron status (ferritin)
Thyroid function test	Reduced thyroid-stimulating hormone and elevated free T ₃ and T ₄ levels would be suggestive of overt hyperthyroidism
Erythrocyte sedimentation rate and C-reactive protein	Elevated levels may indicate inflammatory bowel disease
Antibody testing for coeliac disease	IgA tissue transglutaminase antibody or IgA endomysial antibody
IgA, Immunoglobulin A.	

The promotion of handwashing may reduce the incidence of diarrhoea by approximately one-third ([Ejemot-Nwadiaro et al., 2015](#)). Exclusion from work or school until the patient is free of diarrhoea is advised. In acute, self-limiting diarrhoea, children, healthcare workers and food handlers should be symptom free for 48 hours before returning to school or work. More exacting criteria for return to work, such as testing for negative stool samples, are rarely required.

Patients, either adults or children, should be advised to commence eating as soon as they want. In babies, breast-feeding and bottle-feeding should be continued, although there is some evidence that moving bottle-fed babies to lactose-free milk may be beneficial ([MacGillivray et al., 2013](#)). The BRAT diet (bananas, rice, applesauce and toast) has long been recommended by healthcare workers. However, there is little evidence to promote this diet, and it is believed to be too restrictive ([Churgay and Aftab, 2012](#)). In weaned and non-weaned children with gastroenteritis, early feeding after rehydration has been shown to result in higher weight gain, no deterioration or prolongation of the diarrhoea and no increase in vomiting or lactose intolerance ([Conway and Ireson, 1989](#)).

Dehydration treatment

The interventions of greatest impact on acute diarrhoea are hydration and nutrition ([Brandt et al., 2015](#)). Because diarrhoea results in fluid and electrolyte loss, it is important to prevent or reverse any fluid and electrolyte depletion. Most patients can be advised to increase their intake of fluids.

Young children and the frail and elderly are prone to diarrhoea-induced dehydration, and the use of an oral rehydration solution (ORS) is recommended. The formula recommended by the WHO contains glucose, sodium, potassium, chloride and bicarbonate and is almost isotonic with body fluid. A number of similar preparations are available commercially in the form of sachets that require reconstitution in clean water before use ([Table 14.6](#)). The reasoning behind the ingredients within ORS are that the glucose facilitates the absorption of sodium (and hence water) on a 1:1 molar basis in the small intestine. Some preparations replace glucose with rice powder. Sodium and potassium are needed to replace the body losses of these essential ions during diarrhoea (and vomiting), and the citrate corrects the acidosis that occurs as a result of diarrhoea and dehydration ([WHO, 2006](#)). Previously the WHO ORS contained 90 mmol/L sodium, because cholera is more common in developing countries and is associated with rapid loss of sodium and potassium. However, a systematic

Table 14.6 Composition of oral rehydration solutions

	Osmolarity (mOsm/L)	Glucose (mmol/L)	Sodium (mmol/L)	Chloride (mmol/L)	Potassium (mmol/L)	Base (mmol/L)
Dioralyte	240	90	60	60	20	Citrate 10
Electrolade	251	111	50	40	20	Bicarbonate 30
World Health Organisation oral rehydration solution	245	75	75	65	20	Citrate 10

review of trials using a reduced osmolarity ORS concluded that solutions with a reduced osmolarity compared with the standard WHO formula were associated with 33% fewer unscheduled intravenous infusions, a trend towards reduced stool output and less vomiting in children with mild-to-moderate diarrhoea (Hahn et al., 2001). Based on this and other findings, the WHO ORS now has a reduced osmolarity of 245 mOsm/L and contains 75 mmol of sodium.

ORS should be routinely used in both primary and secondary care settings. For healthy adults, an appropriate substitute for a rehydration sachet is 2.5 mL of table salt plus 30 mL of sugar in 1 L of drinking water. The volume of ORS to be taken in treating mild-to-moderate diarrhoea is dependent on age. In adults, 2 L of oral rehydration fluid should be given in the first 24 hours, followed by unrestricted normal fluids with 200 mL of rehydration solution per loose stool or vomit. For children, 30–50 mL/kg of an ORS should be given over 3–4 hours. This can be followed with unrestricted fluids, either with normal fluids alternating with ORS or normal fluids with 10 mL/kg rehydration solution after each loose stool or vomit. The solution is best sipped every 5–10 minutes rather than drunk in large quantities less frequently. However, care is required in patients with diabetes because they may need to monitor blood glucose levels more carefully. They should also be advised not to stop taking insulin.

Drug treatment

Antimotility agents. In uncomplicated acute diarrhoea, antimotility agents such as loperamide, diphenoxylate and codeine are occasionally useful for symptomatic control in adults. They act by binding to opiate receptors in the gut wall, reducing propulsive peristalsis, increasing intestinal transit time and enhancing the reabsorption of water and electrolytes. Antimotility agents are not recommended for use in children because trial results appear contradictory and any benefits are small with unacceptable levels of side effects observed. Antimotility agents should be avoided in severe gastroenteritis or dysentery.

Loperamide. Loperamide is a synthetic opioid analogue. It should have an effect within 1 hour of oral administration. For acute diarrhoea in adults, 4 mg of loperamide is taken initially followed by 2 mg after every loose stool, up to a maximum of 16 mg each day for 5 days. It is relatively free of central nervous system (CNS) effects at therapeutic doses because it does not readily cross the blood–brain barrier, although CNS depression may be seen in overdose, particularly in children. Because it undergoes hepatic metabolism it should be used with caution in patients with hepatic dysfunction. It is also of use in patients with high-output stomas; the tablet rather than the capsule formulation should be dispensed to avoid the formulation passing unchanged into an ostomy bag.

Diphenoxylate. Diphenoxylate is a synthetic opioid available as co-phenotrope in combination with a subtherapeutic dose of atropine. The atropine is present to discourage abuse but may cause atropinic effects in susceptible individuals. Administration of co-phenotrope at the recommended dosage carries minimal risk of dependence. However, prolonged use or administration of high doses may produce a morphine-type dependence. It has a similar adverse effect profile to that of morphine. If an overdose is taken,

the symptoms can be delayed for a considerable period and respiratory depression may not be seen for up to 30 hours. Young children are particularly susceptible to diphenoxylate overdose, where as few as 10 tablets of co-phenotrope may be fatal. Concurrent use of diphenoxylate with monoamine oxidase inhibitors can precipitate a hypertensive crisis, while the action of CNS depressants such as barbiturates, tranquilisers and alcohol is enhanced.

Codeine and morphine. The constipating side effect of the opioid analgesics codeine and morphine may be used to treat diarrhoea. Both are susceptible to misuse and, given in large doses, may induce tolerance and psychological and physical dependence. Morphine may still be obtained in combination with the adsorbent kaolin, but this combination is no longer recommended for the treatment of acute diarrhoea.

Absorbants. Kaolin, used as an absorbant, is not recommended for the treatment of acute diarrhoea.

Antimicrobials. Antibiotics are generally not recommended in diarrhoea associated with acute infective gastroenteritis. This is because the cause is more commonly viral, and the symptoms tend to resolve quickly on their own. Inappropriate treatment of diarrhoea with antibiotics will only further contribute to the problem of resistant organisms. Antibiotics should be reserved for patients who produce a positive stool culture for bacteria and where the symptoms are not receding or for traveller's diarrhoea (De Bruyn et al., 2000). Rifaximin, a rifamycin antibiotic which is not absorbed when administered orally, is licensed in the UK to treat traveller's diarrhoea without fever, blood in the stools and where there have been less than eight unformed stools in the past 24 hours.

C. difficile is a facultative anaerobe and as such will normally respond to a 10-day course of metronidazole. Other effective antibiotics include oral vancomycin and fidaxomicin. Infections which are resistant to antibiotic treatment have been treated with immunoglobulins. More recently attention has focused on faecal transplantation (intestinal microbiota transplantation) as a novel mode of treatment. This involves infusing intestinal microorganisms from a healthy donor into the bowel of an affected patient, most commonly via an enema. A systematic review showed a 92% success rate (Gough et al., 2011).

Enkephalinase inhibitors. Racecadotril is a pro-drug of thioprophan. Thioprophan, an enkephalinase inhibitor, inhibits the breakdown of endogenous opioids, thereby reducing intestinal secretions. It does not change intestinal transit time. Racecadotril can be used as an adjunct to rehydration for the symptomatic treatment of acute uncomplicated diarrhoea.

Probiotics. Probiotics have been defined as components of microbial cells or microbial cell preparations that have a beneficial effect on health. Well-known probiotics include lactic acid bacteria and the yeast *Saccharomyces*. The rationale for their use in infectious diarrhoea is that they act against enteric pathogens in a number of ways and increase the immune responses within the body. A Cochrane review identified a reduction on duration and severity of diarrhoea when probiotics were administered with rehydration therapy. Probiotics were not associated with adverse effects. The use of probiotics is therefore recommended as an adjunct to ORS; however, there was insufficient evidence to develop an evidence-based treatment guideline for probiotics (Allen et al., 2010).

Zinc. The use of zinc has been reviewed in the treatment of diarrhoea in children in developing countries (Lazzerini and Wanzira, 2016). In this context, zinc has been beneficial in children older than 6 months, probably because they have a prior underlying zinc deficiency. The WHO (2011) has recommended both ORS and zinc supplementation for the clinical management of diarrhoea.

Rotavirus vaccine. The monovalent rotavirus vaccine Rotarix was introduced to the standard UK childhood immunisation programme in September 2013. It is administered at 2 and 3 months of age. Reported cases of rotavirus have declined by 74% in 2015/2016 season when compared with the 10-year average (Public Health England, 2016). Considering that Tam et al. (2012) estimated that there were 147 community cases and 10 primary care doctor consultations for every reported case of rotavirus within the UK, this would represent a 220,000 reduction in clinical cases of rotavirus.

Some of the common therapeutic problems in the management of individuals with constipation and diarrhoea are outlined in Table 14.7.

Case studies

Case 14.1

Mrs CB, a woman in her 40s, asks to speak to the pharmacist. She has had constipation on and off for the last 2 months. She is a busy working mother, 5'4" tall (1.63 m) and weighs 13 stone (82.6 kg). She states that she has put on weight over the last 12 months.

Question

What further information do you need to obtain to be in a position to help Mrs CB?

Answer

Constipation can be a common problem in someone of Mrs CB's age. A full medical and social history is required to establish the root cause. Ignoring the need to defecate which could be combined with a diet low in fibre, inadequate fluid intake and inadequate exercise may all be contributory factors. The nature of the condition should be established alongside the duration of the problem and whether there are any other symptoms such as blood in the stools, pain and bloating. Her normal bowel habits could be discussed, and she should be asked to explain why she thinks she is constipated. It would be important to establish if there has been any change which may have precipitated the constipation. These may include physical and social factors such as life changes. Particularly, in this case, one should further probe the weight gain over the past 12 months. If the patient eats a healthy diet and has been exercising on a regular basis, then hypothyroidism could be suspected. If other symptoms of hypothyroidism, such as lethargy, tiredness, malaise and feeling cold are present, then it may be prudent to refer to the primary care doctor for thyroid function tests.

If her replies to the questions raise no suspicion of underlying medical problems, then non-drug advice only may be needed. If the patient would benefit from an increase in exercise, fluid intake or increase in fibre, then this can be recommended. Often patients will request a

Table 14.7 Common therapeutic problems in constipation and diarrhoea

Problem	Comments
Constipation	
Bulk laxative (e.g. ispaghula) taken at bedtime	Drugs such as ispaghula should not be taken before going to bed because of risk of oesophageal blockage.
Urine changes colour	Anthraquinone glycosides (e.g. senna) are excreted by the kidney and may colour urine yellowish brown to red, depending on pH.
Patient claims dietary and fluid advice ineffective in resolving constipation	May find high-fibre diet difficult to adhere to, socially unacceptable, and expect result in less than 4 weeks.
Patient who is taking docusate reports unpleasant aftertaste or burning sensation	Advise to take with plenty of fluid after ingestion.
Sterculia as Normacol and Normacol Plus granules or sachets	The granules should be placed dry on the tongue and swallowed immediately with plenty of water or a cool drink. They can also be sprinkled onto and taken with soft food such as yogurt.
Methylcellulose (Celevac)	Each tablet should be taken with at least 300 mL of liquid.
Diarrhoea	
Antimotility agent requested for a young child	Antimotility agents must be avoided in young children or patients with severe gastroenteritis or dysentery.
Antimotility agent requested by patient with persistent diarrhoea (>10 days)	Antimotility agent inappropriate. Stool culture required to exclude parasitic infection, such as Giardia, Entamoeba and Cryptosporidium.
Adult with diarrhoea stops eating and drinking to allow diarrhoea to settle	Patient should eat and drink as normally as possible. Plenty of fluids are required to prevent dehydration. Fruit juice (glucose and potassium), soup (salt), bread and pasta (carbohydrate) are of particular benefit.
Reconstitution of oral rehydration solution	Each sachet of Dioralyte and Electrolyde; requires 200 mL of water. They should be discarded after 1 h after preparation unless stored in a fridge when they may be kept for 24 h.

particular product. Mrs CB should be recommended a bulk-forming laxative as first-line treatment. It is important to counsel the patient about how long the laxative will take to work (12–36 hours), because patients often have misconceptions about the onset of therapeutic benefit.

Case 14.2

Mr RJ is an 82-year-old man who was admitted to hospital following a fall at home. On admission he was confused and spiking a temperature of 38.7 °C. Urine analysis was strongly positive for nitrites and white blood cells. He was commenced on co-amoxiclav 1.2 g three times a day i.v. for a urinary tract infection. Two days later his temperature was normal and he was eating and drinking well. The decision was made to convert i.v. co-amoxiclav to oral for a further 5 days to ensure resolution of his infection. Three days later you are asked as the ward pharmacist if there is anything you can recommend because Mr RJ has diarrhoea. This morning his temperature is 39.2 °C and his C-reactive protein (CRP) is 45 mg/L. His regular medicines are furosemide 40 mg, lansoprazole 30 mg, atenolol 50 mg and aspirin 75 mg. All these medicines are taken once a day.

Answer

Broad-spectrum antibiotics are often used to treat infections empirically in the hospital setting. In elderly patients this is a potential risk. In addition to treating the infection they will also kill many of the normal gut microflora, which can allow pathogenic organisms to colonise the large intestine. Mr RJ shows two signs of an acute infection with a raised temperature and CRP. New-onset diarrhoea following a course of broad-spectrum antibiotic should always raise the possibility of *C. difficile*-associated diarrhoea. Proton pump inhibitors have been associated with an increased prevalence of *C. difficile* because by raising the pH of the stomach they remove a natural barrier to infection. Because Mr RJ is elderly this also increases the risk of *C. difficile* infection. Stool samples should be sent to the laboratory for culture and enterotoxin testing. Immediate action would involve isolating the patient and stopping any unnecessary treatment with broad-spectrum antibiotics. The lansoprazole should also be stopped to prevent colonisation from further pathogenic species. Antibiotic treatment to eradicate *C. difficile* should be commenced immediately. This normally involves a 10-day course of metronidazole in treatment-naive patients. However, increasingly resistant strains of *C. difficile* are being reported from UK hospitals. As a result local policies may recommend oral vancomycin or fidaxomicin as first-line treatment options. Treatment-resistant cases may be treated with a second antibiotic. In severe cases immunoglobulins or intestinal microflora transplants may be considered before total colectomy which can be lifesaving.

Case 14.3

Mr BT is a busy 45-year-old executive who works for a large, multi-national company. He complains of constipation. He has also noticed blood in his stools over the past 2 weeks, and for 3 days he has had continuous abdominal discomfort. He has discussed his symptoms with his wife, and they suspect haemorrhoids are the cause. Mr BT regularly travels to Africa with work and is due to go again in 6 days. He would like your advice on a suitable treatment.

Question

What advice should be given to Mr BT?

Answer

Blood in the stool is not necessarily serious. If the blood appears fresh and can only be seen on the surface of the stool it is likely the source is the anus or distal colon. It is probably caused by straining

when defaecating, leading to bleeding from haemorrhoids or an anal fissure. Similarly, if the blood appears as specks or as a smear on the toilet paper after defaecation, this is also likely to indicate haemorrhoids, particularly if such a diagnosis has been made previously following clinical examination. Larger amounts of fresh blood in the stool may indicate diverticulitis in older people, or if combined with other infective symptoms such as fever or rash may indicate infection with an enteroinvasive species such as *Shigella*, *E. coli* O157 or typhoid.

If the blood is mixed with the faeces and has a dark or 'tarry' appearance and a particularly offensive smell, then a more serious underlying cause is possible. The darker the faeces, the more suggestive that there has been an upper GI bleed or a substantial loss of blood from the large bowel. If this is the case the patient should be referred to have a full clinical examination, alongside a full blood count and urea and electrolyte tests. Iron tablets or bismuth preparations can cause darkened stools, so it is important to take a medication history from the patient.

However, given Mr BT's age, recent onset of symptoms, travel plans and the presence of continuous abdominal pain accompanying the constipation, referral for further investigation would be appropriate.

Case 14.4

Miss LS, the 15-year-old daughter of one of your regular patients, makes a request for stimulant laxative for herself for constipation. She is normally healthy, if a little thin, and seems a little nervous today.

Questions

What questions would you ask Miss LS in response to her over-the-counter medication request for a laxative?

Answers

Laxative abuse should be a consideration when receiving such a request from a person of this age. For individuals suffering from an eating disorder such as anorexia or bulimia nervosa, the prevalence of laxative abuse has been reported to range from approximately 10% to 60% (Roerig et al., 2010). As a result, although this request should be treated with suspicion, it should always be dealt with professionally and tactfully. Abuse should not be assumed without supporting evidence. Questions, regarding the length and duration of symptoms, any other medication, current diet and exercise patterns and her current social situation, will help to build up a more complete picture of the patient, and possibly help her reveal any underlying issues. It is important to investigate why she wants this product, as well as if she has used stimulant laxatives before and how often to eliminate abuse and chronic use. Stimulant laxatives are more prone to abuse because they are seen as a weight-reduction aid, because of their fast onset of action. Whatever the outcome of the consultation with Miss LS, healthy eating habits should be encouraged. This may include five portions of fruit and vegetables per day, 8 cups of water per day and regular exercise. It may also be useful to measure her weight and height to calculate her body mass index to show her that she does not need to lose weight.

Her age also complicates the issues in this case. Within the UK, Fraser guidelines and Gillick competence can be used to assess whether Miss LS is competent to make decisions about her own care (National Society for the Prevention of Cruelty to Children, 2017). Parents should not be informed as routine practice. If Miss LS has been chronically using stimulant laxatives, referral to her primary care doctor may be advised; however, she should not be forced to go.

Case 14.5

Mr GH is planning to travel to Mexico on business. He was last there 6 months ago but was incapacitated with diarrhoea for 3 of 6 days during a busy work schedule. He does not want a repeat experience on his forthcoming visit and is seeking advice about taking a course of antibiotics with him to use as empirical treatment, should the need arise.

Questions

1. Is there any evidence that antibiotics are of benefit in traveller's diarrhoea?
2. Are there any problems associated with empirical use of antibiotics in traveller's diarrhoea?

Answers

1. The empirical use of antibiotics has been shown to increase the cure rate in individuals suffering from traveller's diarrhoea.

Studies in travellers, including students, package tourists, military personnel and volunteers, have compared antibiotic use against placebo (De Bruyn et al., 2000). The antibiotics studied have included aztreonam, ciprofloxacin, co-trimoxazole, norfloxacin, ofloxacin and trimethoprim given for durations varying from a single dose to a 5-day treatment course. Overall, antibiotics increased the cure rate at 72 hours (defined as cessation of unformed stools or less than one unformed stool/24 hours) without additional symptoms. There has been an increase in reports of fluoroquinolone resistance from South East Asia; macrolides such as azithromycin are a useful treatment in these cases (Tribble et al., 2007).

2. The use of antibiotics in the treatment of traveller's diarrhoea does have problems. Adverse effects in up to 18% of recipients have been reported, with GI (cramp, nausea, or anorexia), dermatological (rash) and respiratory (cough and/or sore throat) symptoms the most frequently reported. Antibiotic-resistant isolates have also been reported following the use of ciprofloxacin, co-trimoxazole and norfloxacin. Rifaximin is licensed for the treatment of traveller's diarrhoea.

Acknowledgement

The authors would like to acknowledge the contribution of Paul Rutter to previous versions of this chapter which appeared in fourth and fifth editions of this book.

15 Adverse Effects of Drugs on the Liver

Sara Sawieres

Key points

- Approximately 20–30% of acute liver failure cases are attributed to drugs.
- The risk of drug-induced liver disorders increases with age and is generally more common in women.
- Generally, drug-induced liver damage is either dose-related or idiosyncratic.
- Drugs can cause all types of liver disorder and should always be considered in patients presenting with liver-related problems.
- The clinical features of drug-induced hepatotoxicity vary widely, depending on the type of liver damage caused.
- Treatment of drug-induced hepatotoxicity relies on correct diagnosis, prompt withdrawal of the causative agent and supportive therapy.
- Patients given potentially hepatotoxic drugs should be monitored regularly and taught how to recognise signs of liver dysfunction and advised to report symptoms immediately.
- Drugs causing dose-related hepatic toxicity may do so at lower doses in patients with liver disease than in patients with normal liver function, and idiosyncratic reactions may occur more frequently in patients with existing liver disease.
- Any new drug has the potential to cause hepatotoxicity. Post-marketing surveillance is important to highlight new potential hepatotoxic effects.

Traditionally, the definition of an adverse drug reaction (ADR) is an effect that is unintentional, noxious and occurs at doses used for diagnosis, prophylaxis and treatment ([World Health Organization \[WHO\], 1972](#)). In 2014 the European Medicines Evaluation Agency (EMA) defined an ADR as

a response to a medicinal product which is noxious and unintended.

[...]

Adverse reactions may arise from use of the product within or outside the terms of the marketing authorisation or from occupational exposure. Use outside the marketing authorisation includes off-label use, overdose, misuse, abuse and medication errors (EMA, 2014).

A hepatic drug reaction is an ADR that predominantly affects the liver.

Drugs can induce almost all forms of acute or chronic liver disease, with some drugs producing more than one type of hepatic reaction. Although not a particularly common form of ADR, drugs should always be considered as a possible cause of liver disease.

Drug-induced liver injury (DILI) is termed as either intrinsic or idiosyncratic DILI. Intrinsic DILI, which can also be termed as type A DILI, includes drugs that have the potential to affect all individuals with varying degrees. The reaction tends to be predictable and is often dose dependent; an example is paracetamol. Idiosyncratic DILI, which can also be termed type B DILI, occurs in susceptible individuals. The reaction is not predictable, so it is not dose dependent ([Chalasanani et al., 2014](#)). The latency period for the manifestation of idiosyncratic reactions is variable, ranging from 5 to 90 days from the initial ingestion of the drug. This type of reaction may be due to either drug hypersensitivity or a metabolic abnormality. Examples of drugs that induce idiosyncratic reactions are chlorpromazine, halothane and isoniazid ([Leise et al., 2014](#)).

Epidemiology

WHO has been tracking ADRs since 1968 and has issued a report indicating that since the 1990s, the number of incidences of DILI has continued to increase ([Bjornsson and Olsson, 2006](#)). However, the incidence of idiosyncratic reactions occurring at therapeutic doses for most drugs remains low, from 1 in every 1000 patients to 1 in every 100,000 patients. DILI is not usually life-threatening; however, for the small number of patients who develop drug-induced acute liver failure (ALF), the prognosis is poor. Ten percent of those who develop hepatocellular damage and jaundice will either need a liver transplant or die. It is estimated that 15–40% of ALF cases may be attributable to drugs ([Chalasanani et al., 2014](#)). [Table 15.1](#) presents the suggested classification of ALF: hyperacute, acute and subacute ([Richardson and O'Grady, 2002](#)).

Hepatotoxicity induced by such drugs as halothane, the anti-tuberculous agents isoniazid and rifampicin, psychotropics, antibiotics and cytotoxic drugs still continues to cause concern. ALF induced by paracetamol has become an important indication for liver transplantation. A trial carried out between 2002 and 2007 using six English hospitals and the National Registry of deliberate self-harm identified that there were 10,208 presentations to hospitals for paracetamol overdose in the UK and 9057 in Ireland ([Hawton et al., 2011](#)).

Many drugs cause elevated liver enzymes with apparently no clinically significant adverse effect, although in a few patients there may be significant hepatotoxicity. For

Table 15.1 Characteristics of the different types of acute liver failure (Richardson and O'Grady, 2002)

Characteristic	Hyperacute	Acute	Subacute
Transition time from jaundice to encephalopathy	0–7 days	8–28 days	29–84 days
Cerebral oedema	Common	Common	Rare
Renal failure	Early	Late	Late
Ascites	Rare	Rare	Common
Coagulation disorder	Marked	Marked	Modest
Prognosis	Moderate	Poor	Poor

example, isoniazid causes elevated liver enzymes in 10–36% of patients taking the drug as a single agent. However, only 1% suffer significant hepatotoxicity, with the liver function tests (LFTs) of the majority returning to normal if therapy is discontinued.

Although it is not possible to identify patients who will suffer ADRs manifesting in hepatic toxicity, a number of risk factors have been identified.

Risk factors

There are three types of risk factors that need to be considered: patient factors, drug factors and disease factors.

Patient factors

Age

Age as a risk factor for DILI only applies to some medications. For example, younger age puts people at risk of Reye's syndrome associated with aspirin. Agents such as erythromycin, halothane, isoniazid, nitrofurantoin and flucloxacillin are considered to have a greater risk of hepatotoxicity as age increases (Chalasanani and Bjornsson, 2010). The US tuberculosis study showed an incidence of isoniazid hepatotoxicity of 4.4 per 1000 patients aged 25–34 years but 20–83 per 1000 patients aged 50 years or older (Fountain et al., 2005). Younger individuals commonly develop hepatocellular DILI, whereas cholestatic DILI is more common in the elderly. The reason for age as a risk factor in DILI or the type of injury is unclear. The clearance of certain CYP3A substrates is altered by older age; however, the activity of phase I or II drug metabolising enzymes is not significantly affected by age. Elderly patients tend to be on multiple medications that may increase the risk of DILI; however, there is conflicting evidence around this (Chalasanani and Bjornsson, 2010).

Sex

Traditionally, it was believed that the frequency of drug-induced hepatotoxicity was higher in females than males. However, Lucena et al. (2009) carried out a prospective study and showed 51% of patients with DILI were male, and 49% were female. Specific medications have shown differences between genders. Halothane, isoniazid, nitrofurantoin, chlorpromazine and erythromycin have been shown to cause DILI more frequently in women, whereas men are more susceptible to azathioprine DILI. Medication causing hepatocellular patterns of damage, that is, damage to the cells in the liver, is seen more frequently in women and is associated with a poorer outcome, whereas cholestatic jaundice associated with co-amoxiclav has been reported to be more common in males than females (Chalasanani and Bjornsson, 2010).

Genetics

The rarity and unpredictable nature of idiosyncratic DILI suggest that there is a strong genetic component. Significant connections have been made between certain genetic traits and DILI. This has only been shown for a few compounds. It is difficult to isolate genetic traits from environmental risk factors. There are different suggestions and studies that have considered mitochondrial DNA mutations and their effect on DILI, genetic changes involved in the glycoproteins used to transport drug metabolites and genetic changes affecting immune response. It is thought that toxic metabolites formed by cytochrome P450 isoenzymes in phase I metabolism are involved in the pathogenesis of DILI. The evidence for this is weak except for in a few compounds where there are some case reports. There is some evidence showing that CYP2E1 mutant genotypes can reduce the risk of isoniazid-induced hepatotoxicity.

N-Acetylation involved in phase II metabolism is also thought to be involved in DILI. The enzyme involved is *N*-acetyltransferase 2 (NAT2); polymorphs of this enzyme have different enzymatic activity, with NAT2*4 having the fastest rate of acetylation. Studies have shown that the polymorphs associated with slower rates of acetylation are linked to hepatotoxicity associated with isoniazid and sulfonamides. Slow acetylators do not detoxify acetyl-hydrazine quickly and so promote oxidation by CYP2E1 into toxic metabolites.

It is thought that a genetic predisposition to allergic forms of drug hypersensitivity could be a factor in some types of liver disease. Flucloxacillin liver injury has been associated with the human leukocyte antigen B*5701. Having this HLA haplotype confers an 80-fold increase in susceptibility to liver injury with flucloxacillin (Chalasanani and Bjornsson, 2010).

Enzyme induction and metabolism

A study carried out in the US looked at the metabolism of 207 of the most commonly prescribed medications and their association with DILI. Drugs that were significantly metabolised by the liver, greater than 50% hepatic metabolism, had a significantly increased incidence of raised alanine aminotransferase, liver failure and fatal DILI. The study looked at four common cytochrome P450 pathways. The different pathways were associated with different indicators of liver injury. CYP2C9 and CYP2C19 were found to have the stronger association with DILI (Lammert et al., 2010).

Alcohol, rifampicin and other drugs that induce cytochrome P450 isoenzyme 2E1 potentiate the risk of hepatotoxicity with other drugs such as paracetamol, isoniazid and halothane. The role of alcohol as a risk factor for DILI is, however, not clear-cut, and acute and chronic alcohol consumption may have different effects.

Concomitant therapy with other anticonvulsants, particularly phenytoin and phenobarbital, is a risk factor for toxicity with sodium valproate, where 90% of cases of liver injury are associated with combination therapy (Chalasan and Bjornsson, 2010).

Drug factors

Daily dose

It has already been mentioned that idiosyncratic DILI cannot be predicted by the dose of a medication. However, co-amoxiclav, flucloxacillin and diclofenac are examples of medications that can cause idiosyncratic DILI that have shown a dose effect. Idiosyncratic DILI can occur at lower doses of these agents; however, an increase in dose has shown a worsening of DILI. Conversely, some agents, such as duloxetine, have caused DILI only on increasing the dose. These patients had previously not suffered from any underlying liver impairment at the lower doses (de Abajo et al., 2004).

Polypharmacy

A typical example of this is seen with non-steroidal anti-inflammatory drugs (NSAIDs). The risk of liver disease with NSAIDs is normally extremely low but is increased when NSAIDs are used with other hepatotoxic drugs. As mentioned previously, there is an association between drugs metabolised by CYP450 isoenzymes and DILI. Co-commitment use of drugs that interact by inducing CYP450 are thought to act as predisposing factors to DILI. CYP inducers include rifampicin, phenytoin, isoniazid, smoking and alcohol. A meta-analysis carried out looking at hepatotoxicity associated with taking isoniazid and rifampicin together or alone showed significantly greater incidences of hepatotoxicity when taken together than alone (Steele et al., 1991).

Disease factors

Pre-existing liver disease

Pharmacodynamics can be altered in pre-existing liver disease, making side effects more pronounced. For example, caution is needed when using anticoagulants in patients with impaired coagulopathy. It is also important to measure the risks of not using a specific agent versus the risks of using it. Patients with pre-existing liver damage should not be excluded from using agents that may cause liver injury. However, there are some agents where greater caution should be exhibited in patients with pre-existing liver disease. Examples include methotrexate, cytotoxic agents, aspirin and sodium valproate. A past medical history of DILI from any medication has been shown to be a predictor of future DILI from other drugs (Chalasan and Bjornsson, 2010).

Table 15.2 Examples of host factors that predispose to drug hepatotoxicity

Risk Factor	Drugs
Female sex	Nitrofurantoin, sulfonamides
Male sex	Azathioprine, amoxicillin/clavulanate
Advanced age	Isoniazid, amoxicillin/clavulanate
Young age	Valproic acid
Chronic alcohol abuse	Paracetamol, isoniazid, methotrexate
Malnutrition or fasting	Paracetamol
Pregnancy	Isoniazid
Diabetes	Methotrexate
Chronic liver disease	Methotrexate, niacin (vitamin B ₃)
Chronic kidney disease	Allopurinol
HIV infection	Dapsone, trimethoprim/sulfamethoxazole
Hepatitis B or C infection	Antiretroviral agents, antituberculosis agents
Genetic predisposition	Phenytoin, sulfonamides, isoniazid, antiepileptics

Adapted from Kim and Phongsamran (2009).

Concurrent diseases and pregnancy

Pre-existing renal disease, diabetes, poor nutrition and pregnancy may all affect the ability of the liver to metabolise drugs effectively and may put the patient at risk of developing liver damage. Table 15.2 summarises the host factors that may predispose a patient to drug hepatotoxicity.

Aetiology/pathophysiology/clinical manifestation

Drug-induced hepatotoxicity may present as an acute insult that may or may not progress to chronic disease, or it can present as an insidious development of chronic disease. The type of lesion may be cytotoxic (cellular destruction) or cholestatic (impaired bile flow). Cytotoxic damage may be further classified as necrotic (cell death) or steatic (fatty degeneration). The liver damage resulting from drug toxicity often presents as a mixed picture of cytotoxic and cholestatic injury. The mechanisms of drug-induced hepatic damage can be divided into intrinsic (type A) and idiosyncratic (type B) hepatotoxicity (Table 15.3). Intrinsic hepatotoxicity is predictable, is dose-dependent and usually has a short latency period ranging from hours to weeks. The majority

Table 15.3 Characteristics of intrinsic and idiosyncratic hepatotoxic reactions

Intrinsic drug-induced liver injury	Idiosyncratic drug-induced liver injury
Dose related reaction (usually at the same dose)	Attacks only susceptible individuals (unclear relationship with dose)
Predictable time frame for onset of symptoms	Variable onset relative to exposure
Distinctive liver lesion	Variable liver pathology
Predictable using routine animal testing	Not predictable using routine animal tests

Adapted from Roth and Ganey (2010).

of individuals who take a toxic dose are affected and exhibit the same type of injury. Examples are paracetamol, salicylates, methotrexate and tetracycline. Toxicity may be avoided by ensuring the recommended doses are not exceeded.

Idiosyncratic reactions occur at a low frequency. The latency period is variable, ranging from 5 to 90 days from the initial ingestion of the drug. The type of injury is less predictable and not dose-related. This type of reaction may be due to either drug hypersensitivity or a metabolic abnormality. Examples of drugs that induce idiosyncratic reactions are chlorpromazine, halothane and isoniazid.

The precise mechanisms resulting in DILI are often not completely understood, although injury to the hepatocytes may result directly from interference with intracellular function or membrane integrity or indirectly by immune-mediated damage to cells.

The range of DILIs is illustrated in Table 15.4. An increased serum level of hepatobiliary enzymes without clinical liver disease occurs with variable frequency between drugs, but for some agents, it may occur in up to half of the patients who receive a drug. This may reflect subclinical liver injury.

Cholestasis

Cholestasis is defined as the stagnated movement of bile throughout the bile ducts. This can occur in the intrahepatic ductules in conditions such as primary biliary cirrhosis or can be extrahepatic due to disruption by gallstones (North-Lewis, 2008).

Aetiology

Some drugs injure bile ducts and cause partial or complete obstruction of the common bile duct, resulting in retention of bile acids. Cholestasis caused by anabolic and contraceptive steroids is due to inhibition of bilirubin excretion from the hepatocyte into the bile.

The penicillins, although commonly associated with allergic drug reactions, are a very rare cause of liver disease. The isoxazolyl group present in the synthetic β -lactamase-resistant oxypenicillins has been implicated as a cause of liver injury. Acute cholestatic hepatitis has increasingly been reported during treatment with flucloxacillin, and in some countries this has become the most important cause of drug-induced cholestatic hepatitis. The incidence

Table 15.4 Examples of adverse drug reactions on the liver (Leise et al., 2014)

Adverse reaction	Drugs associated with reaction
Hepatocellular necrosis	Paracetamol, propylthiouracil, salicylates, iron salts, allopurinol, dantrolene, halothane, ketoconazole, isoniazid, mitomycin, cocaine, 'ecstasy' (methylenedioxymethamphetamine [MDMA])
Fatty liver	Amiodarone, tetracyclines, steroids, sodium valproate, l-asparaginase, methotrexate
Cholestasis	Oral contraceptives, carbimazole, anabolic steroids, ciclosporin
Cholestasis with hepatitis	Chlorpromazine, tricyclic antidepressants, erythromycin, flucloxacillin, co-amoxiclav, angiotensin-converting enzyme (ACE) inhibitors, sulfonamides, sulfonylureas, phenytoin, non-steroidal anti-inflammatory drugs (NSAIDs), cimetidine, ranitidine, trazodone
Granulomatous hepatitis	Phenytoin, allopurinol, carbamazepine, clofibrate, hydralazine, sulfonamides, sulfonylureas
Acute hepatitis	Dantrolene, isoniazid, phenytoin
Chronic active hepatitis	Methyldopa, nitrofurantoin, isoniazid
Fibrosis and cirrhosis	Methotrexate, methyldopa, vitamin A (dose-related)
Vascular disorders	Azathioprine, dactinomycin, dacarbazine

appears to be about twice that of the related isoxazolyl penicillins cloxacillin and dicloxacillin. Moreover, there is likely to be under-reporting due to a delay in onset of up to 42 days after stopping treatment. Female sex, age over 55 years, longer courses and high daily doses also seem to be associated with a higher risk of liver injury associated with flucloxacillin (Farrell, 1997).

Rifampicin causes hyperbilirubinaemia by inhibiting uptake of bilirubin by the hepatocyte and inhibiting bilirubin excretion into bile. This is generally not an indication for interrupting rifampicin therapy, although liver function will need to be closely monitored. Other therapeutic agents affect sinusoidal or endothelial cells and may result in veno-occlusive disease or fibrosis. Vitamin A affects the fat-storing cells, causing toxicity that leads to fibrosis.

Pathophysiology

Cholestasis without hepatitis is associated with a raised bilirubin and a normal or minimally raised alanine aminotransferase level. No inflammation or hepatocellular necrosis is seen. In contrast, cholestasis associated with hepatitis presents with raised bilirubin, alanine aminotransferase and alkaline phosphatase levels and a certain amount of liver damage.

Clinical manifestation

The main clinical feature of pure cholestasis is severe pruritus, with or without other features, according to the severity, such as dark urine, pale stools and jaundice.

Drug-induced cholestatic hepatitis usually presents with gastro-intestinal symptoms after an influenza-like illness. Abdominal pain with typical features of cholestasis then occurs. The pruritus is generally less severe than with pure cholestasis (Leise et al., 2014; North-Lewis, 2008).

Steatosis

The liver is the main organ involved in fat metabolism. Damage to the hepatocytes disrupts this process and leads to steatosis. Steatosis is the accumulation of fat within the hepatocytes. It can also be termed fatty liver. The size of the droplets can be small (micro-vesicular) or large (macro-vesicular).

Aetiology

As mentioned previously, the cause of steatosis is the accumulation of fat in the hepatocytes. Tetracyclines are thought to cause steatosis by interfering with the synthesis of lipoproteins that normally remove triglycerides from the liver.

Pathophysiology

Steatosis is associated with abnormal LFTs, although the elevation of alanine aminotransferase is not as high as that seen in acute hepatocellular necrosis. Hyperammonia, hypoglycaemia, acidosis and clotting factor deficiency may also be present. Histologically, the liver damage resembles the acute fatty liver of pregnancy. Micro-vesicular droplets occur with tetracycline, aspirin and sodium valproate, and macro-vesicular droplets occur with steroids, methotrexate, alcohol and amiodarone.

A less severe, more chronic form of fatty liver, steatohepatitis, also occurs. Steatohepatitis differs from diffuse fatty change. Notably, the clinical symptoms and biochemistry resemble chronic parenchymal disease, and the histology is similar to that seen in alcoholic hepatitis. Amiodarone is an example of a drug that can cause chronic steatohepatitis associated with phospholipidosis (North-Lewis, 2008).

Clinical manifestation

A patient presenting with steatosis generally shows fatigue, nausea, vomiting, hypoglycaemia and confusion. Jaundice is present in severe cases.

Hepatitis

When hepatocytes are damaged or die, an inflammatory response is triggered. The inflammatory response is characterised by inflammatory cells, oedema and congestion surrounding the hepatocytes. Inflammation can be acute or chronic and can present differently depending on the degree of damage.

Aetiology

Hepatitis can occur from any number of insulting agents, such as medication or viruses, or can be autoimmune regulated.

Acute hepatitis

Pathophysiology

Acute hepatitis resembles viral hepatitis, with LFTs raised in proportion to the severity of the hepatocellular damage. The best indicator of severity is the prothrombin time. Histologically, necrosis and cellular degeneration are seen in combination with an inflammatory infiltrate.

Clinical manifestation

Acute hepatitis may present with a prodromal illness with non-specific symptoms or include features of drug allergy followed by anorexia, nausea and vomiting, dark urine, pale stools and jaundice. Jaundice tends to be present in severe cases. Weight loss may also be a feature of acute hepatitis. Fatalities occur in 5–30% of jaundiced patients. Acute hepatitis is second only to paracetamol self-poisoning as a cause of DILI.

Chronic active hepatitis

Pathophysiology

Chronic active hepatitis may present as an acute injury or progress to cirrhosis. Serum transaminases are usually raised, and albumin is low. The histology resembles that of autoimmune chronic active hepatitis and is associated with circulating auto-antibodies. Methyldopa is an example of a drug that can cause chronic active hepatitis (North-Lewis, 2008).

Clinical manifestation

Drug-induced chronic active hepatitis may present with tiredness, lethargy and malaise, in a manner similar to other types of chronic liver disease. The symptoms may evolve over many months. Gastro-intestinal symptoms are usually present, and patients may show one or more complications of severe liver disease, including ascites, bleeding oesophageal varices or hepatic encephalopathy. If the ADR has an allergic component, a skin rash and other extrahepatic features of a drug allergy, such as lymphadenopathy, evidence of bone marrow suppression (particularly petechial haemorrhages) may be present.

Fibrosis

Fibrosis of the liver occurs from excessive accumulation of scar tissue as a result of ongoing inflammation of hepatocytes.

Aetiology

A fibrotic liver is characterised by collagen deposits in response to continuous insult to hepatocytes. This then develops into scar

tissue. The scarred tissue disrupts the blood flow through the liver and disrupts the passage of substrates from the blood to the hepatocytes.

Pathophysiology

In patients with fibrosis, the serum transaminase levels may be only slightly raised and are not good predictors of hepatic damage. Microscopy shows deposition of fibrous tissues. Fibrosis may proceed to cirrhosis. Such damage may be seen with long-term methotrexate use (North-Lewis, 2008).

Clinical manifestations

Clinical manifestations can vary depending on the severity of fibrosis. Some patients may not have any symptoms at all, and some can present with general symptoms such as abdominal pain, fatigue and malaise (North-Lewis, 2008).

Tumours

Tumours that originate in the liver are termed hepatocellular carcinomas (HCCs).

Aetiology

Of patients who develop an HCC, 90–95% have an underlying cirrhosis; the rest will have a non-cirrhotic HCC. Cirrhosis can be caused by hepatitis B or C, alcoholism, primary biliary cirrhosis, diabetes or smoking and, on rare occasions, medications (Forn et al., 2012).

Pathophysiology

Drugs have been associated with a variety of hepatic tumours. The drugs most commonly linked to malignancy are the oral contraceptives, anabolic steroids and danazol (North-Lewis, 2008).

Clinical manifestation

Patients with small tumours tend to be asymptomatic. However, when clinical manifestations occur, symptoms can be very general to liver impairment. Abdominal pain may or may not be reported, together with a feeling of fullness after eating. Weight loss, fatigue, anorexia, nausea and, occasionally, vomiting can occur, especially in advanced cases (North-Lewis, 2008).

Necrosis

The course of liver necrosis is similar to acute toxic liver injury with a sudden onset.

Aetiology

Necrosis is characterised by cytotoxic cellular breakdown (hepatocellular destruction) and is generally associated with a poor prognosis. Drugs commonly associated with DILI have a variable propensity to cause hepatic necrosis. For example, hepatic

necrosis has been reported in 3% of cases with co-amoxiclav DILI compared with 89% in individuals with halothane-induced liver injury cases (North-Lewis, 2008).

Paracetamol causes hepatic necrosis when its normal metabolic pathway is saturated. Subsequent metabolism occurs by an alternative pathway that produces a toxic metabolite that covalently binds to liver cell proteins and causes necrosis (Heard, 2008).

Pathophysiology

In severe cases, acute hepatocellular necrosis presents with jaundice and LFT abnormalities, including a modestly raised alkaline phosphatase and a markedly elevated alanine aminotransferase level of up to 200 times the upper limit of the reference range. Prolongation of the prothrombin time occurs but depends on the severity of the injury, increasing dramatically in severe cases. Microscopy reveals necrosis of the hepatocytes in a characteristic pattern.

Clinical manifestation

In acute hepatocellular necrosis caused by paracetamol, early symptoms include anorexia, nausea and vomiting, malaise and lethargy. Abdominal pain may be the first indication of liver damage but is not usually apparent for 24–48 hours. A period of apparent recovery precedes the development of jaundice and production of dark urine. If the liver injury is severe, deterioration follows, with repeated vomiting, hypoglycaemia, metabolic acidosis, bruising and bleeding, drowsiness and hepatic encephalopathy. Oliguria (diminished urine output) and anuria (complete cessation of urine production) may result from acute tubular necrosis. Renal failure may occur even in the absence of severe liver disease. In addition to acute renal failure, myocardial injury and pancreatitis have also been reported. In fatal cases, death from acute liver failure occurs between 4 and 18 days after ingestion.

Vascular disorders

A variety of drugs can cause veno-occlusive disease, which is characterised by non-thrombotic narrowing of small centrilobular veins and is typically caused by cytotoxic agents and some herbal remedies. The use of oral contraceptives or cytotoxic agents may exacerbate an underlying thrombotic disorder and increase the risk of Budd–Chiari syndrome (obstruction of the large veins) developing. Veno-occlusive disease may present with painful hepatomegaly, ascites and jaundice, along with other features of liver insufficiency. It has been reported after chemotherapy with drugs such as cyclophosphamide, doxorubicin and dacarbazine. It has also been reported as a common complication of bone marrow transplantation (Leise et al., 2014; North-Lewis, 2008).

Investigations

Various types of investigation are used in the diagnosis of drug-induced hepatotoxicity, with the number and type of tests

depending on the clinical presentation. Unfortunately, available laboratory tests do not provide ideal markers for DILI, and the diagnosis is generally one of exclusion.

Biochemical tests

Routine LFTs are measured, which generally include total bilirubin, alanine transaminase (ALT) and alkaline phosphatase (ALP). Impairment of the synthetic function of the liver is detected by total protein, albumin and the prothrombin time. Other biochemical tests may include measurement of γ -glutamyl transpeptidase (GGT), which may be elevated in all forms of liver disease, including drug-induced disease. α -Fetoprotein (AFP) may be measured to exclude malignancy. Conjugated bilirubin may be measured to establish if there is biliary obstruction.

Serological markers

Serological markers for hepatitis A, B and C and other viruses such as the Epstein–Barr virus should be determined in patients with symptoms of hepatitis with appropriate risk factors to exclude an infective cause.

Radiological investigations

Radiological investigations, such as ultrasound, computed tomography (CT), percutaneous cholangiograms and endoscopic retrograde cholangiopancreatography (ERCP), are used to look for physical obstruction of bile ducts by gallstones, masses or strictures.

Liver biopsy

Liver biopsy is seldom helpful for diagnosis of DILI, but certain drugs can cause characteristic lesions, such as the distribution of micro-vesicular fat droplets seen with tetracyclines. Specific diagnostic tests for drug-induced disease exist for few drugs.

Other causes of liver dysfunction, such as autoimmune chronic active hepatitis, acute severe cholestasis, ischemic hepatic necrosis, pregnancy-related liver disease, the Budd–Chiari syndrome, rare metabolic disorders or liver disease related to alcohol abuse, must also be excluded.

Treatment

The aim of treatment for drug-induced hepatotoxicity is a complete recovery. This relies on correct diagnosis, withdrawal of any and all suspected drugs, and supportive therapy, which may include liver transplantation where appropriate.

Diagnosis

Drug-induced hepatic injury should be considered in every patient with jaundice alongside all other causes of liver disease by the clinical history and the results of investigations (Chalasani et al., 2014). The typical process in screening

patients presenting with jaundice is outlined in Fig. 15.1, and the general approach to the differential diagnosis of acute hepatitis is set out in Fig. 15.2.

Identifying the causative agent and stopping it is important in reducing the morbidity and mortality associated with DILI. Agents such as nitrofurantoin, minocycline and statins tend to cause DILI after prolonged use. Agents such as antibiotics and antiepileptics are more common agents known to cause more than 60% of DILI. Antihypertensive and diabetic medications are known to cause DILI; however, their incidence is much less.

A detailed and thorough drug history, including the use of oral contraceptives, over-the-counter medicines, vitamins, herbal preparations and illicit drug use, should be obtained. Examples of herbal and dietary preparations implicated in causing liver damage are listed in Box 15.1. Attention to the duration of treatment with a specific drug and the relationship to the onset of symptoms is important. The likelihood of a drug-related disease is greatest when the abnormality begins between 5 and 90 days after taking the first dose and within 15 days of taking the last dose. The latent period, that is, the time between starting therapy and the appearance of symptoms, may vary but for many drugs is sufficiently reproducible to be of some diagnostic value (Chalasani et al., 2014).

Recovery normally follows discontinuation of a hepatotoxic drug. Serious toxicity or ALF may result if the drug is continued after symptoms appear or the serum transaminases rise significantly. Failure to discontinue the drug may give grounds for claims of negligence.

Predisposing factors for liver toxicity should also be noted. If the liver injury is accompanied by fever, rash and eosinophilia, the likelihood of drug-induced disease increases, although lack of these features does not exclude it. Unequivocal diagnosis cannot be made in most circumstances, and improvement on withdrawal of the implicated drug may provide the strongest evidence for drug-induced disease. Time for resolution of the abnormalities is dependent on the individual drug and type of liver disease. In some cases, several months may elapse.

Idiosyncratic reactions may also need to be considered and the literature consulted for previous reports. A key component of secondary prevention is the reporting of all suspected hepatic drug reactions to the appropriate monitoring agency.

Practice points for diagnosing DILI are shown in Box 15.2, and examples of drugs associated with chronic liver injury are shown in Box 15.3.

Withdrawal

Once drug-induced hepatotoxicity has been recognised as a possibility, therapy should be stopped. If the patient is receiving more than one potentially hepatotoxic drug, all drugs should be stopped. Withdrawal of the agent usually results in recovery that begins within a few days. However, LFTs may take many months or even years to return to normal. Co-amoxiclav and phenytoin are examples of drugs that have been associated with a worsening of the patient's condition for several weeks after withdrawal and a protracted recovery period of several months.

Fig. 15.1 General approach to the diagnosis and management of drug-induced jaundice. MHRA, Medicines and Healthcare Products Regulatory Agency.

Rechallenge

When drug-induced hepatotoxicity has been confirmed by improvement on drug withdrawal, subsequent use in the patient is generally contraindicated. Rechallenge is not normally justified because this is potentially dangerous for the patient, although a positive rechallenge is the most definitive confirmation of drug-induced disease. Inadvertent rechallenge may occur. If the rechallenge is negative, this is usually taken to indicate that the patient may resume using the drug. Another adverse reaction on re-exposure to the drug precludes any further use (Chalasanani et al., 2014).

Management

If clinical or laboratory signs of hepatic failure appear, hospitalisation is mandatory. After withdrawal of the drug, attempts

to remove it from the body are only relevant for acute hepatotoxins such as paracetamol, metals or toxic mushrooms such as *Amanita phalloides* (death cap). If patients present a few hours post-ingestion, any unabsorbed drug may best be removed by gastric lavage, rather than by use of emetics.

Antidotes

Specific antidotes are acetylcysteine and methionine for paracetamol, and desferrioxamine for iron overdose. Desferrioxamine is administered orally as soon as possible after ingestion for acute iron poisoning. Parenteral desferrioxamine is indicated in addition to oral administration, to chelate absorbed iron where the plasma levels exceed 89.5 mmol/L, where the plasma levels exceed 62.6 mmol/L and there is evidence of free iron, and in patients with signs and symptoms of acute iron poisoning.

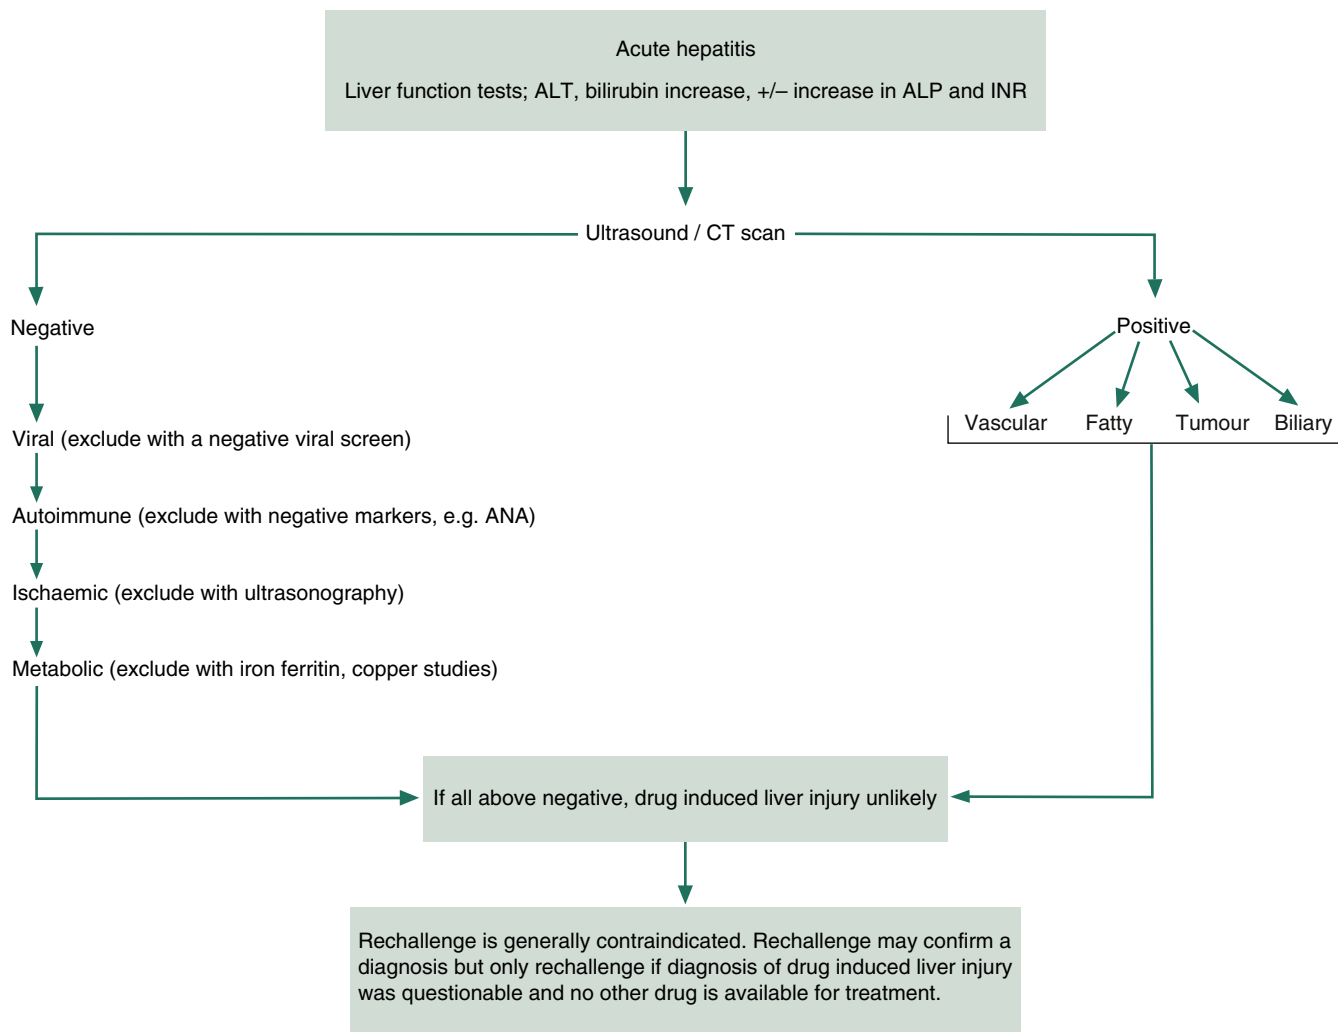

Fig. 15.2 General approach to the differential diagnosis of acute hepatitis. ALP, Alkaline phosphatase; ALT, alanine transferase; ANA, antinuclear antibodies; CT, computed tomography; INR, international normalised ratio.

Paracetamol-induced hepatotoxicity. Paracetamol causes a dose-related toxicity resulting in centrilobular necrosis. It normally undergoes the phase II reactions of glucuronidation and sulphation. However, paracetamol is metabolised by cytochrome P450 2E1 to *N*-acetyl-*p*-benzoquinoneimine (NABQI) if the capacity of the phase II reactions is exceeded or if cytochrome P450 2E1 is induced. After normal doses of paracetamol, NABQI is detoxified by conjugation with glutathione to produce mercaptopyrurine and cysteine conjugates. After overdose, tissue stores of glutathione are depleted, allowing NABQI to accumulate and cause cell damage. Illness, starvation and alcohol deplete glutathione stores and increase the predisposition to paracetamol toxicity, while acetylcysteine and methionine provide a specific antidote by replenishing glutathione stores.

Ingestion of doses as low as 10–15 g of paracetamol has been reported to cause severe hepatocellular necrosis. Activated charcoal may be administered to reduce further absorption of

paracetamol and facilitate removal of un-metabolised paracetamol from extracellular fluids if presenting early after ingestion. A plasma paracetamol concentration should be taken as soon as possible but not within 4 hours of ingestion due to the fact that a misleading and low level may be obtained because of continuing absorption and distribution of the drug. The plasma concentration measured should be compared with a standard nomogram reference line of a plot of plasma paracetamol concentration against time in hours after ingestion. This may be a semilogarithmic plot (Fig. 15.3).

Generally, administration of intravenous acetylcysteine is the treatment of choice for paracetamol overdose when the blood paracetamol level is in the range predictive of possible or probable liver injury (Fig. 15.3). Patients allergic to acetylcysteine may receive oral methionine.

Acetylcysteine is most effective within 8 hours of overdose. However, late administration in patients who present more than

Box 15.1 Examples of herbal remedies and food supplements implicated in hepatotoxicity (Kim and Phongsamran, 2009)

Dietary supplement	Clinical presentation
<i>Atractylis gummifera</i>	Acute hepatitis, fulminant hepatic failure
Black cohosh	Acute hepatitis
<i>Callilepis laureola</i>	Acute hepatitis, fulminant hepatic failure
<i>Camellia sinensis</i>	Acute hepatitis, fulminant hepatic failure
Chaparral	Cholestasis, acute and chronic hepatitis
Chinese herbal medicines (Sho-saiko-to, Dai-saiko-to)	Acute hepatitis, cholestasis, autoimmune hepatitis
Germander	Acute and chronic hepatitis, hepatic fibrosis
Hydroxycut	Acute hepatitis
Jin Bu Huan	Acute hepatitis, chronic cholestatic hepatitis, hepatic fibrosis
Kava	Acute hepatitis, cholestasis, fulminant hepatic failure
Ma Huang	Acute hepatitis, autoimmune hepatitis
Pyrrolizidine alkaloids	Veno-occlusive disease
Valerian	Mild hepatitis

Box 15.2 Practice points for the diagnosis of drug-induced liver disease

- Consider drugs as a cause for all cases of liver damage in patients presenting with liver disease.
- Take a careful drug history, including prescription, over-the-counter, herbal and alternative medicines and illicit drugs.
- Has the drug implicated been previously reported to cause drug-induced liver disease?
- Does the patient have risk factors for drug-induced liver disease?
- Consider the temporal relationship (onset of symptoms between 5 and 90 days after initial exposure?).
- Is there improvement on discontinuation of the suspected agent?
- Rechallenge with the suspected drug is not recommended; however, a positive rechallenge is the most definite evidence of drug-induced disease.

Box 15.3 Examples of drugs associated with the development of chronic liver disease

- Amiodarone
- Flucloxacillin
- Isoniazid
- Methotrexate
- Nitrofurantoin
- Non-steroidal anti-inflammatory drugs
- Pyrazinamide
- Rifampicin

Fig. 15.3 Semilogarithmic plot of plasma paracetamol concentration versus time in hours after ingestion.

16–24 hours post-ingestion may be appropriate. Acetylcysteine administered at this stage will not counteract the oxidative effects of paracetamol, but it may have a cytoprotective role in hepatic failure and has been shown to reduce morbidity and mortality in patients who have already developed ALF (Brok et al., 2006).

Corticosteroids

Immunosuppression with corticosteroids has been used in the management of drug-induced hepatotoxicity, but evidence indicates their use does not affect the survival of patients with ALF. However, there have been anecdotal reports of impressive responses to corticosteroids that are persuasive, and it may be appropriate to conduct a short trial in rare types of drug-induced disease (Chalasanani et al., 2014).

Supportive treatment

For most patients there is no specific treatment available. General supportive treatment is necessary in liver failure, with appropriate attention to fluid and electrolyte balance. Nutritional support should be along conventional medical lines for those suffering from malnourishment as a result of chronic injury.

Pruritus

The main symptom of drug-induced cholestasis is pruritus due to high systemic concentrations of bile acids deposited in tissues. General measures include light clothing (avoid wool), cooling the skin with tepid baths or calamine lotion and use of a general moisturising agent such as aqueous cream. The management of liver-induced pruritus is discussed in Chapter 16.

Coagulation disorders

Coagulation disorders should be treated by correcting vitamin K deficiency with intravenous phytomenadione injection. This should correct the prothrombin time within 3–5 days. Oral

phytomenadione is ineffective in cholestasis. Menadiol sodium phosphate, the water-soluble vitamin K analogue, may be effective in an oral dose of 10 mg daily. If bleeding occurs, infusion of fresh frozen plasma or clotting factor concentrates will be indicated. The administration of other fat-soluble vitamins may also be necessary (North-Lewis, 2008).

Long-term treatment

When the DILI is under control, consideration will have to be given to the treatment of the original condition for which the implicated drug was prescribed. In many cases, drug therapy will still be required, and caution must therefore be exercised because drugs with similar chemical structures may cause similar hepatotoxicity.

Hepatotoxicity may occur with different derivatives of a drug. Erythromycin-induced cholestatic hepatitis has been more frequently reported with the estolate preparation than with other erythromycin esters (ethylsuccinate, stearate, propionate and lactobionate). It is not clear which part of the drug is responsible for hypersensitivity.

Patient counselling

Patients who recover from drug-induced hepatotoxicity should be informed of the causative agent, warned to avoid it in the future, and advised to inform their doctor, dentist, nurse and pharmacist about the occurrence of such an event.

Patients who purchase preparations containing paracetamol should be made aware of the danger of overdosing, which may occur if other preparations containing paracetamol are taken simultaneously. Since 1994 the European guidelines on package labelling have required products containing paracetamol to warn patients of the need to avoid other products containing paracetamol. The pack size of paracetamol sold from general sales outlets has been limited to 16 tablets or capsules (32 where paracetamol is sold under the supervision of a pharmacist) with the aim of limiting availability and reducing residual stocks in the home. This appears to have reduced the incidence of ALF secondary to paracetamol overdose (Hawton et al., 2011).

All patients should be advised of potential side effects. This information needs to be reinforced with the use of patient information leaflets. For medications known to cause liver injury, patients and their carers should be helped to recognise signs of liver disorder and know to report immediately symptoms such as malaise, nausea, fever and abdominal discomfort that may be significant. If these are accompanied by elevated LFTs, the drug needs to be assessed for its safety.

Parents of children commenced on sodium valproate should be warned to report side effects that may be suggestive of liver injury, such as the onset of anorexia, abdominal discomfort, nausea and vomiting. Early features include drowsiness and disturbed consciousness. DILI associated with sodium valproate usually occurs within 6 months. The maximum risk period is between 2 and 12 weeks of starting.

The challenge for all members of the healthcare team is to alert patients to the potentially toxic effects of drugs without creating so much concern that they fail to comply with vital medication. For the limited number of drugs presented in Table 15.5,

careful monitoring of LFTs during the first 6 months of treatment is advisable, although not always practical. Thereafter, regular monitoring of LFTs is appropriate in patients who are at greater risk of hepatotoxicity. Such patients would include those with known liver disease, those taking other hepatotoxic drugs, those older than 40 years, and heavy alcohol consumers. Surveillance should be particularly frequent in the first 2 months of treatment. In patients with no risk factors and normal pretreatment liver function, LFTs need only be repeated if fever, malaise, vomiting, jaundice or unexplained deterioration during treatment occurs.

Because many drugs cause elevation of LFTs, there may be difficulty in assessing when to stop a drug, particularly when treating an individual for tuberculosis or epilepsy. An empirical guideline is that the drug should be stopped if the levels of alanine transaminase exceed three times the upper limit of the reference range (Joshi et al., 2015). Any clinical features of liver disease or drug allergy would require immediate discontinuation of the drug. Conversely, a raised γ -glutamyl transpeptidase level and elevated alanine transaminase level in the absence of symptoms often reflect microsomal induction and would not indicate drug-induced injury.

It should be noted that monitoring of LFTs is not a complete safeguard against hepatotoxicity because some drug reactions develop very quickly, and the liver enzymes are an unreliable indicator of fibrosis.

Minimising the risk of drug-induced liver injury

The risk of acute liver injury with co-amoxiclav is higher than that of amoxicillin and increases with treatment courses longer than 14 days. Hence, the indications for co-amoxiclav have been restricted to cover infections caused by amoxicillin-resistant β -lactam-producing infections.

Patients admitted for procedures requiring a general anesthetic should be questioned about past exposure and any previous reactions to halothane. Halothane is well known to be associated with hepatotoxicity, particularly if patients are re-exposed. Repeated exposure to halothane within a period of less than 3 months should be avoided, and some increase in risk persists regardless of the time interval since last exposure. Unexplained jaundice or delayed-onset postoperative fever in a patient who has received halothane is an absolute contraindication to future use in that individual. Patients with a family history of halothane-related liver injury should also be treated with caution.

Although hepatic ADRs are rare for most drugs, when they do occur they can cause significant morbidity and mortality. More than 600 drugs have been associated with hepatotoxicity, and any new drug released to the market may have the potential to cause hepatotoxicity. Pemoline and troglitazone are examples of drugs withdrawn from the market due to reports of serious hepatic reactions. These examples help highlight the importance of post-marketing surveillance and yellow card reporting.

Appropriate selection of drugs, an awareness of predisposing factors and avoidance of toxic dose thresholds and potentially hepatotoxic drug–drug interactions will minimise the risk to patients.

Practice points for patient care and minimising the risk of DILI are outlined in Box 15.4.

Table 15.5 Examples of drugs where regular monitoring of liver function is recommended

Drug	Baseline measurement ^a	Frequency of monitoring
Anti-TB therapy (isoniazid, rifampicin, pyrazinamide)	Yes	Patients with pre-existing chronic liver disease: check LFTs regularly, every week for the first 2 weeks, then twice a week for the first 2 months. Patients with normal liver function tests and no evidence of pre-existing liver disease: regular monitoring is not necessary, but LFTs repeated if signs of liver dysfunction develop, e.g. fever, malaise, vomiting or jaundice. Patients with raised pretreatment hepatic transaminases: two or more times normal: check LFTs weekly for 2 weeks, then twice a week until normal. Less than two times normal: check LFTs at 2 weeks. If these transaminases have fallen, further tests are only needed if symptoms occur.
Amiodarone	Yes	Check LFTs every 6 months.
Cyproterone	Yes	Recheck if any symptoms.
Dantrolene	Yes	Repeat LFTs after first 6 weeks of therapy.
Itraconazole	Yes	Monitor LFTs if therapy continues for more than 1 month. Recheck if any symptoms.
Ketoconazole	Yes	LFTs checked on weeks 2 and 4 of therapy and then every month.
Methotrexate	Yes	LFTs checked every 2 weeks for the first 2 months, then monthly for 4 months, then every 3 months.
Methyl dopa	Yes	Check LFTs at intervals during the first 6–12 weeks of treatment.
Micafungin	Yes	Periodic monitoring of LFTs recommended. Recheck if any symptoms.
Nevirapine	Yes	Check LFTs every 2 weeks for the first 2 months, then at month 3 and then regularly.
Pioglitazone	Yes	Periodic monitoring of LFTs recommended. Recheck if any symptoms.
Sodium valproate	Yes	Check LFTs regularly during the first 6 months of therapy.
Statins	Yes	LFTs checked 12 weeks after initiation or after a dose increase and periodically thereafter.
Sulfasalazine	Yes	LFTs checked every 2 weeks for the first 2 months, then monthly for 4 months then every 3 months
Tipranavir	Yes	Check LFTs on weeks 2, 4 and 8 of treatment and then every 2–3 months.
Vildagliptin	Yes	LFTs checked every 3 months for the first year and then periodically.

^aBaseline and subsequent LFTs difficult to interpret in critically ill patients because LFTs will be affected by multiple factors.
LFT, Liver function test; TB, tuberculosis.

Box 15.4 Practice points for minimising the risk of drug-induced liver injury

- Minimise DILI by ensuring appropriate monitoring of drugs associated with hepatotoxicity.
- Minimise DILI by following recommendations – e.g. use co-amoxiclav for penicillin β -lactam-resistant infections only; counsel all patients on paracetamol not to exceed 4 g/day and to be alert to other preparations containing paracetamol.
- Counsel all patients (or carers of patients) on potentially hepatotoxic medicines to recognise and report signs of liver damage.
- Inform all patients who have DILI of the causative agent and the importance of avoiding this in the future.

DILI, Drug-induced liver injury.

Case studies**Case 15.1**

Mrs RS, a 42-year-old female, presented to her local hospital after a paracetamol overdose. She had recently separated from her husband, went on an alcohol binge and then on impulse had taken approximately 90 paracetamol tablets. She presented to her local hospital 30 hours after the overdose. At presentation she was feeling nauseous and had right subcostal pain. Her results at this time were as follows:

	Actual value (normal range)
Paracetamol	18 mg/mL
Albumin	24 g/dL (30–50 g/L)
Alanine transaminase	6543 units/L (0–50 units/L)
Bilirubin	70 mmol/L (<17 mmol/L)
Alkaline phosphatase	66 units/L (30–135 units/L)
Prothrombin time	58 s (9.8–12.6 s)
Creatinine	200 mmol/L (35–125 mmol/L)
Urea	5.6 mmol/L (0–7.5 mmol/L)

Other test results:

Hepatitis screen negative

Autoantibody screen negative

At this stage, supportive treatment was given. However, she deteriorated, with worsening test results and the development of encephalopathy. She was then transferred to a specialist intensive care unit, with a diagnosis of ALF secondary to paracetamol overdose. Her test results on admission to the intensive care unit were as follows:

	Actual value (normal range)
Albumin	22 g/dL (30–50 g/L)
Alanine transaminase	10,000 units/L (0–50 units/L)
Bilirubin	150 mmol/L (<17 mmol/L)
Alkaline phosphatase	80 units/L (30–135 units/L)
Prothrombin time	90.8 s (9.8–12.6 s)
Arterial pH	7.226 (7.350–7.450)
Lactate	8 mmol/L (0.4–2.2 mmol/L)
Creatinine	420 mmol/L (35–125 mmol/L)
Urea	7.4 mmol/L (0–7.5 mmol/L)

She was discussed by a liver transplant multidisciplinary team and was identified as needing a liver transplant extremely urgently. Within 2 days of the overdose, she was transplanted.

Questions

1. What risk factors does Mrs RS have that suggest a worse prognosis?
2. On initial presentation, what treatment should have been initiated?
3. What is the significance of the high creatinine result?
4. Can Mrs RS be prescribed paracetamol for pain relief?

Answers

1. The progression of paracetamol toxicity can be categorised into four stages: preclinical, hepatic injury, hepatic failure and recovery. The prognosis varies depending on the stage at presentation. Mrs RS's late presentation to hospital also increases her risk of a worse prognosis. She presented to hospital 30 hours after the overdose, with raised ALT and some symptoms of liver injury, indicating that she was in the hepatic injury stage and progressed to the liver failure stage with the development of encephalopathy. Patients presenting with liver injury have a variable prognosis, but patients who present with hepatic failure have a mortality rate of 20–40%. Had she presented in the preclinical stage, she would have been expected to make a full recovery with treatment. Although Mrs RS had acutely ingested alcohol at the time of paracetamol overdose, this is not a risk factor for a worse prognosis. Theoretically, acute alcohol ingestion competes with paracetamol for CYP2E1 metabolism, resulting in lower formation of NAPQI and thus less toxicity. Chronic alcohol consumption induces the CYP2E1 isoenzyme, resulting in increased NAPQI production and increased risk of hepatotoxicity. Mrs RS developed hepatorenal syndrome; this is a poor prognostic indicator and has an associated mortality of 50–100%. A poor prognosis is also associated with the following:

Prothrombin time	>36 s
Creatinine	>200 mmol/L
pH	<7.3
Encephalopathy	Present
Cerebral oedema	Present
Time from onset of jaundice to encephalopathy	0–7 days

2. A plasma paracetamol level needs to be taken as soon as possible, although not within the first 4 hours after paracetamol overdose. A toxic screen should be performed to exclude other drug overdoses. Supportive therapy with intravenous fluids and oxygen, if necessary, should be given. This patient should also have been treated with *N*-acetylcysteine. Treatment with *N*-acetylcysteine is particularly beneficial when administered within 8 hours of paracetamol overdose when the blood paracetamol level is in the range predictive of possible or probable liver injury (see Fig. 15.3). However, late administration in patients who present more than 16–24 hours post-ingestion is also appropriate. Acetylcysteine administered at this stage will not counteract the oxidative effects of paracetamol, but it may have a cytoprotective role in hepatic failure, improving hemodynamics and oxygen use. Late administration of *N*-acetylcysteine has been shown to reduce morbidity and mortality in patients who have already developed hepatic failure. Available data for the use of *N*-acetylcysteine after paracetamol overdose suggests that although the evidence for benefit is limited, it should be given to patients with overdose (Brok et al., 2006).

- Mrs RS developed renal impairment secondary to the liver damage, which is known as the hepato-renal syndrome (HRS). Other causes of renal impairment should be excluded. Where necessary, drug doses should be adjusted for renal impairment. Once the liver recovers, or transplantation of the liver occurs, the kidneys are likely to recover.
- Paracetamol should be avoided in the acute phase after an overdose. However, if the patient needs either an analgesic or antipyretic after the acute phase, then paracetamol in small doses may be used. After a liver transplant, standard paracetamol doses can be used as long as the patient is adequately nourished and does not have any psychological issues with the use of paracetamol.

Case 15.2

Mr SS is a 43-year-old man with type 2 diabetes who was commenced on simvastatin 40 mg at night 3 months ago. He has no other relevant past medical history. He does not drink alcohol and does not consume grapefruit. He also takes metformin 1g twice a day. A routine blood test revealed an increase in ALT from baseline (pre-simvastatin) of 21–197 units/L (0–50 units/L) at 3 months.

Questions

- What are the likely causes of the increase in ALT?
- Should liver function tests be routinely monitored in patients on a statin?
- What action, if any, should be taken in this case?
- Can statins be used in patients with pre-existing liver disease?

Answers

- The most likely cause of the increase in ALT is the introduction of simvastatin 3 months previously. All statins are reported to cause elevations in transaminases, which may be transient or persistent. The incidence of transaminitis with statins is low, being reported to occur between 1 in 1000 and 1 in 10,000 patients. Other causes of liver disease should also be considered in this case, for example, non-alcoholic steatohepatitis (NASH) associated with diabetes.
- Monitoring of liver function tests in patients taking a statin is recommended in the Summary of Product Characteristics and hence should be monitored for medico-legal reasons (McKenney et al., 2006). It is recommended to monitor liver function tests at baseline and then at 12 weeks or after a dose increase. However, the true value for monitoring liver function test is not clear as it does not identify those at risk of liver damage, is expensive and may lead to patient anxiety and unnecessary cessation of statin therapy. Moreover, hepatic function does not appear to be compromised by statin use, and there is no apparent link between an elevation in liver function tests and the development of toxicity (McKenney et al., 2006).
- Mr SS had a single high ALT result. The general recommendation is that if the patient is asymptomatic and the transaminase levels are greater than three times the upper limit of normal, the test should be repeated. If transaminases are still more than three times the upper limit of normal, the patient should have a full liver investigation. In this case, the simvastatin was switched to atorvastatin before a repeat liver function test. Follow-up liver function tests showed that the ALT had returned to within the normal range. It is highly probable that this rise in ALT on simvastatin would have been transient, and had the patient continued with simvastatin, the ALT would have normalised. However, the patient was anxious, did not want to risk any progression of liver toxicity and was keen to switch to an alternative statin.

- Statin are contraindicated in ALF and decompensated chronic liver disease. However, they can probably be used safely in liver disease where there is no, or mild, synthetic dysfunction. Statin use may actually improve elevations in transaminases in patients with fatty liver disease (Gomez-Dominguez et al., 2006).

Case 15.3

Mr CB, a 66-year-old who has been recently diagnosed with tuberculosis (TB), was started on Rifater (rifampicin, isoniazid and pyrazinamide) 5 tablets a day and ethambutol 800 mg daily. He takes no other medication; however, he has told his doctor he drinks about 30 units of alcohol a week. He presents to his doctor with a 2-week history of fever, malaise and vomiting. Before starting his treatment, his liver function tests were as follows:

	Actual value (normal range)
Albumin	40 g/dL (30–50 g/L)
Alanine transaminase	30 units/L (0–50 units/L)
Bilirubin	6 mmol/L (<17 mmol/L)
Aspartate aminotransferase	20 units/L (10–50 units/L)

His doctor repeated his liver function tests, kidney function test and full blood count and tested for viruses such as cytomegalovirus (CMV) and hepatitis A, B, C, D and E. His viral screens all came back as negative. His liver and kidney function tests were as follows:

	Actual value (normal range)
Albumin	32 g/dL (30–50 g/L)
Alanine transaminase	500 units/L (0–50 units/L)
Bilirubin	120 mmol/L (<17 mmol/L)
Aspartate aminotransferase	600 units/L (10–50 units/L)
Creatinine	89 mmol/L (35–125 mmol/L)
Urea	6 mmol/L (0–7.5 mmol/L)

He was admitted to hospital.

Questions

- For which drug(s) would Mr CB be having routine liver function tests?
- Does Mr CB have any risk factors for developing drug-associated hepatotoxicity?
- What actions should be taken in relation to Mr CB's TB medication?

Answers

- Rifampicin, isoniazid and pyrazinamide
Each of these drugs has been associated with liver dysfunction. LFTs should be carried out for all patients receiving these agents pre-treatment. This includes baseline hepatic enzymes and bilirubin, as well as serum creatinine and a full blood count including platelets. Patients should be seen monthly throughout the duration of treatment and questioned about symptoms associated with adverse reactions.
Mr CB would be considered to have normal LFTs pre-treatment. In addition to his LFTs, he would need to be monitored for symptoms of vomiting, jaundice or other signs of deterioration. He should be advised to see his doctor should he develop any of these symptoms.

- Age increases the risk associated with DILI caused by isoniazid, as well as large amounts of alcohol (Kumar et al., 2014). Patients older than 35 years have a higher frequency of isoniazid-associated hepatitis. A transaminase measurement should be obtained at baseline and at least monthly during the duration of treatment in this age group. Other risk factors that will increase the risk of hepatitis include daily use of alcohol, chronic liver disease, intravenous drug use and being a black or Hispanic woman. Mr CB only has alcohol as an additional risk factor.
- In general, Rifater should be discontinued in hepatotoxicity after a discussion with the chest physicians. Mr CB shows signs

of clinical hepatitis, with symptoms of general malaise and vomiting, in conjunction with raised LFTs. On discontinuation, his liver function should be monitored closely. Once his liver function has settled, individual agents could be cautiously reintroduced with close monitoring. This is as per guidance from the British Thoracic Society (BTS) and the American Thoracic Society (ATS). Because rifampicin has been shown to be the least toxic of the three agents, it should be started first. Subsequent agents should only be reintroduced if the liver function remains stable. If hepatotoxicity continues, the causative agent should be stopped and an alternative started (Kumar et al., 2014).

16 Liver Disease

Apostolos Koffas and Patrick Kennedy

Key points

- The liver is a complex organ central to the maintenance of homeostasis.
- The liver is notable for its capacity to regenerate unless cirrhosis has developed. However, now some evidence suggests that cirrhosis can, in fact, be reversible in selected cases (e.g. treated hepatitis B virus).
- The spectrum of liver disease extends from mild, self-limiting conditions to serious illnesses which may carry significant morbidity and mortality.
- Liver disease is defined as acute or chronic on the basis of whether the history of disease is less than or greater than 6 months, respectively.
- Viral infections and paracetamol overdose are leading causes of acute liver disease, but a significant number of patients have no defined cause (seronegative hepatitis).
- Alcohol abuse and chronic viral hepatitis (B and C) are the major causes of chronic liver disease.
- Cirrhosis may be asymptomatic for considerable periods.
- Ascites, encephalopathy, varices and hepatorenal failure are the main serious complications of cirrhosis.
- A careful assessment is required before the use of any drug in a patient with liver disease because of unpredictable effects on drug handling.

The liver weighs up to 1500 g in adults and as such is one of the largest organs in the body. The main functions of the liver include protein synthesis, storage and metabolism of fats and carbohydrates, detoxification of drugs and other toxins, excretion of bilirubin and metabolism of hormones, as summarised in [Fig. 16.1](#). The liver has considerable reserve capacity, reflected in its ability to function normally despite surgical removal of 70–80% of the organ or the presence of significant disease. It is noted for its capacity to regenerate rapidly. However, once it has been critically damaged, multiple complications develop involving many body systems. The distinction between acute and chronic liver disease is conventionally based on whether the history is less than or greater than 6 months, respectively.

The hepatocyte is the functioning unit of the liver. Hepatocytes are arranged in lobules and within a lobule hepatocytes perform different functions depending on how close they are to the portal tract. The portal tract is the ‘service network’ of the liver and contains an artery and a portal vein delivering blood to the liver and bile duct which forms part of the biliary drainage system ([Fig. 16.2](#)). The blood supply to the liver is 30% arterial, and

the remainder is from the portal system which drains most of the abdominal viscera. Blood passes from the portal tract through sinusoids that facilitate exposure to the hepatocytes before the blood is drained away by the hepatic venules and veins. There are a number of other cell populations in the liver, but two of the most important are Kupffer cells, fixed monocytes that phagocytose bacteria and particulate matter, and stellate cells responsible for the fibrotic reaction that ultimately leads to cirrhosis.

Acute liver disease

Acute liver disease is a self-limiting episode of hepatocyte damage which in most cases resolves spontaneously without clinical sequelae, but acute liver failure (ALF) can develop. This is a rare condition in which there is a rapid deterioration in liver function with associated encephalopathy (altered mentation) and coagulopathy. ALF carries a significant morbidity and mortality and may require emergency liver transplantation.

Chronic liver disease

Chronic liver disease occurs when permanent structural changes within the liver develop secondary to longstanding cell damage, with the consequent loss of normal liver architecture. In many cases this progresses to cirrhosis, where fibrous scars divide the liver cells into areas of regenerative tissue called nodules ([Fig. 16.3](#)). Conventional wisdom is that this process is irreversible, but therapeutic intervention in hepatitis B (and even hepatitis C virus) in addition to haemochromatosis has demonstrated the ability to reverse cirrhosis ([Sohrabpour et al., 2012](#)). Once chronic liver disease progresses, patients are at risk of development of liver failure, portal hypertension or hepatocellular carcinoma (HCC). Cirrhosis is a sequel of chronic liver disease of any aetiology and it develops over a variable time frame from 5 to ≥ 20 years.

Causes of liver disease

Viral infections

Viruses commonly affect the liver and can result in a transient and an innocuous hepatitis. Viruses which target the liver primarily are

described as hepatotropic viruses, and each of these can lead to clinically significant hepatitis and in some cases to the development of chronic viral hepatitis with viral persistence. Five human viruses have been well described to date: hepatitis A (HAV), B (HBV), C (HCV), D (HDV) and E (HEV). Each type of viral hepatitis causes a similar pathology with acute inflammation of the liver. HAV and HEV are classically associated with an acute and sometimes severe hepatitis which is invariably self-limited, but occasionally fatal. HBV causes acute hepatitis in the majority of adults; only 5% of patients become chronic carriers, whereas 95% of those infected in the neonatal period or early childhood

experience chronic infection. HCV rarely causes an acute hepatitis, but up to 85% of patients become chronic carriers. Both viruses cause chronic liver inflammation or hepatitis, cirrhosis and HCC.

Hepatitis A

HAV is a non-enveloped RNA virus and a major cause of acute hepatitis worldwide, accounting for up to 25% of clinical hepatitis in the developed world (Brook et al., 2016). HAV is an enteric virus and the faecal–oral route is the main mechanism of transmission. The virus is particularly contagious and constitutes a public health problem throughout the world. The virus may go unnoticed by the patient in the absence of an icteric episode, particularly in children. However, HAV can cause ALF in less than 1% of patients (Brook et al., 2016); this is typically seen in older adults. The virus is particularly prevalent in areas of poor sanitation and is often associated with water- and food-borne epidemics. HAV has a relatively short incubation period (2–7 weeks), during which time the virus replicates and abnormalities in liver function tests (LFTs) can be detected.

Hepatitis B

Up to 500 million people worldwide are chronically infected with HBV. Chronic hepatitis B (CHB) is characterised by the presence of hepatitis B surface antigen (HBsAg) for a period of more than 6 months. In endemic areas of Africa and the Far East, up to

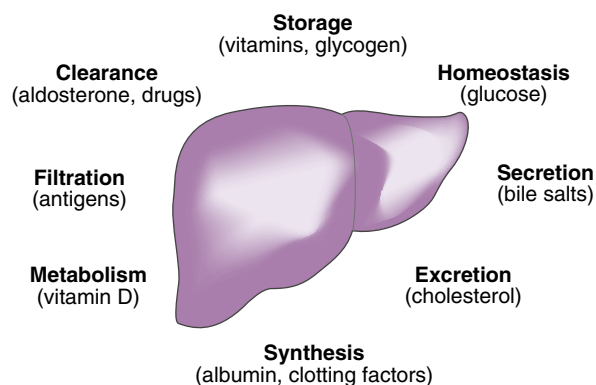

Fig. 16.1 Normal physiological functions of the liver, with examples of each.

Fig. 16.2 Illustration of the relationship among the three structures that comprise the portal tract, with blood from both the hepatic artery and portal vein perfusing the hepatocytes before draining away towards the hepatic veins (central veins). Each hepatocyte is also able to secrete bile via the network of bile ducts. (Reproduced with permission of McGraw-Hill from Vander, 1980.)

Fig. 16.3 The gross postmortem appearance of (A) a normal and (B) a cirrhotic liver demonstrating scarring and nodule formation in B.

20% of the population are chronic carriers of HBV (Brook et al., 2016), and exposure to HBV at birth (vertical or perinatal transmission) is the single most important risk factor for the development of CHB infection. Acquisition of HBV in adulthood is often via sexual transmission and is usually associated with a discrete episode of hepatitis. HBV can also be transmitted parenterally, by the transfusion of blood or blood products from contaminated stocks and by intravenous drug use or needle sharing.

Many factors determine the outcome of HBV infection, ranging from age at the time of exposure and genetic factors of the host to virus characteristics. Acute HBV infection by definition resolves within a 6-month time frame. It is generally self-limiting, and antiviral therapy is not indicated in the majority of patients. Most patients recover within 1–2 months of the onset of jaundice. The protracted incubation period of HBV and the ability of the virus to escape the host immune response contribute to the development of CHB. CHB is associated with varying levels of viraemia and hepatic inflammation. The level of viraemia, and thus infectivity, is determined by the presence of the hepatitis B e antigen (HBeAg); thus, HBeAg loss and the development of anti-HBe antibody (HBeAg seroconversion) results in a significant reduction in replicating virus and the potential to transmit the virus. Low levels of HBV DNA and normal transaminases are associated with a more favourable disease outcome. However, HBeAg-negative chronic hepatitis can progress with the development of significantly elevated levels of HBV DNA and associated biochemical activity; a disease profile with a poorer prognosis is now recognised as a growing healthcare challenge globally. HBeAg-negative CHB results as a consequence of the emergence of escape mutants from the core promoter or pre-core regions of the virus. It is estimated that 10–50% of HBV carriers will develop serious sequelae during their lifetime (Brook et al., 2016), namely, liver cirrhosis and/or HCC, which may even develop in CHB in the absence of cirrhosis. Perinatal or childhood infection is synonymous with a higher percentage of patients developing CHB, characterised by a protracted disease phase often referred to as immune-tolerant CHB. Because of this protracted phase of disease and long-term exposure to the virus, a higher proportion of those infected at birth or in early childhood (up to 25%) are at risk of development of cirrhosis and/or HCC.

Hepatitis D

Hepatitis D (HDV) is an incomplete virus that can establish infection only in patients simultaneously infected by HBV. It is estimated that 5% of HBV carriers worldwide are infected with HDV. It is endemic in the Mediterranean Basin and is transmitted percutaneously, percutaneously or sexually. In other geographical areas, it is confined to intravenous drug users.

Hepatitis C

An estimated 185 million people worldwide are chronically infected with HCV (Brook et al., 2016). HCV is a hepatotropic, non-cytopathic, predominantly blood-borne virus with greater infectivity than the human immunodeficiency virus (HIV). It is estimated that more than 2.7 million people in the USA are

chronically infected with HCV (Centers for Disease Control and Prevention, 2017), where it is the leading cause of death from liver disease. An estimated 214,000 people are chronically infected with hepatitis C in the UK (Public Health England, 2015), although a considerable proportion of individuals have not yet been diagnosed. HCV is transmitted parenterally, most commonly through intravenous drug use and the sharing of contaminated needles. Before its identification in 1990, HCV (previously known as non-A, non-B viral hepatitis) was also contracted through contaminated blood and blood products. The introduction of widespread screening of blood donors and pooled blood products has largely consigned blood transfusion as a mode of transmission to history. There remains a small risk of HCV infection associated with tattooing, electrolysis, ear piercing, acupuncture and sexual contact. The vertical transmission rate from HCV-infected mother to child is less than 3% (Tosone et al., 2014).

HCV infection is associated with the development of a recognised episode of acute hepatitis in only a small percentage of individuals. The majority of patients remain asymptomatic and so are often unaware of the infection or the timing at which they contracted the virus. Symptoms associated with HCV infection tend to be mild constitutional upset, with malaise, weakness and anorexia being most commonly reported. Up to 85% of subjects exposed to HCV experience development of chronic disease (Brook et al., 2016), which can lead to progressive liver damage, cirrhosis and HCC. Unlike HBV, the risk of development of HCC is almost totally linked to the presence of cirrhosis. Up to 30% of patients with chronic HCV infection progress to end-stage liver disease within 14–30 years (Brook et al., 2016), and alcohol consumption is a recognised co-factor that accelerates disease progression. HCV infection is the leading indication for liver transplantation worldwide and accounts for approximately 400,000 deaths per year (World Health Organization, 2017).

Hepatitis E

HEV is endemic in India, Asia, the Middle East and parts of Latin America. It is an RNA virus which is transmitted enterically and leads to acute hepatitis. It has an average incubation period of 42 days. The symptoms of HEV are no different from other causes of viral hepatitis. It is believed that the risk of death is increased in pregnancy, especially in the final trimester (World Health Organization, 2016).

Alcohol

Alcohol is the single most significant cause of liver disease throughout the Western world, accounting for between 40% and 60% of cases of cirrhosis in different countries. In general, deaths from alcoholic liver disease (ALD) in each country correlate with the consumption of alcohol per head of population, although additional factors can influence this trend. Liver disease related to recent alcohol consumption can present as a broad spectrum of conditions, ranging from the relatively benign fatty liver disease or hepatic steatosis to the development of alcoholic hepatitis (AH). An estimated 20% of alcohol abusers develop progressive

liver fibrosis, which can eventually lead to alcoholic cirrhosis, typically after a period of 10–20 years of alcohol misuse (Mueller et al., 2009).

The central event in the development of hepatic fibrosis is the transformation of hepatic stellate cells into matrix-secreting cells producing pericellular fibrosis. This network of collagen fibres develops around the liver cells and gradually leads to hepatocyte cell death. The extent of fibrosis progresses and micronodular fibrotic bands develop characterising alcoholic cirrhosis. The anatomical changes within the liver increase resistance to blood flow from the portal system, causing an increase in pressure within this system resulting in portal hypertension. As the number of normally functioning liver cells reduces further, because of continued liver cell failure and death, the clinical condition is characterised by a progressive deterioration and ultimately liver failure. The rate of disease progression, and indeed regression, is strongly linked to whether patients continue to consume alcohol.

Non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) refers to a spectrum of disease ranging from simple hepatic steatosis to liver fibrosis and cirrhosis. Hepatic steatosis, which is the most common entity of NAFLD, refers to the infiltration of more than 5% of the liver with fat and is now the most common liver disorder in the developed world; it is estimated that at least one in five people (20%) in the UK are affected. Non-alcoholic steatohepatitis (NASH) is characterised by inflammation of the liver and hepatocellular injury which may progress to fibrosis or cirrhosis. The majority of cases previously reported as cryptogenic cirrhosis probably reflect the end stage of the NAFLD/NASH disease process, even though by this advanced stage the characteristic fatty infiltrate has disappeared. By definition, alcohol consumption of more than 20 g/day (about 25 mL/day net ethanol) excludes the condition. People who are more at risk of development of NAFLD are overweight or obese individuals, smokers, those who have a poor diet and lack of physical exercise, in addition to those with the metabolic syndrome. Its prevalence is increasing worldwide, and in the USA, NASH is reported to be the second leading cause of liver disease among adults awaiting liver transplantation (Wong et al., 2015). Different theories regarding the pathogenesis of NAFLD exist, but insulin resistance plays a key role in the development of the disorder.

Immune disorders

Autoimmune disease can affect the hepatocyte or bile duct and is characterised by the presence of auto-antibodies and raised serum immunoglobulin levels.

Autoimmune hepatitis

Autoimmune hepatitis (AIH) is an unresolving inflammation of the liver characterised by the presence of auto-antibodies (anti-smooth muscle [type 1] or anti-kidney, liver microsomal [type 2]), hypergammaglobulinemia and an interface hepatitis on liver histology. It is usually a chronic, progressive disease which can occasionally present acutely with a severe hepatitis.

AIH typically occurs in young women, between 20 and 40 years, and a history or family history of autoimmune disorders is often present.

Primary biliary cholangitis

Primary biliary cholangitis (PBC) is an autoimmune disease of the liver which predominantly affects middle-aged women (95% of cases are female). It is characterised by the presence of anti-mitochondrial antibodies and a granulomatous destruction of the interlobular bile ducts leading to progressive ductopenia, fibrosis and cirrhosis. The disease is progressive, albeit over a period of 20 years or longer if diagnosed at an early age; liver transplantation is often the only effective treatment.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is an idiopathic chronic inflammatory disease resulting in intrahepatic and extrahepatic biliary strictures, cholestasis and eventually cirrhosis. There is a strong association with inflammatory bowel disease, particularly ulcerative colitis (UC); 75% of patients with PSC have UC and 5% of patients with UC develop PSC (Lee and Kaplan, 1995; Loftus et al., 2005). It has a predilection for young Caucasian males (mean age at presentation 39 years), but it can occur in infancy or childhood and can affect any race. Cholangiocarcinoma develops in up to 10% of patients with PSC.

Vascular abnormalities

Budd–Chiari syndrome is a rare, heterogeneous and potentially fatal condition related to the obstruction of the hepatic venous outflow tract. The prevalence of underlying thrombophilias is markedly increased in patients with Budd–Chiari syndrome. Affected patients are commonly women with an average age at presentation of 35 years. Early recognition and immediate use of anticoagulation has vastly improved outcome. More advanced disease can be treated in a number of ways including venoplasty, transjugular intrahepatic portosystemic shunt (TIPSS), surgical shunts or liver transplantation.

Metabolic and genetic disorders

Various inherited metabolic disorders can affect the functioning of the liver.

Haemochromatosis

Hereditary haemochromatosis is the most commonly identified genetic disorder in the Caucasian population. It is associated with increased absorption of dietary iron resulting in deposition within the liver, heart, pancreas, joints, pituitary gland and other organs. This can lead to cirrhosis and HCC.

Wilson's disease

Wilson's disease is an autosomal recessive disorder of copper metabolism. The disorder leads to excessive absorption and

deposition of dietary copper within the liver, brain, kidneys and other tissues. Presentation can vary widely from chronic hepatitis, asymptomatic cirrhosis, ALF to neuropsychiatric symptoms with cognitive impairment.

α_1 -Antitrypsin deficiency

α_1 -Antitrypsin deficiency is an autosomal recessively inherited disease and is the most common genetic metabolic liver disease. The disease results in a reduction in α_1 -antitrypsin which is protective against a variety of proteases including trypsin, chymotrypsin, elastase and proteases present in neutrophils. The homozygous form of the disease (ZZ phenotype) is associated with the development of liver disease and cirrhosis in 15–30% of both adult and paediatric patients.

Glycogen storage disease

Glycogen storage disease is a rare disease that occurs in 1 in 100,000 births. Enzymatic deficiencies at specific steps in the pathway of glycogen metabolism cause impaired glucose production and accumulation of abnormal glycogen in the liver.

Gilbert's syndrome

Gilbert's syndrome is characterised by persistent mild unconjugated hyperbilirubinaemia. It is most frequently recognised in adolescents and young adults with an incidence rate between 2% and 7% in the general population. Serum bilirubin levels fluctuate but can increase to 80–100 mmol/L during periods of stress, sleep deprivation, prolonged fasting, menstruation and intercurrent infections. Gilbert's syndrome is an asymptomatic condition that requires no therapy. However, patients may inappropriately associate being jaundiced with the symptoms of the condition that triggered the increased bilirubin levels.

Drugs

Drugs are particularly important causes of abnormal LFTs and acute liver injury, including ALF. DILI (drug-induced liver injury) is an acronym for any drug toxin that causes abnormal liver enzymes. Drugs can also be relevant to a number of chronic liver diseases including steatosis, fibrosis/cirrhosis, autoimmune and vascular disease. In most situations the drug is implicated because of an appropriate temporal relationship between the disease and drug exposure.

Clinical manifestations of liver disease

Symptoms of liver disease

In patients who have liver disease, weakness, increased fatigue and general malaise are common but non-specific symptoms. Weight loss and anorexia are more commonly seen in chronic liver disease, and loss of muscle bulk is a characteristic of

advanced disease. Abdominal discomfort may be described by patients with an enlarged liver or spleen, whereas abdominal distension with the accumulation of ascites is usually the cause in more advanced disease. Abdominal pain is common in hepatobiliary disease, frequently localised to the right upper quadrant. This is often a feature of rapid or gross enlargement of the liver when the pain is thought to be a consequence of capsular stretching. Tenderness over the liver is a symptom of acute hepatitis, hepatic abscess or hepatic malignancy.

Jaundice is the most striking symptom of liver disease and can present with or without pain, depending on the underlying aetiology of disease. Pruritus can be a distressing symptom in cholestatic liver disease, and patients usually report that it is worse at night. Patients with acute and chronic liver disease can develop bleeding complications because of defective hepatic synthesis of coagulation factors and low platelet counts.

Signs of liver disease

Table 16.1 presents physical signs of chronic liver disease.

Cutaneous signs

Hyperpigmentation is common in chronic liver disease and results from increased deposition of melanin. It is particularly associated with PBC and haemochromatosis. Scratch marks on the skin suggest pruritus, which is a common feature of cholestatic liver disease. Vascular 'spiders', referred to as spider naevi, are small vascular malformations in the skin and are found in the drainage area of the superior vena cava, commonly seen on the face, neck, hands and arms. Examination of the limbs can reveal several signs, none of which are specific to liver disease. Palmar erythema, a mottled reddening of the palms of the hands, can be associated with both acute and chronic liver disease. Dupuytren's contracture, thickening and shortening of the palmar fascia of the

Table 16.1 Physical signs of chronic liver disease

Common findings	End-stage findings
Jaundice	Ascites
Gynaecomastia and loss of body hair	Dilated abdominal blood vessels
Hand changes:	Fetor hepaticus
Palmar erythema	Hepatic flap
Clubbing	Neurological changes:
Dupuytren's contracture	Hepatic encephalopathy
Leukonychia	Disorientation
Liver mass reduced or increased	Changes in consciousness
Parotid enlargement	Peripheral oedema
Scratch marks on skin	Pigmented skin
Purpura	Muscle wasting
Spider naevi	
Splenomegaly	
Testicular atrophy	
Xanthelasma	
Hair loss	

hands causing flexion deformities of the fingers, was traditionally associated with alcoholic cirrhosis. It is now considered to be multifactorial and not to reflect primary liver disease. Nail changes, highly polished nails or white nails (leukonychia) can be seen in up to 80% of patients with chronic liver disease. Leukonychia is a consequence of low serum albumin. Finger clubbing is most commonly seen in hypoxaemia related to hepato-pulmonary syndrome, but it is also a feature of chronic liver disease.

Abdominal signs

Abdominal distension, notably of the flanks, is suggestive of ascites which can develop in both acute (less commonly) and chronic liver disease. An enlarged liver (hepatomegaly) is a common finding in acute liver disease. In cirrhotic patients the liver may be large, but alternatively it may be small and shrunken, reflecting end-stage chronic disease. An enlarged spleen (splenomegaly) in the presence of chronic liver disease is the most important sign of portal hypertension. Dilated abdominal wall veins are a notable finding in chronic liver disease with the detection of umbilical and para-umbilical veins a feature of portal hypertension.

Jaundice

Jaundice is the physical sign regarded as synonymous with liver disease and is most easily detected in the sclerae. It reflects impaired liver cell function (hepatocellular pathology), or it can be cholestatic (biliary) in origin. Hepatocellular jaundice

is commonly seen in acute liver disease, but may be absent in chronic disease until the terminal stages of cirrhosis are reached. The causes of jaundice are shown in Fig. 16.4.

Portal hypertension

The increased pressure in the portal venous system leads to collateral vein formation and shunting of blood to the systemic circulation. Portal hypertension is an important contributory factor to the formation of ascites and the development of encephalopathy due to bypassing of blood from the liver to the systemic circulation. The major, potentially life-threatening complication of portal hypertension is a variceal bleed (torrential venous haemorrhage) from the thin-walled veins in the oesophagus and upper stomach. Patients with portal hypertension are often asymptomatic, whereas others may present with bleeding varices, ascites and/or encephalopathy.

Ascites

Ascites is the accumulation of fluid within the abdominal cavity. The precise mechanism by which ascites develops in chronic liver disease remains unclear, but the following factors are all thought to contribute:

- Activation of the renin–angiotensin–aldosterone axis as a consequence of central hypovolaemia, leading to a reduction in sodium excretion by the kidney and fluid retention. Reduced aldosterone metabolism caused by reduced liver function may also contribute to increased fluid retention.

Fig. 16.4 Common causes of jaundice: obstructive, due to blockage of the bile ducts; hepatocellular, due to drugs, hepatitis, chronic liver disease or tumour formation; and prehepatic, due to increased blood breakdown such as occurs in haemolysis.

- A reduction in serum albumin and reduced oncotic pressure is thought to contribute to the collection of fluid in the third space. Peripheral oedema (swollen lower limbs) occurs through this mechanism in a manner similar to the development of ascites.
- Portal hypertension and splanchnic arterial vasodilation alter intestinal capillary pressure and permeability, and thus facilitate the accumulation of retained fluid in the abdominal cavity.

Sexual characteristics

Endocrine changes are well documented in chronic liver disease and tend to be more common in ALD. Hypogonadism is common in patients with cirrhosis. In males, hypogonadism results in testicular atrophy, female body hair distribution and gynaecomastia. This is thought in part to occur because the cirrhotic liver cannot metabolise oestrogen, leading to feminisation in males. Gynaecomastia is found particularly in alcoholics but is also seen in those who are taking spironolactone, when there is usually associated tenderness of the nipples. In women with chronic liver disease, menstrual irregularity, amenorrhoea and reduced fertility are common findings in females of reproductive age, but few detectable physical signs are seen as a result of gonadal atrophy.

Investigation of liver disease

All patients with liver disease must undergo a comprehensive and thorough assessment to ascertain the underlying aetiology. Although causes of acute and chronic liver disease may differ, a similar approach is used to investigate both patient groups to ensure no primary cause or co-factor is overlooked.

Biochemical liver function tests

Biochemical LFTs are simple, inexpensive and easy to perform, but they usually cannot be used in isolation to make a diagnosis. Biochemical parameters provide very useful information in monitoring disease progression or response to therapy. The liver enzymes usually measured are the aminotransferases, which reflect hepatocellular pathology and the cholestatic liver enzymes serum alkaline phosphatase (AST) and γ -glutamyl transpeptidase. Serum aspartate transaminase and alanine transaminase (ALT) are two intracellular enzymes present in hepatocytes which are released into the blood of patients as a consequence of hepatocyte damage. Extremely high values, where transaminases are recorded in the thousands, occur in acute liver disease (e.g. viral hepatitis or paracetamol overdose). In chronic hepatitis serum transaminases are rarely more than five to eight times the upper limit of normal. Alkaline phosphatase is present in the canalicular and sinusoidal membranes of the liver but is also present in some other sites, especially bone. Concomitant elevation of the enzyme γ -glutamyl transpeptidase confirms the hepatic origin of an elevated alkaline phosphatase. The serum alkaline

phosphatase activity may be raised by up to four to six times the normal limit in intrahepatic or extrahepatic cholestasis. It can also be raised in conditions associated with liver infiltration, such as metastases.

Bilirubin is commonly elevated in hepatocellular pathology and especially in acute hepatitis and end-stage chronic liver disease. An increase in bilirubin concentration results in jaundice and is usually clinically apparent when the serum bilirubin level exceeds 50 mmol/L. In acute liver disease the serum bilirubin reflects severity of disease but is of little prognostic value. In chronic liver disease a gradual increase for no apparent reason usually reflects serious disease progression. Hepatocellular damage, cholestasis and haemolysis can all cause elevations in the serum bilirubin concentration.

Synthetic function capacity is very important in assessing liver disease. Prothrombin time (PT), international normalised ratio (INR) and other coagulation studies are useful short-term markers of the synthetic function, especially in acute liver insults, where they reflect the severity of the liver injury. PT or INR are also important indicators of chronic liver disease when combined with serum albumin levels. Albumin is synthesised in the liver and serum albumin levels reflect liver function over the preceding months rather than days as with coagulation studies. Alternative causes of hypoalbuminaemia need to be considered, especially proteinuria.

Laboratory investigation of aetiology

All individuals presenting with derangement of liver function should be tested for HAV, HBV, HCV and HEV as part of a routine liver disease screen. Auto-antibodies and immunoglobulins to screen for autoimmune disease are also relevant to both acute and chronic liver disease. Serum ferritin, caeruloplasmin (in patients <40 years old), α_1 -antitrypsin phenotype and lipid profile are standard investigations in patients with evidence of chronic liver disease.

Imaging techniques

Ultrasound is a non-invasive, low-risk procedure that is pivotal in the preliminary assessment of liver disease because it assesses the size, shape and echotexture of the liver and screens for dilatation of the biliary tract. In patients with chronic liver disease it assesses patency of the portal vein and may detect signs of portal hypertension (e.g. increased spleen size, ascites). It is also routinely used to screen for HCC and other hepatobiliary malignancies. Computed tomography and magnetic resonance imaging scans are regularly used for further characterisation of any abnormalities identified on ultrasound.

Liver biopsy and Fibroscan

Liver biopsy is an invasive procedure with an associated morbidity and mortality, albeit extremely low. Nevertheless, it remains the gold standard in establishing a diagnosis and assessing the severity of chronic liver disease. Significant progress has been made in developing non-invasive techniques for the assessment

of liver fibrosis, and elastography (Fibroscan) is now widely used in clinical practice. Although Fibroscan is considered the first-line investigation for the assessment of liver fibrosis, in some instances liver histology can still contribute to the diagnostic and management process (e.g. whether to initiate antiviral therapy for HBV or less commonly HCV). In acute hepatic dysfunction, a liver biopsy is usually unnecessary, especially if the condition is self-limiting.

Patient care

Pruritus

Pruritus is a prominent and sometimes distressing symptom of chronic liver disease and tends to be most debilitating in the context of cholestatic conditions. The pathogenesis of pruritus in liver disease is poorly understood, but the deposition of bile salts within the skin is considered to be central to its development. However, the concentration of bile salts in the skin does not appear to correlate with the intensity of pruritus. Management of pruritus is variable. Relief of biliary obstruction by endoscopic, radiological or surgical means is indicated in patients with obstructed biliary systems. In other cases pharmacological agents are used initially, but in some cases plasmapheresis, molecular absorbants recirculating system or even liver transplantation may be needed.

Anion exchange resins

Colestyramine and colestipol act by binding bile acids and preventing their reabsorption. These anion exchange resins are the first line of therapy in the treatment of pruritus. Colestyramine is usually initiated at a dosage of 4 g once or twice daily, and the dosage is then titrated to optimise relief without causing side effects, which are predominantly gastro-intestinal. Such adverse effects are common and include constipation, diarrhoea, fat and vitamin malabsorption. Palatability is variable, and consequently adherence is often a problem. To enhance adherence, patients should be advised that the benefits of therapy may take time to become apparent, often up to a week. Anion exchange resins can reduce the absorption of concomitant therapy, and such drugs should be taken 1 hour before or 4–6 hours after colestyramine or colestipol ingestion. Drugs which are susceptible to this interaction include digoxin, levothyroxine, ursodeoxycholic acid (UDCA), thiazide diuretics, lomitapide, tetracycline, sodium valproate, mycophenolate, raloxifene, calcitriol and paracetamol.

Antihistamines

Although frequently used, antihistamines are usually ineffective in the management of the pruritus caused by cholestasis and should not be considered first-line therapy. A non-sedating antihistamine such as cetirizine (10 mg once daily) or loratadine (10 mg once daily) is preferred because these avoid precipitating or masking encephalopathy. Antihistamines such as chlorphenamine or hydroxyzine provide little more than sedative properties,

although they may be useful at night if the severity of pruritus is sufficient to prevent a patient from sleeping.

Ursodeoxycholic acid

The bile acid UDCA (13–15 mg/kg daily in two divided doses) has been used frequently in cholestatic liver disease. However, its effect on pruritus is uncertain; for instance, two large trials in PBC and PSC demonstrated no improvement in pruritus when used at the above dose (Heathcote et al., 1994; Lindor, 1997). In comparison, in a different report it was shown that ursodeoxycholic at a higher dosage (30 mg/kg/day in three divided doses) led to relief of itching within 1 month (Matsuzaki et al., 1990).

Rifampicin

Rifampicin induces hepatic microsomal enzymes, which may benefit some patients, possibly by improving bile flow. Rifampicin, administered at a dosage of up to 600 mg/day, may be effective in the treatment of pruritus, albeit over a more prolonged period (1–3 weeks). It is most commonly used in patients with primary biliary cirrhosis (PBC). Its use is restricted by its potential hepatotoxicity and drug interactions with other agents.

Opioid antagonists

A growing spectrum of opioid antagonists have been used to treat pruritus because it is believed that endogenous opioids in the central nervous system are potent mediators of itch. As a consequence the centrally acting opioid antagonists naloxone, naltrexone and nalmefene are thought to reverse the actions of these endogenous opioids. The use of such agents is limited by their route of administration. Naloxone is given by subcutaneous, intramuscular or intravenous injection, whereas naltrexone and nalmefene are reported to be more substantially bioavailable after oral administration.

Topical preparations

Topical therapy may benefit some patients. Calamine lotion or menthol 2% in aqueous cream are standard preparations, but improvement of pruritus with such agents is variable.

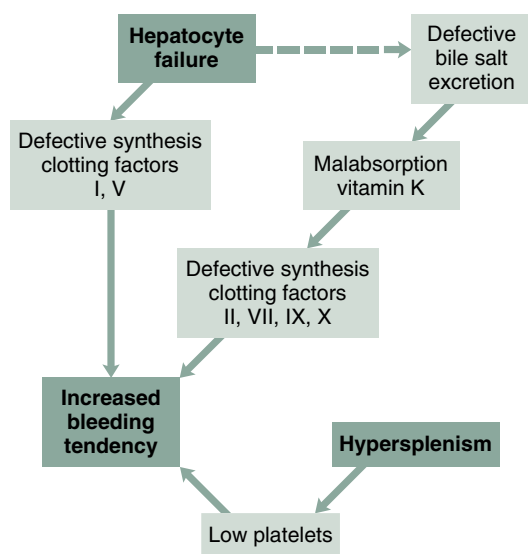

A summary of drugs used in the management of pruritus is shown in Table 16.2.

Clotting abnormalities

The relationship of liver disease to clotting abnormalities is shown diagrammatically in Fig. 16.5. Haemostatic abnormalities develop in approximately 75% of patients with chronic liver disease and 100% of patients with ALF. The majority of clotting factors (with the exception of factor V) are dependent on vitamin K. Patients with liver disease who experience deranged blood clotting should receive intravenous doses of phytomenadione (vitamin K), usually 10 mg daily for 3 days. Administration of vitamin K to patients with significant liver disease does not usually improve the PT because the liver is unable to utilise the

Table 16.2 Drugs commonly used in the management of pruritus

Drug	Indications	Daily dose	Advantages	Disadvantages
Colestyramine	Cholestatic jaundice Itching (first line)	4–16 g (in two or three divided doses)	Reduce systemic bile salt levels	Poor patient adherence because of unpalatability Diarrhoea/constipation Increased flatulence Abdominal discomfort
Ursodeoxycholic acid	Cholestatic jaundice Itching	13–15 mg/kg (in two divided doses)		Variable response
Menthol 2% in aqueous cream	Itching	As required	Local cooling effect	Variable response
Chlorphenamine	Itching	4–16 mg (in three or four divided doses)	Sedative effects may be useful for nighttime itching	May precipitate/aggravate encephalopathy
Hydroxyzine	Itching	25–100 mg (in three or four divided doses)	Sedative effects may be useful for nighttime itching	May precipitate/aggravate encephalopathy
Cetirizine	Itching	10 mg (once daily)	Antihistamine with low incidence of sedation	Variable response
Naltrexone	Itching	50 mg/day	Shown to be beneficial in primary biliary cirrhosis	Opiate withdrawal symptoms, usually transient

**Fig. 16.5** Mechanisms of deranged clotting in chronic liver disease.

vitamin to synthesize clotting factors. Oral vitamin K is less effective than the parenteral form, and thus has little or no place in the management of clotting abnormalities and bleeding secondary to liver disease.

Aspirin, non-steroidal anti-inflammatory drugs (NSAIDs) and anticoagulants should be avoided in all patients with liver disease because of the risk of altering platelet function, causing gastric ulceration and bleeding. NSAIDs have also been implicated in precipitating renal dysfunction and variceal bleeding in patients

with end-stage liver disease. Although cyclo-oxygenase-2 inhibitors may cause a lower incidence of bleeding complications, currently they are avoided in patients with liver disease because their use still poses a risk.

Ascites

The aim in the treatment of ascites is to mobilise the collection of third space fluid (intra-abdominal fluid), and this can be achieved by simple measures such as reduced sodium intake. A low-salt diet (60–90 mEq/day) may be enough to facilitate the elimination of ascites and delay reaccumulation of fluid. Salt reduction combined with fluid restriction (approximately 1–1.5 L/day) are practical measures taken to mobilise fluid and provide weight reduction and symptomatic relief.

Aggressive weight reduction in the absence of peripheral oedema should be avoided because it is likely to lead to intravascular fluid depletion and renal failure. To prevent renal failure, weight loss should not exceed 300–500 g/day in the absence of peripheral oedema and 800–1000 g/day in those with peripheral oedema. However, diuretics and/or paracentesis are the cornerstone in the management of moderate- to large-volume ascites. [Box 16.1](#) outlines a sequential approach to the management of ascites.

Diuretics

The aldosterone antagonist spironolactone is usually used as a first-line agent in the treatment of ascites. In most instances a negative sodium balance and loss of ascitic fluid can be achieved with low

doses of diuretics. Spironolactone can be used alone or in combination with a more potent loop diuretic. The specific agents and dosages used are outlined in Table 16.3. Spironolactone acts by blocking sodium reabsorption in the collecting tubules of the kidney. It is usually commenced at 50–100 mg/day, but this varies, depending on the patient's clinical status, electrolyte levels and concomitant drug therapies. It can take many days to have a therapeutic effect, so dose augmentation should be conducted with caution and with strict monitoring of renal parameters. The addition of a loop diuretic, furosemide 40 mg/day, enhances the natriuretic activity of spironolactone and should be used when ascites is severe or when spironolactone alone fails to produce acceptable diuresis.

The use of more potent diuretic combinations may result in excessive diuresis which can lead to renal failure of pre-renal origin. The initiation and augmentation of diuretic therapy should ideally be carried out in hospital. This allows strict urea and electrolyte monitoring to detect impending hyperkalaemia and/or hyponatraemia, which commonly occur with diuretic therapy. It also allows the baseline measurement of urinary sodium excretion; subsequent changes in diuretic dose should be titrated against urinary sodium excretion. Aggressive and unchecked diuresis will precipitate the hepatorenal syndrome, which has a very poor prognosis. Generally if the serum sodium level

decreases to less than 130 mmol/L or if serum creatinine levels rise to greater than 130 mmol/L, then the diuretic regimen should be reviewed and stopped if indicated. Diuretic therapy can be complicated by hepatic encephalopathy, hyperkalaemia, hyponatraemia and azotaemia. Gynaecomastia and muscle cramps are side effects of diuretic therapy.

Refractory ascites, which occurs in 5–10% of patients with ascites, is associated with a 6-month to 1-year survival rate of as low as 50% (Arroyo et al., 1996; Guardiola et al., 2002). Therapeutic strategies include repeated large-volume paracentesis combined with the administration of plasma expanders, or alternatively, TIPSS, and in some cases the Alfapump. In some patients liver transplantation may be indicated. Ascites is considered to be refractory or diuretic resistant if there is no response with once-daily doses of 400 mg spironolactone and 160 mg furosemide. Again, urinary sodium excretion provides important information in terms of the response to or viability of dose augmentation with diuretic therapy. Patients on lower doses of diuretics are also considered to have refractory ascites if side effects are a problem (e.g. hepatic encephalopathy, hyperkalaemia, hyponatraemia or azotemia).

Paracentesis

Repeated large-volume paracentesis in combination with albumin administration is the most widely accepted therapy for refractory ascites. Patients generally require paracentesis every 2–4 weeks, and the procedure is often performed in the outpatient setting. Paracentesis, however, does not affect the mechanism responsible for ascitic fluid accumulation, and thus early recurrence is common. Intravenous colloid replacement or plasma expanders are used to prevent adverse effects on the renal and systemic circulation. Colloid replacement in the form of 6–8 g albumin per litre of ascites removed – equivalent to 100 mL of 20% human albumin solution (1 unit) for every 2.5 L of ascitic fluid removed – is a standard regimen.

Transjugular intrahepatic portosystemic shunting

TIPSS is an invasive procedure, used to manage refractory ascites or control refractory variceal bleeding. It is carried out under radiological

Table 16.3 Diuretics used in the management of ascites

Drug	Indication	Daily dose	Advantage	Disadvantage
Spironolactone	Fluid retention	50–400 mg	Aldosterone antagonist Slow diuresis	Painful gynaecomastia Variable bioavailability Hyperkalaemia
Furosemide	Fluid retention	40–160 mg	Rapid diuresis Sodium excretion	Nephrotoxic Hypovolaemia Hypokalaemia Hyponatraemia Caution in pre-renal uraemia
Amiloride	Mild fluid retention	5–10 mg	As K ⁺ -sparing agent or weak diuretic if spironolactone contraindicated	Lacks potency

guidance. An expandable intrahepatic stent is placed between the hepatic vein and the portal vein by a transjugular approach (Fig. 16.6). In contrast with paracentesis, the use of TIPSS is effective in preventing recurrence in patients with refractory ascites. It reduces the activity of sodium-retaining mechanisms and improves the renal response to diuretics. However, a disadvantage of this procedure is the high rate of shunt stenosis (up to 30% after 6–12 months), which leads to recurrence of ascites. TIPSS can also induce or exacerbate hepatic encephalopathy (Zervos and Rosemurgy, 2001).

Automated low-flow pump system (Alfapump)

The Alfapump is a device recently introduced for the management of refractory ascites. It consists of an intra-peritoneal catheter connected to a subcutaneously implanted, battery-powered device that moves fluid from the peritoneal cavity, with a second catheter that connects the subcutaneous pump to the urinary bladder, resulting in patients directly urinating the ascites. Implantation of the Alfapump requires a minor surgical procedure usually performed under general anaesthesia. Post-implant, the need for paracentesis is markedly reduced and in some instances is not required at all (Stirnemann et al., 2017). The most frequently encountered complications in clinical practice relate to the surgery, development of infections, catheter dysfunction and renal insufficiency.

Spontaneous bacterial peritonitis

Patients with ascites should be closely observed for spontaneous bacterial peritonitis (SBP) because it develops in 10–30% of patients and has a high mortality rate. Hepatorenal syndrome can complicate SBP in up to 30% of patients and also carries a high mortality rate. Conventional signs and symptoms of peritonitis are rarely present in such patients and if suspected, treatment with appropriate antibiotics should be started immediately after a diagnostic ascitic tap has been taken. A polymorphonuclear leucocyte count of greater than 250 cells/mm³ is diagnostic of this condition. The causative organism is of enteric origin in approximately

three-fourths of infections, and originates from the skin in the remaining one-fourth. Cefotaxime (2 g, 8 hourly) is effective in 85% of patients with SBP and is commonly used as first-line antimicrobial therapy. Other antibiotic regimens have been used including co-amoxiclav, but third-generation cephalosporins are the treatment of choice. The quinolone norfloxacin (400 mg/day) has a role in the prevention of recurrence of SBP, estimated as 70% at 1 year, and is recommended for long-term antibiotic prophylaxis (Moore and Aithal, 2006). However, the emergence of quinolone-resistant bacteria is a growing problem in the management of SBP.

Hepatic encephalopathy

Hepatic encephalopathy is a reversible neuropsychiatric complication that occurs with significant liver dysfunction. The precise cause of encephalopathy remains unclear, but three factors are known to be implicated, namely, portosystemic shunting, metabolic dysfunction and an alteration of the blood–brain barrier. It is thought that intestinally derived neuroactive and neurotoxic substances such as ammonia pass through the diseased liver or bypass the liver through shunts and go directly to the brain. This results in cerebral dysfunction. Ammonia is thought to increase the permeability of the blood–brain barrier, enabling other neurotoxins to enter the brain and indirectly alter neurotransmission. Other substances implicated in causing hepatic encephalopathy include free fatty acids, γ -aminobutyric acid and glutamate.

Clinical features of hepatic encephalopathy range from trivial lack of awareness, altered mental state to asterixis (liver flap) through to gross disorientation and coma. During low-grade encephalopathy, the altered mental state may present as impaired judgement, altered personality, euphoria or anxiety. Reversal of day/night sleep patterns is typical of encephalopathy. Somnolence, semistupor, confusion and finally coma can ensue (Table 16.4).

Encephalopathy associated with cirrhosis and/or portal systemic shunts may develop as a result of specific precipitating factors (Box 16.2) or can occur spontaneously. Common precipitating factors include gastro-intestinal bleeding, SBP, constipation, dehydration, electrolyte abnormalities and certain drugs (including narcotics and sedatives). Identification and removal of such precipitating

Fig. 16.6 Intrahepatic stent shunt links the hepatic vein with the intrahepatic portal vein.

Table 16.4 Grading of hepatic encephalopathy

Grade 0	Normal
Subclinical	Abnormal psychometric tests for encephalopathy (e.g. number correction test)
Grade 1	Mood disturbance, abnormal sleep pattern, impaired handwriting with or without asterixis
Grade 2	Drowsiness, grossly impaired calculation ability, asterixis
Grade 3	Confusion, disorientation, somnolent but arousable, asterixis
Grade 4	Stupor to deep coma, unresponsive to painful stimuli

factors are mandatory. Therapeutic management is then aimed at reducing the amount of ammonia or nitrogenous products in the circulatory system. Treatment with laxatives increases the throughput of bowel contents, by reducing transit time, and also increases soluble nitrogen output in the faeces. Drug therapies for encephalopathy are summarised in [Table 16.5](#).

Lactulose, a non-absorbable disaccharide, decreases ammonia production in the gut. It is widely used because it is broken down by gastro-intestinal bacteria to form lactic, acetic and formic acids. The effect of lactulose is to acidify the colonic contents which leads to the ionisation of nitrogenous products within the bowel, with a consequent reduction in their absorption from the gastro-intestinal tract. Lactulose is commenced in doses of 30–40 mL/day and titrated to result in two to three bowel motions each day. Patients unable to take oral medication or those with worsening encephalopathy are treated with phosphate enemas.

The non-absorbable antibiotic rifaximin has emerged as a key therapeutic strategy in the management of hepatic encephalopathy. Rifaximin is concentrated in the gastro-intestinal tract, has broad-spectrum *in vitro* activity against Gram-positive and Gram-negative aerobic and anaerobic enteric bacteria, and appears to carry a low risk of inducing bacterial resistance. A potential mechanism for the activity of rifaximin is its effects on the metabolic function of the gut microbiota, rather than a change in the relative bacterial abundance. Rifaximin is administered in dosages of 550 mg twice daily. Peripheral oedema and nausea are reported by patients. Metronidazole or neomycin may also be used to reduce ammonia production from gastro-intestinal

Box 16.2 Precipitating causes of hepatic encephalopathy

- Gastro-intestinal bleeding
- Infection (spontaneous bacterial peritonitis [SBP], other sites of sepsis)
- Hypokalaemia, metabolic alkalosis
- High-protein diet
- Constipation

- Deterioration of liver function
- Postsurgical portosystemic shunt or transjugular intrahepatic portosystemic shunt

bacteria, but both of these options have largely been abandoned with the emergence of rifaximin. Other therapies investigated for the treatment of encephalopathy include L-ornithine-L-aspartate, sodium benzoate, L-dopa, bromocriptine and the benzodiazepine receptor antagonist flumazenil.

Oesophageal varices

Variceal bleeding is the most feared complication of portal hypertension in patients with cirrhosis, and there is a 30% lifetime risk of at least one bleeding episode among patients with cirrhosis and varices. Treatment of variceal bleeding includes endoscopic band ligation (EBL), or rarely sclerotherapy, of oesophageal varices in parallel with splanchnic vasoconstrictors and intensive medical care. Patients with variceal bleeding refractory to endoscopic intervention or patients bleeding from ectopic or uncontrolled gastric varices will need TIPSS or surgical decompressive shunts. Refractory variceal bleeding should therefore be managed in centres with an appropriate level of expertise.

Initial treatment is aimed at stopping or reducing the immediate blood loss, treating hypovolaemic shock, if present, and subsequent prevention of recurrent bleeding. Immediate and prompt resuscitation is an essential part of treatment. Only when medical treatment has been initiated and optimised should endoscopy be performed. Endoscopy confirms the diagnosis and allows therapeutic intervention. Fluid replacement is invariably required and should be in the form of colloid or packed red cells and administered centrally. Sodium chloride 0.9% should generally be avoided in all patients with cirrhosis. Fluid replacement must be administered with caution because over-zealous expansion of the circulating volume may precipitate further bleeding by raising portal pressure, thereby exacerbating the clinical situation. A flow chart for the management of bleeding oesophageal varices is shown in [Fig. 16.7](#).

Endoscopic management

Variceal band ligation uses prestretched rubber bands applied to the base of a varix which has been sucked into the banding chamber attached to the front of an endoscope. Endoscopic balloon ligation controls bleeding in the majority of cases. It is at

Table 16.5 Drugs commonly used in the management of encephalopathy

Drug	Dosage	Comment	Side effects
Lactulose	15–30 mL orally 2–4 times daily	Aim for two to three soft stools daily	Bloating, diarrhoea
Metronidazole	400–800 mg orally daily in divided doses	Metabolism impaired in liver disease	Gastro-intestinal disturbance and neurotoxicity (especially when administered prolongedly)
Neomycin	2–4 g orally daily in divided doses	Maximum duration of 6 days, used less frequently now	Potential for nephrotoxicity and ototoxicity
Rifaximin	550 mg twice daily	Unclear whether long-term treatment could induce microbial resistance	Potential for nausea, peripheral oedema, and <i>Clostridium difficile</i> infection

least as effective as sclerotherapy, which it has largely superseded, and is associated with fewer side effects. Balloon tamponade with a Sengstaken–Blakemore balloon or Linton balloon may be used to stabilise a patient with actively bleeding varices by direct compression, until more definitive therapy can be undertaken. Balloon tamponade can control bleeding in up to 80% of cases, but 50% re-bleed when the balloon is deflated (Avgerinos and Armonis, 1994). Gastric varices develop in approximately 20% of patients with portal hypertension (Chang et al., 2013). The risk of gastric variceal bleeding is lower than that of oesophageal variceal bleeding, but bleeding from fundal varices is notoriously more difficult to manage and is associated with a higher mortality. The most effective treatment strategy for fundal varices is now considered to be variceal obturation with tissue adhesives or ‘glue injection’. The use of cyanoacrylate injection in the treatment of fundal varices is associated with less re-bleeding and is now the treatment of choice in the hands of experienced endoscopists (National Institute for Health and Care Excellence, 2012).

Pharmacological therapy

Several pharmacological agents are available for the emergency control of variceal bleeding (Table 16.6). Most act by lowering portal venous pressure. They are generally used to control bleeding in addition to balloon tamponade and emergency endoscopic techniques. Vasopressin was the first vasoconstrictor used to reduce portal pressure in patients with actively bleeding varices. However, its associated systemic vasoconstrictive adverse effects limited its use. The synthetic vasopressin analogue, terlipressin,

is highly effective in controlling bleeding and in reducing mortality. It can be administered in bolus doses every 4–6 hours and has a longer biological activity and a more favourable side effect profile. Once a diagnosis of variceal bleeding has been established, a vasoactive drug infusion (usually terlipressin) should be started without further delay and continued for 2–5 days. Somatostatin and the somatostatin analogue, octreotide, are reported to cause selective splanchnic vasoconstriction and reduce portal pressure. Although they are reported to cause less adverse effects on the systemic circulation, terlipressin remains the agent of choice.

Self-expanding metallic stents

Current treatment strategies of variceal bleeding are highlighted earlier in this section; however, up to 10% of bleeding events remain refractory to standard therapy and are associated with high mortality. Implantation of a self-expanding metallic stent appears to sufficiently result in immediate haemostasis and stopping of bleeding in refractory variceal bleeding. Additionally it appears to be associated with fewer adverse effects compared with conventional therapeutic strategies and decreased incidence of bleeding recurrence. The Danis stent system is an example of a self-expanding stent which offers effective haemostasis through direct compression of the bleeding oesophageal varices. It does not require image guidance, allows post-procedure endoscopic investigations and patients can also resume oral intake of food. The main clinically significant adverse outcomes reported to date are stent migration and oesophageal ulceration; the former does not appear to be associated with increased incidence of re-bleeding, and the latter occurs in approximately 6% (Kumbhari et al., 2013).

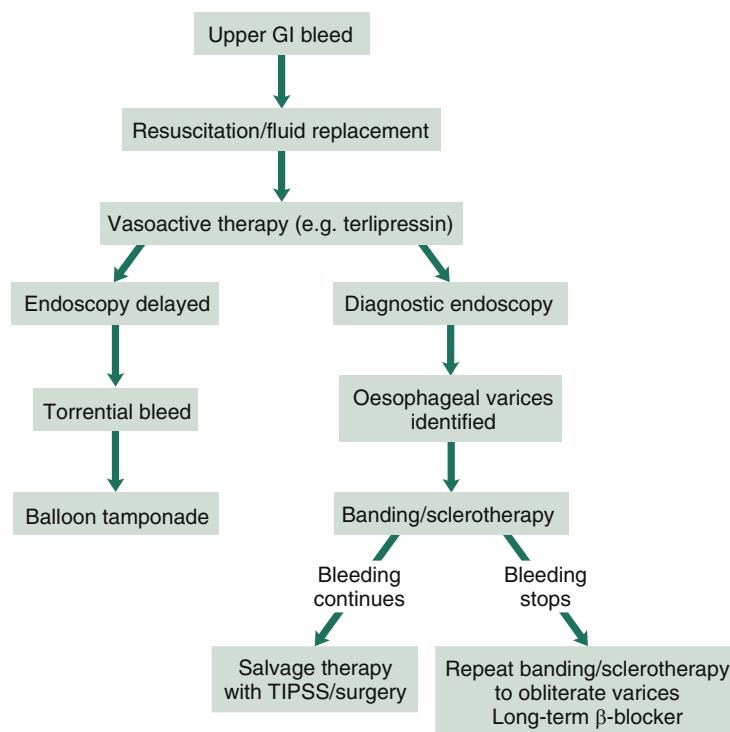

Fig. 16.7 Management of oesophageal variceal haemorrhage. GI, Gastro-intestinal; TIPSS, transjugular intrahepatic portosystemic shunt.

Transjugular intrahepatic portosystemic stent shunt

TIPSS stent is now established as the preferred rescue therapy in cases where endoscopic intervention has failed to control bleeding (see Fig. 16.7). Recent data suggest the use of early TIPSS within the first 48 hours may be lifesaving in patients with advanced liver failure (Lopera, 2005).

Prevention of re-bleeding

EBL is performed at regular intervals (1–2 weeks) as part of an eradication programme to obliterate the varices. Once varices have been eradicated, endoscopic follow-up can be performed less frequently (3 monthly) for the first year, and then twice yearly thereafter. If varices reappear they should be banded regularly until eradicated again. Non-selective β -blockers, such as propranolol, are the medication of choice to prevent re-bleeding and can also be used as primary prophylaxis against variceal bleeding in patients with known varices. The mechanism of action is complex, but they reduce portal hypertension by causing splanchnic vasoconstriction and reduced portal blood flow. At higher doses they can have a more marked negative effect on cardiac output and thus must be titrated accordingly.

Acute liver failure

ALF occurs when there is a rapid deterioration in liver function in previously healthy individuals, resulting in encephalopathy and a coagulopathy. ALF is a multisystem disorder, with cerebral oedema and renal impairment being particularly important complications. In the past, viral hepatitis was a major consideration in the cause of ALF. However, the development of a commercial vaccine for hepatitis B has seen a dramatic decline in the contribution of HBV to ALF in Western countries. The most common cause of ALF in the UK and USA is paracetamol (acetaminophen) toxicity. Seronegative hepatitis is the other common aetiological group. Management of ALF is complicated, involving supporting the central nervous, cardiovascular and renal systems. All patients with ALF are at risk of infection, and prophylactic administration of broad-spectrum antibiotics and antifungal agents is standard practice. Coagulopathy and bleeding resulting from liver failure are well-recognised life-threatening complications which require specialised monitoring and early correction.

Liver transplantation

Liver transplantation is the established treatment for selected patients with ALF, decompensated chronic liver disease, inherited

metabolic disorders and primary liver cancer. HCV and alcohol-related end-stage liver disease are the commonest indications for liver transplantation in Europe and the USA. Typical 1-year survival rates are around 90% for elective transplants. Remarkably few transplants fail because of rejection and, nowadays, technical problems, infection and multisystem failure account for most deaths in the first year. Recurrence of the primary disease, malignancy and death with a functioning graft account for most late deaths.

An increasing number of immunosuppressive agents are now available, and this has enabled clinicians to tailor immunosuppression to achieve a balance of good graft function and an acceptable side effect profile. The calcineurin inhibitors, tacrolimus and ciclosporin, remain the mainstay of immunosuppressive therapy. Corticosteroids are still commonly used, at least during the first 3 months after transplantation. The other drugs used regularly for long-term immunosuppression include azathioprine, mycophenolate, sirolimus and everolimus. Therapy is monitored closely and increasingly tailored to individual patients, with a particular emphasis on preserving renal function and reducing the risk of cardiovascular disease.

Disease-specific therapies

Hepatitis B

The primary goal in the management of CHB infection is to prevent cirrhosis, hepatic failure and HCC. The ideal treatment endpoint is HBsAg loss, which is considered a functional cure. However, the eradication of HBV at this juncture is considered impossible because of integration of HBV into the host genome and the presence of an intracellular conversion pathway which replenishes the pool of transcriptional templates in the hepatocyte nucleus without the need for reinfection. For this reason, current treatment strategies revolve around continuous viral suppression to reduce immune-mediated liver damage and prevent the development of fibrosis and cirrhosis. Although viral suppression can significantly reduce the risk of HCC, it does not necessarily prevent it.

It is the persistence of covalently closed circular DNA (cccDNA) which is considered to preclude eradication of HBV. Thus, therapies currently available for the treatment of CHB are measured in terms of HBeAg seroconversion (in eAg-positive disease), viral suppression, ALT normalisation and improvement in liver histopathology. There has been increased focus on HBsAg quantification, with HBsAg levels considered a surrogate of cccDNA levels (Martinot-Peignoux et al., 2013). Thus, all new therapies for the treatment of HBV should be benchmarked against their ability to achieve HBsAg loss, which is associated with reduced risk of disease progression and the development of HCC.

Recommended first-line therapies vary in different guidelines. Both the international guidelines from the European Association for the Study of the Liver (EASL) and the American Association for the Study of Liver Diseases (AASLD) offer flexibility in treatment selection, with the choice of first-line agent being left to physician's discretion along with an element of patient choice in making a joint decision (EASL, 2017; Terrault et al., 2016). Treatment strategies have broadened and include the potent oral antiviral agents tenofovir and entecavir, as well as pegylated

Table 16.6 Drugs used in the treatment of acute bleeding varices

Drug	Dosage and administration
Terlipressin	1–2 mg bolus 4–6 hourly for 2–5 days
Octreotide	50 micrograms/h i.v. infusion for ≥ 48 h

interferon (peginterferon) alfa-2a. Tenofovir and entecavir have emerged as the leading oral antivirals, and agents with a low genetic barrier to resistance, such as telbivudine, lamivudine and adefovir, should not be used as first-line antivirals. The use of lamivudine or adefovir as a monotherapy is no longer recommended and should be avoided if at all possible, owing to high rates of resistance with these drugs. Peginterferon alfa-2a is also used in the treatment of CHB. This is due primarily to its potent immunomodulatory effects which give it a clear advantage over oral antivirals. Significant rates of HBsAg loss have been reported in both eAg- positive and -negative disease, and the inclusion of quantitative HBsAg levels provides an objective 'stopping rule' to terminate treatment early where the response is deemed suboptimal. The advantages of interferon therapy, such as a finite treatment course and good rates of HBsAg loss in selected patients, must be weighed against the disadvantages associated with an injection-based therapy and the inherent side effect profile associated with interferons. Therefore, a careful and rational approach must be followed when considering treatment of CHB. The treatment landscape for CHB has changed dramatically from the high rates of resistance previously seen with lamivudine and adefovir to the extremely low rates of resistance reported for entecavir and tenofovir. However, when commencing oral antiviral agents, the patient and treating prescriber must be aware that they are potentially embarking on a lifelong course of treatment.

An issue which must be considered nonetheless is the potential side effect profile of these relatively new drugs, notwithstanding their potency and documented efficacy. More recently, reports of renal toxicity have emerged in some patients treated with tenofovir (glomerular and tubular dysfunction); as a consequence, tenofovir alafenamide (TAF), a prodrug of tenofovir, has emerged as an alternative antiviral agent with non-inferior efficacy but a better safety profile (Kayaaslan and Guner, 2017; Scott and Chan, 2017). TAF is now considered a first-line treatment for the management of CHB, owing to its high genetic barrier to resistance, but distinguished by its better safety profile. Access to TAF in clinical practice is likely to be determined by cost, while the existing antivirals (tenofovir and entecavir) come off patent and relatively cheap generics will be available. However, prescribers will need to remain vigilant for the emergence of resistant virus (and the development of side effects), even with these newer more potent agents, because the treatment landscape in CHB is set to change dramatically over the coming years.

Hepatitis C

The primary aim of treating patients with chronic HCV is viral clearance with sustained virologic response (SVR). SVR is defined as the absence of viraemia, that is, undetectable HCV RNA in a sensitive assay (≤ 15 IU/mL), 12 weeks (SVR 12) and 24 weeks (SVR 24) after antiviral therapy has been completed. The goal of therapy is ultimately to eradicate HCV and prevent the development of liver cirrhosis, decompensated liver disease, HCC and death.

The backbone of hepatitis C treatment had been for many years an interferon-based regimen with the addition of ribavirin

in 1998 and pegylation of interferon in 2001. This antiviral regimen was characterised by suboptimal response rates, that is, 55% for genotypes 1 and 4 and 80–85% for genotypes 2 and 3. The main limitation of interferon-based treatment was the side effect profile, complications of therapy and poor patient tolerability. Common side effects of therapy included influenza-like symptoms, decrease in haematological parameters (haemoglobin, neutrophils, white blood cell count and platelets), gastrointestinal complaints, psychiatric disturbances (anxiety and depression), and hypothyroidism or hyperthyroidism. Hence HCV management was characterised more by toxicity than treatment success.

The landscape changed significantly with the emergence of the first direct-acting antiviral (DAA) agents boceprevir and telaprevir in 2011. More recently, second-generation DAAs, approved in 2013, have revolutionised treatment of HCV, and they are now considered the standard of care in HCV management. DAAs are molecules that target specific non-structural proteins of the virus that results in disruption of viral replication and infection. There are four classes of DAAs, which are defined by their mechanism of action and therapeutic target. The four classes are non-structural proteins 3/4A (NS3/4A), protease inhibitors, NS5B nucleoside polymerase inhibitors, NS5B non-nucleoside polymerase inhibitors and NS5A inhibitors.

In 2013 the U.S. Food and Drug Administration approved sofosbuvir and simeprevir as the first all-oral therapies to be used in clinical practice and were subsequently followed by the approval of daclatasvir, ledipasvir, ombitasvir, paritaprevir, ritonavir and dasabuvir. DAAs are used with or without the addition of ribavirin and/or peginterferon-alfa. Selection of a combination of drugs and duration of treatment (either a 12- or 24-week course) is considered primarily on the basis of whether the patient has cirrhosis; other factors which may determine the treatment regimen and duration include prior treatment failure and HCV genotype. SVR is achievable in more than 90% of all patients irrespective of the presence/absence of cirrhosis, varying between 82% and 100% (Solbach and Wedemeyer, 2015). DAAs are well tolerated with few individuals reporting side effects and even fewer, if any, discontinuing treatment because of adverse effects. The most common side effects reported are fatigue, headache, rash and pruritus, nausea, insomnia and asthenia.

A recognised episode of acute hepatitis in individuals with HCV develops only in a small percentage of individuals. Based on recently published guidelines, patients with acute hepatitis C should be treated with a combination of DAAs, in order to prevent progression to chronic hepatitis C. High SVR rates (>90%) have been reported with sofosbuvir-based, interferon-free regimens (EASL, 2016).

DAAs should also be used in patients with an indication for liver transplantation because antiviral treatment prevents graft rejection, and similarly they should be considered in patients with HCC who are being considered for transplantation. The tolerability of the DAAs means there are few cases where their use is precluded, and drug cost is often the main barrier to their wider use. Treatment with DAAs in transplanted patients with post-transplant HCV recurrence is now considered routine, and the debate about the use of DAAs in the transplant setting now

revolves around the most appropriate timing of treatment, be that pretransplantation or restriction to the post-transplant setting. Special groups such as individuals with HIV co-infection, HBV co-infection, individuals with bleeding disorders, active drug addicts and patients on stable maintenance substitution have all shown excellent treatment outcomes with DAAs. More challenging subgroups, such as individuals with renal failure (creatinine clearance <30 mL/min and/or on renal replacement therapy), should be considered for treatment with DAAs; however, there remains a paucity of data, mainly on pharmacokinetics, safety and efficacy, in these patients which mandates further research to establish the best treatment strategy.

It is clear that the emergence of the DAAs marked the dawn of a new era in the management of patients with HCV infection. The challenges faced in a real-world setting with restricted access to DAAs, because of drug cost, have resulted in patients with the greatest clinical need being treated first. Even in this setting, treating those with the most advanced disease has reinforced the potency of the DAAs and the potential to achieve HCV cure in these difficult-to-treat patients without jeopardizing patients' health.

Alcoholic liver disease

The backbone of managing ALD and more specifically alcoholic cirrhosis is abstinence from alcohol which reduces the risks of complications and associated mortality. Additionally, cofactors which include obesity, insulin resistance, smoking, malnutrition, iron overload and viral hepatitis should be identified and managed. Liver transplantation was shown to be beneficial in patients with a Child-Pugh C ALD and/or a Model for End-Stage Liver Disease score ≥ 15 . All the major liver disease organisations concur that a 6-month period of abstinence is necessitated to assess patient progress and the potential to avoid liver transplantation in those with spontaneous improvement.

AH is a clinical syndrome characterised by jaundice and/or ascites of recent onset in a patient with ongoing alcohol misuse. The recommended first-line treatment of choice in patients with AH is corticosteroids. In the recent STOPAH study conducted in the UK (Thursz et al., 2015), it was suggested that the administration of 40 mg prednisolone daily for 1 month may have a beneficial effect on short-term mortality, but not on the medium-term or long-term outcome of AH. Early non-response to steroids should be identified, and cessation of therapy should be considered. Until recently, pentoxifylline was considered an alternative first-line treatment to steroids in patients with AH and ongoing sepsis; however, the STOPAH trial did not show improvement of outcomes in patients with AH treated with pentoxifylline.

N-acetylcysteine, an antioxidant substance that replenishes glutathione stores in hepatocytes, could also be considered in addition to steroids because it was suggested that the combination regimen has a better 1-month survival (Nguyen-Khac et al., 2011).

Non-alcoholic fatty liver disease

Epidemiological evidence suggests a strong relationship between an unhealthy lifestyle and NAFLD; therefore, all patients with NAFLD should receive counselling for lifestyle intervention,

namely, a more healthy diet and increased physical activity. A target 7–10% weight loss should be set for patients because this has been correlated with improvement of liver enzymes and histology.

Pharmacotherapy should be reserved for those with evidence of NASH and stage 2 or higher fibrosis and/or those with the potential for disease progression. Although further studies are necessitated, pioglitazone appears to improve all histological features (except for fibrosis) and additionally improves ALT and insulin resistance (Shyangdan et al., 2011); resolution of the clinical features of NASH was achieved more often (when compared with placebo). Vitamin E at a dosage of 800 IU/day also appears to improve steatosis, inflammation and ballooning and could induce resolution of NASH in a third of patients with NASH based on recent studies; vitamin E demonstrated better safety and tolerability in the short-term in comparison with pioglitazone (Sanyal et al., 2010). A combination of the above could also be used. The role of statins is more clear; they can be used with confidence to reduce cardiovascular risk without having any benefits (or conversely causing harm) to the liver.

As a strategy to tackle obesity and diabetes, bariatric surgery has a role in the management of NAFLD because it reduces fat in the liver and therefore is thought to reduce NASH progression; prospective data showed improvement of all histological lesions of NASH, including fibrosis (Nostedt et al., 2016). Finally, liver transplantation may be the only therapeutic option for some patients with end-stage NAFLD; in this cohort overall survival is comparable with other indications for transplantation.

Autoimmune hepatitis

Corticosteroids and/or azathioprine are the standard therapies for AIH. Prednisone or prednisolone are administered at dosages of 40–60 mg/day (0.5–1 mg/kg/day) alone or at lower dosages when combined with azathioprine. The steroid dosage is reduced over a 6-week to 3-month period to a target maintenance dosage of ≤ 7.5 mg/day. The disturbance in aminotransferases usually normalises within 6–12 weeks, but histological remission tends to lag by 6–12 months. Azathioprine at a dosage of 1–2 mg/kg/day is used as an adjunct to corticosteroid therapy. Azathioprine used alone is ineffective in treating the acute phase of AIH, and therefore is usually added in once the steroid therapy has improved the biochemical abnormality. In patients intolerant of azathioprine, or in cases of proven treatment failure, other immunosuppressive agents have been used (e.g. tacrolimus and mycophenolate). Newer corticosteroids such as budesonide, which is associated with fewer systemic side effects, have also been used effectively, but this is not recommended in patients with established cirrhosis. Budesonide is likely to have a greater role in the treatment of AIH in the future.

Primary biliary cholangitis

Several therapies have been associated with short-term improvements in LFTs. UDCA 13–15 mg/kg/day is the medication of choice and is widely used to treat PBC by reducing the retention of bile acids and increasing their hepatic excretion; therefore, it is effective in protecting against the cytotoxic effects

of dihydroxy bile acids which accumulate in PBC. UDCA has been demonstrated to markedly decrease serum bilirubin, alkaline phosphatase (ALP), gamma-glutamyl transpeptidase (γ GT), cholesterol and immunoglobulin M levels and also to ameliorate histological features in patients with PBC when compared with placebo (Pares et al., 2000). However, no significant effect on symptoms such as fatigue or pruritus were observed. Additionally, it was shown that long-term treatment with UDCA delayed the histological progression of the disease, especially in patients in whom treatment was started at an early stage (Angulo et al., 1999). With respect to the effect of UDCA on survival, most large studies do not show a significant beneficial effect, although, in a combined analysis of raw data from the French, Canadian and Mayo cohorts, treatment was associated with a significant reduction in the likelihood of liver transplantation or death (Tsochatzis et al., 2009).

There is currently no consensus on how to treat patients with a suboptimal biochemical response to UDCA; one approach could be the combination of UDCA and budesonide (6–9 mg/day) in non-cirrhotic patients, although further studies are required. Development of portal vein thrombosis, probably related to short-term budesonide administration, was reported in stage 4 patients with portal hypertension; therefore, budesonide should not be administered to patients with cirrhosis.

Liver transplantation remains the only effective option in patients with end-stage disease. Survival rates above 90% and 80–85% at 1 and 5 years, respectively, have been reported by many centers. After orthotopic liver transplantation, most patients' antimitochondrial antibody status does not change, but they have no signs of liver disease. PBC has a calculated weighted disease recurrence rate of 18%. However, recurrence is rarely associated with graft failure.

Immunosuppressive agents such as ciclosporin, azathioprine and methotrexate have also been assessed for the treatment of PBC, but clinically significant adverse events outweigh the potential benefits. Other medications, including antifibrotic agents such as D-penicillamine and colchicine or antiretroviral agents, were also studied, but outcomes were shown to be inferior or non-superior to UDCA or reported adverse events outweighed the benefits (Angulo et al., 1999).

Recent results on the use of obeticholic acid show promise for its role in the treatment of PBC (Bowlus, 2016). Obeticholic acid binds to the farnesoid X receptor; a key regulator of bile acid metabolic pathways found in the nucleus of cells in the liver and intestine. Obeticholic acid, given orally, appears to increase bile flow from the liver and to suppress bile acid production in the liver, thus reducing exposure of the liver to toxic levels of bile acids. It is indicated in combination with UDCA in adults with an inadequate response to UDCA, or as monotherapy in adults unable to tolerate UDCA. Most common side effects (>5%) include, amongst others, pruritus, fatigue and gastro-intestinal disturbances.

Primary sclerosing cholangitis

Effective treatment for PSC does not exist to date. Although paucity of data does not allow a specific recommendation

for the general use of UDCA in the management of PSC, it appears that UDCA at a higher dosage (>15 mg/kg/day) can be used to manage associated cholestasis. This has been shown to improve serum liver enzymes and surrogate markers of prognosis, but it has not been shown to have proven benefit on survival. Studies with various immunosuppressive agents have been disappointing, and transplantation remains the only effective treatment option in patients with advanced disease.

Wilson's disease

Wilson's disease, a rare autosomal recessive condition, is usually managed with chelation therapy. Penicillamine is the agent of choice in Wilson's disease because it promotes urinary copper excretion in affected patients and prevents copper accumulation in presymptomatic individuals. Initial treatment of 1.5–2 g/day is given in divided doses. Initially neurological symptoms may worsen because of deposition of mobilised copper in the basal ganglia, but symptomatic patients tend to improve over a period of several weeks. Other therapy-related adverse effects include renal dysfunction, haematological abnormalities and disseminated lupus erythematosus. Therefore, regular monitoring of full blood count and electrolytes is required, as well as small doses of pyridoxine (25 mg), to counteract the antipyridoxine effect of penicillamine and the associated neurological toxicity. Patients unable to tolerate penicillamine may respond to trientine. This chelating agent is less potent than penicillamine but has fewer adverse effects. Oral zinc is also used, but again is limited by its lack of potency when compared with penicillamine.

Case studies

Case 16.1

Mr AD, a 56-year-old man, is admitted to hospital following haematemesis and melaena. He has a known history of ALD (stopped drinking alcohol 1 year ago) with marked ascites. A provisional diagnosis of bleeding oesophageal varices is made. A Sengstaken–Blakemore tube is inserted and the balloon inflated as a temporary measure to arrest bleeding. The patient is transferred 8 hours later to a specialist regional centre for further management.

Laboratory data on admission are:

		Reference range
Na ⁺	124	133–143 mmol/L
K ⁺	3.0	3.5–5.0 mmol/L
Creatinine	131	80–124 mmol/L
Urea	14.3	2.7–7.7 mmol/L
Bilirubin	167	3–17 mmol/L
ALT	24	0–35 IU/L
PT	18.9	13 seconds
Albumin	24	35–50 g/dL
Haemoglobin	8.9	13.5–18 g/dL

Drugs on admission:

spironolactone 200 mg one each morning.

Questions

1. What other action would you have recommended before Mr AD was transferred to the regional centre?
2. What options (drug and/or non-drug) are likely to be available at the regional centre for managing the patient's bleeding varices?
3. What further long-term measures would you recommend for Mr AD?

Answers

1. Initial restoration of circulating blood volume with colloid, followed by cross-matched blood. Fluid replacement is necessary to protect renal perfusion. In view of Mr AD's ascites, sodium chloride 0.9% should be avoided. Dextrose 5% with added potassium (hypokalaemia present) would be a reasonable choice. A pharmacological agent to reduce portal pressure, such as terlipressin 1–2 mg every 4–6 hours or octreotide 50 micrograms/h, should be started (Abid et al., 2009). Broad-spectrum intravenous antibiotics such as a fluoroquinolone (including ciprofloxacin and norfloxacin) for short-term use (7 days) are recommended in most expert guidelines (Lee et al., 2014). Intravenous cephalosporin (especially ceftriaxone), given in a hospital setting with prevalent quinolone-resistant organisms, has also been shown to be beneficial, particularly in high-risk patients with advanced cirrhosis. There is no evidence that gastric acid suppression is beneficial, and routine commencement of a proton pump inhibitor (PPI) is not recommended; if the bleeding is caused by a gastric mucosal lesion, a PPI such as lansoprazole or omeprazole, or a histamine type 2 receptor antagonist such as ranitidine can be administered. Spironolactone is likely to be either causing or exacerbating the low sodium and should be discontinued. Vitamin K, 10 mg intravenously once daily for 3 days, should be administered in an attempt to correct the raised PT. Because the patient has severe liver disease with varices and ascites there is a possibility he may experience development of encephalopathy. It would be advisable to start lactulose or, if the patient is unable to take medicines orally, administer an enema such as a phosphate enema.
2. Banding/ligation: This is considered superior to sclerotherapy with fewer postendoscopic complications. It involves mechanical strangulation of variceal channels by small elastic plastic rings mounted on the tip of the endoscope. TIPSS: This can be used to reduce portal pressure, but there is a risk of precipitating encephalopathy. Banding is the first-line option for managing bleeding oesophageal varices. Balloon tamponade with a Sengstaken–Blakemore balloon or Linton balloon may be used to stabilise a patient with active bleeding varices by direct compression, until more definitive therapy can be undertaken. Implantation of a self-expanding metal stent (SEMS) can also result in immediate haemostasis and bleeding control in refractory variceal bleeding. Patients who continue to bleed after two endoscopic treatments should be considered for TIPSS. Surgery involving portal-systemic shunts or devascularisation are possible options if the above alternative modalities fail. Extrahepatic portal-systemic shunts are situated outside the liver and divert portal blood flow into the systemic circulation bypassing the liver. Devascularisation involves obliteration of the collateral vessels supplying blood to the varices.
3. Banding/ligation can be performed on Mr AD at regular intervals of 1–2 weeks to obliterate bleeding varices. Once varices have been eradicated, endoscopic follow-up should be undertaken every 3 months for the first year, then every 6–12 months thereafter. If varices reappear they should be banded regularly until endoscopic eradication. Non-selective β -blockers, such as propranolol, are used in the prophylaxis of further bleeds, with the

dose adjusted until the heart rate is reduced by 25%, but to not less than 55 beats/min.

Case 16.2

Mrs AL, a 68-year-old woman with a long-standing history of ALD, is admitted to hospital with a 2-week history of vomiting, confusion, increased abdominal distension and worsening jaundice.

On admission laboratory data are as follows:

		Reference range
Na	116	133–143 mmol/L
K	3.8	3.5–5.0 mmol/L
Urea	8.5	2.7–7.7 mmol/L
Creatinine	119	80–124 mmol/L
Bilirubin	459	3–17 mmol/L
Albumin	23	35–50 g/L
ALT	23	0–35 IU/L
Alkaline phosphatase	524	70–300 IU/L
PT	18.6	13 seconds

Drugs on admission are as follows:

spironolactone 300 mg each morning
temazepam 10 mg at night
lactulose 10 mL twice daily

Questions

Discuss Mrs AL's initial treatment plan for the management of:

1. ascites
2. nausea and vomiting
3. confusion

Answers

From the presenting features and LFTs on admission it is apparent that Mrs AL's liver disease is getting progressively worse, probably as a result of continued alcohol intake. She is confused on admission and this suggests encephalopathy, a common complication of chronic liver disease.

1. Ascites management: Mrs AL has increased abdominal distension on admission suggestive of worsening ascites. This might be due to poor adherence with spironolactone, or alternatively her ascites may have become diuretic resistant. The patient should be sodium restricted and confined to bed. Spironolactone therapy should be stopped in view of the low sodium and confusion, because over-use of diuretics can precipitate encephalopathy. Fluid restriction is necessary to reduce the ascites, but sufficient fluid is required to rehydrate the patient following vomiting. Paracentesis should be used to manage the ascites. Every litre of ascitic fluid removed should be replaced with 6–8 g of albumin. A diagnostic ascitic tap should be undertaken to exclude the presence of spontaneous bacterial peritonitis (or infection in the ascites).
2. Nausea/vomiting management: Mrs AL's urea is slightly raised, indicating possible dehydration as a result of vomiting. Given the low serum sodium, Mrs AL should be rehydrated with 20% human albumin solution until formal assessment of the total body sodium status; 5% dextrose in this instance may further exacerbate the hyponatraemia. Additional potassium should be given to correct the low serum potassium. Note that if Mrs AL has been taking spironolactone, there would normally be an increase in potassium, but in this case the vomiting has probably reduced this. Mrs AL's nausea can be managed

with a suitable antiemetic such as domperidone 10 mg four times a day initially and then titrated according to the response.

- Confusion may be an early sign of encephalopathy in Mrs AL. Temazepam should be stopped. The patient is on an inadequate dose of lactulose for the management of encephalopathy, so this should be increased to produce two to three loose motions per day. A typical dose would be 20 mL three or four times daily. In view of Mrs AL's confusion it may be worth considering other agents in the management of the encephalopathy, such as rifaximin 550 mg twice daily. Precipitating factors should be identified and treated appropriately, such as the profound hyponatraemia.

Case 16.3

Mrs PB, a 54-year-old woman with PBC, has been complaining of increasing backache over the last 3 months. Her general condition has deteriorated over the past year during which she has suffered from ascites and encephalopathy. Her main complaint is of continuous back pain, which disturbs her sleep.

Question

How would you manage Mrs PB's back pain?

Answer

Back pain secondary to osteoporosis-related vertebral fractures is common in patients with chronic liver disease, such as PBC. This is due to the fact that most patients with PBC are postmenopausal women in their late fifties on whom loss of bone density is likely, secondary to both menopause and chronic liver disease. Once the diagnosis has been confirmed, the patient should be counselled that the bone pain is chronic, tends to be intermittent, and may take several months to settle depending on the presence and extent of fractures. Bed rest is useful in the acute situation, but prolonged bed rest can accelerate bone loss; adequate exercise is therefore recommended. The patient should be advised to take adequate calcium supplementation of 1–1.5 g/day in addition to her normal

diet. Vitamin D deficiency is common in chronic liver disease and should be corrected; it is advisable to administer 800 IU daily or alternatively 25,000 IU once or twice per week. Oral bisphosphonates have been found to be safe, especially in patients with PBC, and can improve bone mineral density. Hormone replacement therapy remains contentious because of potential carcinogenic properties and the increased risk of thromboembolism; thus, it is not considered a first-line therapy. In patients with chronic liver disease, transdermal oestradiol is considered a safer option.

For symptomatic management of the pain, a variety of analgesics are available. The choice of drug is influenced by both the severity of the pain and the degree of liver impairment. For mild pain, paracetamol is the mainstay of treatment and may be used in standard doses in the majority of patients with liver dysfunction. Patients pretreated with cytochrome P450-inducing drugs or patients with a history of alcohol abuse are at increased risk of paracetamol-induced liver injury and should receive only short courses at low doses (maximum of 2 g/day for an adult). Opioid analgesics should usually be avoided in liver disease because of their sedative properties and the risks of precipitating or masking encephalopathy. If a patient has stable mild-to-moderate liver disease, then short-term use of opioids can be considered. Moderate potency opioids, such as dihydrocodeine and codeine, are eliminated almost entirely by hepatic metabolism. Therapy should be initiated at a low dose, and the dosage interval titrated according to the response of the patient. Despite their low potency, these preparations may still precipitate encephalopathy.

In severe pain, the use of potent opioids is usually unavoidable. They undergo hepatic metabolism and are therefore likely to accumulate in liver disease. To compensate for this, it is important to increase the dosage interval when using these drugs. Morphine, pethidine or diamorphine should be administered at doses at the lower end of the dosage range at intervals of 6–8 hours. The patient should be regularly observed and the dose titrated according to patient response. In any patient with liver disease who is receiving an opioid it is advisable to co-prescribe a laxative because constipation can increase the possibility of development of encephalopathy. NSAIDs should be avoided in patients with liver disease. All NSAIDs can prolong bleeding time via their effects on platelet function. Impaired liver function itself can lead to a reduced synthesis of clotting factors and an increased bleeding tendency. NSAIDs may also be dangerous because of the increased risk of gastro-intestinal haemorrhage and potential to precipitate renal dysfunction.

17 Acute Kidney Injury

Paul Cockwell, Stephanie Stringer and John Marriott

Key points

- Acute kidney injury (AKI) is diagnosed when the excretory function of the kidney declines rapidly over a period of hours or days and is usually associated with the accumulation of metabolic waste products and water.
- A wide range of factors can precipitate AKI, including trauma, obstruction of urine flow or any event that causes a reduction in renal blood flow, including surgery and medical conditions, for example, sepsis, diabetes, acute liver disease and rapidly progressive glomerulonephritis.
- Drug involvement in the development of AKI is common.
- There are no specific signs and symptoms of AKI. The condition is typically indicated by raised blood levels of creatinine and/or a low urine output.
- The clinical priorities in AKI are to manage life-threatening complications, correct intravascular fluid balance and establish the cause, reversing factors causing damage where possible.
- The aim of medical treatment is to remove causative factors and maintain patient well-being so that the kidneys have a chance to recover.
- Treatment of AKI is essentially supportive, although there are conditions that cause AKI that are reversible with specific treatment.
- AKI is a serious condition with mortality rates up to 70%, varying according to cause and at its highest with concurrent failure of other organs.

Definition and incidence

Acute kidney injury (AKI) is a common and serious problem in clinical medicine. It is characterised by an abrupt reduction (usually within a 48-hour period) in kidney function. This results in an accumulation of nitrogenous waste products and other toxins. Many patients become oliguric (low urine output) with subsequent salt and water retention. In patients with pre-existing chronic kidney disease (CKD), a rapid decline in renal function is termed *acute on chronic*. The nomenclature of AKI has recently entered clinical practice and has replaced the previously used term *acute renal failure*.

The diagnostic and classification criteria for AKI are based on an increase in serum creatinine or the presence of oliguria (Table 17.1 and Fig. 17.1).

The large majority of cases of AKI occur in patients who are already hospitalised for other medical conditions; up to 7% of

Table 17.1 Kidney Disease Improving Global Outcomes (KDIGO) classification criteria for acute kidney injury staging (only one criterion is required to fulfil stage)

Stage	Serum creatinine criteria	Urine output criteria
Stage 1	Rise by ≥ 0.3 mg/dL (≥ 26.4 mmol/L) or ≥ 1.5 – 2 times from baseline	< 0.5 mL/kg/h for ≥ 6 h
Stage 2	Rise to ≥ 2 – 2.9 times from baseline	< 0.5 mL/kg/h for ≥ 12 h
Stage 3	Rise to ≥ 3 times from baseline or ≥ 4.0 mg/dL (≥ 352 mmol/L) or receiving renal replacement therapy	< 0.3 mL/kg/h for ≥ 24 h or anuria for ≥ 12 h

these cases sustain AKI, and this increases to $\geq 30\%$ in those who are critically ill. Most cases are caused by pre-renal AKI and are reversed with appropriate intervention. However, severe AKI, which may include a requirement for dialysis treatment, is often associated with failure of one or more non-renal organs (this is called *multi-organ failure*); in this setting there is a mortality rate of 70% in patients with sepsis and AKI and 45% in patients without sepsis. AKI that occurs in the community is responsible for around 1% of all hospital admissions.

Classification and causes

AKI is not a single disease state with a uniform aetiology, but a consequence of a range of different diseases and conditions. The most useful practical classification comprises three main groupings: (1) pre-renal, (2) renal or (3) post-renal. More than one category may be present in an individual patient. Common causes of each type of AKI are outlined in Table 17.2.

The kidneys are predisposed to haemodynamic injury owing to hypovolaemia or hypoperfusion. This relates to the high blood flow through the kidneys in normal function; the organs represent 5% of total body weight but receive 25% of blood flow. Furthermore, the renal microvascular bed is unique. Firstly, the glomerular capillary bed is on the arterial side of the circulation. Secondly, the

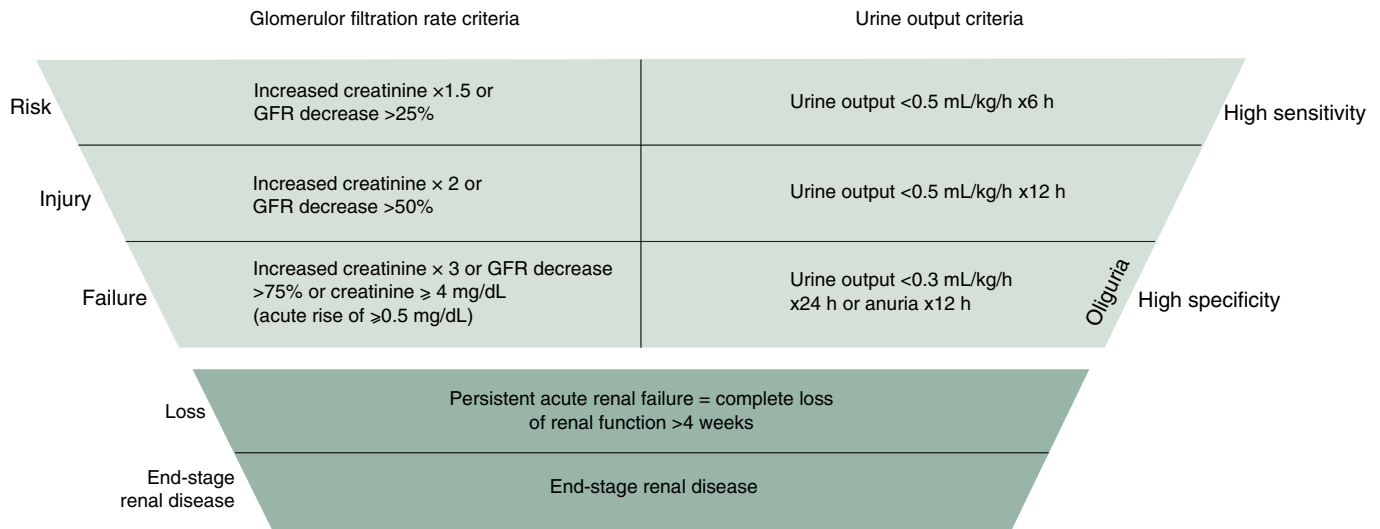

Fig. 17.1 The RIFLE (risk, injury, failure, loss, end-stage renal disease) criteria for the definition and staging of acute renal disease.

Table 17.2 Common causes of the categories of acute kidney injury

Pre-renal	Renal	Post-renal
Sepsis	Prolonged pre-renal AKI	Tumours (pelvic or retroperitoneal)
Hypovolaemia	Rapidly progressive glomerulonephritis	Prostate disease (in men)
Vaso-active drugs ^a (e.g. NSAIDs and ACEi/ARBs)	Acute interstitial nephritis	Renal calculi (obstructing the ureter)

^aMore common in patients with chronic kidney disease; drugs that are usually protective (e.g. ACEi/ARBs) can increase the risk of if a patient has an acute intercurrent illness (e.g. sepsis, diarrhea, acute heart failure). ACEi, angiotensin-converting enzyme inhibitors; AKI, acute kidney injury; ARB, angiotensin receptor blocker; NSAIDs, non-steroidal anti-inflammatory drugs.

peri-tubular capillaries are downstream of the glomerular capillary bed. Finally, renal cells are highly specialised and are, therefore, predisposed to ischaemic and inflammatory injury.

Pre-renal acute kidney injury

Pre-renal AKI is caused by impaired perfusion of the kidneys with blood and is usually a consequence of decreased intravascular volumes (hypovolaemia) and/or decreased intravascular pressures. Some of the commonest causes of pre-renal AKI are summarised in Fig. 17.2. Perfusion of the kidneys at the level of the microvascular beds (glomerular and tubulo-interstitial) is usually maintained through wide systemic variations in pressure and flow through highly efficient auto-regulatory pathways, including the renin–angiotensin–aldosterone system (RAAS) and regulated prostaglandin synthesis. However, when the systolic blood pressure (BP) drops below 80 mmHg, AKI

may develop. In individuals with CKD or in the elderly, AKI may occur at higher levels of systolic BP. Drugs that inhibit the RAAS, such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), or block the production of prostaglandins, such as non-steroidal anti-inflammatory drugs (NSAIDs), can predispose to the development of pre-renal AKI. These drugs are discussed in more detail in the following sections.

Hypovolaemia

Hypovolaemia results from any condition that causes intravascular fluid depletion, either directly by haemorrhage or indirectly to compensate for extravascular loss. Examples of this include diarrhoea and vomiting, burns and excessive use of diuretics. Hypotension is a secondary effect of significant hypovolaemia.

Hypotension

In addition to hypovolaemia, hypotension can result from pump (cardiac) failure, of which there are a number of causes, the most common of which is ischaemic heart disease. Another important cause is septic shock, where there is peripheral vasodilatation and low peripheral resistance which leads to profound hypotension despite a high cardiac output.

Intra-renal acute kidney injury

Intra-renal acute kidney injury has a variety of causes (see Tables 17.2 and 17.3), most commonly (in $>80\%$ of cases) acute tubular necrosis (ATN). ATN usually occurs in patients with sustained pre-renal AKI leading to tubular injury; this is caused by hypotension and hypovolaemia, often in the setting of sepsis and nephrotoxic agents including drugs. Other endogenous sources can cause direct tubular damage, including myoglobin, haemoglobin and immunoglobulin light chains in multiple myeloma.

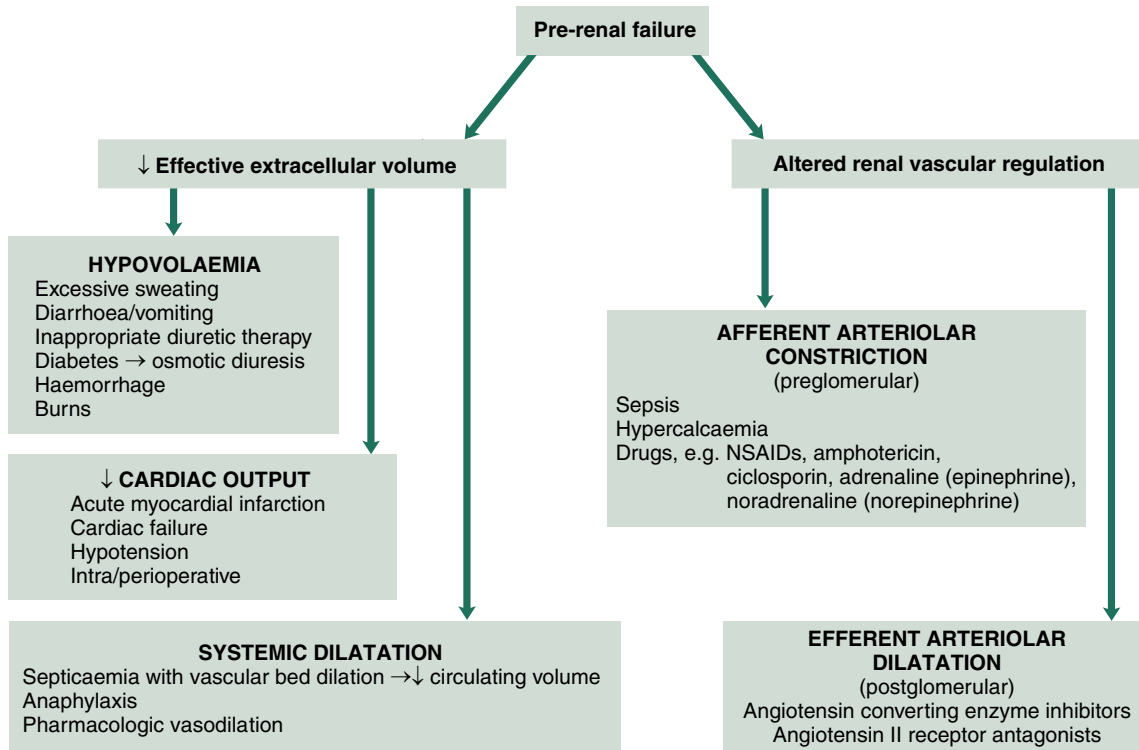

Fig. 17.2 Causes of pre-renal failure.

Acute tubular necrosis

ATN is a diagnosis made by renal biopsy; the findings can include damage to the proximal tubule and the ascending limb of the loop of Henle, interstitial oedema and sparse infiltrating inflammatory cells. Although severe and sustained hypoperfusion can lead to ATN, it usually develops when there is a combination of factors including the presence of one or more of a range of nephrotoxins. These may arise exogenously from drugs or chemical poisons, or from endogenous sources such as haemoglobin, myoglobin, crystals (uric acid, phosphate), immunoglobulin light chains and toxic products from sepsis or tumours (see Table 17.3). Some endogenous toxins may be released as a direct consequence of drug exposure. For example, myoglobin may be released (rhabdomyolysis) following muscle injury or necrosis, hypoxia, infection or after drug treatment, for example, with fibrates and statins, particularly when both are used in combination. The mechanism of the subsequent damage to renal tissue is not fully understood but probably results from a combination of factors including hypoperfusion, haem-catalysed free radical tubular cytotoxicity and haem cast formation and precipitation leading to tubular injury.

Vascular bed and development of acute tubular necrosis. Regional blood flow within the kidney varies, resulting in relatively hypoxic regions such as the outer medulla. This area is also the site of highly metabolically active parts of the nephron. Owing to the relatively poor oxygen supply and high metabolic demands, the outer medulla is at risk of ischaemia, even under normal conditions. The regulation of regional blood flow, and therefore the oxygen supply to these areas, relies upon vasomotor

mechanisms mediated in part by adenosine. Adenosine appears to exert either vasoconstrictor or vasodilator effects within the kidney depending upon the relative distribution of A_1 and A_2 receptors.

Clearly any circumstance that interferes with the delicate balance of blood flow and, therefore, oxygen supply within the kidney can result in ATN because of ischaemia and a greater vulnerability to nephrotoxins. The likelihood of ATN is increased by underlying conditions that predispose to ischaemia such as pre-existing CKD of any cause, atheromatous renovascular disease and cholesterol embolisation from upstream atheromatous plaque rupture.

Common causes of acute tubular necrosis. Table 17.3 shows a summary of some of the common factors encountered clinically that may cause ATN.

Immune and inflammatory renal disease

The kidney is vulnerable to a range of immunological processes that can cause AKI. These are divided into glomerular causes (glomerulonephritis) and interstitial causes (interstitial nephritis). Rarely acute pyelonephritis, which is an infection of renal parenchyma, usually as a consequence of ascending infection, can cause AKI.

Rapidly progressive glomerulonephritis. Glomerulonephritis refers to an inflammatory process within the glomerulus. If that process causes AKI it is called rapidly progressive glomerulonephritis (RPGN). Most cases of RPGN are caused by a small-vessel vasculitis (SVV); this gives a pattern of injury in the glomerulus that is called a focal segmental necrotising glomerulonephritis

Table 17.3 Common clinical factors known to cause acute tubular necrosis

Clinical factor	Mechanism
Hypoperfusion	Reduced oxygen/nutrient supply
Radiocontrast media	Medullary ischaemia may result from contrast media-induced renal vasoconstriction. The high ionic load of contrast media may produce ischaemia, particularly in patients with diabetes and those with myeloma (who produce large quantities of light chain immunoglobulins)
Sepsis	Infection produces endotoxaemia and systemic inflammation in combination with a pre-renal state and nephrotoxins. The immunological response to sepsis involves release of vasoconstrictors and vasodilators (e.g. eicosanoids, nitric oxide) and damage to vascular endothelium with resultant thrombosis
Rhabdomyolysis	Damaged muscles release myoglobin, which can cause ATN through direct nephrotoxicity and by a reduction in blood flow in the outer medulla
Renal transplantation	The procedures and conditions encountered during renal transplantation can induce ischaemic ATN, which can be difficult to distinguish from the nephrotoxic effects of immunosuppressive drug therapy used in these circumstances and rejection
Hepato-renal syndrome	Renal vasoconstriction is frequently seen in patients with end-stage liver disease. Progression to ATN is common
Nephrotoxins	
Aminoglycosides	Aminoglycosides are transported into tubular cells, where they exert a direct nephrotoxic effect. Current dosage regimens recommend once-daily doses, with frequent monitoring of drug levels, to minimise total uptake of aminoglycoside
Amphotericin	Amphotericin appears to cause direct nephrotoxicity by disturbing the permeability of tubular cells. The nephrotoxic effect is dose dependent and minimised by limiting total dose used, by limiting rate of infusion, and by volume loading. These precautions also apply to newer liposomal formulations
Immunosuppressants	Ciclosporin and tacrolimus cause intra-renal vasoconstriction that may result in ischaemic ATN. The mechanism is unclear but enhanced by hypovolaemia and other nephrotoxic drugs
NSAIDs	Vasodilator prostaglandins, mainly E ₂ , D ₂ and I ₂ (prostacyclin), produce an increase in blood flow to the glomerulus and medulla. In normal circumstances they play no part in the maintenance of the renal circulation. However, increased amounts of vasoconstrictor substances arise in a variety of clinical conditions such as volume depletion, congestive cardiac failure or hepatic cirrhosis associated with ascites. Maintenance of renal blood flow then becomes more reliant on the release of vasodilatory prostaglandins. Inhibition of prostaglandin synthesis by NSAIDs may cause unopposed arteriolar vasoconstriction, leading to renal hypoperfusion
Cytotoxic chemotherapy	For example, cisplatin
Anaesthetic agents	Methoxyflurane, enflurane
Chemical poisons/naturally occurring poisons	Insecticides, herbicides, alkaloids from plants and fungi, reptile venoms
ATN, Acute tubular necrosis; NSAIDs, non-steroidal anti-inflammatory drugs.	

(FSNGN) with crescent proliferation; crescents are the presence of cells and extracellular matrix in Bowman's space. Most cases of FSNGN are caused by anti-neutrophil cytoplasmic antibody (ANCA)-associated SVV. ANCAs refer to the presence of circulating antibodies that are targeted against primary neutrophil cytoplasmic antigens (proteins including proteinase 3 and myeloperoxidase).

The two main types of ANCA-associated SVV are granulomatosis with polyangiitis, previously known as Wegener's granulomatosis, and microscopic polyangiitis. Other important causes of RPGN include Goodpasture's disease, which is caused by antibodies against glomerular basement membrane

(anti-GBM antibodies). Systemic lupus erythematosus, which usually affects young women and is more common with black ethnicity, and secondary vasculitis are triggered by drugs, infection and tumours. There are many drug triggers for secondary vasculitis; the commonest clinical presentation is a cutaneous vasculitis, secondary to immune complex deposition. Kidney involvement can occur and has been reported with a range of drugs.

Interstitial nephritis. Interstitial nephritis is thought to be a nephrotoxin-induced hypersensitivity reaction associated with infiltration of inflammatory cells into the interstitium with secondary involvement of the tubules. The nephrotoxins involved

Table 17.4 Differentiating pre-renal from renal acute kidney injury

Laboratory test	Pre-renal	Renal
Urine osmolality (mOsm/kg)	>500	<400
Urine sodium (mEq/L)	<20	>40
Urine/serum creatinine (mmol/L)	>40	<20
Urine/serum urea (mmol/L)	>8	<3
Fractional excretion of sodium (%)	<1	>2

are usually drugs and/or the toxic products of infection. Drugs that have been most commonly shown to be responsible include NSAIDs, antibiotics (especially penicillins, cephalosporins and quinolones), proton pump inhibitors such as omeprazole, furosemide, allopurinol and azathioprine, although many other drugs have been implicated.

Differentiating pre-renal from renal acute kidney injury

It is sometimes possible to distinguish between cases of pre-renal and renal AKI through examination of biochemical markers (Table 17.4). In renal AKI, the kidneys are generally unable to retain Na⁺ because of tubular damage. This can be demonstrated by calculating the fractional excretion of sodium (FENa); in practice this is not often done because it lacks sensitivity and specificity, and may be difficult to interpret in the elderly who may have pre-existing concentrating defects.

$$\text{FENa} = \text{sodium clearance/creatinine clearance}$$

$$\text{FENa} = \frac{\text{urine sodium} \times \text{serum creatinine}}{\text{serum sodium} \times \text{urine creatinine}}$$

If FENa is less than 1%, this indicates pre-renal AKI with preserved tubular function; if FENa is greater than 1%, this is indicative of ATN. This relationship is less robust if a patient with renal AKI has glycosuria, pre-existing renal disease, has been treated with diuretics or has other drug-related alterations in renal haemodynamics, for example, through use of ACE inhibitors or NSAIDs. One potential use of urinary electrolytes is in the patient with liver disease and AKI, where the diagnosis of hepato-renal syndrome is being considered; one of the diagnostic criteria is a urinary sodium concentration less than 10 mmol/L.

Post-renal acute kidney injury

Post-renal AKI results from obstruction of the urinary tract by a variety of mechanisms. Any mechanical obstruction from the renal pelvis to the urethral orifice can cause post-renal AKI; these can be divided into causes within the ureters (e.g. calculi or clots), a problem within the wall of the ureter (e.g. malignancies or benign strictures) and external compression (e.g. retroperitoneal tumours). It is extremely unusual for drugs to be responsible

Table 17.5 Factors associated with acute kidney injury

	Volume depletion	Volume overload
History	Thirst Excessive fluid loss (vomiting or diarrhoea) Oliguria	Weight increase Orthopnoea/ nocturnal dyspnea
Physical examination	Dry mucosae ↓ Skin elasticity Tachycardia ↓ Blood pressure ↓ Jugular venous pressure	Ankle swelling Oedema Jugular venous distension Pulmonary crackles Pleural effusion

for post-renal AKI. Proctolol-induced retroperitoneal fibrosis resulting in bilateral ureteric obstruction is a rare example.

Clinical manifestations

The signs and symptoms of AKI are often non-specific, and the diagnosis can be confounded by co-existing clinical conditions. The patient may exhibit signs and symptoms of volume depletion or overload, depending upon the precipitating conditions, course of the disease and prior treatment.

Acute kidney injury with volume depletion

In those patients with volume depletion, a classic pathophysiological picture is likely to be present, with tachycardia, postural hypotension, reduced skin turgor and cold extremities (Table 17.5). The most common sign in AKI is oliguria, where urine production declines to <0.5 mL/kg/h for several hours. This is less than the volume of urine required to effectively excrete products of metabolism to maintain a physiological steady state. Therefore, the serum concentration of those substances normally excreted by the kidney will rise and differentially applies to all molecules up to a molecular mass of around 50 kDa. This includes serum creatinine, which at a molecular mass of 113 Da is normally freely filtered by the kidneys, but with loss of kidney function the serum level climbs. Although the term uraemia is still in widespread use, it merely describes a surrogate for the overall metabolic disturbances that accompany AKI; these include excess potassium, hydrogen ions (acidosis) and phosphate in blood. Most cases of AKI are first identified by an abnormal blood test, although some patients may have symptoms that are specifically attributable to AKI; these include nausea, vomiting, diarrhoea, gastro-intestinal haemorrhage, muscle cramps and a declining level of consciousness.

Acute kidney injury with volume overload

In those patients with AKI who have maintained a normal or increased fluid intake as a result of oral or intravenous administration, there may be clinical signs and symptoms of fluid overload (see Table 17.5).

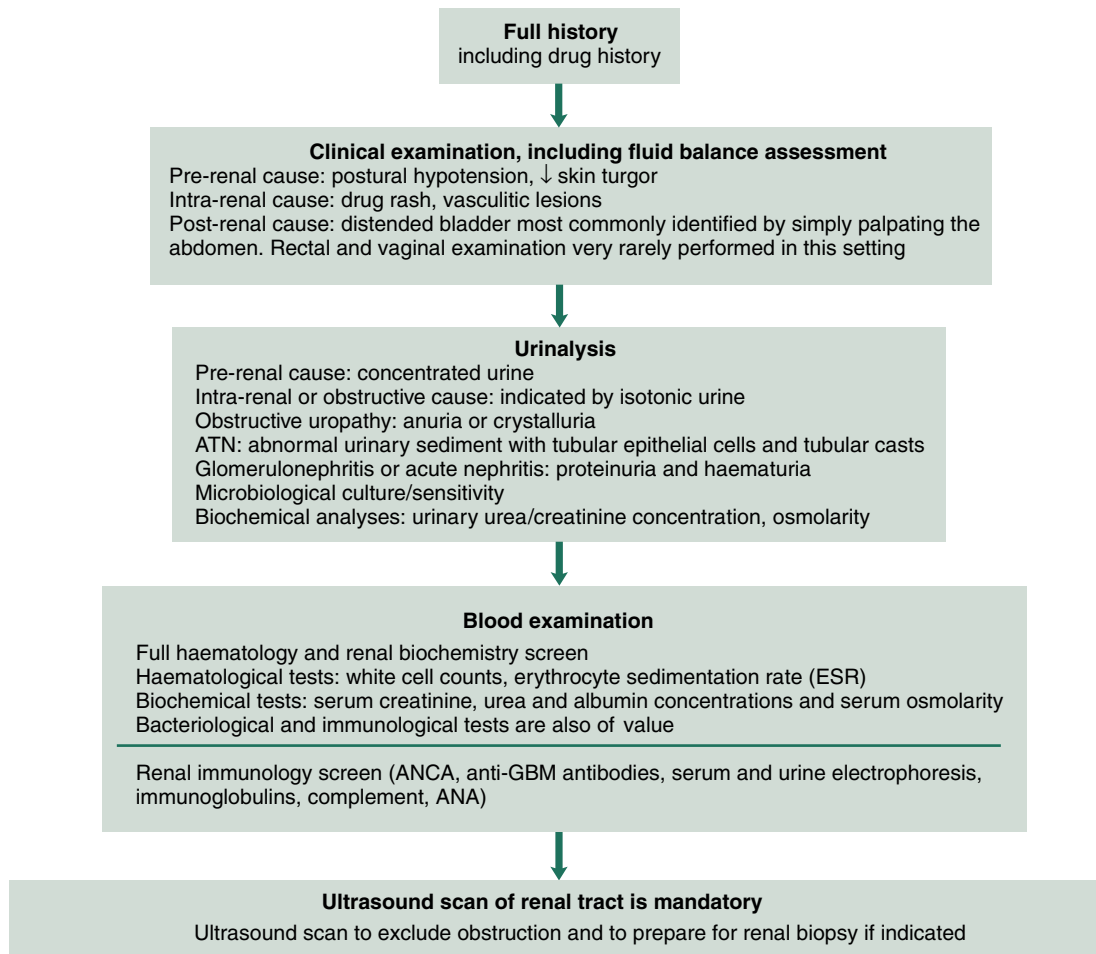

Fig. 17.3 Investigations of acute kidney injury. ANA, Anti-nuclear antibody; ANCA, Anti-neutrophil cytoplasmic antibodies; GBM, glomerular basement membrane.

Diagnosis and clinical evaluation

In hospitalised patients, AKI is usually diagnosed incidentally by the detection of increasing serum creatinine and/or a reduction in urine output.

The assessment of renal function is described in detail in [Chapter 18](#). However, unless a patient is at steady state, measurement of serum creatinine does not provide a reliable guide to renal function. For example, serum creatinine levels will usually rise by only 50–100 mmol/L/day following complete loss of renal function in a previously normal patient. Thus changes in serum creatinine are not sufficiently responsive to serve as a practical indicator of a rapidly changing glomerular filtration rate (GFR), particularly in AKI in critical care scenarios.

In the hospital situation, when AKI is detected incidentally, the cause(s) of the condition, such as fluid depletion (hypovolaemia), infection or the use of nephrotoxic drugs, are often apparent on close examination of the clinical history. The development of AKI in this setting is more likely to occur in people with pre-existing CKD. People with normal baseline kidney function usually need to

sustain at least two separate triggers for the development of AKI; for example, hypovolaemia will rarely cause AKI in this setting, but when hypovolaemia occurs in the presence of nephrotoxic drugs, then AKI may occur. In patients with pre-existing CKD, AKI (i.e. acute on chronic renal failure) can occur in patients with one trigger. By definition, the worse the baseline kidney function, the smaller the trigger required for the development of AKI.

Irrespective of the presentation of AKI, it is wise to consider the complete differential diagnosis in all people; active exclusion of post-renal AKI and immune and inflammatory AKI should be considered in all cases. In AKI without an obvious precipitating pre- or post-renal cause, there is a greater need to consider these causes. Although the majority of patients have ATN, other causes such as RPGN, interstitial nephritis, multiple myeloma or urinary tract obstruction must be screened for and systematically excluded. In addition to supportive care that is generic for all causes of AKI, disease-specific treatment may also be required. The investigation of AKI is outlined in [Fig. 17.3](#).

Various other parameters should be monitored through the course of AKI. Fluid balance charts may be inaccurate and should

not be relied upon exclusively. Records of daily weight are more reliable indicators of volume status but are dependent on the mobility of the patient.

Monitoring fluid balance in acute kidney disease

Maintaining appropriate fluid balance in AKI is a critical component of the clinical management of the patient. Detailed clinical assessment includes:

1. measurement of BP, which needs to be interpreted in respect of the baseline for the affected patient together with the patient's heart rate;
2. auscultation of the heart for the presence of third (and fourth) heart sounds, the presence of which indicate cardiac strain associated with fluid overload;
3. presence of added sounds in the chest, in particular fine inspiratory crackles that are found in some patients with pulmonary oedema;
4. a chest X-ray for the presence of pulmonary oedema;
5. pulse oximetry to assess arterial oxygen saturation;
6. although the presence of pitting oedema of the legs or sacrum indicates longer-term fluid overload, it may also be a useful marker of overall endothelial function and the potential for extravascular fluid accumulation;
7. evaluation for decreased skin turgor, which is a sign of fluid loss.

Intravascular monitoring

Central venous pressure (CVP) can be measured following insertion of a central venous catheter and is a measure of the pressure in the large systemic veins and the right atrium produced by venous return. CVP assesses circulating volume and, therefore, the degree of fluid deficit, and reduces the risk of pulmonary oedema following over-rapid transfusion. CVP should usually be maintained within the normal range of 5–12 cm H₂O.

Most patients with AKI do not require invasive monitoring to the extent described earlier and recover with supportive care based on careful clinical observations.

Monitoring key parameters in acute kidney disease

Serum electrolytes, including potassium, bicarbonate, calcium, phosphate and acid–base balance, should be measured on a daily basis. In patients with severe AKI, acid–base balance may need to be assessed every few hours because this may direct fluid replacement, respiratory support and dialysis treatment. Patients should be weighed daily as this is an important measure of fluid balance.

Course and prognosis

Pre-renal acute kidney injury

The majority of cases will recover within days of onset following prompt correction of the underlying causes. The urine output improves and waste products of metabolism are cleared by the

kidneys. Even though the kidney function usually stabilises to the pre-event baseline, in some patients long-term kidney function resets to lower than previous values. There is excellent evidence that some patients experience CKD as a consequence of one or more episodes of AKI.

ATN may be divided into three phases. The first is the oliguric phase (<400 mL/day of urine produced), where patients have sustained pre-renal AKI and move from the potential for early reversibility to a situation where uraemia and hyperkalaemia develop and the patient may die unless renal replacement therapy (RRT) with dialysis is started. The oliguric phase is usually no longer than 7–14 days but may last for up to 6 weeks. This is followed by a diuretic phase, which is characterised by a urine output that rises over a few days to several litres per day. This phase lasts for up to 7 days and corresponds to the commencement of tubular function. The onset of this phase is associated with an improving prognosis unless the patient sustains an intercurrent infection or a vascular event. Finally, the patient enters a recovery phase, where tubular cells regenerate slowly over several months, although the GFR often does not return to initial levels. The elderly recover renal function more slowly and less completely.

The mortality rate of AKI varies according to the cause but increases when AKI occurs in patients with multi-organ failure, where mortality rates of up to 70% are seen. Higher mortality rates are seen in patients aged more than 60 years.

Death resulting from uraemia and hyperkalaemia is very uncommon. Consequently, the major causes of death associated with AKI are septicaemia and intercurrent acute vascular events such as myocardial infarction and stroke. High circulating levels of uraemic toxins that occur in AKI result in general debility. These, together with the significant number of invasive procedures such as bladder catheterisation and intravascular cannulation, which are necessary in the management of AKI, leave such patients prone to infection and septicaemia. Uraemic gastro-intestinal haemorrhage is a recognised consequence of AKI, probably as a result of reduced mucosal cell turnover.

Post-renal acute kidney injury

Prompt identification and relief of the obstruction is important. The prognosis is then dependent on the underlying cause of the obstruction of the renal tract and the baseline to which the kidney function returns after the obstruction has been relieved. If the underlying problem is benign, then there may be no long-term adverse consequences. However, if the cause of the obstruction is due to an underlying malignancy, then long-term survival is dependent on whether this can be cured.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in acute kidney injury

ACE inhibitors and ARBs are not directly nephrotoxic and can be used in most patients with kidney disease. However, profound hypotension can occur if they are initiated in susceptible patients such as those who are receiving high-dose diuretics as treatment

for fluid overload. This might result in the development of pre-renal AKI. It is, therefore, wise to monitor BP and carefully titrate dosages whilst monitoring renal function in such patients. Nonetheless, it is common to see increases in serum creatinine levels of up to 25% on initiation of an ACE inhibitor or ARB, and this is not necessarily a cause for discontinuing therapy with these agents.

ACE inhibitor use is, however, absolutely contraindicated when a patient has bilateral renal artery stenosis, or renal artery stenosis in a patient with a single functioning kidney. If an ACE inhibitor or ARB is initiated under these circumstances, then pre-renal AKI may ensue. This may occur because the renin-angiotensin system is stimulated by low renal perfusion resulting from stenotic lesions in the arteries supplying the kidneys, most often at the origin of the renal artery from the abdominal aorta. Angiotensin II is produced which causes renal vasoconstriction, in part, through increased efferent arteriolar tone. This creates a 'back pressure' which paradoxically maintains glomerular filtration pressure in an otherwise poorly perfused kidney. If angiotensin II production is inhibited by an ACE inhibitor, or the effect is blocked by an ARB, then efferent arteriole dilatation will result. Because increased efferent vascular tone maintains filtration in such patients, then the overall result of ACE inhibitor or ARB therapy will be to reduce or shut down filtration at the glomerulus and put the patient at risk of pre-renal AKI (Fig. 17.4).

Importantly, many patients with renal artery stenosis have not been identified. Consequently this is one of the reasons why patients should have kidney function testing before commencing an ACE inhibitor or ARB, and a repeat kidney function test 7–14 days after starting the drug or after a dose increase. In patients with an increase in creatinine level of more than 25%, the drug should be stopped and referral to a nephrologist considered for further investigation and management.

Management

The aim of the medical management of a patient with AKI is to stabilise the patient to allow recovery of kidney function. Effective management of AKI depends upon a rapid diagnosis. If the underlying acute deterioration in renal function is detected early enough, it is often possible to prevent progression. If the condition is advanced, however, management consists mainly of supportive strategies, with close monitoring and appropriate correction of metabolic, fluid and electrolyte disturbances. Patients with severe AKI often require RRT with dialysis. Specific therapies that promote recovery of ischaemic renal damage remain under investigation. Patients with immune-mediated causes of AKI should be treated with appropriate immunosuppressant regimens to treat the underlying cause of the AKI. Post-renal AKI is treated by relieving the obstruction.

Early preventive and supportive strategies

Identification of patients at risk

Any patient who has concurrent or pre-existing conditions that increase the risk of development and progression of AKI must be identified, and this includes those with pre-existing CKD, diabetes, jaundice, myeloma and the elderly. These patients either have baseline impaired renal function (CKD) or are sensitised to the development of AKI by the comorbid condition. Meticulous attention to fluid balance, assessment of infection and the use of drugs are crucial to minimise the risk of development of AKI.

Withdrawal and avoidance of nephrotoxic agents

Irrespective of whether the aetiology of the AKI directly involves nephrotoxic drugs, the drug and treatment regimens should be examined so that potential nephrotoxins are withdrawn. Particular care

Fig. 17.4 Actions of angiotensin-converting enzyme (ACE) inhibition and angiotensin receptor blockade in patients with renal artery stenosis.

should be taken with ACE inhibitors, NSAIDs, radiological contrast media and aminoglycosides. The doses should be adjusted of any drugs or their active metabolites that are excreted by the kidneys.

Optimisation of renal perfusion

Initial treatment should include rapid correction of fluid and electrolyte balance to maximise renal perfusion. In patients for whom it is difficult to assess fluid balance by use of clinical examination, a urinary catheter may be placed in order that fluid losses may be easily measured. With the recent focus on the prevention of catheter-related bacteraemia, central lines are seldom used outside specialist renal and intensive care units, but they should be considered in patients with multi-organ failure.

A diagnosis of pre-renal AKI caused by renal underperfusion secondary to hypovolaemia and/or hypotension implies that restoration of renal perfusion would reverse impairment by improving renal blood flow, reducing renal vasoconstriction and flushing nephrotoxins from the kidney. The use of crystalloids in the form of 0.9% sodium chloride is an appropriate initial choice of intravenous fluid because it replaces both water and sodium ions in a concentration approximately equal to serum. The usual approach to fluid replacement is to use 250–500 mL bolus fluids up to a maximum initial volume of 2 L. If the patient does not respond to this, then senior medical review is required. In the patient with sustained hypotension that does not respond to a fluid challenge, the patient may need to move to an intensive care unit and be commenced on vasoconstrictor and inotropic drugs (e.g. noradrenaline) to improve BP.

The effect of fluid replacement on urine flow and intravascular pressures should be carefully monitored. Over-hydration of sick patients is very common and associated with an increased mortality risk. There is no evidence that colloids such as gelofusine or albumin provide any additional benefit for volume expansion and renal recovery over the use of crystalloids. A [National Institute of Health and Care Excellence \(NICE, 2013\)](#) intravenous fluid guideline provides detailed guidance.

The use of inotropes such as noradrenaline and cardiac doses of dopamine should be restricted to non-renal indications.

Establishing and maintaining an adequate diuresis

Although loop diuretics (most commonly furosemide) may facilitate the management of fluid overload and hyperkalaemia in early or established AKI, there is no evidence that these agents are effective for the prevention of, or early recovery from, AKI. It is reasonable to use these agents whilst the urine output is maintained because this provides space for intravenous drugs and parenteral feeding including oral supplements. In experimental settings loop diuretics decrease renal tubular cell metabolic demands and increase renal blood flow by stimulating the release of renal prostaglandins, a haemodynamic effect inhibited by NSAIDs. However, there is no demonstrable impact on clinical outcomes. Indeed, diuretic therapy should only be initiated in the context of fluid overload. If not, any diuresis might produce a negative fluid balance and precipitate or exacerbate a pre-renal state.

Doses of up to 100 mg/h of furosemide can be given as bolus injections or as an infusion. Higher infusion rates may cause transient deafness. There is probably little practical difference

between using bolus intravenous doses of furosemide or a continuous infusion.

The addition of small oral doses of metolazone has been used for diuretic purposes in patients with renal impairment and volume overload. Metolazone is a weak thiazide diuretic alone but produces a synergistic action with loop diuretics. It should be used with great care because it may initiate a profound diuresis and the patient can rapidly experience intravascular depletion and worsen renal failure.

Mannitol. Mannitol has historically been recommended for the treatment of AKI. The rationale for using mannitol in AKI arises from the concept that tubular debris may contribute to oliguria. There is no evidence for mannitol-producing benefit in AKI over and above aggressive hydration. Indeed, mannitol can cause volume overload. Consequently, mannitol is now not recommended for patients with AKI.

Dopamine. Historically, dopamine has been recommended at low dose to improve renal blood flow and urine output. Dopamine at low dose acts as a renal vasodilator in normal kidneys, but in renal failure it is a renal vasoconstrictor even at a low dose. This translates into no demonstrable clinical benefit and it should no longer be used. Dopamine has α - and β -adrenergic effects. Fenoldopam, a pure dopaminergic D₁ agonist, has been investigated in a range of clinical trials; the results have not currently demonstrated a trend towards benefit in recovery of renal function from AKI ([Gillies et al., 2015](#)).

Drug therapy and renal auto-regulation

Intra-renal blood flow is controlled by an auto-regulatory mechanism unique to the kidney called tubuloglomerular feedback. This mechanism produces arteriolar constriction in response to an increased solute load to the distal nephrons. GFR and kidney workload are thus reduced. It has been proposed that oliguria is an adaptive response to renal ischaemia, and therapy designed to improve GFR would increase solute load to the nephrons and might increase kidney workload and worsen AKI. Clearly, reversal of a pre-renal state with fluids is a logical therapeutic aim.

Non-dialysis treatment of established acute kidney injury

Uraemia and intravascular volume overload

In AKI (and CKD) the symptoms of uraemia include nausea, vomiting and anorexia, and result principally from accumulation of toxic products of protein metabolism including urea.

Unfortunately, because uraemia causes anorexia, nausea and vomiting, many severely ill patients are unable to tolerate any kind of diet. In these patients and those who are catabolic, the use of enteral or parenteral nutrition should be considered at an early stage.

Intravascular fluid overload must be managed by restricting NaCl intake to about 1–2 g/day if the patient is not hyponatraemic and total fluid intake to less than 1 L/day plus the volume of urine and/or loss from dialysis. Care should be taken with the so-called low-salt products, because these usually contain KCl, which will exacerbate hyperkalaemia.

Hyperkalaemia

Hyperkalaemia is a particular problem in AKI not only because urinary excretion is reduced but also because intracellular potassium may be released. Rapid rises in extracellular potassium are to be expected when there is tissue damage, as in burns, crush injuries and sepsis. Acidosis also aggravates hyperkalaemia by provoking potassium leakage from healthy cells. The condition may be life-threatening, causing cardiac arrhythmias, and, if untreated, can result in asystolic cardiac arrest.

Dietary potassium should be restricted to less than 40 mmol/day, and potassium supplements and potassium-sparing diuretics removed from the treatment schedule. Emergency treatment is necessary if the serum potassium level reaches 7.0 mmol/L (reference range 3.5–5.5 mmol/L) or if there are the progressive changes in the electrocardiogram (ECG) associated with hyperkalaemia. These include tall, peaked T waves, reduced P waves with increased QRS complexes or the 'sine wave' appearance that often presages cardiac arrest (see [Chapter 18](#), [Fig. 18.11](#)).

Emergency treatment of hyperkalaemia consists of the following:

1. 10–30 mL (2.25–6.75 mmol) of calcium gluconate 10% intravenously over 5–10 minutes: This improves myocardial stability but has no effect on the serum potassium levels. The protective effect begins in minutes but is short-lived (<1 hour), although the dose can be repeated.
2. 50 mL of 50% glucose together with 8–12 units of soluble insulin over 10 minutes: Endogenous insulin, stimulated by a glucose load or administered intravenously, stimulates intracellular potassium uptake, thus removing it from the serum. The effect becomes apparent after 15–30 minutes, peaks after about 1 hour, and lasts for 2–3 hours and will decrease serum potassium levels by around 1 mmol/L.
3. Nebulised salbutamol has also been used to lower potassium; however, this is not effective for all patients and does not permanently lower potassium. If used it is seen as a temporary emergency measure.

Acidosis

The inability of the kidney to excrete hydrogen ions may result in a metabolic acidosis. This may contribute to hyperkalaemia. It may be treated orally with sodium bicarbonate 1–6 g/day in divided doses (although this is not appropriate for acute metabolic acidosis seen in AKI), or 50–100 mmol of bicarbonate ions (preferably as isotonic sodium bicarbonate 1.4% or 1.26%, 250–500 mL over 15–60 minutes) intravenously may be used. The administration of bicarbonate in acidotic patients will also tend to reduce serum potassium concentrations. Bicarbonate will cause an increase in intracellular Na^+ through activation of the cell membrane Na^+/H^+ exchanger, which promotes increased activity of Na/K ATPase producing increased intracellular sequestration of K^+ .

If calcium gluconate is used to treat hyperkalaemia, care should be taken not to mix it with sodium bicarbonate (by giving this through the same intravenous access site) because the resulting calcium bicarbonate forms an insoluble precipitate. If elevation of serum sodium or fluid overload precludes the use of sodium bicarbonate, extreme acidosis (serum bicarbonate of <10 mmol/L) is best treated by dialysis.

Hypocalcaemia

Calcium malabsorption, probably secondary to disordered vitamin D metabolism, can occur in AKI. Hypocalcaemia usually remains asymptomatic, as tetany of skeletal muscles or convulsions does not normally occur until serum concentrations are as low as 1.6–1.7 mmol/L (reference range 2.20–2.55 mmol/L). Should it become necessary, oral calcium supplementation with calcium carbonate is usually adequate, and although vitamin D may be used to treat the hypocalcaemia of AKI, it rarely has to be added. Effervescent calcium tablets should be avoided because they contain a high sodium or potassium load.

Hyperphosphataemia

Because phosphate is normally excreted by the kidney, hyperphosphataemia can occur in AKI but rarely requires treatment. Should it become necessary to treat, phosphate-binding agents may be used to retain phosphate ions in the gut. The most commonly used agents are calcium containing, such as calcium carbonate or calcium acetate, and are given with food. For further information, see [Chapter 18](#).

Infection

Patients with AKI are prone to infection and septicaemia, which can ultimately cause death. Bladder catheters, central catheters and even peripheral intravenous lines should be used with care to reduce the chance of bacterial invasion. Leucocytosis is sometimes seen in AKI and does not necessarily imply infection. However, pyrexia must be immediately investigated and treated with appropriate antibiotic therapy if accompanied by toxic symptoms such as disorientation or hypotensive episodes. Samples from blood, urine and any other material such as catheter tips should be sent for culture before antibiotics are started. Antibiotic therapy should be broad spectrum until a causative organism is identified.

Other problems

Uraemic gastro-intestinal erosions

Uraemic gastro-intestinal erosions are a recognised consequence of AKI, probably as a result of reduced mucosal cell turnover owing to high circulating levels of uraemic toxins. Proton pump inhibitors and H_2 antagonists are effective. However, proton pump inhibitors should be used with caution in hospitals where there are significant rates of *Clostridium difficile* diarrhoea, because they may predispose to the development of this organism. H_2 antagonists are an appropriate alternative. In addition, there is increasing epidemiological evidence linking proton pump inhibitors with kidney disease ([Lazarus et al., 2016](#)).

Nutrition

There are two major constraints concerning the nutrition of patients with AKI:

- patients may be anorexic, vomiting and too ill to eat;
- oliguria associated with renal failure limits the volume of enteral or parenteral nutrition that can be safely given.

The introduction of dialysis or haemofiltration allows fluid to be removed easily and, therefore, makes parenteral nutrition possible. Large volumes of fluid may then be administered without producing fluid overload. A requirement for parenteral nutrition is rare, but where needed the factors to be considered include fluid balance, calorie/protein requirements, electrolyte balance/requirements, and vitamin and mineral requirements.

The basic calorie requirements are similar in patients with AKI irrespective of whether they require dialysis, although the need for protein may occasionally be increased in haemodialysis and haemofiltration because of amino acid loss. In all situations, protein is usually supplied as 12–20 g/day of an essential amino acid formulation, although individual requirements may vary.

Electrolyte-free amino acid solutions should be used in parenteral nutrition formulations for patients with AKI because they allow the addition of electrolytes as appropriate. Potassium and sodium requirements can be calculated on an individual basis depending on serum levels. There is usually no need to try to normalise serum calcium and phosphate levels because they will stabilise with the appropriate therapy or, if necessary, with haemofiltration or dialysis. Water-soluble vitamins are removed by dialysis and haemofiltration, but the standard daily doses normally included in parenteral nutrition fluids more than compensate for this loss. Magnesium and zinc supplementation may be required, not only because tissue repair often increases requirements but also because they may be lost during dialysis or haemofiltration.

It is necessary to monitor the serum urea, creatinine and electrolyte levels daily to make the appropriate alterations in the required nutritional support. The glucose concentration should also be checked daily because patients in renal failure sometimes develop insulin resistance. The plasma pH should be checked initially to determine whether addition of amino acid solutions is causing or aggravating metabolic acidosis. It is also valuable to check calcium, phosphate and albumin levels regularly, and when practical, daily weighing gives a useful guide to fluid balance.

Renal replacement therapy

RRT is indicated in a patient with AKI when kidney function is so poor that life is at risk. However, it is desirable to introduce RRT early in AKI, because complications and mortality are reduced if the serum urea level is kept to less than 35 mmol/L. Generally, RRT is urgently indicated in AKI to:

1. remove uraemic toxins when severe symptoms are apparent, for example, impaired consciousness, seizures, pericarditis and rapidly developing peripheral neuropathy;
2. remove fluid resistant to diuretics, for example, pulmonary oedema;
3. correct electrolyte and acid–base imbalances, for example, hyperkalaemia greater than 6.5 or 5.5–6.5 mmol/L where there are ECG changes, increasing acidosis (pH < 7.1 or serum bicarbonate < 10 mmol/L) despite bicarbonate therapy, or where bicarbonate is not tolerated because of fluid overload.

Forms of renal replacement therapy

The types of RRTs used in clinical practice for AKI (and with the addition of kidney transplantation for end-stage renal failure secondary to CKD) are:

- haemodialysis
- haemofiltration
- haemodiafiltration
- peritoneal dialysis

Although the basic principles of these replacement therapies are similar, clearance rates, that is, the extent of solute removal, vary.

In all types of dialysis, blood is presented to a dialysis solution across some form of semi-permeable membrane that allows free movement of low molecular weight compounds. The processes by which movement of substances occur are:

- *Diffusion*: Diffusion depends upon concentration differences between blood and dialysate and molecule size. Water and low molecular weight solutes (up to a molecular weight of about 10,000) move through pores in the semi-permeable membrane to establish equilibrium. Smaller molecules can be cleared from blood more effectively as they move more easily through pores in the membrane.
- *Ultrafiltration*: A pressure gradient (either +ve or –ve) across a semi-permeable membrane will produce a net directional movement of fluid from relative high- to low-pressure regions. The quantity of fluid dialysed is the ultrafiltration volume.
- *Convection*: Any molecule carried by ultrafiltrate may move passively with the flow by convection. Larger molecules are cleared more effectively by convection.

Haemodialysis

In haemodialysis, the form of vascular access used in AKI is a dialysis line. This is placed in a vein (the jugular, femoral or subclavian), which has an arterial lumen through which the blood is removed from the patient and a venous lumen by which it is returned to the patient after passing through a dialyser. The terms arterial and venous lumen can be misleading because both lumens are situated in the same vein. They are part of the same line which bifurcates and has two lumens: the longer lumen is the ‘arterial’ lumen, and the shorter the ‘venous’ lumen.

Heparin is added to the blood as it leaves the body to prevent the dialyser clotting. Blood is then actively pumped through the artificial kidney before being returned to the patient (Fig. 17.5). In those patients at high risk of haemorrhage, the amount of heparin used can be reduced or even avoided altogether. The dialyser consists of a cartridge comprising a bundle of hollow tubes (hollow fibre dialyser) made of a synthetic semi-permeable membrane. Dialysis fluid flows around the membrane countercurrent (opposite) to the flow of blood to maximise diffusion gradients. The dialysis solution is essentially a mixture of electrolytes in water with a composition approximating to extracellular fluid into which solutes diffuse. The ionic concentration of the dialysis fluid can be manipulated to control the rate and extent of electrolyte transfer. Calcium and bicarbonate concentrations can also be increased in dialysis fluid to promote diffusion into blood as replacement therapy. By manipulating the hydrostatic pressure of the dialysate and blood circuits, the extent and rate of water removal by ultrafiltration can be controlled.

Haemodialysis can be performed in either intermittent or continuous schedules. The latter regimen is preferable in the critical care situation, providing 24-hour control and minimising swings in blood volume and electrolyte composition that are found using intermittent regimens. The haemodialysis described in this section is indistinguishable from that used as maintenance therapy for many patients with end-stage renal failure; the method of access in this group is often via an arterio-venous fistula (see Chapter 18).

The capital cost of haemodialysis is considerable, requires specially trained staff and is seldom undertaken outside a renal unit. It does, however, rapidly treat renal failure and is, therefore, essential in hypercatabolic renal failure where urea is produced faster than, for example, it could be removed by peritoneal dialysis. Haemodialysis can also be used in patients who have recently undergone abdominal surgery in whom peritoneal dialysis would be ill advised.

Haemofiltration

Haemofiltration is an alternative technique to dialysis where simplicity of use, fine fluid balance control and low cost have ensured its widespread application in the treatment of AKI.

A similar arrangement to haemodialysis is employed, but dialysis fluid is not used. The hydrostatic pressure of the blood drives a filtrate, similar to interstitial fluid, across a high-permeability dialyser (passes substances of molecular weight up to 30,000) by ultrafiltration. Solute clearance occurs by convection. Commercially prepared haemofiltration fluid may then be introduced into the filtered blood in quantities sufficient to maintain optimal fluid balance. As with haemodialysis, haemofiltration can be intermittent or continuous. In continuous arterio-venous haemofiltration, blood is diverted, usually from the femoral artery, and returned to the femoral vein; this is now very seldom used.

In continuous venovenous haemofiltration, a dual-lumen vascular catheter is inserted into a vein (as described earlier). Blood is removed from the body via the distal lumen (the one farthest from the right side of the heart) in a process assisted by a blood pump, passed through a haemofilter and returned to the body via the proximal lumen. In slow, continuous ultrafiltration, the process is performed so slowly that no fluid substitution is necessary.

In addition to avoiding the expense and complexity of haemodialysis, this system enables continuous but gradual removal of fluid, thereby allowing very fine control of fluid balance in addition to

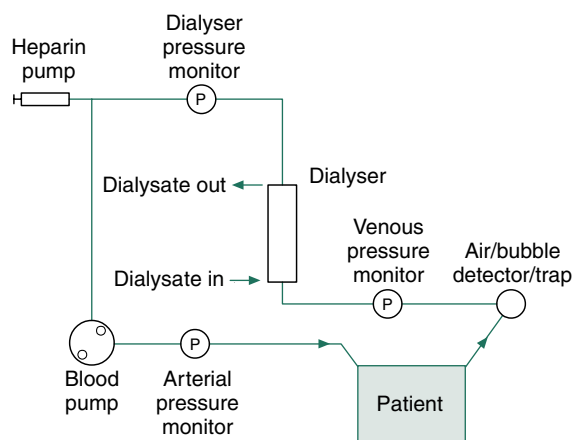

Fig. 17.5 A typical dialysis circuit representing emergency dialysis via a dialysis catheter.

electrolyte control and removal of metabolites. This control of fluid balance often facilitates the use of parenteral nutrition. Because of the advantages of haemofiltration over peritoneal dialysis and haemodialysis, continuous haemofiltration is currently the most common type of RRT used in patients in intensive care units.

Haemodiafiltration

Haemodiafiltration is a technique that combines the ability to clear small molecules, as in haemodialysis, with the large-molecule clearance of haemofiltration. It is more expensive than traditional haemodialysis, but does offer potential benefits. Although some studies suggest that haemodiafiltration may provide a clinical benefit compared with haemofiltration or haemodialysis, this is controversial (Borthwick et al., 2017). However, the enhanced combined control of fluid and solute removal provided by this technique means that it is being increasingly used in clinical practice. However, the evidence base for the optimum haemodialysis, haemofiltration or haemodiafiltration approach in patients with AKI is of poor quality, and further clinical trials are required to identify the best treatment (Borthwick et al., 2017).

Acute peritoneal dialysis

Acute peritoneal dialysis is rarely used now for AKI except in circumstances where haemodialysis is unavailable. A semi-rigid catheter is inserted into the abdominal cavity. Warmed sterile peritoneal dialysis fluid (typically 1–2 L) is instilled into the abdomen, left for a period of about 30 minutes (dwell time) and then drained into a collecting bag (Fig. 17.6). This procedure may be performed manually or by semi-automatic equipment. The process may be repeated up to 20 times a day, depending on the condition of the patient.

Acute peritoneal dialysis is relatively cheap and simple, and does not require specially trained staff or the facilities of a renal unit. It does, however, have the disadvantages of being

Fig. 17.6 Procedure for peritoneal dialysis.

uncomfortable and tiring for the patient. It is associated with a high incidence of peritonitis and permits protein loss, because albumin crosses the peritoneal membrane.

Drug dosage in renal replacement therapy

Whether a drug is significantly removed by dialysis or haemofiltration is an important clinical issue. Drugs that are not removed may well require dose reduction to avoid accumulation and minimise toxic effects. Alternatively, drug removal may be significant and require a dosage supplement to ensure an adequate therapeutic effect is maintained. In general, because haemodialysis, peritoneal dialysis and haemofiltration depend on filtration, the process of drug removal can be considered analogous to glomerular filtration. Table 17.6 gives an indication of approximate clearances of common renal replacement therapies, which for continuous regimens provide an estimate for the creatinine clearance of the system.

Drug characteristics that favour clearance by the glomerulus are similar to those that favour clearance by dialysis or haemofiltration. These include:

- low molecular weight
- high water solubility
- low protein binding
- small volume of distribution
- low metabolic clearance

Unfortunately, a number of other factors inherent in the dialysis process affect clearance; they include:

- duration of dialysis procedure,
- rate of blood flow to dialyser,
- surface area and porosity of dialyser,
- composition and flow rate of dialysate.

For peritoneal dialysis other factors come into play and include:

- rate of peritoneal exchange,
- concentration gradient between plasma and dialysate.

In view of the above, it is usually possible to predict whether a drug will be removed by dialysis, but it is very difficult to quantify the process except by direct measurement, which is rarely practical. Consequently, a definitive, comprehensive guide to drug dosage in dialysis does not exist. However, limited data for specific drugs are available in the literature, whereas many drug manufacturers have information on the dialysability of their products and some include dosage recommendations in their summaries of product characteristics. The most practical method for treating patients undergoing dialysis is to assemble appropriate dosage guidelines for a range of drugs likely to be used in patients with renal impairment and attempt to restrict use to these.

Table 17.6 Approximate clearances of common renal replacement therapies

Renal replacement therapy	Clearance rate (mL/min)
Intermittent haemodialysis	150–200
Intermittent haemofiltration	100–150
Acute intermittent dialysis	10–20
Continuous haemofiltration	5–15

Because drug clearance by haemofiltration is more predictable than in dialysis, it is possible that standardised guidelines on drug elimination may become available. In the interim, a set of individual drug dosage guidelines similar to those described earlier would be useful in practice.

Factors affecting drug use

How the drug to be used is absorbed, distributed, metabolised and excreted, and whether it is intrinsically nephrotoxic are all factors that must be considered. The pharmacokinetic behaviour of many drugs may be altered in renal failure.

Absorption

Oral absorption in AKI may be reduced by vomiting or diarrhoea, although this is frequently of limited clinical significance.

Metabolism

The main hepatic pathways of drug metabolism appear unaffected in renal impairment. The kidney is also a site of metabolism in the body, but the effect of renal impairment is clinically important in only two situations. The first involves the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (the active form of vitamin D) in the kidney, a process that is impaired in renal failure. Patients with AKI occasionally require vitamin D replacement therapy, and this should be in the form of 1 α -hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). The latter is the drug of choice in the presence of concomitant hepatic impairment. The second situation involves the metabolism of insulin. The kidney is the major site of insulin metabolism, and the insulin requirements of patients with diabetes with AKI are often reduced.

Distribution

Changes in drug distribution may be altered by fluctuations in the degree of hydration or by alterations in tissue or serum protein binding. The presence of oedema or ascites increases the volume of distribution, whereas dehydration reduces it. In practice these changes will be significant only if the volume of distribution of the drug is small, that is, less than 50 L. Serum protein binding may be reduced because of either protein loss or alteration in binding caused by uraemia. For certain highly bound drugs the net result of reduced protein binding is an increase in free drug, and care is therefore required when interpreting serum concentrations. Most analyses measure the total serum concentration, that is, free plus bound drug. A drug level may, therefore, fall within the accepted concentration range but still result in toxicity because of the increased proportion of free drug. However, this is usually only a temporary effect. Because the unbound drug is now available for elimination, its concentration will eventually return to the original value, albeit with a lower total bound and unbound level. The total drug concentration may, therefore, fall below the therapeutic range while therapeutic effectiveness is maintained.

The time required for the new equilibrium to be established is about four or five elimination half-lives of the drug, and this may be altered itself in renal failure. Some drugs that show reduced serum protein binding include diazepam, morphine, phenytoin, levothyroxine,

theophylline and warfarin. Tissue binding may also be affected; for example, the displacement of digoxin from skeletal muscle binding sites by metabolic waste products that accumulate in renal failure result in a significant reduction in digoxin's volume of distribution.

Excretion

Alteration in renal clearance of drugs in renal impairment is the most important parameter to consider when considering dosage. Generally a decline in renal drug clearance indicates a decline in the number of functioning nephrons. The GFR can be used as an estimate of the number of functioning nephrons. Thus, a 50% reduction in the GFR will suggest a 50% decline in renal clearance.

Renal impairment, therefore, often necessitates drug dosage adjustments. Loading doses of renally excreted drugs are often necessary in renal failure because of the prolonged elimination half-life which leads to an increased time to reach steady state. The equation for a loading dose is the same in renal disease as in normal patients, thus:

$$\text{loading dose (mg)} = \frac{\text{target concentration (mg/L)} \times \text{volume of distribution (L)}}{1}$$

The volume of distribution may be altered but generally remains unchanged.

It is possible to derive other formulae for dosage adjustment in renal impairment. One of the most useful is:

$$DR_{rf} = DR_n \times [(1 - F_{eu}) + (F_{eu} \times RF)]$$

where DR_{rf} is the dosing rate in renal failure, DR_n is the normal dosing rate, RF is the extent of renal impairment = patient's

creatinine clearance (mL/min)/ideal creatinine clearance (120 mL/min) and F_{eu} is the fraction of drug normally excreted unchanged in the urine. For example, when $RF = 0.2$ and $F_{eu} = 0.5$, 60% of the normal dosing rate should be given.

An alteration in dosing rate can be achieved by altering either the dose itself or the dosage interval, or a combination of both as appropriate. Unfortunately, it is not always possible to obtain the fraction of drug excreted unchanged in the urine. In practice it is simpler to use the guidelines for prescribing in renal impairment found in the British National Formulary. These are adequate for most cases, although the specialist may need to refer to other texts.

Nephrotoxicity

The list of potentially nephrotoxic drugs is long. Although the most common serious forms of renal damage are interstitial nephritis and glomerulonephritis, the majority of drugs only cause damage by hypersensitivity reactions and are safe in many patients. Some drugs, however, are directly nephrotoxic, and their effects on the kidney are more predictable. Such drugs include aminoglycosides, amphotericin, colistin, the polymyxins and ciclosporin. The use of any drug with recognised nephrotoxic potential should be avoided where possible. This is particularly true in patients with pre-existing CKD. Fig. 17.7 summarises the most important and common adverse effects of drugs on renal function, indicating the likely regions of the nephron in which damage occurs. Additional information on adverse effects can be found in Hems and Currie (2005).

Fig. 17.7 Common adverse effects of drugs on the kidney. The likely sites of damage to the nephron (stylised) are indicated.

NSAID, Non-steroidal anti-inflammatory drug.

Box 17.1 Characteristics of the ideal drug for use in a patient with renal failure

- No active metabolites
- Disposition unaffected by fluid balance changes
- Disposition unaffected by protein binding changes
- Response unaffected by altered tissue sensitivity
- Wide therapeutic margin
- Not nephrotoxic

Inevitably, occasions will arise when the use of potentially nephrotoxic drugs becomes necessary, and on these occasions constant monitoring of renal function is essential. In conclusion, when selecting a drug for a patient with renal failure, an agent should be chosen that approaches the ideal characteristics listed in [Box 17.1](#).

Case studies**Case 17.1**

Mrs J, a 60-year-old widow, had long-standing hypertension that was unsatisfactorily controlled on a variety of agents. Her drug therapy included furosemide 40 mg once a day, amlodipine 10 mg daily and a salt-restricted diet. Following a routine review of her therapy, ramipril 2.5 mg once daily was added to her treatment regimen in an attempt to improve BP control.

Mrs J was recently diagnosed with gastroenteritis. A week after her diagnosis she presented to her local hospital accident and emergency unit with ongoing diarrhoea. Her BP was found to be 100/60 mmHg and serum biochemistry revealed creatinine levels of 225 mmol/L (50–120 mmol/L), Na⁺ 125 mmol/L (135–145 mmol/L) and K⁺ 5.2 mmol/L (3.5–5.0 mmol/L).

Questions

1. What was the likely cause and underlying mechanism to this patient's problem?
2. What treatment should be given?

Answers

1. ACE inhibitors reduce angiotensin II production and, thus, attenuate angiotensin II-mediated vasoconstriction of the efferent arterioles that contributes to the high-pressure gradient across the glomerulus necessary for filtration. It is not usually a problem in the majority of individuals; however, in patients with pre-existing compromised renal blood flow, such as renal artery stenoses, the kidney relies more heavily on angiotensin-mediated vasoconstriction of the postglomerular arterioles to maintain renal function. Hypovolaemia caused, for example, by diuretic use and a diarrhoeal illness would tend to exacerbate this problem. Moreover, it is likely that sodium depletion would render the kidney even more dependent upon vasoconstriction of efferent arterioles through activation of the tubuloglomerular feedback system, further sensitising the kidney to the effects of ACE inhibitors.

Mrs J might well have been suffering from incipient renal failure, but remained asymptomatic until her renal reserve diminished.

2. The inappropriate use of an ACE inhibitor should be stopped, as should the diuretic temporarily. Mrs J should be rehydrated using sodium chloride 0.9% and kidney function markers monitored in the hope that recovery will occur. Investigations should be arranged to determine whether Mrs J has renal artery stenosis as a cause of her AKI after initiation of the ACE inhibitor (see [Chapter 18](#)).

Case 17.2

Mr B, a known intermittent heroin and cocaine abuser, was discovered comatose in his room early in the morning. He was admitted to hospital as an emergency. An indirect history from an acquaintance indicated that Mr B had been drinking very heavily prior to the incident (probably more than a bottle of whisky in a 24-hour period) and had smoked both heroin and cocaine of unknown source and purity.

On examination he was found to be dehydrated and serum biochemistry revealed the following:

		Reference range
Sodium	147 mmol/L	135–145 mmol/L
Potassium	6.1 mmol/L	3.5–5.0 mmol/L
Calcium	1.72 mmol/L	2.20–2.55 mmol/L
Phosphate	2.0 mmol/L	0.9–1.5 mmol/L
Creatinine	485 mmol/L	50–120 mmol/L
Creatinine kinase	120,000 IU/L	<200 IU/L

Urine dipstick reacted positive for blood with no signs of red blood cells on microscopy. The urine was faintly reddish brown.

Question

What is likely to have occurred, and how should Mr B be treated?

Answer

Cocaine, heroin or alcohol abuse sometimes causes muscle damage resulting in rhabdomyolysis. The mechanism is unclear, but includes vasoconstriction and an increase in muscle activity, possibly because of seizures, self-injury, adulterants in the drug (e.g. arsenic, strychnine, amphetamine, phencyclidine, quinine) or compression (associated with long periods of inactivity). ATN may ensue from a direct nephrotoxic effect of the myoglobin released from damaged muscle cells, microprecipitation of myoglobin in renal tubules (as casts) or a reduction in medullary blood flow. The presence of myoglobin is suggested by the urine dipstick test, which reacts not only to red cells but also to free haemoglobin and myoglobin. Extremely high levels of myoglobinuria may result in urine the colour of black tea. High serum creatinine kinase levels are indicative of rhabdomyolysis together with the presence of free myoglobin in serum and urine. Serum levels of potassium and phosphate are elevated partly by the effects of incipient renal failure but also through tissue breakdown and intracellular release. Creatinine levels are often higher than expected because of muscle damage.

Treatment should involve fluid replacement with normal saline to reverse dehydration. Furosemide and other loop diuretics should be avoided because these decrease intra-tubular pH which may be a co-factor for cast precipitation. Indeed, in cases where urine pH is less than 6, administration of intravenous isotonic sodium bicarbonate may be of use. The patient's ECG should be monitored because of the risks involved with rapid elevation in serum potassium. Timely, appropriate corrective therapy must be instigated where necessary. In 50–70% of cases with rhabdomyolysis, dialysis is required to support recovery.

Case 17.3

Mr D is a patient who has been admitted to an intensive care unit with AKI, which developed following a routine cholecystectomy. His electrolyte results are as follows:

		Reference range
Sodium	138 mmol/L	135–145 mmol/L
Potassium	7.2 mmol/L	3.5–5.0 mmol/L
Bicarbonate	19 mmol/L	22–31 mmol/L
Urea	32.1 mmol/L	3.0–6.5 mmol/L
Creatinine	572 mmol/L	50–120 mmol/L
pH	7.28	7.36–7.44

The patient was connected to an ECG monitor, and the resultant trace indicated absent P waves and a broad QRS complex.

Question

Explain the biochemistry and ECG abnormalities, and indicate what therapeutic measures must be implemented?

Answer

Hyperkalaemia is one of the principal problems encountered in patients with renal failure. The increased levels of potassium arise from failure of

the excretory pathway and also from intracellular release of potassium. Attention should also be paid to pharmacological or pharmaceutical processes that might lead to potassium elevation (e.g. inappropriate potassium supplements, ACE inhibitors). The acidosis noted in this patient, which is common in AKI, also aggravates hyperkalaemia by promoting leakage of potassium from cells. A serum potassium level greater than 7.0 mmol/L indicates that emergency treatment is required because the patient risks life-threatening ventricular arrhythmias and asystolic cardiac arrest. If ECG changes are present, as in this case, emergency treatment should be initiated when serum potassium concentration rises to more than 6.5 mmol/L. The emergency treatment should include:

1. Stabilisation of the myocardium is achieved by intravenous administration of 10–30 mL of calcium gluconate 10% over 5–10 minutes. The effect is temporary, but the dose can be repeated.
2. Intravenous administration of 10–20 units of soluble insulin with 50 mL of 50% glucose stimulates cellular potassium uptake. The dose may be repeated. The blood glucose should be monitored for at least 6 hours to avoid hypoglycaemia.
3. Acidosis may be corrected with an intravenous dose of sodium bicarbonate, preferably as an isotonic solution. Correction of acidosis stimulates cellular potassium reuptake.
4. Intravenous salbutamol 0.5 mg in 100 mL 5% dextrose administered over 15 minutes has been used to stimulate the cellular Na/K ATPase pump and thus drive potassium into cells. This may cause disturbing muscle tremors at the doses required to reduce serum potassium levels.

18 Chronic Kidney Disease and End-Stage Renal Disease

John Marriott, Paul Cockwell and Stephanie Stringer

Key points

- The prevalence of chronic kidney disease (CKD) increases with age and is greater in females and some ethnic populations.
- CKD is classified according to severity from G1 to G5, where G5 is the most advanced and G1 the least.
- Stage G1–G3 CKD is common and may not cause symptoms. It is unusual for stage G1–G3 CKD to progress to end-stage renal disease (ESRD) requiring renal replacement therapy (dialysis and/or transplantation).
- CKD is an important risk factor for cardiovascular disease (CVD).
- As CKD becomes more advanced (stage G4 and G5), virtually all body systems are adversely affected.
- Clinical symptoms and signs of advanced CKD include oedema, nocturia, hypertension, anaemia, bone pain, neurological changes and disordered muscle function.
- The aims of treatment are to slow or halt the progression of CKD, relieve symptoms and reduce CVD morbidity and mortality.
- Adequate control of blood pressure and reduction of proteinuria are essential to slow progression of CKD.
- Renal anaemia is common when the glomerular filtration rate (GFR) falls to lower than 30 mL/min but can be corrected by iron supplementation and erythropoiesis-stimulating agents (ESAs) in 90–95% of cases.
- ESRD is the point at which life can only be sustained by dialysis or transplantation. Some patients present with ESRD, but the large majority have been previously identified as having less severe CKD which has subsequently progressed to ESRD.
- The need for dialysis therapy is increasing at about 2% per annum with attendant resource implications.
- There are two principal types of dialysis: haemodialysis and peritoneal dialysis. In both, waste products and metabolites are transferred from the patient's blood across a semi-permeable membrane to a dialysis solution.
- Renal transplantation remains the treatment of choice for many patients with ESRD. However, up to 60% of patients on dialysis programmes are not fit enough to be put on the transplant list.

Chronic kidney disease (CKD) is defined by a reduction in the glomerular filtration rate (GFR) and/or urinary abnormalities or structural abnormalities of the renal tract. The severity of CKD is classified from G1 to G5 depending upon the level of GFR (Table 18.1). CKD is additionally classified by the degree of proteinuria, measured in clinical practice as albumin/creatinine ratio (ACR), from normal range (A1) to very heavy (A3). Stages G1 and G2, in a person with A1, will classify that individual as having CKD only if there is persistent haematuria of renal origin and/or if there is a

structural abnormality of the renal tract, for example, renal cysts and/or a hereditary renal disease or a history of kidney transplantation.

It is a common condition that affects up to 15% of the population in Western societies and is more common in some ethnic minority populations and in females. The incidence increases with age such that many people older than 80 years of age have CKD. Social deprivation is also associated with a higher prevalence of CKD. The scale of CKD and the consequences for the health service have been appreciated only in the last few years.

Estimates for the prevalence of the stages of CKD are shown in Table 18.1 and have been derived from population-based studies, including from the UK. In the past, patients with CKD were often unrecognised because kidney function tests were not routinely performed in many individuals who were at high risk of CKD. However, individuals at higher risk of CKD are now routinely screened and monitored by kidney function testing. The accuracy of CKD assessment has improved over the past two decades; this is a consequence of utilising equations to estimate kidney function by incorporating serum creatinine into equations that correct for confounders of creatinine that are independent of kidney function, including age, gender and ethnicity. National guidance on the management of CKD has been published and includes management in primary and secondary care (National Institute for Health and Care Excellence [NICE], 2014).

CKD differs from acute kidney injury (AKI) in terms of cause, speed of onset and occurring in the community, rather than in hospitalised patients. However, AKI and CKD are not mutually exclusive; patients with AKI may not recover renal function to their baseline and may be left with residual CKD. In addition, patients with CKD are at increased risk of AKI.

Renin–angiotensin–aldosterone system

The renin–angiotensin–aldosterone system (RAAS) has a critical role in the progression of CKD, and an awareness of this system is important for understanding the pathophysiology of CKD and the targets for therapeutic intervention. Most of the renal effects of this system are through regulating intraglomerular pressures and salt and water balance. Renin is an enzyme which is formed and stored in the juxtaglomerular apparatus and released in response to decreased afferent intra-arterial pressures, decreased glomerular ultrafiltrate sodium levels and sympathetic nervous

system activation. In patients with CKD, intra-renal pressures are often low, and sympathetic overactivity is common; these factors lead to increased renin secretion. This can occur with both normal and elevated systemic blood pressure (BP).

Renin cleaves the protein angiotensinogen, which is produced by the liver, to produce angiotensin I (ATI). ATI is converted to angiotensin II (ATII) by angiotensin-converting enzyme (ACE). ATII has two major physiological effects. First, it acts on the zona glomerulosa of the adrenal cortex to promote production of the mineralocorticoid hormone aldosterone, with resultant increased distal tubular salt and water reabsorption. Furthermore, ATII promotes antidiuretic hormone (ADH) release, which increases proximal tubular sodium reabsorption and promotes thirst. In combination, these cause salt and fluid retention, high intravascular volumes, hypertension and oedema. Second, ATII is a direct vasoconstrictor and promotes systemic and (preferential) renal hypertension. The renal effects are predominantly on the efferent glomerular arteriole. Vasoconstriction at this site is mediated by a high density of ATII receptors. When these receptors are ligated by ATII, there is increased intra-glomerular pressure. Although this leads to an overall increase in GFR in the short-term over a longer period glomerular hypertension promotes accelerated glomerular scarring and worsening CKD. In addition to the vascular and endocrine effects of the RAAS, it is now recognised that there is a local immune-modulatory role for this system. Both resident (e.g. tubular epithelial) and inflammatory (monocytes and macrophages) cells synthesise components of the RAAS and are themselves targeted by the system. For example, monocytes and macrophages express the ATII receptor, and activation through this receptor leads to an enhanced inflammatory and fibrotic phenotype of the cell. This raises the intriguing concept

that some of the effects of blocking the RAAS are due to direct anti-inflammatory and antifibrotic effects. Fig. 18.1 shows this pathway and identifies the points at which pharmacological interventions targeted for a biological effect translate into improved clinical outcomes.

Measurement of renal function

The scale of CKD has only been recognised in recent years because detection is dependent upon an accurate estimation of the GFR. The GFR is defined as the volume of filtrate produced by the glomeruli of both kidneys each minute and is a reliable indicator of renal function.

It is laborious and expensive to measure GFR by gold standard tests such as inulin or radiolabelled isotope clearance. These tests are used only when extremely accurate assessment of kidney function is required. An example of this is measurement of kidney function in a potential living kidney donor where an individual is proposing to donate a kidney to a family member or close friend.

As a consequence, a number of equations have been validated for use in the routine clinical setting. These equations provide an estimate of glomerular filtration rate (eGFR) based on the combination of serum or plasma creatinine and a number of variables, which add precision to the estimation of kidney function. The equation that is currently recommended for clinical practice is the CKD epidemiology (EPI) equation; this has generally taken over from the four-variable MDRD (Modification of Diet in Renal Disease Study) equation. The biochemical variable that the eGFR equations utilise is serum creatinine.

Table 18.1 Classification of chronic kidney disease

Glomerular filtration rate stage ^a	Global prevalence ^b (%)	eGFR (mL/min/1.73 m ²)	Description
G1	3.5	≥90	Normal or high
G2	3.9	60–89	Normal or mildly decreased
G3a	7.6 (stage 3 total)	45–59	Mild to moderately decreased
G3b		30–44	Moderate to severely decreased
G4	0.4	15–29	Severely decreased
G5	0.1	<15 (or dialysis)	Kidney failure
Albuminuria stage (by ACR)	ACR (mg/mmol) (urine dip test)	Description	
A1	<3 (–ve to trace)	Normal to high normal	
A2	3–30 (trace to 1+)	High	
A3	>30 (>1+)	Very high	

^aUse the suffix p- to denote the presence of proteinuria when staging chronic kidney disease. Clinically important proteinuria is defined by an ACR ≥3 mg/mmol.

^bData are from Hill et al. (2016).

ACR, Albumin/creatinine ratio.

Serum creatinine

Although serum creatinine concentration is related to renal function, it is also dependent upon the rate of production of creatinine by the patient. Creatinine is a by-product of normal muscle metabolism and is formed at a rate proportional to muscle mass (20 g of muscle equates to approximately 1 mg of creatinine production), and therefore is related to age, sex and ethnicity.

Creatinine is freely filtered by the glomerulus, so when muscle mass is stable any change in serum creatinine levels reflects a change

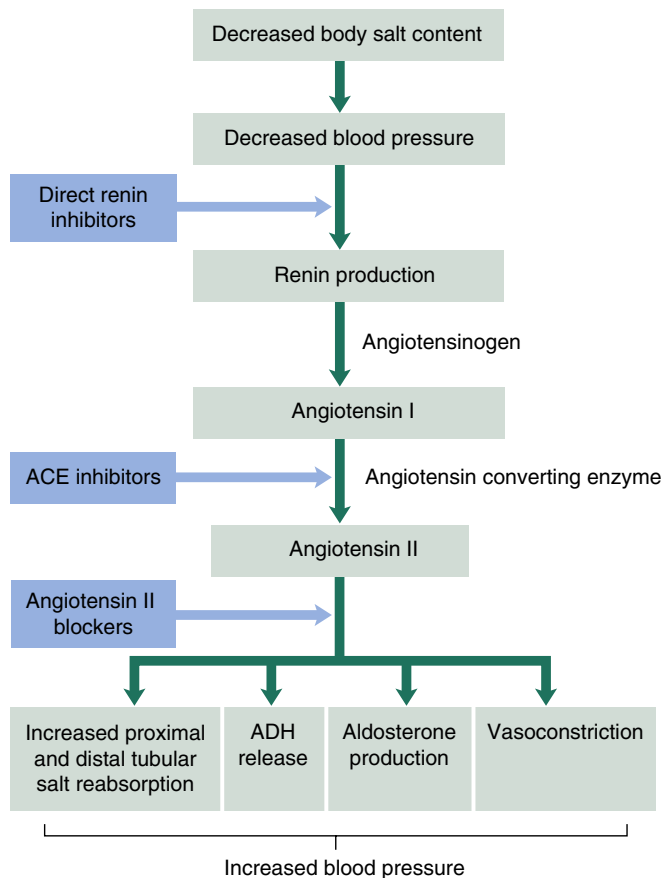

Fig. 18.1 The renin–angiotensin–aldosterone system and targets for pharmaceutical intervention.

ACE, Angiotensin-converting enzyme; ADH, antidiuretic hormone.

$$\text{GFR} = 141 \times \min(S_{\text{Cr}}/k, 1)^\alpha \times \max(S_{\text{Cr}}/k, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ [if female]} \times 1.159 \text{ [if black]}$$

where:

S_{Cr} is serum creatinine in mmol/L,

k is 61.9 for females and 79.6 for males,

α is -0.329 for females and -0.411 for males,

min indicates the minimum of S_{Cr}/k or 1,

and max indicates the maximum of S_{Cr}/k or 1.

The equation does not require weight because the results are reported normalised to 1.73 m² body surface area, which is an accepted average adult surface area.

Fig. 18.2 The chronic kidney disease epidemiology (EPI) estimate of glomerular filtration rate (eGFR) equation.

$$\text{MDRD eGFR (mL/min/1.73m}^2\text{)} = 186 \times [\text{serum creatinine (mmol/L)/88.4}]^{-1.154} \times [\text{age}]^{-0.203} \times [0.742 \text{ if female}] \times [1.212 \text{ if African-American}]$$

Fig. 18.3 Four-variable MDRD (Modification of Diet in Renal Disease Study) equation used to calculate estimate of glomerular filtration rate (eGFR).

in renal clearance. Consequently, measurement of serum creatinine can be utilised to give an estimate of the kidney function. It is important to note, however, that creatinine also undergoes significant tubular secretion (~10–20%). This becomes important in advanced CKD (stages G4 and G5) and limits the value of measuring serum creatinine to determine renal function in stage G4–G5 CKD.

Chronic kidney disease epidemiology estimate of glomerular filtration rate equation

The CKD EPI equation was first published in 2009 and is now recommended in the UK and elsewhere for reporting eGFR. It uses creatinine, age, gender and ethnicity (black or other ethnic groups) to report an eGFR (Fig. 18.2).

This equation is the most accurate equation for estimating kidney function where the patient has kidney function that is either in or close to the normal range. However, caution is needed because the equation performs differently in different populations of patients. The CKD classification system is based on the eGFR.

Previously the four variable MDRD equation (Fig. 18.3) was recommended for eGFR. Some laboratories are still reporting this equation.

Other estimates of kidney function

Creatinine clearance

Creatinine clearance (Cl_{Cr}) is similar to the GFR because nearly all the filtered creatinine appears in the urine. It is a measurement of the volume of blood that is cleared of creatinine with time. Measurements of Cl_{Cr} require accurate collection of 24-hour urine samples with a serum creatinine sample midway through this period. This is time-consuming, inconvenient, prone to inaccuracy and now is rarely used in clinical practice. Fig. 18.4 shows the equation for measuring Cl_{Cr} .

Cockcroft–Gault equation

The Cockcroft–Gault equation uses weight, sex and age to estimate Cl_{Cr} and was derived using average population data (Cockcroft and Gault, 1976). The equation is shown in Fig. 18.5.

Estimates of glomerular filtration rate in paediatric patients

Estimates of GFRs in paediatric patients can be made using the Schwartz formula (Schwartz, 1985) or the Counahan–Barratt method (Counahan et al., 1976), which both rely upon inclusion of the height of the child in estimating Cl_{Cr} , because height correlates with muscle mass.

Urea

Serum urea is also used in the assessment of renal function despite a variable production rate and diurnal fluctuation in response to the protein content of the diet. Urea may also be elevated by dehydration or an increase in protein catabolism such as that accompanying gastro-intestinal haemorrhage, severe infection, trauma (including surgery) and high-dose steroid therapy. Serum urea levels are, therefore, an unreliable measure of renal function, but they can be used as an indicator of the patient's general condition and state of hydration. A rapid elevation of serum urea, before any rise in corresponding creatinine levels, is often a sign of an impending deterioration in renal function or a marker for pre-renal failure associated with intravascular volume depletion.

Significance of chronic kidney disease

CKD is significant because it indicates the possibility of progression to end-stage renal disease (ESRD) and a strong association with accelerated cardiovascular disease (CVD) similar in magnitude to that observed in individuals with diabetes. The CVD risk increases with the severity of CKD but is detectable at all levels. Thus, it is important to pay particular attention to traditional CVD risk factors such as smoking, cholesterol and BP in patients with CKD. However, these risk factors contribute only around 50% of the total CVD risk, and there is great interest in the identification of novel risk factors to explain the remainder of the risk.

$$Cr_{Cl} = \frac{(U \times V)}{S}$$

where U is the urine creatinine concentration (mmol/L), V is the urine flow rate (mL/min) and S is the serum creatinine concentration (mmol/L)

Fig. 18.4 Creatinine clearance (Cr_{Cl}) calculation.

$$Cr_{Cl} = \frac{F (140 \text{ age (years)}) \times \text{weight (kg)}}{\text{Serum creatinine (mmol/L)}}$$

where $F = 1.04$ (females) or 1.23 (males)

Fig. 18.5 The Cockcroft–Gault formula. Cr_{Cl} , creatinine clearance.

It is important to make a distinction between CVD related to macrovascular atherosclerosis and arteriosclerosis which causes vascular stiffness and which contributes also to microvascular changes associated with endothelial dysfunction. In patients with more severe CKD, arteriosclerosis becomes the dominant lesion. As a consequence, cardiac disease in patients with CKD can represent a spectrum from left ventricular hypertrophy associated with hypertension, through to classical myocardial ischaemia, both irreversible (as in myocardial infarction) and reversible, and progressing to fibrotic myocardial disease with a high risk of sudden death, which is very common in patients with ESRD.

Progression to more advanced stages of CKD may occur, particularly if the BP is high and there is significant proteinuria. With good BP control, many patients with CKD can have stable kidney function for years or even decades. These patients need to be followed up with regular blood and urine tests to monitor for progression. Most patients with stage G1–G3 CKD do not require long-term follow-up by a kidney specialist, and their monitoring and management of risk factors are carried out in primary care.

Patients with stage G1–G3 CKD (see Table 18.1) are frequently asymptomatic. The reduction of GFR does not cause uraemic symptoms, and the presence in the urine of protein (proteinuria) or blood (haematuria) is usually not noticed by the patient and is only detectable on monitoring by specialist tests. There is a frequent association with high BP, which may be the cause or a consequence of renal damage. Recognition of these patients is important because it allows early modification of traditional cardiovascular risk factors. These patients should be investigated to determine whether there is a treatable cause for their CKD and followed up to identify those individuals with progressive disease.

Patients with stage G4 and G5 CKD and/or A3 level albuminuria (see Table 18.1) should usually be followed up in a nephrology clinic because they may require specialist management of the complications of CKD such as anaemia and bone disease, whilst many will also be undergoing preparation for renal replacement therapy (RRT).

Causes of chronic kidney disease

The reduction in renal function observed in CKD is often a patchy process, resulting from damage to the infrastructure of the kidney in discrete areas rather than throughout the kidney. The functional unit of the kidney is the nephron; there are 1 million nephrons in each kidney. Although the mechanism of damage depends on the underlying cause of renal disease, as individual nephrons become damaged and fail, remaining nephrons compensate for loss of function through hyperfiltration secondary to raised intra-glomerular pressure. This causes ‘bystander’ damage with secondary nephron loss. This vicious cycle is illustrated in Fig. 18.6. The patient remains well until so many nephrons are lost that the GFR can no longer be maintained despite activation of compensatory mechanisms. As a consequence, there is a progressive decline in kidney function.

CKD arises from a variety of causes (Table 18.2), although by the time a patient has established CKD it may not be possible to identify the exact cause. However, attempting to establish the cause is useful in the identification and elimination of reversible factors, to plan for likely outcomes and treatment needs, and for

appropriate counselling when a genetic basis is established. The causes of CKD listed in Table 18.2 are ordered according to prevalence. It is important to note that the prevalence of these factors is different in CKD and ESRD. In ESRD some diseases (e.g. adult polycystic kidney disease [APKD]) are overrepresented and some (e.g. ischaemic/hypertensive nephropathy) are underrepresented. The reasons for this are that individuals with APKD are likely to survive to reach ESRD, whereas those with ischaemic renal damage are more likely to die of CVD before ESRD is reached.

Ischaemic/hypertensive renal disease

Ischaemic nephropathy was traditionally referred to as under-perfusion of the kidneys caused by renal artery stenosis. This explanation fell from favour and this term is now used for impairment of renal function caused by vascular disease distal to occlusion

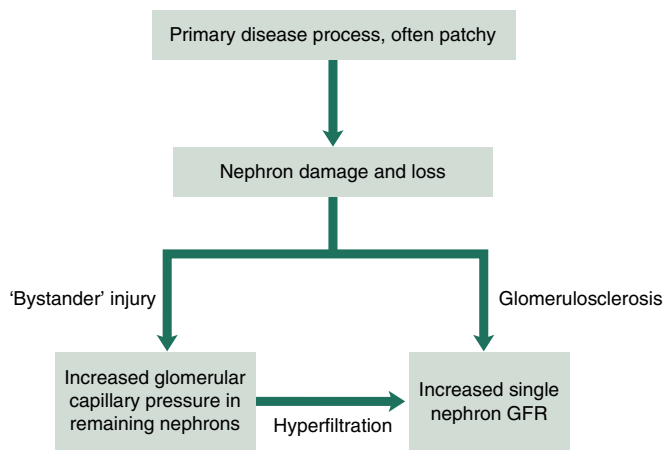

Fig. 18.6 Mechanism of progressive renal damage. GFR, Glomerular filtration rate.

of the main renal arteries. Hypertension results in atherosclerosis and arteriosclerosis which can cause occlusive renovascular disease and small-vessel damage. In patients with significant large-vessel occlusive disease, arteriolar nephrosclerosis, interstitial fibrosis and glomerular collapse may be present (Lerman and Textor, 2001). These diagnoses account for around 30% of CKD and a smaller proportion of ESRD. The effective management of hypertension is crucial to reduce renal damage.

Metabolic diseases

Diabetes mellitus is the most common metabolic disease that causes CKD. The predominant lesion is glomerular and is referred to as diabetic nephropathy or diabetic kidney disease when diabetic nephropathy is likely but the patient has not had a kidney biopsy performed to confirm the diagnosis. Around 95% of all diabetes cases are type 2 diabetes. Diabetes is present in up to one-third of patients with CKD (see Table 18.2), but in many of these patients processes other than diabetic nephropathy cause kidney disease. Diabetic nephropathy is associated with a faster decline in kidney function than other pathologies; these patients are also at high risk of CVD as a consequence of CKD and diabetes functioning as independent risk factors for CVD. Both type 1 and type 2 diabetes can result in diabetic nephropathy. Patients with type 1 diabetes usually present with CKD at a younger age, and if they progress to ESRD may benefit from combined kidney and pancreas transplantation. Patients with diabetes usually have high levels of protein in the urine (proteinuria); high levels of proteinuria are associated with an increased risk of progression of CKD to ESRD.

Chronic glomerulonephritis

Glomerulonephritis is a term that is used to describe the process of inflammation of the glomerulus. Chronic glomerulonephritis causes around 15% of cases of advanced CKD. The commonest

Table 18.2 Primary diagnosis in patients receiving renal replacement therapy by age and gender (UK Renal Registry, 2008)

Primary diagnosis	% All patients	Inter-centre range (%)	Age <65 years (%)	Age >65 years (%)	Male/female ratio
Aetiology uncertain/glomerulonephritis (not biopsy proven)	21.6	2.1–84.3	19.2	26.6	1.6
Glomerulonephritis (biopsy proven)	15.3	2.3–22.4	17.8	10.0	2.2
Pyelonephritis	11.9	3.2–19.4	13.6	8.3	1.1
Diabetes	13.2	2.8–26.0	12.3	15.1	1.6
Polycystic kidney	9.2	2.0–15.8	9.6	8.3	1.1
Hypertension	5.4	1.0–16.0	4.6	6.9	2.4
Renal vascular disease	3.5	0.3–16.1	1.1	8.2	2.0
Other	14.5	1.9–36.1	16.0	11.3	1.3
Not sent	5.5	0.1–46.2	5.7	5.2	1.5

cause of chronic glomerulonephritis is IgA nephropathy; this is characterised by deposition of polymeric IgA in the glomerulus with subsequent immune activation. Other patterns of glomerulonephritis include membranous nephropathy, where there is granular deposition of immunoglobulin on the glomerular capillary basement membrane. Systemic autoimmune diseases such as systemic lupus erythematosus can cause a variety of types of glomerulonephritis. Finally, some chronic forms of glomerulonephritis are pauci-immune; that is, they have no immune deposition. An example of this type is focal and segmental glomerulosclerosis.

Lower urinary tract disease

A variety of differing pathologies make up this group and together they represent 5–10% of all cases of CKD. They include the following conditions: reflux disease, renal stone disease, chronic pyelonephritis and extrinsic renal tract obstruction.

Reflux disease

Reflux disease results from reflux of urine back up the renal tract towards the kidneys. This can result in recurrent infections and subsequent scarring.

Renal stone disease

Kidney stones are primarily formed of calcium oxalate and calcium phosphate. They can cause urinary tract obstruction and infection.

Chronic pyelonephritis

Recurrent urinary tract infections which ascend to involve the kidneys can cause renal scarring; this is often associated with reflux disease but may occur without it.

Extrinsic renal tract obstruction

In males the commonest cause of extrinsic renal tract obstruction is prostatic hypertrophy. There are many other causes.

Hereditary/congenital diseases

There are many inherited renal diseases and together they represent 5% of CKD cases. It is, however, important to remember that they make up a higher proportion of cases of ESRD. The commoner inherited conditions are APKD and Alport's syndrome. Autosomal dominant polycystic kidney disease is an inherited condition which results in the formation of multiple cysts in both kidneys throughout life. The kidneys become enlarged and frequently fail in middle age. Alport's syndrome is a disorder of glomerular basement membranes caused by a mutation affecting type IV collagen; X-linked, autosomal dominant and autosomal recessive forms of inheritance are all seen. The clinical manifestations include progressive nephritis with haematuria, proteinuria and sensorineural deafness.

Unknown cause

The cause of CKD is unknown in around 30% of patients, who typically present with small kidneys and unremarkable

immunological investigations. When the kidneys are small it is often not possible to carry out a renal biopsy to determine the underlying cause.

Clinical manifestations

Symptoms of advanced kidney disease are known as uraemic symptoms. Although uraemic symptoms are rare in stage G4 CKD, they become more apparent as the patient enters stage G5 CKD and approaches ESRD. In some patients symptoms only develop when ESRD develops, and as a consequence some patients are admitted to hospital as an emergency and require immediate dialysis at their first contact with the medical professional.

ESRD is characterised by the requirement of RRT to sustain life. It is usually accompanied by symptoms of uraemia and variably, anaemia, acidosis, osteodystrophy, and neuropathy. Most patients have hypertension and fluid retention. There is an increased susceptibility to infections (Fig. 18.7). These clinical features result from the major reduction in excretory, homeostatic, metabolic and endocrine functions of the kidney that have usually occurred over many years.

In the following sections the clinical features of CKD are described, along with the underlying pathogenesis.

Polyuria and nocturia

Polyuria, where the patient frequently voids high volumes of urine, is often seen in CKD and results from medullary damage and insensitivity to ADH. In people with advanced CKD it can also be related to the osmotic effect of a high serum urea level (>40 mmol/L). The ability to concentrate urine is also accompanied by physiological nocturnal antidiuresis, which when modified in CKD invariably results in nocturia, where the patient will wake overnight needing to pass urine.

Proteinuria and albuminuria

A small amount of protein is detectable in normal urine. However, when protein levels in the urine climb above a threshold level the patient is classified as having proteinuria. Around 70% of all proteinuria is albuminuria, and it is albuminuria that is used to contribute to the classification of CKD (see Table 18.1). Albuminuria is measured in clinical practice by using single urine samples to determine the ACR or (in some laboratories) the protein/creatinine ratio. These spot methods have almost entirely replaced the previously used 24-hour urine collection which was inconvenient and often unreliable. An ACR of 3–30 mg/mmol is classified as high albuminuria (previously micro-albuminuria) and an ACR greater than 30 mg/mmol as very high albuminuria (previously macroalbuminuria). In nephrotic-range proteinuria the ACR is greater than 250 mg/mmol.

Around 5% of adults have albuminuria/proteinuria. There are two reasons why this is measured. Firstly, it helps in making the diagnosis of the underlying cause of CKD. Albuminuria suggests glomerular pathology (e.g. diabetic nephropathy) in a patient with diabetes mellitus or a newly diagnosed glomerulonephritis. Secondly, albuminuria is a major risk factor for CKD

Fig. 18.7 Typical signs and symptoms of chronic kidney disease.

progression; therefore, it identifies patients who require additional attention for management of risk factors and counselling about the long-term impact of CKD.

Haematuria

Haematuria refers to the presence of blood in the urine and can be caused by either renal or lower urinary tract pathology. The presence of blood and/or protein in the urine is described as an active urinary sediment. Whenever blood in the urine is detected, an infection should be considered and excluded by quantification of white cells (by microscopy or flow cytometry) and culture for organisms.

Haematuria can be either invisible (microscopic) or visible (macroscopic). The best way to test for haematuria is with a urinary dip test. This is a near-patient test, carried out when the patient provides the sample. If there is a delay in testing, the sample red cells in urine can lyse so microscopy may miss the presence of haematuria. Microscopy, however, does have a role in identifying the presence of casts, which are also seen in glomerular diseases and allow the discrimination of the course of haematuria.

Hypertension and fluid overload

Most patients with CKD will have hypertension, and this may be a cause or a consequence (or a combination of both) of their kidney disease. Furthermore, raised BP may exacerbate renal damage and lead to accelerated deterioration of CKD.

CKD leads to sodium retention, which in turn produces circulatory volume expansion with consequent hypertension. Volume-dependent hypertension occurs in about 80% of patients with CKD, and this is more prevalent with more advanced CKD. This form of hypertension is often termed ‘salt-sensitive’ because it

may be exacerbated by salt intake. Lesser degrees of renal impairment reduce kidney perfusion, which activates RAAS. Treatment of BP, irrespective of choice of therapy, generally slows the rate of deterioration of kidney function in patients with CKD. As the eGFR falls to very low levels the kidneys are unable to excrete salt and water adequately, resulting in the retention of extravascular fluid. All patients with fluid overload will by definition also have salt retention; this does not show itself as an increase in serum sodium levels, but reflects the fact that extracellular fluid including excess extravascular fluid is sodium rich.

Clinical findings

Hypertension can lead to cardiac disease (left ventricular hypertrophy, ischaemic heart disease and heart failure), peripheral vascular disease, and cerebrovascular disease (including strokes). Fluid retention can manifest as peripheral and pulmonary oedema and ascites. Oedema may be seen around the eyes on waking, the sacral region in supine patients and from the feet upwards in ambulatory patients.

Uraemia

Many small molecules including urea, creatinine and water are normally excreted by the kidney and accumulate as renal function decreases. Uraemia refers to the clinical manifestation of the accumulation of small molecules in CKD. In patients with ESRD, some of the molecules responsible for the toxicity of uraemia are intermediate in size between small, readily dialysed molecules and large, non-dialysable proteins. These are described as ‘middle molecules’ and include phosphate, guanidines, phenols and organic acids. There are a wide range of uraemic toxins, but it is

the blood level of urea that is still used to estimate the degree of toxin accumulation in CKD. True symptomatic uraemia occurs only in very advanced CKD.

Clinical findings

The symptoms of uraemia include anorexia, nausea, vomiting, constipation, foul taste and skin discolouration that is presumed to be due to pigment deposition compounded by the pallor of anaemia. The characteristic complexion is often described as 'muddy' and can be associated with severe pruritus without an underlying rash. In severe cases crystalline urea is deposited on the skin (uraemic frost).

In uraemia, there is also an increased tendency to bleed, which can exacerbate pre-existing anaemia because of impaired platelet adhesion including modified interactions between platelets and blood vessels resulting from altered blood rheology.

Anaemia

Anaemia affects most people with stages G4 and G5 CKD. The decrease in haemoglobin level is a slow, insidious process accompanying the decline in renal function. A normochromic, normocytic pattern is usually seen with haemoglobin levels declining to around 80 g/L by ESRD.

Several factors contribute to the pathogenesis of anaemia in CKD, including shortened red cell survival, marrow suppression by uraemic toxins and iron or folate deficiency associated with poor dietary intake or increased loss, for example, from gastro-intestinal bleeding. However, the principal cause results from damage of peritubular cells leading to inadequate secretion of erythropoietin. This hormone, which is produced mainly, although not exclusively, in the kidney, is the main regulator of red cell proliferation and differentiation in bone marrow. Hyperparathyroidism also reduces erythropoiesis by damaging bone marrow and, therefore, exacerbates anaemia associated with CKD. The RAAS is also involved in erythropoiesis; ACE inhibitors can cause small reductions in haemoglobin through reducing ATII production; ATII can also function as a stimulator of erythropoiesis.

Clinical findings

Anaemia in CKD is a major cause of fatigue, breathlessness at rest and on exertion, and lethargy. Patients may also complain of feeling cold, poor concentration and reduced appetite and libido. Compensatory haemodynamic changes include an increase in cardiac output to improve oxygen delivery to tissues, although this may result in tachycardia and palpitations. The anaemia of CKD usually responds to treatment with erythropoietin-stimulating agents (ESAs).

Bone disease (renal osteodystrophy)

Renal osteodystrophy describes the four types of bone disease associated with CKD:

- secondary hyperparathyroidism
- osteomalacia (reduced mineralisation)
- mixed renal osteodystrophy (both hyperparathyroidism and osteomalacia)

Fig. 18.8 Renal and hepatic involvement in vitamin D metabolism.

- adynamic bone disease (reduced bone formation and resorption)

Cholecalciferol, the precursor of active vitamin D, is both absorbed from the gastro-intestinal tract and produced in the skin by the action of sunlight. Production of active vitamin D, 1,25-dihydroxycholecalciferol (calcitriol) requires the hydroxylation of the cholecalciferol molecule at both the 1 α and the 25 position (Fig. 18.8).

Hydroxylation at the 25 position occurs in the liver, whereas hydroxylation of the 1 α position occurs in the kidney; this latter process is impaired in CKD. The resulting deficiency in active vitamin D leads to defective mineralisation of bone and subsequent osteomalacia, which occurs in patients with stage G3–G5 CKD.

The deficiency in vitamin D with the consequent reduced calcium absorption from the gut in combination with the reduced renal tubular reabsorption results in hypocalcaemia (Fig. 18.9).

These disturbances are compounded by hyperphosphataemia caused by reduced phosphate excretion, which in turn reduces the concentration of ionised serum calcium by sequestering calcium phosphate in bone and in soft tissue. Hypocalcaemia, hyperphosphataemia and a reduction in the direct suppressive action of 1,25-dihydroxycholecalciferol on the parathyroid glands result in an increased secretion of parathyroid hormone (PTH).

Because the failing kidney is unable to respond to PTH by increasing renal calcium reabsorption, serum PTH levels remain persistently elevated, and hyperplasia of the parathyroid glands occurs. The resulting secondary hyperparathyroidism produces a disturbance in the normal architecture of bone, and this is termed osteosclerosis (hardening of the bone). A further possible consequence of secondary hyperparathyroidism produced in response to hypocalcaemia is that bone reabsorption is increased to maintain adequate calcium levels. This, in combination with hyperphosphataemia, may result in soft tissue calcification caused by calcium phosphate deposition.

Clinical findings

Bone pain is the main symptom, and distinctive appearances on radiography may be observed, such as 'ruger-jersey' spine, where there are alternate bands of excessive and defective mineralisation in the vertebrae (Fig. 18.10).

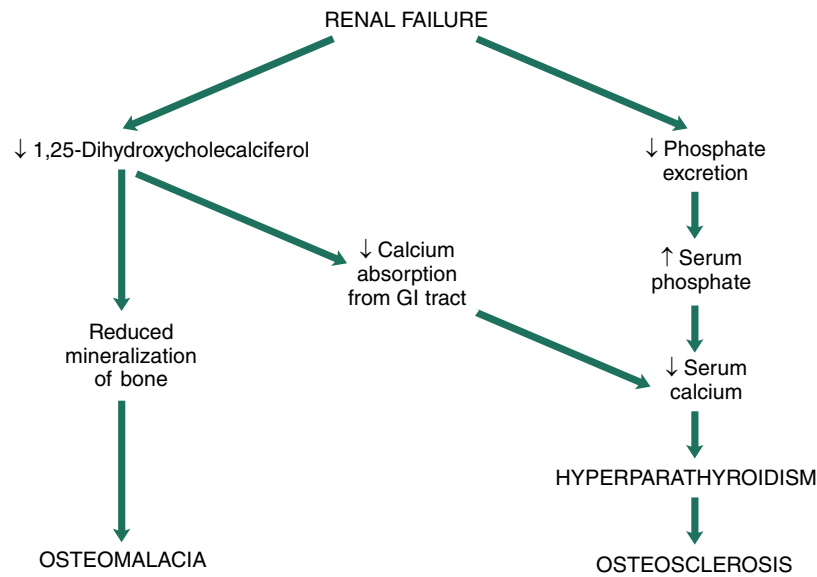

Fig. 18.9 Disturbance of calcium and phosphate balance in chronic renal failure. GI, Gastro-intestinal.

Fig. 18.10 Lateral radiograph of the spine in a patient with chronic renal failure. Characteristic endplate sclerosis (arrows) is referred to as 'rigger-jersey spine'. (Reproduced by kind permission of Dr M. J. Kline, Department of Diagnostic Radiology, Cleveland Clinic Foundation.)

Neurological changes

The most common neurological changes are non-specific and probably caused by uraemic toxins; they include poor concentration, memory impairment, irritability and stupor.

Clinical features

Fits caused by cerebral oedema or hypertension may occur. A 'glove and stocking' peripheral neuropathy and/or a mono-neuritis multiplex can occur.

Muscle function

Muscle symptoms are probably caused by general nutritional deficiencies and electrolyte disturbances, notably of divalent cations and especially by hypocalcaemia.

Clinical findings

Muscle cramps and restless legs are common and may be major symptoms causing distress to patients, particularly at night. Rarely a proximal myopathy of shoulder and pelvic girdle muscles may develop.

Electrolyte disturbances

Because the kidneys play such a crucial role in the maintenance of volume, extracellular fluid composition and acid-base balance, disturbances of electrolyte levels are common in CKD.

Sodium

Serum sodium levels are usually normal, even when the GFR is very low. However, patients may have hyponatraemia or hypernatraemia depending upon the condition and therapies (Table 18.3).

Potassium

Potassium levels can be elevated (hyperkalaemia) in CKD; this is a potentially catastrophic complication because the first indication of elevated potassium levels may be a cardiac arrest. Serum potassium levels greater than 7.0 mmol/L are life-threatening and should be treated as an emergency. Hyperkalaemia may be exacerbated in acidosis as potassium shifts from within cells.

Electrocardiogram (ECG) changes occur with an increase in serum potassium and become more pronounced as levels increase. The progressive changes comprise: T wave peak ('tenting'), reduction in P wave size, increase in the PR interval and widening of the QRS complex. P waves eventually disappear

Table 18.3 Causes and mechanism of serum sodium abnormalities in chronic kidney disease

	Mechanism	Cause/effect
Hypernatraemia	Sodium overload	Drugs, e.g. antibiotic sodium salts
	Hypotonic fluid loss	Osmotic diuresis Sweating
	↓ Water intake	Unconsciousness
Hyponatraemia	Dilution by intracellular water movement	Mannitol
Hyperglycaemia	Water overload	Acute dilution by intravenous fluids, e.g. 5% dextrose infusion Excessive intake Congestive cardiac failure Nephrotic syndrome

A. Normal serum potassium (3.5–5.0) mmol/L

B. Serum potassium approximately 7.0 mmol/L

C. Serum potassium approximately 8.0–9.0 mmol/L

D. Serum potassium greater than 10.0 mmol/L

**Fig. 18.11** Typical electrocardiogram changes in hyperkalaemia.

and the QRS complex becomes even wider. Ultimately, the ECG assumes a sinusoidal appearance prior to a cardiac arrest (Fig. 18.11).

Hydrogen ions

Hydrogen ions (H^+) are a common end-product of many metabolic processes, and about 40–80 mmol is normally excreted by the kidneys each day. In CKD, H^+ is retained, causing acidosis; the H^+ combines with bicarbonate (HCO_3^-), resulting in removal

of some hydrogen as water, elimination of carbon dioxide via the lungs and reduction in serum bicarbonate level.

Diagnosis, investigations and monitoring

Although the diagnosis of CKD may be suspected because of signs and symptoms of renal disease, it is usually discovered on a routine blood test. In some patients no cause of CKD can be identified, often because they have two small kidneys which are not safe to biopsy. This appearance results from damage at some unspecified time in the past.

Family, drug and social histories are all important in elucidating the causes of CKD, because genetics or exposure to toxins, including prescription, over-the-counter and herbal drugs, might be implicated.

Physical examination may be helpful. Signs of anaemia and skin pigmentation, excoriations from scratching and whitening of the skin with crystalline urea ('uraemic frost') may indicate severe CKD. Palpable or audible bruits over the femoral arteries are strongly associated with extensive atherosclerosis and are commonly found in patients with co-incident renal vascular disease. Ankle oedema and a raised jugular venous pressure suggest fluid retention. In severe CKD a fishy smell on the breath known as 'uraemic foetor' is characteristic. In some patients the kidneys may be palpable. Large, irregular kidneys are indicative of polycystic kidney disease, whereas smooth, tender enlarged kidneys are likely to be infected or obstructed. However, in the large majority the kidneys are not palpable. A palpable bladder suggests outflow tract obstruction which is often due to prostatic hypertrophy in men.

Functional assessment of the kidney may be performed by testing serum and urine. The serum creatinine level, incorporated into an eGFR equation, is the measurement of choice for estimating excretory kidney function. Hyperkalaemia, acidosis with a correspondingly low serum bicarbonate level, hypocalcaemia and hyperphosphataemia are frequently present and can help to differentiate a new presentation of CKD from AKI.

The patient may report a change in urine colour, which might result from blood staining by whole cells or haemoglobin, drugs or metabolic breakdown products. Urine may also appear milky after connection with lymphatics; cloudy following infection; contain solid material such as stones, crystals and casts; or froth excessively in proteinuria. Urine should be examined visually, by dipstick test, microscopically if indicated, and with a spot urine assessment for ACR.

Dipstick tests enable simple, rapid estimation of a wide range of urinary parameters including pH, specific gravity, leucocytes, nitrites, glucose, blood and protein. Positive results should, however, be quantified by more specific methods.

Structural assessments of the kidney may be performed using a number of imaging procedures, including:

- ultrasonography;
- intravenous urography (IVU);
- plain abdominal radiography;
- computed tomography (CT), magnetic resonance imaging (MRI) and magnetic resonance angiography.

Ultrasonography

Ultrasonography produces two-dimensional images using sound waves and is used as the first-line investigational tool in many hospitals. The technique is harmless, non-invasive, quick, inexpensive, enables measurements to be made and produces images in real time. The latter feature allows accurate and safe positioning of biopsy needles for patients who undergo a kidney biopsy. Ultrasonography is particularly useful in the differentiation of renal tumours from cysts and in the assessment of renal tract obstruction. Doppler ultrasonography enables measurement of flow rate and direction of the intra-renal and extra-renal blood supply.

Computed tomography, magnetic resonance imaging and intravenous urography

Recently introduced cross-sectional imaging techniques have transformed the assessment of kidney disease. Both CT and MRI can produce very detailed images that include an assessment of the blood supply into the kidney and the drainage of the kidneys. IVU is now rarely used because it uses high doses of radiation and contrast media, and provides less information. For example, a CT urogram is now used as an investigation of choice for patients with obstruction of the renal tract by renal imaging. MRI scans provide enhanced soft tissue assessment and also avoid the use of contrast media that can cause kidney damage. However, the use of gadolinium as a contrast medium for MRI has been associated, in patients with stage G4 and G5 CKD, with nephrogenic systemic fibrosis which results in death in a proportion of patients. Although the use of gadolinium is not contraindicated in this group, it must be used with great care, and protocols will vary from unit to unit.

Cross-sectional imaging with CT or MRI can provide information that includes:

- the presence, length and position of the kidneys; in CKD the kidneys generally shrink in proportion to nephron loss, the exception being the enlarged kidneys seen in polycystic disease;
- the presence or absence of renal scarring and the shape of the calices and renal pelvis; renal cortical scarring and caliceal distortion indicate chronic pyelonephritis;

- obstruction to the ureters, for example, by a stone, tumour or retroperitoneal fibrosis; these may require surgical intervention;
- the presence of a cyst or solid mass in the kidneys and the features of this;
- detailed information on the blood supply into and out of the kidneys.

Nuclear medicine investigations

There are two commonly used nuclear medicine investigations. The first uses mercapto acetyl triglycerine. This is used for assessment of renal perfusion and the identification of outflow obstruction. The other is a dimercaptosuccinic acid scan, the purpose of which is to ascertain the percentage that each kidney contributes to overall function.

Renal biopsy

If imaging techniques fail to give a cause for the reduction in renal function, then a renal biopsy may be performed, although in advanced disease extensive scarring of the renal tissue may obscure the original (primary) diagnosis. Also, it is difficult to perform a biopsy of the small shrunken kidneys often seen in CKD and they may subsequently bleed. Most clinicians do not perform biopsies in this setting.

Rate of progression of chronic kidney disease

All patients with CKD should be monitored regularly. The recommendations for monitoring frequency can be found in the NICE guideline for assessment and management of CKD (NICE, 2014). In some patients with CKD the decline in renal function progresses at a constant rate and may be monitored by plotting the eGFR against time (see Fig. 18.11). The intercept with the x -axis indicates the time at which renal function will fall to zero and can be used to predict when the GFR will reach approximately 10 mL/min, that is, the level at which RRT should be initiated (Fig. 18.12A). If an abrupt decline in the slope of the reciprocal plot is noted (see Fig. 18.12B), this indicates a worsening of the condition or the presence of an additional renal insult.

It is, however, increasingly recognised that most patients with CKD do not sustain a predictable decline. Many stabilise or follow a path of episodes of accelerated decline followed by months or years of stability. These observations are of great interest and are an increasing focus of clinical research.

Prognosis

When the GFR has declined to about 20 mL/min, a continuing deterioration in renal function to ESRD is common even when the initial cause of the kidney damage has been removed and appropriate treatment instigated. The mechanisms for this decline in renal function include uncontrolled hypertension, proteinuria and damage resulting from hyperfiltration through the remaining intact nephrons. Serial GFR measurements should be monitored in conjunction with the patient's clinical condition to ensure the

Fig. 18.12 Stylised reciprocal creatinine plots. (A) Linear, uniform progression in the decline in renal function. (B) Sudden decline in renal function (arrow).

Box 18.1 Factors that might exacerbate established chronic renal failure

Reduced renal blood flow

Obstruction, e.g. prostatic hypertrophy

detection of the most appropriate point at which to commence RRT. Patients with an eGFR less than 20 mL/min should be supported to ensure that decisions have been made about the preferred modality of dialysis if ESRD is reached, suitability for and timing of transplantation, and for those patients who do not wish to receive dialysis or transplantation supportive care for symptom management if they reach ESRD.

There is now an accurate online tool for assessing the risk of progression of CKD to ESRD at the level of the individual patient (the Kidney Failure Risk Equation, see Useful Websites).

Treatment

The following are the aims of the treatment of CKD:

- halt or slow the process causing the renal damage (this may not be possible);
- avoid conditions that might worsen renal failure (Box 18.1);
- treat the secondary complications of CKD (renal anaemia and bone disease);
- relieve symptoms;
- implement treatment for ESRD in a controlled and timely manner.

Reversal or arrest of primary disease

By definition, CKD rarely has a readily reversible component, in contrast with acute renal failure. However, it is sometimes possible to identify a disease-specific factor that is contributing to declining renal function and remove it. Glomerulonephritis may respond to immunosuppressants and/or steroids. When drug-induced renal disease is suspected, the offending agent should be stopped. A post-renal lesion such as a ureter obstructed by a stone or a ureteric tumour may be successfully treated.

Hypertension

Optimum control of BP is usually the most important therapeutic measure. There is a cycle of events whereby hypertension causes damage to the intrarenal vasculature resulting in thickening and hyalinisation of the walls of arterioles and small vessels. This damage effectively reduces renal perfusion, contributing to stimulation of the RAAS. Arteriolar vasoconstriction, sodium and water retention result, which in turn exacerbates the hypertension.

Antihypertensive therapy with certain agents might produce a transient reduction in eGFR over the first 3 months of treatment as the systemic and glomerular BP drop; this is mainly seen with ACE inhibitors/angiotensin receptor blockers (ARBs). However, this is not an indication to stop the drugs unless the decline in eGFR is greater than 25%, because in the long-term the improvement in BP will slow the decline in renal function.

The drugs used to treat hypertension in CKD are generally the same as those used in other forms of hypertension, although allowance must be made for the effect of renal failure on drug disposition (NICE, 2014).

Calcium channel blockers

For patients without proteinuria, calcium channel blockers (CCBs) are the agents of choice. They produce vasodilatation principally by reducing Ca^{2+} influx into vascular muscle cells. CCBs also appear to promote sodium excretion in hypertension associated with fluid overload. The mechanism of this is unclear but may relate to the finding that high sodium levels can cause vasoconstriction by interfering with calcium transport.

Both verapamil and diltiazem (non-dihydropyridine CCBs) block conduction across the atrioventricular node and should not be used in conjunction with β -blockers. They are also negative cardiac inotropes. By contrast, dihydropyridine CCBs such as nifedipine and amlodipine produce less cardiac depression and differentially dilate afferent arterioles in the kidney.

CCBs can produce headache, facial flushing and oedema. The latter can be confused with the symptoms of volume overload but is resistant to diuretics. These effects occur because of changes in pre-capillary hydrostatic pressure, which forces fluid into the interstitial compartment. The oedema is not related to salt or water retention; hence the lack of response to diuretic therapy.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

The role of ACE inhibitors and ARBs in the management of CKD is now firmly established. In some patients the drugs have a protective effect over and above their impact on BP control. For example, patients with diabetes and albuminuria should be treated with ACE inhibitors or ARBs regardless of BP. In patients with CKD, but not with diabetes, the evidence indicates the use of these drugs as first-line treatment in patients with very heavy proteinuria.

ACE inhibitors reduce circulating ATII, and ARBs block binding to the ATII receptor; these actions result in vasodilatation and reduced sodium retention. ACE inhibitors and ARBs preferentially protect the glomerulus over and above their effect as systemic hypertensive agents, through decreasing

effluent glomerular arteriolar vasoconstriction and therefore intraglomerular hypertension and hyperfiltration. In the short-term they can cause a reduction in GFR by preventing the ATII-mediated vasoconstriction of the effluent glomerular arteriole. However, this decline is offset in the long-term by the protective effect of the agents in clinical practice.

Although the evidence for use of these drugs in patients with diabetic renal disease and proteinuric non-diabetic CKD is clear, care must be exercised in the following settings:

- Patients who sustain an early decline (in the first 7–10 days after ACE inhibitors/ARBs commencement) in kidney function of more than 25%: The drug should be stopped and potential renal artery stenosis investigated.
- Patients with non-proteinuric, non-diabetic CKD: These agents may be overused in this setting. There is no evidence that they provide a real renal benefit over other antihypertensive drugs.
- Patients with an accelerated decline in kidney function in the months to years after commencement of ACE inhibitors/ARBs: This is increasingly described and may reflect a resetting of the intra-renal perfusion to a level that potentiates chronic renal ischaemia present in most cases of CKD irrespective of cause.
- Patients with an intercurrent acute illness, particularly those admitted to hospital: Hypotension or infection will put patients at an increased risk of AKI.

For long-term management, it is usually preferable to use an agent with a duration of action that permits once-daily dosing. There is little to choose clinically between the ACE inhibitors currently on the market; however, consideration should be given to the cost benefits of choosing an agent that does not require dose adjustment in renal failure.

It has been reported that ACE inhibitors may reduce thirst, which may be useful in those patients who have a tendency to fluid overload as a result of excessive drinking. ACE inhibitors are potassium sparing; therefore, serum potassium should be monitored. If the potassium level is greater than 5.5 mmol/L on an ACE inhibitor or ARB, then a loop diuretic can be added because this will increase renal potassium clearance and lower serum potassium. A low-potassium diet may be necessary.

ARBs have properties similar to ACE inhibitors; however, because they do not inhibit the breakdown of kinins such as bradykinin, they do not cause the dry cough associated with the ACE inhibitors. There was interest in the potential use of dual blockade of the RAAS using ACE inhibitors and ARBs to produce more complete blockade of ATII. However, a number of studies have shown no added benefit and some evidence of worse outcomes, and this combination of drugs should be avoided (Mann and Böhm, 2015). Recently renin inhibitors have also been evaluated in clinical practice; however, this group of drugs was associated with a higher complication rate when used in combination with an ACE inhibitor and should not be used.

Diuretics

Diuretics are of use in patients with salt and volume overload, which is usually indicated clinically by the presence of oedema. This type of hypertension may be particularly difficult to treat. The choice of agent is generally limited to a loop diuretic.

Potassium-sparing diuretics are usually contraindicated because of the risks for development of hyperkalaemia, and thiazides become ineffective as renal failure progresses. In combination with ACE inhibitors, the mineralocorticoid receptor antagonists spironolactone and eplerenone can significantly reduce proteinuria; however, the combination of these agents raises the risk of significant hyperkalaemia, and care must be taken (Bianchi et al., 2005). The combination should be avoided when the eGFR falls to less than 30 mL/min. Studies are currently in progress assessing a role for spironolactone in patients with stage G1–G3 CKD.

Because loop diuretics need to be filtered to exert an action, progressively higher dosages are required as CKD worsens. Dosages of more than 250 mg/day furosemide may be required in advanced renal failure. Patients who do not respond to oral loop diuretic therapy alone may benefit from concomitant administration of metolazone, which acts synergistically to produce a profound diuresis. Alternatively, the loop diuretic may be given intravenously (i.v.). Care must be taken to avoid hypovolaemia (by monitoring body weight) and electrolyte disturbances such as hypokalaemia and hyponatraemia.

Thiazide diuretics, with the notable exception of metolazone, are ineffective at an eGFR less than 30 mL/min and may accumulate, causing an increased incidence of side effects.

β-Blockers

β-Blockers are commonly used in the treatment of hypertension in CKD. They exhibit a range of actions including a reduction of renin production. Consequently, β-blockers have a particular role in the rational therapy of hypertension without fluid overload. However, β-blockers can reduce cardiac output, cause peripheral vasoconstriction and exacerbate peripheral vascular disease.

It is advisable to use the more cardioselective β-blockers atenolol or metoprolol. Atenolol is excreted renally and consequently should require dosage adjustment in renal failure. In practice, however, atenolol is effective and tolerated well by renal patients at standard doses. Metoprolol is theoretically a better choice because it is cleared by the liver and needs no dosage adjustment, although small initial doses are advised in renal failure because there may be increased sensitivity to its hypotensive effects.

Selective α₁-blockers

These vasodilators produce a variety of actions that may be of benefit in hypertension associated with CKD. Sympathetic adrenergic activity can lead to sodium retention. Selective α₁-blockers have also been shown to produce improvements in insulin sensitivity, adverse lipid profiles and obstruction caused by hypertrophy of the prostate, all of which might be associated with some forms of CKD. These agents are used less commonly because there is some evidence that, in comparison with other antihypertensives, use is associated with adverse cardiovascular outcomes, especially the development of heart failure.

Vasodilators

The vasodilators hydralazine and minoxidil have been used to treat hypertension in CKD with varying degrees of success but

are usually only used when other measures inadequately control BP. The sensitivity of patients to these drugs is often increased in renal failure, so, if used, therapy should be initiated with small doses. These agents cause direct peripheral vasodilation with resultant reflex tachycardia, which may require suppression by co-prescription of a β -blocker.

Centrally acting drugs

Methyl dopa and clonidine are not commonly used as antihypertensives in CKD because of their adverse side effect profiles. If they are used in renal failure, initial doses should be small because of increased sensitivity to their effects.

Management of symptoms

Gastro-intestinal

Nausea and vomiting may persist after starting a low-protein diet. Metoclopramide is useful to treat this, but sometimes accumulation of the drug and its metabolites may occur, leading to extrapyramidal side effects. Patients should be started on a low dose, which should then be increased slowly. Prochlorperazine or cyclizine may also be useful. The 5-HT₃ antagonists such as ondansetron have also been shown to be effective. The patient with anaemia often becomes less nauseated when treated with an ESA.

Constipation is a common problem in patients with renal disease, partly as a result of fluid restriction and anorexia, and partly as a consequence of drug therapy with agents such as phosphate binders. It is particularly important that patients managed with peritoneal dialysis do not become constipated because this can reduce the efficacy of dialysis. Conventional laxative therapy may be used, such as bulk-forming laxatives or increased dietary fibre for less severe constipation. Alternatively, a stimulant such as senna with enemas or glycerine suppositories may be used for severe constipation. Higher doses of senna, typically two to four tablets at night, may be required. It should be noted that certain brands of laxatives that contain ispaghula husk may also contain significant quantities of potassium, and should be avoided in renal failure because of the risk of hyperkalaemia. Sterculia preparations are an effective alternative.

Pruritus

Pruritus (itching) associated with advanced CKD can be extremely severe, distressing and difficult to treat. It can also be disfiguring as a result of scratching. The exact mechanism responsible for the itching is not clear; the possibilities include one or more of xerosis (dry skin), skin micro-precipitation of divalent ions, elevated PTH levels and increased dermal mast cell activity.

Sometimes correction of serum phosphate or calcium levels improves itching, as does parathyroidectomy in patients with severe secondary or tertiary hyperparathyroidism. Conventionally, oral antihistamines have been used to treat pruritus; however, topical versions should not be used because of the risk of allergy. Non-sedating antihistamines such as loratadine are generally less effective than sedating antihistamines such as chlorphenamine or

alimemazine, which may be useful, particularly at night. Topical crotonamiton lotion and creams may also be useful in some patients. Other non-drug therapies include either warming or cooling the skin using baths, three times weekly ultraviolet B phototherapy and modified electrical acupuncture.

Recently, there is increasing evidence for the use of gabapentin, a drug which affects the neurotransmitter γ -aminobutyric acid and is usually used for epilepsy and neuropathic pain. Although gabapentin can be extremely effective for the itch associated with CKD (Rayner et al., 2012), dosing adjustments are required as it accumulates in CKD. There is less experience with the related drug, pregabalin, which can also be effective because it has a similar mechanism of action.

Dietary modifications

Historically, low-protein diets were used for patients with CKD; however, it is now accepted that this modification has limited evidence and is not used in mainstream clinical practice. The dietary modifications currently used include sodium and fluid restriction to reduce the risk of fluid overload, potassium restriction to reduce the risk of hyperkalaemia, and phosphate restriction. The dietary restrictions for patients with CKD can be arduous and difficult to follow.

Fluid retention

Oedema may occur as a result of sodium retention and the resultant associated water retention. Patients with CKD may also have hypoalbuminaemia secondary to very heavy proteinuria, and this can contribute to extravascular fluid retention (oedema) both through further activation of the RAAS and osmotic extravasation of fluid and its retention in tissues. The daily fluid intake for patients with CKD should be individualised, based on their predisposition to develop oedema. There is no clear evidence for a target fluid input (e.g. 3 L/day); however, it may be important to avoid dehydration because this may increase the risk of AKI.

For patients with ESRD, pulmonary and peripheral oedema is treated or avoided by using dialysis; however, the loop diuretic furosemide (often used at a very large dose) is used in patients who have a residual urine output because it can maintain urine output. In patients with ESRD, who have little (oliguria) or no (anuria) urine output, fluid restriction is critical. The fluid restriction for patients with ESRD can be limited to as little as 750 mL/day. This fluid allowance can be very difficult to maintain because it must include fluids ingested in any form, including sauces, medicines and fruits, in addition to drinks. Sucking ice cubes may relieve an unpleasant dry mouth, but patients should be encouraged not to swallow the melted water.

Sodium restriction. Sodium intake can be limited to 80 mmol/day by avoiding convenience foods and snacks or the addition of salt to food at the table. This is usually tolerable to patients. It is important to be aware of the potential contribution of sodium-containing medication to sodium loading, including some antibiotics, soluble or effervescent preparations, magnesium trisilicate mixture, Gaviscon, sodium bicarbonate and the plasma expanders hetastarch and gelatin.

Potassium restriction. Hyperkalaemia often occurs in CKD and may cause life-threatening cardiac arrhythmias. If untreated, asystolic cardiac arrest and death may result. Patients are often put on a potassium-restricted diet by avoiding potassium-rich foods such as fruit and fruit drinks, vegetables, chocolate, beer, instant coffee and ice cream. Many medicines have a high potassium content, for example, potassium citrate mixture, some antibiotics and ispaghula husk sachets. Emergency treatment is necessary if the serum potassium level is greater than 7.0 mmol/L or if there are ECG changes. The most effective treatment is dialysis, but if this is not available other measures may be tried (see [Chapter 17](#)).

The rationale and necessity for a renal diet and fluid restriction can be difficult for a patient to understand, and adherence may be a problem. A renal dietician is highly important in the management of patients with advanced CKD and is an established member of the multidisciplinary team of healthcare professionals required for a specialist renal service.

Anaemia

The anaemia of CKD is normochromic, normocytic and does not respond to iron or folic acid unless there is a coexisting deficiency. Functional iron deficiency in patients with CKD can occur at levels of serum ferritin that are in the normal range for patients with normal kidney function; consequently, there is a lower threshold for iron supplementation in patients with CKD. In addition, oral iron supplements are not well absorbed and/or tolerated in many patients with CKD, and therefore i.v. iron supplementation is commonly used.

Historically, the only treatment available for severe anaemia was red blood cell transfusions; however, this approach was a blood-borne infection risk, led to iron overload and promoted alloantibody formation, which decreased the likelihood of and increased the risk of subsequent kidney transplantation. The introduction of ESAs, initially as recombinant human erythropoietins (epoetin alfa and beta), into clinical practice in the early 1990s transformed the management of renal anaemia. Epoetin alfa and beta were thought to be indistinguishable in practical terms, as well as being immunologically and biologically indistinguishable from physiological erythropoietin. However, it has now been recognised that epoetins can be associated with the production of anti-erythropoietin antibodies leading to a severe anaemia which is unresponsive to exogenous epoetin. This is known as pure red cell aplasia and is more commonly associated with epoetin alfa when given by the subcutaneous route. The subcutaneous route is preferred because it provides equally effective clinical results while using similar or smaller doses (up to 30% less) than i.v. Most patients report a dramatically improved quality of life after starting epoetin therapy.

Epoetin alfa and beta have a short half-life and require dosing up to three times a week. Darbepoetin alfa is a novel erythropoiesis-stimulating protein that is a recombinant hyperglycosylated analogue of epoetin which stimulates red blood cell production by the same mechanism as the endogenous hormone. The terminal half-life in human is three times longer than that of epoetin and consequently requires a once-weekly

or alternate weekly dosing schedule. A longer acting ESA has been introduced (methoxy polyethylene glycol-epoetin beta, pegzerepoetin alfa). This is a continuous erythropoietin receptor activator, which can be used in a once-monthly dosing schedule.

Iron and folate deficiencies must be corrected before therapy is initiated; patients receiving ESAs generally require concurrent iron supplements because of increased marrow requirements. Supplemental iron is usually given i.v. Maintaining iron stores ensures the effect of ESA is optimised for minimum cost, because with insufficient iron stores a patient will not respond to treatment with epoetin.

ESA therapy should aim to achieve a slow rise in the haemoglobin concentration to avoid cardiovascular side effects associated with a rapidly increasing red cell mass, such as hypertension, increased blood viscosity/volume, seizures and clotting of vascular accesses. BP should be closely monitored.

An initial subcutaneous or i.v. epoetin dosage of 50 units/kg body weight three times weekly, increased as necessary in steps of 25 U/kg every 4 weeks, should be given to produce a haemoglobin increase of not more than 2 g/dL per month. The target haemoglobin concentration is 10–12 g/dL, with most aiming for a target around 11.5 g/dL. Once this has been reached, a maintenance dosage of epoetin in the region of 33–100 U/kg three times a week or 50–150 U/kg twice weekly should maintain this level. Dosing adjustment and equivalence calculations are available for all currently used ESAs.

Several studies of ESAs have shown an increased risk of cardiovascular morbidity and overall mortality in people treated to a target greater than 12.5 g/dL ([Phrommintikul et al., 2007](#)). As a consequence, a discontinuation or reduction of dose is required in patients with a haemoglobin level greater than 12.5 g/dL.

Correcting anaemia usually helps control the symptoms of lethargy and myopathy, and often greatly reduces nausea. Improved appetite while receiving ESA therapy can, however, increase potassium intake and may necessitate additional dietary adjustment.

Acidosis

Because the kidney is the main route for excreting H⁺ ions, CKD may result in a metabolic acidosis. This will cause a reduction in serum bicarbonate that may be treated readily with oral doses of sodium bicarbonate of 1–6 g/day. Because the dose of bicarbonate is not critical, it is easy to experiment with different dosage forms and strengths to suit individual patients. If acidosis is severe and persistent, then dialysis may be required. There is some evidence that correcting acidosis may slow the decline in renal function.

Neurological problems

Neurological changes are generally caused by uraemic toxins and improve on the treatment of uraemia by dialysis or diet. Muscle cramps are common and are often treated with quinine sulphate. Restless legs may respond to low doses of clonazepam or cocareldopa. In addition to their use for itching, gabapentin and pregabalin can also be used for restless legs.

Osteodystrophy

The osteodystrophy of renal failure is associated with three factors: hyperphosphataemia, vitamin D deficiency and hyperparathyroidism.

Hyperphosphataemia

The management of hyperphosphataemia depends initially upon restricting dietary phosphate. This can be difficult to achieve effectively, even with the aid of a specialist dietician, because phosphate is found in many palatable foods such as dairy products, eggs, chocolate and nuts. Phosphate-binding agents, when taken a few minutes before or with meals, can be used to reduce the absorption of orally ingested phosphate in the gut, by forming insoluble, non-absorbable complexes. Traditionally, phosphate-binders were usually salts of a di- or trivalent metallic ion, such as aluminium, calcium or occasionally magnesium. Although calcium-containing phosphate binders remain in widespread use, sevelamer and lanthanum-based binders are increasingly used.

Calcium carbonate has been used as a phosphate binder but is less effective as a phosphate binder than aluminium, and sometimes has been used in dosages of up to 10 g daily. However, this is no longer mainstream clinical practice and many clinicians advocate limiting elemental calcium dosing to ≤ 2 g/day because there is increasing evidence in patients with ESRD showing a relationship between calcium load and an increased risk of CVD events and early mortality (West et al., 2010). Calcium acetate is widely used as a phosphate binder. The capacity of calcium acetate and calcium carbonate to control serum phosphate appears to be similar. However, phosphate control is achieved using between half and a quarter of the dose of elemental calcium when calcium acetate is used.

Sevelamer, a hydrophilic but insoluble polymeric compound, is used increasingly as a phosphate binder. Sevelamer binds phosphate with an efficacy similar to calcium acetate but with no risk of hypercalcaemia. Mean levels of total and low-density cholesterol are also reduced with sevelamer use. This compound does not appear to present any risk of toxicity but may cause bowel obstruction and is relatively expensive when compared with other phosphate binders.

Lanthanum, like sevelamer, is a non-calcium-containing phosphate binder; there is therefore no resultant risk of hypercalcaemia, but there are gastro-intestinal side effects and these drugs are significantly more expensive than the alternatives. Although both of the non-calcium-containing phosphate binders available have been shown to reduce phosphate levels and keep calcium within acceptable levels, there is limited evidence to date for improvements in cardiovascular endpoints.

Historically, aluminium hydroxide was widely used as a phosphate binder because of the avid binding capacity of aluminium ions. However, a small amount of aluminium may be absorbed by patients with CKD owing to poor clearance of this ion, which can produce toxic effects including encephalopathy, osteomalacia, proximal myopathy and anaemia. Dialysis dementia was a disease observed among haemodialysis patients associated with aluminium deposition in the brain and exacerbated by aluminium in the water supply and the use of aluminium cooking pans.

Desferrioxamine (4–6 g in 500 mL of saline 0.9% per week) has been used to treat this condition by removing aluminium from tissues by chelation. The tendency of aluminium to cause constipation is an added disadvantage. Therefore, aluminium as a phosphate binder in CKD is controversial, and most clinicians advocate that it should only be used in shorter courses (e.g. months).

Vitamin D deficiency and hyperparathyroidism

Vitamin D deficiency may be treated with the synthetic vitamin D analogue 1 α -hydroxycholecalciferol (alfacalcidol) at 0.25–1 microgram/day or 1,25-dihydroxycholecalciferol (calcitriol) at 1–2 micrograms/day. The serum calcium level should be monitored, and the dose of alfacalcidol or calcitriol adjusted accordingly. Hyperphosphataemia should be controlled before starting vitamin D therapy because the resulting increase in the serum calcium concentration on commencing vitamin D treatment may result in soft tissue calcification.

Paricalcitol is a synthetic, biologically active vitamin D analogue that selectively upregulates the vitamin D receptor in the parathyroid glands, reducing PTH synthesis and secretion. It also upregulates the calcium-sensing receptor in the parathyroids and reduces PTH by inhibiting parathyroid proliferation, PTH synthesis and secretion without affecting calcium or phosphorus levels. Paricalcitol is expensive, and the clinical evidence for the use of the drug is not strong enough at present for routine clinical practice.

The rise in 1,25-dihydroxycholecalciferol and calcium levels that result from starting vitamin D therapy usually suppresses the production of PTH by the parathyroids. If vitamin D therapy does not correct PTH levels, then parathyroidectomy, to remove part or most of the parathyroid glands, may be needed. This surgical procedure was once commonly performed on patients with CKD, but is now less frequent because of effective vitamin D supplementation and the introduction of cinacalcet.

Cinacalcet is a calcimimetic which increases the sensitivity of calcium-sensing receptors to extracellular calcium ion; this results in reduced PTH production. The benefit of this treatment is the suppression of PTH without resultant hypercalcaemia. It is recommended for use as an alternative to parathyroidectomy for patients who are not fit enough to undergo this procedure (NICE, 2007).

Common therapeutic problems in CKD are summarised in Table 18.4.

Renal transplantation

Renal transplantation has transformed the outlook for many patients with ESRD. The clinical outcomes of renal transplantation are now excellent. One-year patient and graft survival rates are 98% and 90–95%, respectively, and most patients who receive a transplant will never need to return to dialysis treatment. A renal transplant performed today in the developed world will continue to function, on average, in excess of

Table 18.4 Common therapeutic problems in chronic renal failure

Problem	Comment
Drug choice	Care with choice/dose of all drugs. Care to avoid renotoxic agents pre-dialysis to preserve function. Beware of herbal therapies because some contain immune system boosters (reverse immunosuppressant effects) and some are nephrotoxic.
Drug excretion	Chronic kidney disease will lead to accumulation of drugs and their active metabolites if they are normally excreted by the kidney.
Dietary restrictions	Restrictions on patient are often severe. Fluid allowance includes foods with high water content, e.g. gravy, custard, and fruit.
Hypertension	Frequently requires complex multiple-drug regimens. Calcium channel blockers can cause oedema that might be confused with fluid overload.
Analgesia	Side effects are increased. Initiate with low doses and gradually increase. Avoid pethidine as metabolites accumulate. Avoid non-steroidal anti-inflammatory drugs unless specialist advice is available.
Anaemia	Epoetin requires sufficient iron stores to be effective. Absorption from oral iron supplements may be poor, and intravenous iron supplementation might be required. Care is required to make sure that epoetin use does not produce hypertension.
Immunosuppression	Use of live vaccines should be avoided (i.e. bacille Calmette–Guérin, MMR [measles, mumps, rubella], mumps, oral polio, oral typhoid, smallpox, yellow fever).
Pruritus (itching)	Symptoms can be severe. Treat with chlorphenamine; less sedating antihistamines are often less effective. Some relief given with topical agents, e.g. crotamiton.
Restless legs	Involuntary jerks can prevent sleep. Clonazepam 0.5–1 mg at night may help.

15 years. However, an important consideration is that renal transplantation is the treatment of choice for patients with ESRD who are fit to receive a renal transplant; this recognises that many patients with advanced kidney disease are frail and elderly and/or have a number of co-existing medical problems such that they are not fit to undergo a major operation (implantation of the kidney) or to tolerate the immunosuppressive drugs that are required to prevent transplant rejection. This means that at any given time the majority of patients with ESRD are not actually on a national waiting list for a renal transplant.

For those patients who are fit enough to receive a renal transplant and are successfully transplanted, there is a profound survival benefit compared with remaining on dialysis treatment. The average transplant recipient lives two or three times as long as a matched dialysis patient who does not receive a renal transplant but remains on dialysis treatment. In addition, a transplant patient is less likely to be hospitalised and has a better quality of life than a dialysis patient. The secondary complications of CKD such as anaemia and bone disease resolve in many patients who are successfully transplanted. Furthermore, there are major health economic benefits to renal transplantation compared with dialysis. Transplantation is a far less expensive treatment than dialysis, particularly after the first year, when the large majority of the costs are limited to payment for the immunosuppressive drugs.

One of the major challenges for renal transplantation is the identification of a sufficient number of donor kidneys to fulfil demand. This is reflected in the increasing number of people

who are waiting for a kidney; in the UK the average time on the waiting list before transplantation is around 3 years. Kidneys donated for the national waiting list are harvested from deceased donors. At the time of donation, donors are classified as dead as a consequence of either brainstem or cardiac death; these are also called heart beating and non-heart beating donors, respectively.

There is a shortage in the numbers of deceased donor kidneys available for transplantation; therefore, living donor transplantation has become increasingly common. In addition to addressing the scarcity of donor organs, patients who receive kidney transplants from living donors have better outcomes than patients who receive deceased donor kidneys. This is due to a number of factors, including the quality of the organs; living donors undergo a detailed health screening and if there is any indication that they have significant medical problems they are excluded from donation.

One of the major factors responsible for excellent outcomes for kidney transplant recipients is the use of immunosuppressive drugs to control the response as the immune system of the recipient mounts against the donor kidney. This is called an alloresponse. Alloimmunity refers to an immune response against tissue derived from an individual of the same species as the recipient of the tissue.

The major disadvantage of all immunosuppressive agents is their relative non-specificity, in that they cause a general depression of the immune system. This exposes the patient to an increased risk of malignancy and infection, which is an important cause of morbidity and mortality.

Table 18.5 Mechanism of action of immunosuppressants commonly used following renal transplantation

Drug	Mechanism	Comment
Steroids	Bind to steroid receptors and inhibit gene transcription and function of T cells, macrophages and neutrophils	Prophylaxis against and reversal of rejection
Ciclosporin	Forms complex with intracellular protein cyclophilin → inhibits calcineurin; ultimately inhibits interleukin-2 synthesis and T cell activation	Long-term maintenance therapy against rejection
Tacrolimus	Forms complex with an intracellular protein → inhibits calcineurin	Long-term maintenance therapy against rejection Rescue therapy in severe or refractory rejection
Sirolimus	Inhibits interleukin-2 cell signalling → blocks T cell cycling and inhibits B cells	Usually used in combination with ciclosporin ± steroids
Mycophenolate	Inhibits inosine monophosphate dehydrogenase → reduces nucleic acid synthesis → inhibits T and B cell function	Usually used in combination with ciclosporin/tacrolimus ± steroids
Azathioprine	Incorporated as a purine in DNA → inhibits lymphocyte and neutrophil proliferation	Usually used in combination with ciclosporin/tacrolimus ± steroids
Muromonab (OKT3, mouse monoclonal anti-CD3)	Binds to CD3 complex → blocks, inactivates or kills T cell; short $t_{1/2}$	Prophylaxis against rejection Reversal of severe rejection
Polyclonal horse/rabbit antilymphocyte or antilymphocyte globulin	Antibodies against lymphocyte proteins → alter T and B cell activity	Prophylaxis against rejection Reversal of severe rejection
Humanised or chimeric anti-CD25 (basiliximab and daclizumab)	Monoclonal antibodies that bind CD25 in interleukin-2 complex → prevent T cell proliferation	Prophylaxis against acute rejection in combination with ciclosporin and steroids

Immunosuppressants

The major pharmacological groups of immunosuppressive agents are summarised in [Table 18.5](#).

Transplant recipients receive a high load of immunosuppression at the time of transplantation; this is known as induction immunosuppression. Induction immunosuppression is to protect the transplant from the high immunological risk that is present in the first few weeks after surgery. In the months following the transplant, the immunosuppression load is then incrementally reduced. Most patients will reach long-term low-dose maintenance immunosuppression sometime between 6 and 12 months after the transplant. However, whilst the transplant remains in the recipient it continues to represent an immunological risk; although overt, late rejection is uncommon, it can occur at any time if the patient stops taking his or her immunosuppressants. For a transplant to last many years, sustained day-to-day adherence with treatment is essential.

The most common combination used at induction is the calcineurin inhibitor (CNI) tacrolimus, the antiproliferative agent mycophenolate mofetil (MMF) and corticosteroids. Most patients also receive antibody induction. The antibody that is most commonly used is a monoclonal anti-CD25 antibody for people at low or medium immunological risk and anti-T cell polyclonal antibodies (thymoglobulin or ATG) for people at high immunological risk. There is also increasing use of alemtuzumab, a humanised CD52-specific complement-fixing (lymphocyte-depleting)

antibody. Patients at high immunological risk include those who have lost a previous transplant because of rejection, the presence of preformed circulating anti-human leucocyte antigen (HLA) antibodies at the time of transplantation (sensitisation), and major HLA mismatches (particularly at HLA-DR) between donor and recipient. Guidelines for the use of immunosuppressive therapy in kidney transplant patients have been issued and are currently being revised ([NICE, 2004](#)). International consensus guidelines now recommend use of newer agents such as MMF and emphasise the use of tacrolimus (rather than ciclosporin) as the CNI of choice ([Kasiske et al., 2009](#)). Tacrolimus is associated with less acute rejection than ciclosporin and may be associated with better graft function at 1 year and less graft loss ([Knoll and Bell, 1999](#)). It should be noted that generic/proprietary formulations of some drugs (e.g. tacrolimus and ciclosporin) are not interchangeable.

Calcineurin inhibitors (ciclosporin and tacrolimus)

The discovery and development of ciclosporin and latterly tacrolimus has led to a step improvement in 1-year renal transplant survival rate from 50–70% to 85–95%.

In T cells that have been exposed to T cell receptor ligation (signal 1) and co-stimulation (signal 2), there is activation of intra-cytoplasmic signalling pathways that include mobilisation of a molecule called calcineurin. Calcineurin contributes to the activation of a molecule called nuclear factor of activated T cells.

This factor then migrates to the nucleus and initiates transcription of interleukin-2 (IL-2) and other proinflammatory cytokines which are involved in driving an activated T cell into a proliferative phase, so that it makes multiple copies of itself. Cyclosporin and tacrolimus affect calcineurin through blocking binding proteins (cyclophilin and tacrolimus-binding protein, respectively) that are important for calcineurin activity.

The action of CNIs is partially selective in that they predominantly target T cells and have no direct effect on B cells; as a consequence, CNIs are associated with infections seen in people with deficiencies in the cellular limb of the immune response. These are predominantly intracellular infections such as viral, fungal, protozoal and mycobacterial infections.

Both cyclosporin and tacrolimus are critical dose drugs. That is, there is a narrow therapeutic window between underdosing and toxicity. Both drugs, therefore, require monitoring by serum levels. Trough levels are usually taken 12 hours after the previous dose and immediately before the next dose.

Cyclosporin

Cyclosporin causes a wide range of side effects, including nephrotoxicity, hypertension, fine muscle tremor, gingival hyperplasia, nausea and hirsutism. Hyperkalaemia, hyperuricaemia, hypomagnesaemia and hypercholesterolaemia may also occur. Nephrotoxicity is a particularly serious side effect and occasionally necessitates the withdrawal of cyclosporin. There is major inter-patient and intra-patient variation in absorption of cyclosporin. Blood level monitoring is required to achieve maximum protection against rejection and minimise the risk of side effects. The range regarded as acceptable varies between centres, but for cyclosporin it is commonly around 100–200 ng/mL in the first 6 months after transplantation and 80–150 ng/mL from 6 months onwards.

Cyclosporin interacts with a number of drugs that either lead to a reduction in cyclosporin levels, increase the risk of rejection or cause an elevation in cyclosporin levels leading to increased toxicity. Some drugs enhance the nephrotoxicity of cyclosporin (Box 18.2).

Cyclosporin should not be administered with grapefruit juice, which should also be avoided for at least an hour pre-dose, because this can result in marked increases in blood concentrations. This effect appears to be due to inhibition of enzyme systems in the gut wall resulting in transiently reduced cyclosporin metabolism.

Tacrolimus

Tacrolimus is not chemically related to cyclosporin, but acts by a similar mechanism. The side effect profile is similar to that of cyclosporin with some subtle differences. Disturbances of glucose metabolism leading to impaired glucose tolerance and new-onset diabetes after transplantation occurs in around 10–15% of patients who receive tacrolimus; this is twice as common as the incidence seen in patients who receive cyclosporin. In contrast, hirsutism is less of a problem in patients who receive tacrolimus than those who receive cyclosporin. In patients who are commenced on cyclosporin and then experience an episode of acute

Box 18.2 Examples of drug interactions involving cyclosporin

- Reduce cyclosporin serum levels (hepatic enzyme inducers): phenytoin, phenobarbital, rifampicin, isoniazid
- Increase cyclosporin serum levels (hepatic enzyme inhibitors): diltiazem, erythromycin, corticosteroids, ketoconazole
- Enhance cyclosporin nephrotoxicity: aminoglycosides, amphotericin, co-trimoxazole, melphalan

rejection, conversion to tacrolimus lowers the risk of recurrent rejection. Tacrolimus is an easier drug to use than cyclosporin. Careful monitoring is required with a target level of 8 ng/mL in the first weeks following transplantation, which is usually decreased in patients who follow an uncomplicated course to 5 ng/mL from 6 months.

Steroids

Prednisolone is the oral agent commonly used for immunosuppression after renal transplantation, whereas high-dose i.v. methylprednisolone is given as a single dose at induction with further use limited for cases of acute rejection. The maintenance dose of prednisolone to minimise adrenal suppression is around 0.1 mg/kg/day given as a single dose in the morning. The use of steroid therapy often leads to complications, particularly if high doses are given for long periods. In addition to a cushingoid state, the use of steroids may cause gastro-intestinal bleeding, hypertension, dyslipidaemia, diabetes, osteoporosis and mental disturbances. Patients who are temporarily unable to take oral prednisolone should be given an equivalent dose of hydrocortisone i.v.

Developments in therapy have led to an increasing use of steroid avoidance regimens. This term is misleading because patients still receive steroids, but use is restricted to the first week of transplantation. Currently, there is no long-term evidence to show this approach provides equivalence to a continuous steroid dosing regimen, but 1-year outcomes are comparable (Haller et al., 2016). If steroids are subsequently withdrawn months after the transplant, then outcomes with steroid avoidance regimens are worse.

Azathioprine

Azathioprine is derived from 6-mercaptopurine and is, therefore, an antimetabolite which reduces DNA and RNA synthesis-producing immunosuppression.

Azathioprine is given orally in a dosage of up to 2 mg/kg/day. There is no advantage in giving it in divided doses. Because azathioprine interferes with nucleic acid synthesis, it may be mutagenic, and pharmacy and nursing staff should avoid handling the tablets. Azathioprine has a significant drug interaction with allopurinol, causing fatal marrow suppression, and this combination should be avoided.

Mycophenolate mofetil

MMF is a prodrug of mycophenolic acid. It inhibits the enzyme inosine monophosphate dehydrogenase needed for guanosine

synthesis which leads to reduced B cell and T cell proliferation. However, other rapidly dividing cells are less affected, as guanosine is produced in other cells. Consequently, mycophenolate has a more selective mode of action than azathioprine.

The drug is given in combination with tacrolimus at a dosage of 1 g twice a day which can subsequently be reduced after 6 weeks to 750 mg twice a day. A dose of 1.5 g twice a day is prescribed when used in combination with ciclosporin because the ciclosporin interferes with enterohepatic recirculation of mycophenolate metabolites with consequent lower exposure at a similar dose.

Compared with azathioprine, MMF reduces the risk of acute rejection episodes and improves long-term graft survival. However, it is a more potent immunosuppressant than azathioprine and is associated with a significantly increased risk of opportunistic infections.

Sirolimus

Sirolimus is a macrolide antibiotic that binds to the FKBP-25 cellular receptor. This complex initiates a sequence that produces modulation of regulatory kinases that ultimately interfere with the proliferative effects of IL-2 on lymphocytes. The progression of T cells from the G₁ to S phase is blocked, thus inhibiting cell division and therefore cell proliferation.

Adverse effects include hyperkalaemia, hypomagnesaemia, hyperlipidaemia, hypertriglyceridaemia, leukopenia, anaemia, impaired wound healing and joint pain. Sirolimus should not be used in the first few weeks after transplantation because it inhibits wound healing through an antiproliferative effect. In combination with CNIs, it produces additive nephrotoxicity; when used with MMF it increases the risk of marrow suppression and mucosal side effects. Most experts currently limit the use of sirolimus to patients who have declining kidney function as a consequence of CNIs, but where graft function is still maintained to a GFR greater than 40 mL/min without significant proteinuria. Sirolimus may improve the outcomes of patients with skin cancer, and switching from a CNI to sirolimus in patients in this setting is increasingly utilised in clinical practice.

Monoclonal antibodies

The humanised or chimeric anti-CD25 monoclonal antibodies basiliximab and daclizumab are clinically similar and bind to CD25 in the IL-2 complex of activated T lymphocytes. This renders all T cells resistant to IL-2, and therefore prevents T cell proliferation. They are used as prophylaxis against acute rejection in combination with CNIs and steroids (NICE, 2004). Daclizumab is currently not available in the UK.

Polyclonal antibodies

Polyclonal antibodies were the first antibodies used as immunosuppressants and contain antibodies with a number of different antigen-combining sites. Polyclonal antibodies are used perioperatively as prophylaxis against rejection and in some cases to reverse episodes of severe rejection. The main preparations are antithymocyte globulin (ATG) or antilymphocyte globulin (ALG).

ATG is produced from rabbit or equine serum immunised with human T cells. It contains antibodies to human T cells, which on injection will attach to, neutralise and eliminate most T cells, thereby weakening the immune response. ALG is similar to ATG, is of equine origin, but is not specific to T cells as it also acts on B cells.

Polyclonal antibodies may act to inhibit T cell-mediated immune responses through a variety of mechanisms, including depletion of circulating T cells, modulation of cell surface receptor molecules, induction of anergy and apoptosis of activated T cells.

The main drawback to the use of anti-T cell sera is the relatively high incidence of side effects, notably anaphylactic reactions including hypotension, fever and urticaria. These reactions are more frequently observed with the first dose and may require supportive therapy with steroids and antihistamines. Severe reactions may necessitate stopping treatment. Steroids and antihistamines may be given prophylactically to prevent or minimise allergic reactions. Pyrexia often occurs on the first day of treatment but usually subsides without requiring treatment. Tolerance testing by administration of a test dose is advisable, particularly in patients such as asthmatics who commonly experience allergic reactions. In the event of adverse reactions, ALG and ATG can be substituted for each other.

Other precautions

Transplant patients are given prophylactic antibiotic therapy for varying periods postoperatively because of the risks of infection associated with immunosuppression. Treatment with co-trimoxazole to prevent *Pneumocystis carinii*, isoniazid and pyridoxine in high-risk patients to prevent tuberculosis, valganciclovir to prevent cytomegalovirus, and nystatin or amphotericin to prevent oral candidiasis are commonly used. Vaccination with live organisms (e.g. bacille Calmette–Guérin, MMR [measles, mumps, rubella], oral poliomyelitis, oral typhoid) must be avoided in the immunosuppressed patient.

Implementation of regular dialysis treatment

End-stage renal failure is the point at which the patient will die without the institution of renal replacement by dialysis or transplantation.

The principle of dialysis is simple. The patient's blood and a dialysis solution are positioned on opposing sides of a semi-permeable membrane across which exchange of metabolites occurs. The two main types of dialysis used in CKD are haemodialysis and peritoneal dialysis. Neither has been shown to be superior to the other in any particular group of patients, and so the personal preference of the patient is important when selecting dialysis modality. Haemodialysis and acute peritoneal dialysis are discussed in Chapter 17.

Because patients with ESRD may require dialysis treatment for many years, adaptations to the process of peritoneal dialysis have been made that enable the patient to follow a lifestyle

as near normal as possible. Continuous ambulatory peritoneal dialysis involves a flexible non-irritant silicone rubber catheter (Tenckhoff catheter) that is surgically inserted into the abdominal cavity. Dacron cuffs on the body of the catheter become infiltrated with scar tissue during the healing process, causing the catheter to be firmly anchored in place. Such catheters may remain viable for many years. During the dialysis process thereafter, a bag typically containing 2.5 L of warmed dialysate and a drainage bag are connected to the catheter using aseptic techniques. Used dialysate is drained from the abdomen under gravity into the drainage bag, fresh dialysate is run into the peritoneal cavity and the giving set is disconnected. The patient continues his or her activities until the next exchange some hours later. The procedure is repeated regularly so that dialysate is kept in the abdomen 24 hours a day. This is usually achieved by repeating the process four times a day with an average dwell time of 6–8 hours. A number of different dialysis solutions are available of which the majority are glucose based.

Another form of peritoneal dialysis is known as automated peritoneal dialysis in which exchanges are carried out overnight while the patient sleeps. Dialysis fluid is exchanged, three to five times over a 10-hour period with volumes of 1.5–3 L each time. During the daytime the patient usually has a dwell of fluid within the abdominal cavity.

Because peritoneal dialysis is continuous and corrects fluid and electrolyte levels constantly, dietary and fluid restrictions are less stringent than required for patients treated with haemodialysis. Blood loss is also avoided, meaning that ESA requirements may be less. Unfortunately, peritoneal dialysis is not an efficient process; it only just manages to facilitate excretion of the substances required and, as albumin crosses the peritoneal membrane, up to 10 g of protein a day may be lost in the dialysate. It is also uncomfortable and tiring for the patient, and is contraindicated in patients who have recently undergone abdominal surgery.

Peritonitis is the most frequently encountered complication of peritoneal dialysis. Its diagnosis usually depends on a combination of abdominal pain, cloudy dialysate or positive microbiological culture. Empirical antibiotic therapy should, therefore, be commenced as soon as peritonitis is clinically diagnosed. Gram-positive cocci (particularly *Staphylococcus aureus*) and Enterobacteriaceae are the causative organisms in the majority of cases, while infection with Gram-negative species and *Pseudomonas* species are well recognised. Fungal infections are also seen, albeit less commonly.

Most centres have their own local protocol for antibiotic treatment of peritonitis. In one example, levofloxacin, a quinolone with good Gram-negative activity, is given orally, in combination with vancomycin, which has excellent activity against Gram-positive bacteria, being administered via the intraperitoneal route. As in all situations, the antibiotic regimen should be adjusted appropriately after the results of microbiological culture and sensitivity have been obtained.

Haemodialysis is particularly suitable for patients producing large amounts of metabolites, such as those with high nutritional demands or a large muscle mass, where these substances are produced faster than peritoneal dialysis can remove them. It also provides a backup for those patients in whom peritoneal dialysis has failed.

The various techniques of haemofiltration, a technique related to haemodialysis, are also discussed in detail in [Chapter 17](#).

Case studies

Case 18.1

Mr D, a 19-year-old undergraduate student, visited his university health centre describing a 3-month history of fatigue, weakness, nausea and vomiting that he had attributed to 'examination stress'. His medical history indicated an ongoing history of bed wetting from an early age. Laboratory results from a routine blood screen showed the following:

		Reference range
Sodium	137 mmol/L	135–145 mmol/L
Potassium	4.8 mmol/L	3.5–5.0 mmol/L
Phosphate	2.5 mmol/L	0.9–1.5 mmol/L
Calcium	1.6 mmol/L	2.20–2.55 mmol/L
Urea	52 mmol/L	3.0–6.5 mmol/L
Creatinine	620 µmol/L	50–120 µmol/L
Haemoglobin	7.5 g/dL	13.5–18.0 g/dL

Subsequent referral to a specialist hospital centre established a diagnosis of CKD secondary to reflux nephropathy.

Question

Explain the signs and symptoms experienced by Mr D and the likely course of his disease?

Answer

Mr D is suffering from the signs and symptoms of uraemia resulting from CKD. Mechanical reflux damage to his kidneys has compromised renal function and resulted in an accumulation of toxins, including urea and creatinine, that, in turn, have contributed to his nausea, vomiting and general malaise. His biochemical results indicate other features typical of uraemic syndrome associated with chronic renal failure. The low haemoglobin is indicative of reduced erythropoietin production following progressive kidney damage. Renal osteodystrophy is also present, because inadequate vitamin D production and the raised serum phosphate have contributed to the hypocalcaemia.

This patient is likely to have remained symptom free for a period of years despite progressively worsening renal function. The kidneys operate with a substantial functional reserve under normal conditions. Patients generally remain asymptomatic as their renal reserve diminishes. Eventually there is a failure in the ability of the damaged kidney to compensate and symptoms appear late in the condition.

Case 18.2

Mr K, a 43-year-old man with established CKD, had been maintained for 3 years on continuous ambulatory peritoneal dialysis. He was admitted to hospital for cadaveric renal transplantation. On examination he was found to have slight ankle oedema. He weighed 60 kg, his BP was 135/90 mmHg and pulse rate 77 beats/min. He was administered the following immunosuppressants pre-operatively: an anti-CD25 antibody, tacrolimus, mycophenolate and prednisolone.

Question

How should the immunosuppressants be administered to Mr K, and how should immunosuppression be managed postoperatively?

Answer

Anti-CD25 antibodies and high-dose methylprednisolone are given i.v. at the time of the operation. Typically tacrolimus at 200–300 micrograms/kg/day is given as two split doses, although once-daily formulations are also available. Specific tacrolimus preparations are not interchangeable, and as a result they must be prescribed by brand name; changes between preparations must only be made by a transplant specialist. Mycophenolate mofetil (MMF) at 1 g twice a day and prednisolone at 10 mg twice a day are given as oral doses to continue in the days and weeks following transplantation. These are commenced within 12 hours of the operation. In living kidney donation where the transplant operation is planned, patients are preloaded for several days before the transplant. i.v. tacrolimus is available, but should only be used in exceptional circumstances, usually when the gut is not working and all drugs and nutrition need to be given by the parenteral route. Early dose adjustments in tacrolimus following transplantation are common and directed by drug levels. These are checked daily for the first week following transplantation; by 6 months they will be checked on alternate weeks. In the long-term the median dose of tacrolimus is around 2 mg twice a day and the dosage of mycophenolate mofetil can be reduced to 500–750 mg twice a day in the large majority of patients. The dosage of prednisolone is titrated down so that by 3 months it is 5–10 mg/day. Acute rejection episodes, diagnosed on a renal biopsy performed for a decline in graft function, are treated with high-dose steroids. For antibody-mediated (severe) rejection, plasma exchange and i.v. immunoglobulin are used.

Case 18.3

Mr A is a patient with CKD secondary to chronic interstitial nephritis. He reports chronic fatigue, lethargy and breathlessness on

exertion, palpitations and poor concentration. His recent haematological results were found to be:

		Reference range
Haemoglobin	7.6 g/dL	13.5–17.5 g/dL
Red cell count	$2.92 \times 10^9 \text{ L}^{-1}$	$4.5\text{--}6.5 \times 10^9 \text{ L}^{-1}$
Haematocrit	0.208	0.40–0.54
Serum ferritin	88.0 micrograms/L	15–300 micrograms/L

Question

Explain Mr A's symptoms and haematological results, and outline the optimal treatment.

Answer

Mr A's symptoms are most likely a result of a normochromic, normocytic anaemia caused by CKD. Levels of erythropoietin produced by the kidney are reduced in renal failure. Production of erythropoietin from extra-renal sites (e.g. liver) are not sufficient to maintain erythropoiesis, which is also inhibited by uraemic toxins and hyperparathyroidism. The anaemia associated with renal failure is further compounded by a reduction in red cell survival through low-grade haemolysis, bleeding from the gastro-intestinal tract, and blood loss through dialysis, aluminum toxicity which interferes with haem synthesis, and iron deficiency, usually through poor dietary intake. Therapy with erythropoietin-stimulating agent is the treatment of choice. However, iron and folate deficiencies should be corrected if epoetin therapy is to be successful. Iron demands are generally raised during epoetin treatment, and iron status should be regularly monitored. If serum ferritin declines to less than 200 micrograms/L, then iron supplementation should be started. Often i.v. iron is required to provide an adequate supply.

19 Hypertension

Helen Williams

Key points

- Hypertension can be defined as a condition in which blood pressure (BP) is elevated to a level likely to lead to adverse consequences. There is no clear-cut blood pressure threshold separating normal blood pressure from high blood pressure, with hypertension arbitrarily defined as a systolic blood pressure equal to or greater than 140 mmHg and/or diastolic blood pressure equal to or greater than 90 mmHg. The risk of complications is related to the degree to which blood pressure is elevated.
- The World Health Organization has identified hypertension as the leading risk factor for death worldwide. The complications of hypertension include stroke, myocardial infarction, heart failure, renal failure and dissecting aortic aneurysm. Modest reductions in blood pressure result in substantial reductions in the relative risks of these complications.
- Hypertension should not be seen as a risk factor in isolation, and decisions on management should not focus on blood pressure alone but on the total cardiovascular risk present for an individual, which, in the absence of established cardiovascular (CV) disease, should be calculated using a validated CV risk calculator such as QRisk2.
- The diagnosis of hypertension should be based on the results of ambulatory blood pressure monitoring or home blood pressure monitoring, not on clinic blood pressure readings.
- Non-pharmacological interventions are important and include weight reduction, avoidance of excessive salt and alcohol, increased intake of fruit and vegetables and regular physical activity. Other cardiovascular risk factors, such as smoking, dyslipidaemia and diabetes, should be addressed.
- Different antihypertensive drugs are available. Drug choice should aim to maximise blood-pressure-lowering effectiveness and minimise patient side effects.
- The most appropriate choice of initial drug therapy depends on the age and racial origin of the patient, as well as the presence of other medical conditions. For patients younger than 55 years, an angiotensin-converting enzyme (ACE) inhibitor is recommended as first-line treatment. For older patients and people of black African or Caribbean origin of any age, a calcium channel blocker is an appropriate initial choice. Most people need a combination of drugs to achieve adequate blood pressure control.

Hypertension (high blood pressure) is an important risk factor for the future development of cardiovascular disease. It can be defined as a condition in which blood pressure (BP) is elevated to a level likely to lead to adverse consequences and where clinical benefit will be obtained from BP lowering. BP

measurement includes systolic and diastolic components, and both are important in determining an individual's cardiovascular risk.

Blood pressure is continuously distributed in the population, and there is no clear cut-off point between hypertensive and normotensive subjects, although a figure of systolic/diastolic blood pressure of 140/90 mmHg is considered the upper limit of 'normal'. Hypertension has therefore been arbitrarily defined as a systolic blood pressure above 140 mmHg or a diastolic blood pressure above 90 mmHg, or both. Hypertension is largely a condition affecting older individuals. Whereas diastolic pressure peaks at age 50, systolic pressure continues to increase with advancing age, and hence isolated systolic hypertension is a common feature of older age. Generally, the risk of cardiovascular disease doubles for every 20/10-mmHg rise in blood pressure.

The cardiovascular complications associated with hypertension are shown in [Box 19.1](#). The most common and important of these are stroke and myocardial infarction. The risk associated with increasing blood pressure is continuous, with each 2-mmHg rise in systolic blood pressure associated with a 7% increased risk of mortality from ischemic heart disease and a 10% increased risk of mortality from stroke ([National Institute for Health and Care Excellence \[NICE\], 2011](#)). The risk of heart failure is increased sixfold in hypertensive subjects. Meta-analysis of clinical trials has indicated that these risks are reversible, with relatively modest reductions in blood pressure of 10/6 mmHg associated with a 38% reduction in stroke and 16% reduction in coronary events ([Collins et al., 1990](#)), whereas a 5-mmHg reduction in blood pressure is associated with a 25% reduction in risk of renal failure. There is considerable evidence

Box 19.1 Complications of hypertension

- Myocardial infarction
- Stroke
 - Cerebral/brainstem infarction
 - Cerebral haemorrhage
 - Lacunar syndromes
 - Multi-infarct disease
- Hypertensive encephalopathy/malignant hypertension
- Dissecting aortic aneurysm
- Hypertensive nephrosclerosis
- Peripheral vascular disease

from clinical trials to demonstrate that the treatment of subjects with blood pressures above the threshold (BP >140/90 mmHg) currently used in clinical practice results in important clinical benefits.

The absolute benefits of blood pressure lowering achieved as a result of these relative risk reductions depend on the underlying level of cardiovascular risk present for an individual. High-risk subjects gain more benefit in terms of events saved per year of therapy. Absolute risk is highest in those who already have evidence of cardiovascular disease, such as previous myocardial infarction, transient ischaemic attack or stroke, or who have other evidence of cardiovascular dysfunction such as electrocardiogram (ECG) or echocardiograph abnormality. Risk is also increased in the elderly and in people with diabetes or renal failure and is further enhanced by other risk factors, such as smoking, dyslipidaemia, obesity and sedentary lifestyle. In those under the age of 75, men are at greater risk than women. Cardiovascular risk of an individual with no known cardiovascular disease can be estimated using cardiovascular risk calculators, such as QRisk (UK) (<https://www.qrisk.org/>), SCORE (Europe) (<https://www.escardio.org/Education/Practice-Tools/CVD-prevention-toolbox/SCORE-Risk-Charts#>) and ASSIGN (Scotland) (<http://assign-score.com>).

Epidemiology

Hypertension is a very common condition. It is estimated that approximately 25% of the adult population has hypertension, rising to above 50% of people over the age of 60 years old (NICE, 2011), although much of this remains undiagnosed.

In 90–95% of cases of hypertension, there is no underlying medical illness to cause high blood pressure. This is termed ‘essential’ hypertension, so named because at one time it was erroneously believed to be an ‘essential’ compensation mechanism to maintain adequate circulation. The precise aetiology of essential hypertension is currently unknown. Genetic factors clearly play a part because the condition clusters in families, with hypertension being twice as common in subjects who have a hypertensive parent. Genetic factors account for about one-third of the blood pressure variation between individuals, although no single gene appears to be responsible except in some rare conditions such as polycystic kidney disease and other metabolic conditions such as Liddle’s syndrome (Beevers et al., 2001). The remaining 5–10% of cases are secondary to some other disease process (Box 19.2).

Hypertension is more common in black people of African or Caribbean family origin, who are also at particular risk of stroke and renal failure. Hypertension is exacerbated by other factors, for example, high salt or alcohol intake or obesity.

Regulation of blood pressure

The mean blood pressure is the product of cardiac output and total peripheral resistance. In most hypertensive individuals, cardiac output is not increased, and high blood pressure arises as a

Box 19.2 Causes of hypertension

Primary hypertension (90–95%)

- Essential hypertension

Secondary hypertension (5–10%)

- Renal diseases
- Endocrine diseases
 - Steroid excess: hyperaldosteronism (Conn’s syndrome); hyperglucocorticoidism (Cushing’s syndrome)
 - Growth hormone excess: acromegaly
 - Catecholamine excess: phaeochromocytoma
 - Others: pre-eclampsia
- Vascular causes
- Renal artery stenosis: fibromuscular hyperplasia; renal artery atheroma; coarctation of the aorta
- Drugs
 - Sympathomimetic amines
 - Oestrogens (e.g. combined oral contraceptive pills)
 - Ciclosporin
 - Erythropoietin
 - Non-steroidal anti-inflammatory drugs
 - Steroids

result of increased total peripheral resistance caused by constriction of small arterioles.

Control of blood pressure is important in evolutionary terms, and homeostatic reflexes have evolved to provide blood pressure homeostasis. Minute-to-minute changes in blood pressure are regulated by the baroreceptor reflex, whereas the renin–angiotensin–aldosterone system is important for longer-term salt, water and blood pressure control. Long-term increases in shear stress can cause vascular remodelling of the endothelium, which leads to the formation of a procoagulant rather than anticoagulant surface. At the same time, systems that lead to vascular relaxation, for example, nitric oxide, are overcome by increased sensitivity to vasoconstrictor substances such as endothelin, which predispose to vascular disease and further increases in peripheral resistance, which lead to a vicious cycle that increases blood pressure further due to the increase in vascular resistance. Other substances with a role in controlling blood pressure include atrial natriuretic peptide, bradykinin and antidiuretic hormone.

Clinical presentation

Hypertension is asymptomatic in most cases and is often, therefore, an incidental finding when subjects present with unrelated conditions or may be identified during a cardiovascular risk assessment. Severe cases may present with headache, visual disturbances or evidence of target organ damage (including stroke, ischaemic heart disease, renal failure or retinopathy). In the UK, adults, particularly those over 40 years of age, should have their blood pressure checked at least every 5 years, with an annual review for those with high normal values in the range 135–139 mmHg systolic or 85–89 mmHg diastolic.

Malignant (accelerated) hypertension

Malignant or accelerated hypertension is an uncommon condition characterised by greatly elevated blood pressure (usually BP >220/120 mmHg) associated with evidence of ongoing small vessel damage. Fundoscopy may reveal papilloedema, haemorrhages and/or exudates, and renal damage can manifest as haematuria, proteinuria and impaired renal function. The condition may be associated with hypertensive encephalopathy, which is caused by small vessel changes in the cerebral circulation associated with cerebral oedema. The clinical features are confusion, headache, visual loss, seizures and coma. Brain imaging, particularly magnetic resonance imaging (MRI), usually demonstrates extensive white matter changes. Malignant hypertension is a medical emergency that requires hospital admission and rapid control of blood pressure over 12–24 hours towards normal levels.

Urgent specialist care is recommended for patients with accelerated hypertension, defined as BP usually higher than 180/110 mmHg with signs of papilloedema and/or retinal haemorrhage or suspected pheochromocytoma (labile or postural hypotension, headache, palpitations, pallor and diaphoresis) (NICE, 2011).

Management of hypertension

In the UK, the management of hypertension is guided by guidelines produced by NICE (2011). Joint guidelines from the European Society of Hypertension and European Society of Cardiology were published in 2013 (Mancia et al., 2013).

Diagnosis of hypertension

Blood pressure should be measured using a validated manual or automated sphygmomanometer, which should be well maintained and regularly calibrated. Blood pressure should initially be measured in both arms, and if there is a difference of more than 20 mmHg sustained after repeat measurement, the arm with the highest value should be used for subsequent monitoring readings. Differences of more than 15 mmHg between arms may indicate risk of underlying vascular disease and an increased risk of all-cause and cardiovascular (CV) mortality (Clark et al., 2012).

The subject should be relaxed, and at least at the first presentation, blood pressure should be measured in both the sitting and the standing positions to identify any postural changes. An appropriate-sized cuff should be used because one that is too small will result in an overestimation of the patient's blood pressure. The arm should be supported level with the heart. Where blood pressure is measured manually, the Korotkov sounds appear (the first phase) and disappear (the fifth phase) over the brachial artery as pressure in the cuff is released. Cuff deflation should occur at approximately 2 mmHg per second to allow accurate measurement of the systolic and diastolic blood pressures. The fourth Korotkov phase (muffling of sound) has previously been used for diastolic blood pressure measurement but is not currently recommended unless Korotkov V cannot

be defined. Where blood pressure is measured using an automated device, it is important to palpate the radial or brachial pulse before measuring blood pressure to identify if there is a pulse irregularity, for example, atrial fibrillation. In such situations the automated device may not measure blood pressure accurately, and therefore blood pressure should be measured manually.

If the manual or automated blood pressure reading is 140/90 mmHg or higher, a second measurement should be taken, and if the result is substantially different from the first, a third measurement should be taken. The lower of the last two measurements should be recorded as the clinic blood pressure.

Having established that the blood pressure in the clinic setting is 140/90 mmHg or greater, a diagnosis of hypertension should be confirmed by ambulatory blood pressure monitoring (ABPM) or home blood pressure monitoring (HBPM), except in the case of severe hypertension (systolic blood pressure equal to or greater than 180 mmHg and diastolic blood pressure equal to or greater than 110 mmHg), when the treatment should be initiated immediately.

Ambulatory or home blood pressure measurements

NICE (2011) recommended that ambulatory or home blood pressure monitoring should be used to confirm the diagnosis of blood pressure because some people develop excessive and unrepresentative blood pressure rises when in the clinic setting, so-called 'white-coat' hypertension. White-coat hypertension can be largely excluded by 24-hour ABPM or by the patients checking their blood pressure at home away from the clinic setting. A systematic review of the relative effectiveness of clinic BP monitoring and HBPM compared with ABPM in diagnosis of hypertension concluded that ABPM was the most accurate strategy based on the evidence available at the time (Hodgkinson et al., 2011). ABPM over 24 hours is also useful for patients who have unusual variability in blood pressure, resistant hypertension or symptoms suggesting hypotension. Home blood pressure measurement is inexpensive, but it is important to have a machine of validated accuracy that the patient can use properly. Because ambulatory and home blood pressure measurements are usually lower than clinic recordings, NICE (2011) recommended that the diagnostic threshold for hypertension using these strategies should be systolic BP equal to or greater than 135 mmHg and/or diastolic BP equal to or greater than 85 mmHg.

Hypertension classification

The NICE (2011) guidance classifies hypertension as follows:

- Stage 1 hypertension: Clinic blood pressure is 140/90 mmHg or higher, and subsequent ABPM daytime average or HBPM average blood pressure is 135/85 mmHg or higher.
- Stage 2 hypertension: Clinic blood pressure is 160/100 mmHg or higher, and subsequent ABPM daytime average or HBPM average blood pressure is 150/95 mmHg or higher.
- Severe hypertension: Clinic systolic blood pressure is 180 mmHg or higher or clinic diastolic blood pressure is 110 mmHg or higher.

Assessment of the hypertensive patient

Secondary causes

Although most cases of hypertension are essential or primary, it is important to take a careful history, checking for features that might suggest a possible secondary cause of hypertension. Examples would be symptoms of renal disease, such as haematuria or polyuria, or the paroxysmal symptoms that suggest the rare diagnosis of pheochromocytoma and include headache, postural dizziness and syncope. A careful physical examination should be performed for abdominal bruits, which suggests possible renal artery stenosis; radiofemoral delay, which suggests coarctation of the aorta; and palpable kidneys, which suggests polycystic kidney disease. Laboratory analysis should include a full blood count, electrolytes, urea, creatinine and urinalysis, checking the albumin/creatinine ratio (ACR) as well as for glucosuria. In some patients, further investigations may be appropriate, for example, ultrasound of the abdomen or isotope renogram where renal disease is suspected. A renin/angiotensin ratio is a useful screening test to investigate for possible hyperaldosteronism, and serum metanephrine and urinary catecholamines may detect underlying pheochromocytoma.

A low serum potassium may alert to the presence of hyperaldosteronism, but it should be remembered that renin levels are suppressed by β -blockers and aldosterone by ACE inhibitors and receptor antagonists. A very high aldosterone/renin ratio may suggest Conn's syndrome or primary hyperaldosteronism. This is usually caused by a benign adenoma or simple hyperplasia within the zona glomerulosa of the adrenal gland, the presence of which may be demonstrated by computed tomography (CT) or magnetic resonance imaging (MRI) scanning. The tumours may be surgically resected, but where there is a suggestion of hyperaldosteronism and no obvious tumour on imaging, patients may still respond to spironolactone, an aldosterone antagonist, while remaining relatively resistant to other antihypertensives.

Contributing factors

The patient should also be assessed for possible contributory factors to the development of hypertension, such as obesity, excess alcohol or salt intake and lack of exercise. Occasionally, hypertension may be provoked by the use of drugs (see [Box 19.2](#)), including over-the-counter medicines used as cold and flu remedies. Other risk factors should also be documented and addressed, for example, smoking, diabetes and hyperlipidaemia. It is important to establish whether there is a family history of cardiovascular disease.

Evidence of end-organ damage

The patient should also be examined carefully for evidence of end-organ damage from hypertension. This should include examination of the optic fundi to detect retinal changes. An ECG should be performed to detect left ventricular hypertrophy or subclinical ischaemic heart disease. It is advisable to check the renal function and test the urine for signs of microalbuminuria,

which may be an indicator of a higher risk of future end-stage renal disease and overall vascular risk. The presence of end-organ damage indicates the need for early intervention with drug therapy to control blood pressure in patients with stage 1 hypertension.

Determination of cardiovascular risk

An accurate assessment of cardiovascular disease risk is essential before recommending appropriate management in hypertension. Patients with documented atheromatous vascular disease, for example, previous myocardial infarction or stroke, angina or peripheral vascular disease are at high risk of recurrent events. Similarly, patients with evidence of target organ damage are at higher risk. For patients without established vascular disease, it is necessary to estimate cardiovascular risk (see [Chapter 24](#)). A 10-year cardiovascular disease (CVD) risk of 20% is regarded as an appropriate threshold for antihypertensive therapy in patients with stage 1 hypertension, with lipid-lowering therapy to be considered in patients with 10-year CVD risk of 10% or more. Treatment decisions based on these calculations will favour treatment in older patients. Although a younger patient with stage 1 hypertension may be at lower absolute risk over 10 years and may not meet the criteria for antihypertensive drug therapy and lipid treatment, the younger patient may be at higher lifetime and longer-term risk of premature death and vascular disease and, thus, still merit risk factor intervention.

Other factors to consider include microalbuminuria, which increases cardiovascular risk by a factor of 2–3, and the combination of reduced glomerular filtration rate (GFR) and microalbuminuria, which may increase risk by as much as sixfold ([Cirillo et al., 2008](#); [Sehestedt et al., 2009](#)).

Treatment

Non-pharmacological approaches

Non-pharmacological management of hypertension is an important aspect of treatment for all people with hypertension and is the first-line strategy in people with stage 1 hypertension at low risk of cardiovascular events. Lifestyle advice should include discussion of weight loss, diet and physical activity, as well as salt and alcohol intake and smoking cessation, with signposting to relevant local services to support the patient's efforts to address these issues. The impact of common lifestyle interventions on systolic blood pressure is summarised in [Table 19.1](#). In order to maximise potential benefit, patients should receive clear and unambiguous advice, including written information they can digest in their own time. Written advice for patients can be downloaded from the British Heart Foundation website (<http://www.bhf.org.uk>) and the Blood Pressure UK website (<http://www.bloodpressureuk.org/Home>).

In patients who are overweight, reductions in systolic blood pressure of 0.5–2 mmHg per kg weight loss can be achieved. The Dietary Approaches to Stop Hypertension (DASH) diet was evaluated in a clinical trial and found to lower blood pressure significantly (4.5/2.7 mmHg) compared with a typical US diet. This diet emphasises fruit, vegetables and low-fat dairy produce in addition to fish, low-fat poultry and whole grains while

Table 19.1 Impact of lifestyle modifications on blood pressure (DiPiro et al., 2014)

Modification	Recommendation	Approximate systolic blood pressure reduction (mmHg) ^a
Weight loss	Maintain normal body weight	5–20 per 10-kg weight loss
DASH-type diet	Consume a diet rich in fruits, vegetables and low-fat dairy products with reduced saturated and total fat	8–14
Reduced salt intake	Reduce daily dietary sodium intake	2–8
Physical activity	Regular aerobic physical activity (at least 30 min/day, most days of the week)	4–9
Moderation of alcohol intake	Limit consumption to 2 drinks/day in men and 1 drink/day in women and lighter-weight persons	2–4

^aEffects of implementing these modifications are time and dose dependent and could be greater for some patients.
DASH, Dietary approaches to stop hypertension.

minimising red meat, confectionaries and sweetened drinks (Appel et al., 1997). Subjects should reduce their salt intake, for example, by not adding salt to food when cooking, using spices to add flavour and not adding additional salt to food on the plate. A daily sodium intake of less than 100 mmol (i.e. 6 g sodium chloride or 2.4 g elemental sodium) should be the aim. There is a significant amount of hidden salt in processed meat, ready meals, cheese and even bread. A dietary assessment may be required to accurately quantify a patient's salt intake and advise on how reductions might be made. Most subjects will need to limit their calorie and saturated fat intake. Regular physical activity should be encouraged, at a level appropriate to the individual subject, aiming for a total of 150 minutes of moderate-intensity exercise per week or 75 minutes of high-intensity activity per week. This results in improved physical fitness and a reduction in blood pressure. Alcohol intake should be restricted to a maximum of 14 units per week, with 2 consecutive days alcohol-free. Although smoking does not have a direct effect on blood pressure, it increases cardiovascular risk, and patients should stop or, if this is not possible, reduce their cigarette consumption.

For low-risk stage 1 hypertension, lifestyle approaches are currently the only recommended intervention. However, if there is a more urgent need for drug treatment, for example, in stage 2 and severe hypertension, non-pharmacological interventions should occur in parallel with the initiation of drug therapy.

Drug treatment

Treatment thresholds

Treatment thresholds are summarised in Table 19.2. Patients with severe hypertension (>180/110 mmHg confirmed on several readings on the same occasion) should be treated immediately, and some guidance suggests that dual therapy should be commenced immediately in patients at high risk or with markedly high baseline blood pressure because monotherapy is unlikely to be effective (Mancia et al., 2013). People with stage 2 hypertension should have drug treatment initiated, alongside

Table 19.2 Threshold blood pressures for intervention

Category	Intervention
Stage 1 hypertension with no additional risk factors	Lifestyle advice and support If under 40 years old, consider referral for specialist assessment of secondary causes and possible target organ damage
Stage 1 hypertension with ≥ 1 of the following: <ul style="list-style-type: none"> established CVD target organ damage (left ventricular hypertrophy, chronic kidney disease, hypertensive retinopathy), renal disease, diabetes, a 10-year CVD risk $\geq 20\%$. 	Lifestyle advice and support Drug treatment for all ages
Stage 2 hypertension	Lifestyle advice and support Drug treatment for all ages
Severe hypertension	Lifestyle advice and support Drug treatment for all ages Refer to specialist care the same day if patient has: <ul style="list-style-type: none"> accelerated hypertension, blood pressure usually higher than 180/110 mmHg with signs of papilloedema, suspected phaeochromocytoma (labile or postural hypotension, headache, palpitations, pallor and diaphoresis).

CVD, Cardiovascular disease.

lifestyle advice. People below the age of 80 with stage 1 hypertension and the presence of other complications, such as evidence of target organ damage, cardiovascular complications, diabetes, renal disease or a calculated cardiovascular risk more than 20% over 10 years, should also have drug treatment

initiated alongside lifestyle advice. Patients with blood pressure in the high normal range (systolic BP 135–139 and/or diastolic BP 85–89 mmHg) should be reassessed annually, whereas those with blood pressure lower than this can be rechecked every 5 years.

Target blood pressures

The optimal blood pressure treatment target has not been established. Current guidance in the UK (NICE, 2011) suggests that for uncomplicated hypertension, patients should be treated to achieve a clinic blood pressure less than 140/90 mmHg, except those older than 80 years, for whom a clinic blood pressure target of 150/90 mmHg is recommended (Table 19.3). More aggressive targets for patients with comorbidities are summarised in Table 19.4.

Studies that have sought to establish optimal blood pressure treatment targets include the following:

- In the Hypertension Optimal Treatment (HOT) study (Hansson et al., 1998), patients were allocated diastolic target blood pressures of less than 90, 85 and 80 mmHg. The study struggled to stratify patients effectively into these treatment groups, but analysis suggested that the optimum target blood pressure was less than 140/85 mmHg, with little benefit in lowering to lower levels of 120/70 mmHg but also little evidence of harm.
- The UK Prospective Diabetes Study Group (1998a, 1998b) suggested ‘tight’ blood pressure control was better than less tight in patients with non-insulin-dependent diabetes (type II

Table 19.3 Target blood pressures in uncomplicated hypertension (NICE, 2011)

	Clinic BP target	ABPM/HBPM target (average daytime BP)
People younger than 80 years	<140/90 mmHg	<135/85 mmHg
People older than 80 years	<150/90 mmHg	<145/85 mmHg

ABPM, Ambulatory blood pressure monitoring; BP, blood pressure; HBPM, home blood pressure monitoring.

Table 19.4 Target clinic blood pressures in the presence of comorbidities (NICE, 2014a, 2015a, 2015b)

	Clinic BP target without complications	Clinic BP target with complications
People with type 1 diabetes mellitus	135/85 mmHg	130/80 mmHg
People with type 2 diabetes mellitus	140/80 mmHg	130/80 mmHg
People with chronic kidney disease	140/90 mmHg	130/80 mmHg

BP, Blood pressure.

diabetes). The targets in the UK Prospective Diabetes Study were ‘tight’ less than 150/85 mmHg and ‘less tight’ less than 180/105 mmHg, but the actually achieved blood pressures were lower, for example, 154/87 mmHg versus 144/82 mmHg.

- The Cardio-Sis study randomised non-diabetic subjects with systolic blood pressure greater than 150 mmHg to target systolic blood pressure of less than 140 or less than 130 mmHg (Verdecchia et al., 2009). The primary end point was left ventricular hypertrophy, although the secondary end point of a composite cardiovascular end point was reduced (as well as the primary end point) in the 130-mmHg group, with no increase in adverse events. This, however, is not robust enough evidence to recommend a reduction in blood pressure target levels and would require a larger study of hard clinical end points to confirm these findings.
- Most recently, the SPRINT study (SPRINT Research Group, 2015) sought to compare the impact of intensive blood pressure (target systolic <120 mmHg) versus standard treatment (target systolic <140 mmHg). The trial was stopped early due to a significant reduction in fatal and nonfatal major cardiovascular events and death from any cause in the intensive-treatment group. Higher rates of some adverse events were observed in this group, including hypotension, syncope, electrolyte abnormalities, and acute kidney injury or failure, but not injurious falls.

A recent systematic review was designed to assess the association of mean achieved systolic blood pressure levels with the risk of cardiovascular disease and all-cause mortality in adults with hypertension treated with antihypertensive therapy. It concluded that reducing systolic blood pressure to levels below currently recommended targets significantly reduces the risk of cardiovascular disease and all-cause mortality, with a mean achieved systolic BP of 120–124 mmHg being associated with the lowest CV risk (Bundy et al., 2017). Although the authors concluded that these data support more intensive control of systolic blood pressure among adults with hypertension, the study did not assess the potential adverse effects of such intensive blood-pressure-lowering therapy.

Antihypertensive drug classes

Renin–angiotensin system antagonists

Angiotensin converting enzyme (ACE) inhibitors block the conversion of angiotensin I to angiotensin II, whereas angiotensin receptor blockers (ARBs) block the action of angiotensin II at the angiotensin II type 2₁ receptor. Because angiotensin II is a vasoconstrictor and stimulates the release of aldosterone, antagonism results in vasodilation and potassium retention, as well as inhibition of salt and water retention. ACE inhibitors also block kininase production and, thus, prevent the breakdown of bradykinin. This appears to be important in the aetiology of ACE-inhibitor-induced cough, which is a troublesome side effect in 10–20% of users. ARBs do not inhibit kininase and are an appropriate choice for patients who are intolerant of ACE inhibitors because of cough. ACE inhibitors are also associated with a significant incidence of angioedema, which can in severe cases cause dangerous swelling of the pharyngolaryngeal area leading to stridor,

threatening the patient's airway. This adverse reaction is more common in black subjects; as a result, ARBs are preferred to ACE inhibitors in people of black African or Caribbean family origin.

Calcium channel blockers

These agents block slow calcium channels in the peripheral blood vessels and/or the heart. The dihydropyridine group work almost exclusively on L-type calcium channels in the peripheral arterioles and reduce blood pressure by reducing total peripheral resistance. In contrast, the effect of verapamil and diltiazem are primarily on the heart, reducing heart rate and cardiac output. Long-acting dihydropyridines are preferred because they are more convenient for patients and avoid large fluctuations in plasma drug concentrations that may be associated with adverse effects.

Although effective for lowering blood pressure and preventing cardiovascular events, adverse effects are common, for example, oedema and flushing. Gum hypertrophy may occur with dihydropyridines and constipation with verapamil. Concerns have previously been raised by observational studies (Psaty et al., 1995) and meta-analysis (Furberg et al., 1995) that there may be an increased risk of coronary heart disease in recipients of dihydropyridine calcium channel blockers, although this was likely associated with use of short-acting preparations causing large fluctuations in blood pressure. Randomised clinical trials utilising long-acting dihydropyridines have not confirmed these observations (Gong et al., 1996; Staessen et al., 1997) and have indicated that dihydropyridines have similar efficacy to thiazide diuretics in preventing cardiovascular events (Brown et al., 2000).

Diuretics

There is substantial clinical trial evidence that benefit is obtained from the use of thiazide diuretics in hypertension. Examples of drugs include bendroflumethiazide and hydrochlorothiazide, or thiazide-like diuretics, for example, chlortalidone and indapamide. These drugs are both inexpensive and well tolerated by most patients. Their diuretic action is achieved by blockade of distal renal tubular sodium reabsorption. Initially, they reduce blood pressure by reducing circulating blood volume, but in the longer-term, they reduce total peripheral resistance, suggesting a direct vasodilatory action. Although generally well tolerated, thiazide and thiazide-like diuretics may cause hypokalaemia, small increases in low-density lipoprotein (LDL) cholesterol and triglycerides, and gout associated with impaired urate excretion. Erectile dysfunction is also common.

Until recently bendroflumethiazide and hydrochlorothiazide were the most commonly prescribed agents at low doses to minimise adverse effects; however, evidence of reduced CV events with these low doses is lacking. NICE (2011) recommended the preferred agents were thiazide-like diuretics, indapamide (1.5 mg modified release or 2.5 mg daily) or chlortalidone (12.5–25 mg daily, due to the greater evidence of reduced CV events at lower doses).

Many studies of diuretics have also incorporated β -blockers, and this combination can have adverse metabolic consequences

that may lead to new-onset diabetes. Within the Anti-hypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the absolute risk of developing diabetes was 3.5% higher in the chlortalidone group than the lisinopril group (ALLHAT Collaborative Research Group, 2002). It remains an issue of contention as to whether this diabetic tendency is clinically significant. There was no reduction in efficacy associated with thiazide use in ALLHAT, and indeed, there was less heart failure in the diuretic-treated patients compared with those receiving calcium channel blockers or ACE inhibitors.

Loop diuretics are no more effective at lowering blood pressure than thiazides unless renal function is significantly impaired or the patient is receiving agents that inhibit the renin–angiotensin system. They are also a suitable choice if heart failure is present.

Spironolactone, an aldosterone antagonist, is not suitable for first-line therapy but is an increasingly important treatment option at low dose (25 mg daily) for patients with resistant hypertension. Where hyperaldosteronism is suspected, spironolactone may prove to be effective. Spironolactone is a potassium-sparing diuretic and should be used with caution, especially if used in combination with ACE inhibitors or ARBs, and should almost always be avoided with other potassium-sparing diuretics, for example, amiloride.

α -Adrenoreceptor blockers

α -Adrenoreceptor blockers antagonise α -adrenoceptors in the blood vessel wall and, thus, prevent noradrenaline (norepinephrine)-induced vasoconstriction. As a result, they reduce total peripheral resistance and blood pressure. Prazosin was originally used but had the disadvantage of being short-acting and causing first-dose hypotension. Newer agents such as doxazosin and terazosin have a longer duration of action. There are concerns about the first-line use of α -blockers because the ALLHAT study has indicated that doxazosin is more often associated with heart failure and stroke than thiazide diuretics (ALLHAT Collaborative Research Group, 2000). However, they may be considered as add-in therapy for patients with resistant hypertension inadequately controlled using other agents. They can frequently cause postural hypotension but may alleviate symptoms in men with prostatic hypertrophy.

Centrally acting agents

Methyldopa and moxonidine inhibit sympathetic outflow from the brain, resulting in a reduction in total peripheral resistance. Methyldopa is not widely used because it has pronounced central adverse effects, including tiredness and depression. It continues to be used in pregnancy because it does not cause fetal abnormalities. It is also occasionally used in patients with resistant hypertension. Moxonidine blocks central imidazoline and α_2 -adrenoceptors found within the medulla oblongata of the brain. It can cause side effects of dry mouth, headache, fatigue and dizziness, although it appears to have fewer central adverse effects than methyldopa. Other centrally acting agents such as clonidine and reserpine are almost never used in modern practice because of their pronounced adverse effects.

β -Adrenoreceptor antagonists

The mode of action of β -adrenoreceptor antagonists in hypertension is uncertain. The β -adrenoreceptor blockade reduces cardiac output in the short-term and during exercise. It also reduces renin secretion by antagonising β -receptors in the juxtaglomerular apparatus. Central actions may also be important for some agents. Non-selective β -blockers may give rise to adverse effects as a result of antagonism of β_2 -adrenoceptors, that is, asthma and worsened intermittent claudication. However, the so-called 'cardioselective' (β_1 -selective) β -blockers are not entirely free of these adverse effects. Patients who develop very marked bradycardia and tiredness may tolerate a drug with partial agonist activity such as pindolol.

β -Adrenoreceptor antagonists also have substantial clinical trial evidence of benefit over placebo in hypertension and are relatively inexpensive. However, their use is declining, and they have been relegated to use as one of a number of options in resistant hypertension in the UK according to NICE (2011) guidance (Fig. 19.1). This recommendation largely stems from the evidence that they may be less effective at preventing stroke in conjunction with their diabetogenic effects. The Losartan for Endpoint Reduction in Hypertension (LIFE) study compared an atenolol/thiazide-based regimen with a losartan-based regimen and demonstrated equivalent levels of blood pressure reduction but with a small excess incidence of stroke in the atenolol arm (Dahlöf et al., 2002). In the Anglo Scandinavian Cardiac Outcomes Trial (ASCOT) study, the risk of diabetes was 2.5% higher in the atenolol arm compared with the amlodipine arm, with similar increased risk of diabetes found within the atenolol arm of the LIFE study (Dahlöf et al., 2005). A Cochrane review warned of the excess risk in developing diabetes in patients prescribed combinations of thiazide diuretics and β -blockers. This would equate to one new case per 500 treated (Mason et al., 2005). The combination of thiazide and a β -blocker should, therefore, be avoided if possible, particularly in those who are at risk of developing diabetes (e.g. obese, strong family history of diabetes, South Asian origin).

To complicate matters, however, a long-term 20-year follow-up study of the UK Prospective Diabetes Study (UKPDS) found similar cardiovascular outcomes between patients on β -blockers and ACE inhibitors, with a reduction in all causes of mortality that actually favoured β -blockers (Holman et al., 2008). β -Blockers do remain suitable for younger hypertensives who have another indication for β -blockade, such as coronary heart disease. β -Blockers are also effective in suppressing atrial fibrillation, and this may be one group of patients where first-line therapy with β -blockers is still merited. Additionally, where anxiety is a significant driver of hypertension, β -blockers may have a role.

Other agents

Several other drugs are available for use for people with more resistant hypertension. Minoxidil is a powerful antihypertensive drug, but its use is associated with severe peripheral oedema and reflex tachycardia. It should be restricted to patients with severe hypertension who are also taking β -blockers and diuretics. It

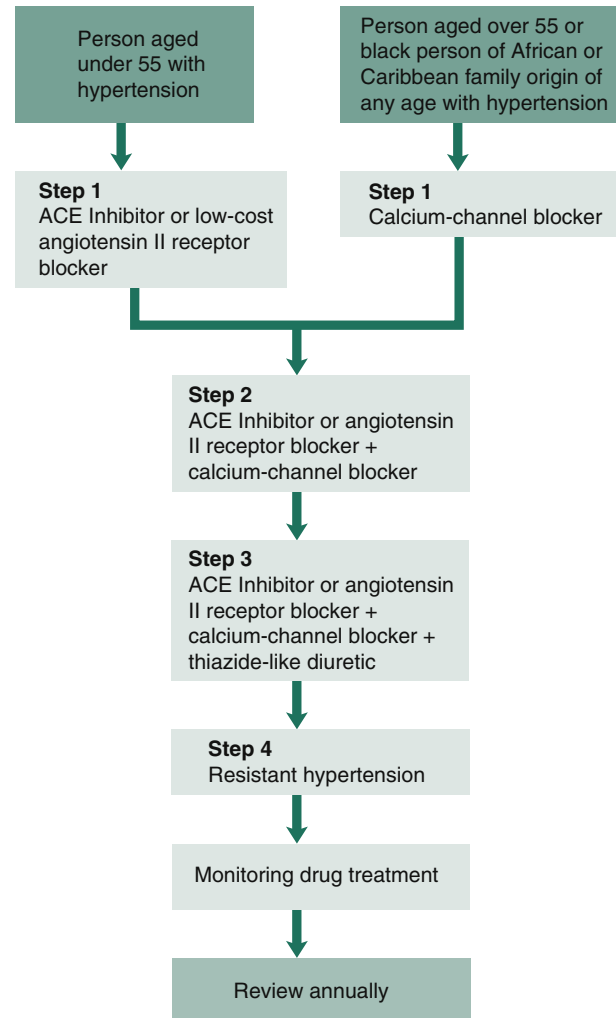

Fig. 19.1 Summary of antihypertensive drug treatment (NICE, 2017). ACE, Angiotensin converting enzyme.

causes pronounced hirsutism and is not a suitable treatment for women. Hydralazine can be used as add-on therapy for patients with resistant hypertension but is not well tolerated because it is a profound vasodilator and may occasionally be associated with drug-induced systemic lupus erythematosus. Sodium nitropruside is a direct-acting arterial and venous dilator that is administered as an intravenous infusion for treating hypertensive emergencies and for the acute control of blood pressure during anaesthesia. Hypertension has previously been treated with ganglion blockers such as guanethidine, but these drugs are now of historical interest only.

There is evidence that the renin antagonist aliskiren may have a blood-pressure-lowering effect similar to that of other agents and may be safely added to other inhibitors of the renin-angiotensin-aldosterone system to provide a greater level of inhibition (O'Brien et al., 2007). Due to its cost and a lack of outcome data, it can only be suggested as an add-on therapy where other, more established treatment options have failed to control blood pressure. It is generally well tolerated but may cause diarrhoea at higher doses.

Drug selection

Drugs should be chosen on the basis of efficacy, safety, convenience to the patient and cost. For assessing efficacy, it is essential to use evidence from large-scale clinical trials that demonstrate measurable effects on hard end points such as the incidence of stroke and other cardiovascular events or death. Smaller-scale studies looking at the effects of drugs on blood pressure and surrogate markers such as left ventricular hypertrophy or carotid artery stenosis may generate a hypothesis of a future treatment strategy but should not be used to change current strategies. When considering safety, it is important to recognise that these drugs will be taken long-term, and there are advantages to using drugs that have long-established safety records. It is also important to recognise the importance of symptomatic adverse effects because these may reduce adherence. Patient convenience is another important factor, and use of once-daily preparations will result in better adherence than more frequent regimens. Because the hypertensive population is very large, it is necessary to be conscious of the cost of individual preparations. Combinations of low doses of antihypertensive drugs are often better tolerated than single drugs taken in high dose. The choice of drugs available for treating hypertension is shown in Table 19.5, and common therapeutic problems are noted.

Clinical trial evidence

Initial evidence of benefit in placebo-controlled clinical trials came from studies that primarily involved thiazide diuretics or β -blockers. However, there is increasing evidence of clinical benefit from newer drug classes, including ACE inhibitors and calcium channel blockers.

The [Blood Pressure Lowering Treatment Trialists Collaboration \(2000\)](#) carried out a meta-analysis of old against new treatments. They concluded that newer treatments were no more effective than older therapies. Since this study was done, several landmark comparative clinical trials have been published.

The Captopril Prevention Project (CAPPP) demonstrated that captopril was as effective as diuretics or β -blockers for preventing cardiovascular morbidity ([Hansson et al., 1999a](#)). However, captopril was associated with a 25% higher stroke risk, perhaps because it did not reduce blood pressure as effectively as conventional therapy in this particular study.

The LIFE study demonstrated that losartan was more effective at preventing vascular events, especially stroke, than atenolol in just over 9000 hypertensive patients with left ventricular hypertrophy, although reductions in blood pressure were similar. Losartan was also better tolerated ([Dahlöf et al., 2002](#)).

The ALLHAT study ([ALLHAT Collaborative Research Group, 2002](#)) involved over 40,000 older, high-risk hypertensive patients with the aim of determining whether the occurrence of fatal coronary heart disease or non-fatal myocardial infarction was lower in those treated with newer agents (amlodipine, lisinopril or doxazosin) compared with a thiazide-like diuretic (chlortalidone). The doxazosin arm was discontinued early because of a higher rate of events, especially heart failure, compared with the diuretic. For the remaining three drugs, there was no difference in the occurrence of the primary end point. Chlortalidone was more effective than amlodipine and lisinopril in lowering blood pressure and

Table 19.5 Summary of oral antihypertensive drugs and common therapeutic problems

Class	Examples	Major adverse effects
Angiotensin-converting enzyme inhibitor	Ramipril Lisinopril Perindopril Enalapril	Cough Rash Taste disturbance Renal dysfunction Angioedema
Angiotensin receptor blockers	Candesartan Irbesartan Losartan Valsartan	Headache Rash Renal failure
Calcium channel blocker	Dihydropyridine: Amlodipine Felodipine Lacidipine Lercanidipine Non-dihydropyridine: Diltiazem Verapamil	Flushing Ankle swelling Headache Bradycardia/heart block Constipation (verapamil only)
Diuretics	Thiazide-type: Indapamide Chlortalidone Thiazide: Bendroflumethiazide Hydrochlorothiazide Loop: Furosemide Bumetanide	Hypokalaemia Gout Glucose intolerance Hyperlipidaemia Impotence Uraemia Dehydration
Aldosterone antagonists	Spirolactone Eplerenone	Hyperkalaemia Renal dysfunction Gynaecomastia (spironolactone only) Dehydration Hyponatraemia
Beta-blockers	Bisoprolol Atenolol Metoprolol Nebivolol Labetalol	Tiredness/fatigue Reduced exercise tolerance Bradycardia Cold peripheries Claudication Wheezing Impotence
α -Blockers	Doxazosin Prazosin	Postural hypotension Headache Rash
Centrally acting vasodilator	Methyldopa Moxonidine	Tiredness Depression

preventing heart failure and was also marginally more effective than lisinopril in preventing stroke.

The second Australian National Blood Pressure Study Group ([Wing et al., 2003](#)) compared enalapril with hydrochlorothiazide

in just over 6000 hypertensive subjects recruited in primary care. The primary end point was any cardiovascular event or death from any cause. In this relatively small study, there was a trend in favour of the ACE inhibitor that was of borderline statistical significance.

The VALUE study (Julius et al., 2004) compared amlodipine and valsartan in high-risk hypertensive subjects. No differences in the primary composite cardiac end point were observed, although non-fatal myocardial infarction was less common with amlodipine, which also lowered blood pressure to a greater extent. Conversely, onset of diabetes was less common with valsartan.

The ASCOT study (Dahlöf et al., 2005) compared a modern treatment regimen based on amlodipine and perindopril with a traditional regimen based on atenolol and bendroflumethiazide. The study involved over 20,000 high-risk hypertensives. The amlodipine-based therapy was associated with better blood pressure reduction and reductions in the occurrence of cardiovascular events, total mortality and diabetes, although the primary composite end point was not significantly affected. It is uncertain how much of the benefit can be attributed to the better blood pressure control achieved in the amlodipine-based arm and how specific these findings are to the drug doses and sequencing specified in the trial protocol for each arm of the study.

These various trials have provided results that are conflicting, in part because of differences in trial design and quality. However, there is increasing evidence that β -blockers may be less effective at preventing cardiovascular end points, as suggested by LIFE and ASCOT studies. In a meta-analysis (Lindholm et al., 2005), β -blockers were less effective than other antihypertensives at preventing stroke, although no significant differences were observed in effects on myocardial infarction or death. There is no consistent evidence that thiazides or thiazide-like drugs are less effective than newer agents in preventing cardiovascular events.

Recommendations for drug sequencing

In England and Wales, the NICE (2011) guidelines include an algorithm for the use of antihypertensive therapies based on the age and ethnicity of the individual being treated (Fig. 19.1).

At step 1, these recommend an initial choice of an ACE inhibitor or ARB as first-line therapy in younger (<55 years) non-black patients. The rationale for this is that these patients often have hypertension associated with high concentrations of circulating renin. It is, therefore, logical to treat these patients with drugs that antagonise the renin–angiotensin system. For patients older than 55 years and patients of black African or Caribbean family origin of any age, who tend to have hypertension associated with low renin concentrations, calcium channel blockers (CCBs) are advocated as the preferred first-line option. Diuretic therapy, in the form of a thiazide-type diuretic, is recommended as an alternative if a CCB is not suitable, for example, because of oedema or intolerance, or if there is evidence of heart failure or a high risk of heart failure.

If initial monotherapy at step 1 fails to control blood pressure, a combination of an ACE inhibitor or ARB and a CCB is recommended at step 2 for both groups of patients, although the

addition of an ARB is preferred in patients of black African or Caribbean family origin due to the higher risk of angioedema with ACE inhibitor seen in this group.

Step 3 recommends a combination of ACE inhibitor/ARB plus CCB plus a thiazide-type diuretic.

Step 4, defined as resistant hypertension, recommends the addition of spironolactone or a higher dose of thiazide-like diuretic, although the evidence for any option at this stage is limited, and other possible additions include β -blockers or α -blockers. β -Blockers may be used in those patients with a high sympathetic drive. European guidance (Table 19.6) has eschewed a formal ranking of treatments and instead suggests a table of drugs and indications where they might be most appropriately indicated (Mancia et al., 2013).

Timing of dosing

There remains uncertainty about the optimal timing for the dosing of antihypertensive drug therapy, with one Cochrane review (Zhao et al., 2011) concluding that evening dosing was associated with a small, but significant reduction in blood pressure compared with morning dosing. However, the quality of the studies included in this meta-analysis was poor, and therefore more research is required in this area.

Special patient groups

Race

People of African Caribbean origin have an increased prevalence of hypertension and left ventricular hypertrophy and are at high risk of stroke and renal failure. They obtain particular benefit from reduced salt intake and are also sensitive to diuretic and calcium channel blockers, whereas β -blockers appear less effective, at least when used as monotherapy. People of black African or Caribbean origin have reduced plasma renin activity, and as a result, ACE inhibitors and ARBs are also less effective. This was illustrated in the ALLHAT study (ALLHAT, 2000, 2002) where stroke and coronary events were more common in black patients randomised to lisinopril compared with those receiving chlorthalidone. In this group NICE recommends CCBs as the first line with the addition of an ARB at step 2.

British Asians also have an increased prevalence of hypertension, diabetes and insulin resistance and a particularly high risk of coronary heart disease and stroke. There is currently no evidence of a difference in drug response when compared with white Europeans. However, combinations of β -blockers and thiazides should be avoided when possible because of the higher risk of diabetes.

Elderly

The elderly have a high prevalence of hypertension, with over 70% having blood pressures greater than 140/90 mmHg. Because they are at high absolute risk of cardiovascular events, the absolute benefits of blood pressure treatment are particularly large in this group. Antihypertensive therapy may also reduce the risk of heart failure and dementia. The Study of Cognition and Prognosis

Table 19.6 European Society of Cardiology: Drugs to be preferred in specific conditions (Mancia et al., 2013)

Condition	Drug
Asymptomatic organ damage	
Left ventricular hypertrophy	ACE inhibitor, CCB, ARB
Asymptomatic atherosclerosis	CCB, ACE inhibitor
Microalbuminuria	ACE inhibitor, ARB
Renal dysfunction	ACE inhibitor, ARB
Clinical cardiovascular event	
Previous stroke	Any agent effectively lowering blood pressure
Previous myocardial infarction	β -Blocker, ACE inhibitor, ARB
Angina pectoris	β -Blocker, CCB
Heart failure	Diuretic, β -blocker, ACE inhibitor, ARB, aldosterone antagonist
Aortic aneurysm	β -Blocker
Atrial fibrillation, prevention	Consider ARB, ACE inhibitor, β -blocker or aldosterone antagonist
Atrial fibrillation, ventricular rate control	β -Blocker, non-dihydropyridine CCB
End-stage renal disease/proteinuria	ACE inhibitor, ARB
Peripheral artery disease	ACE inhibitor, CCB
Other	
Isolated systolic hypertension (elderly)	Diuretic, CCB
Metabolic syndrome	ACE inhibitor, ARB, CCB
Diabetes mellitus	ACE inhibitor, ARB
Pregnancy	Methyldopa, β -blocker, CCB
Blacks	Diuretic, CCB

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCB, calcium channel blocker.

in the Elderly (SCOPE) study (Lithell et al., 2003) was designed to investigate the effects of candesartan on the occurrence of cognitive decline or dementia but revealed no benefit, probably because of the lack of difference in blood pressure between the two arms of the study.

The elderly are at particular risk of certain adverse effects of treatment such as postural hypotension, and it is important that both sitting and standing blood pressure are monitored. Nevertheless, the benefits of therapy are so great that blood-pressure-lowering strategies should be employed at all ages, in the form of lifestyle modification with or without drug therapy (NICE, 2011), unless the patient is very frail or the patient's life expectancy is very short. Isolated systolic hypertension (systolic >160 mmHg, diastolic <90 mmHg) is common in the elderly, and there is irrefutable evidence that drug treatment is beneficial in this group (Staessen et al., 1997; *Systolic Hypertension in the Elderly Programme [SHEP] Co-operative Research Group, 1991*). The elderly have more variable blood pressure, and larger numbers of measurements may be required to confirm hypertension; hence, ABPM is preferred to confirm a diagnosis.

Calcium channel blockers and low-dose thiazide diuretics are safe and effective treatments for elderly hypertensive people, and their use is endorsed by large-scale clinical trials. β -Blockers are less effective at reducing blood pressure and preventing clinical end points. The Swedish Trial in Old Patients with hypertension-2 (STOP-2) compared the effects of conventional (β -blocker or thiazide) and newer drugs (ACE inhibitors or calcium channel blockers) on cardiovascular morbidity in older subjects and did not detect significant differences (Hansson et al., 1999b).

In the Hypertension in the Very Elderly Trial (HYVET) (Beckett et al., 2008), 4000 patients with a mean age of 84 and blood pressure of 160–199 mmHg systolic at entry were treated to a target of systolic 150 mmHg for 1.8 years with indapamide (a thiazide-like diuretic) and, if required, the ACE inhibitor perindopril. There was a 30% reduction in fatal and non-fatal stroke, 21% reduction in death from all causes, and fewer adverse events in the actively treated group (Beckett et al., 2008).

The elderly certainly benefit from treatment of hypertension, but the threshold and target for treatment have not been fully elucidated. Most studies in the elderly recruited patients with relatively high baseline targets (>160–190 mmHg systolic) achieving blood pressure on treatment of between 150 and 170 mmHg, and only one achieved target blood pressure lower than 140 mmHg, and in this study outcome was poorer in the treated group (JATOS Study Group 2008).

The HYVET study (Beckett et al., 2008) was the first to confirm the safety and efficacy of lowering systolic blood pressure to less than 150 mmHg, and therefore this has been established as the treatment target for people older than 80 years.

Diabetes

In type 1 diabetes, the presence of hypertension often indicates the presence of diabetic nephropathy. In this group, blood pressure reduction and ACE inhibition slow the rate of decline in renal function. To achieve adequate blood pressure control, combinations of drugs will be needed. Thiazides, β -blockers, calcium channel blockers and α -blockers are all suitable as add-on treatments to ACE inhibitors, which should be first-line therapy.

Target blood pressure should be less than 135/85 mmHg or less than 130/80 mmHg if there is albuminuria or two or more signs of metabolic syndrome present; however, achieving these targets in clinical practice is challenging (NICE, 2015a).

In type 2 (non-insulin-dependent) diabetes, hypertension is particularly common, affecting 70% of people in this group. It is strongly associated with obesity and insulin resistance, and control of blood pressure is more important for preventing complications than tight glycaemic control. There is no evidence that one group of drugs is more or less effective than any other in terms of lowering blood pressure. The ADVANCE trial treated diabetics with indapamide and perindopril in addition to prestudy antihypertensive agents. The active group was found to have a further reduction in blood pressure and a significant reduction in adverse renal outcomes (21%) (Patel et al., 2007). It remains a subject of debate whether ACE inhibitors and ARBs have specific renoprotective benefits over and above their effects on blood pressure. In 2015, the guideline development group for the NICE diabetes type II guidelines concluded that the best evidence for prevention of renal disease and limitation of metabolic worsening related to the renin–angiotensin–system-blockers (RAS-blockers) (ACEI and ARB) as a class. Hence, NICE (2015b) guidance for England and Wales now recommends an ACE inhibitor as the first line in everyone except those of black African or Caribbean family origin where initial dual therapy with an ACE inhibitor plus diuretic therapy or CCB is recommended. If further antihypertensive therapy is required, ACEI plus CCB with the addition of a diuretic if necessary is endorsed. Many people with diabetes require four or even five antihypertensive agents to approach target levels. After triple therapy, there is little evidence to support the choice of one drug class over another, and any α -blocker, β -blocker or potassium-sparing diuretic can be added at this stage.

Renal disease

In patients with chronic renal impairment, good blood pressure control slows the progression of renal dysfunction. Renin–angiotensin system antagonists, including ACE inhibitors, ARBs and direct renin inhibitors, reduce the incidence of end-stage renal failure, but it is not clear if this is a specific effect or nonspecific action as a result of blood pressure lowering. The drugs also reduce protein loss and should be used in patients with hypertension and an albumin/creatinine ratio (ACR) of 30 mg/mmol or more or rapidly progressive renal dysfunction. Renin–angiotensin–aldosterone system antagonists may worsen renal impairment in patients with renal vascular disease, and careful monitoring of electrolytes and creatinine is mandatory. Salt restriction is particularly important in managing hypertension in renal disease. Thiazide diuretics are ineffective in patients with significant renal dysfunction (eGFR <30 mL/min/1.73 m²), and loop diuretics should be used when a diuretic is needed.

A further note of caution regarding overtreatment of blood pressure to overaggressive targets comes from the ONTARGET study, which randomised patients with vascular disease or high-risk diabetics to high-dose ramipril, telmisartan or both. Many patients were already taking polypharmacy for hypertension, and blood pressures at entry were approximately 142/82 mmHg

in all groups. Treatment reduced blood pressure by 6.4/4.3 mmHg in the ramipril group, 7.4/5.0 mmHg in the telmisartan group and 9.8/6.3 mmHg in the combination group. This would give the combination group a post-treatment blood pressure of 132/76 mmHg. This combination group was associated with adverse renal outcomes, for example, renal failure and high potassium with no improvement in other cardiovascular outcomes (Yusuf et al., 2008). The Medicines and Healthcare Regulatory Agency in the UK issued a warning in 2014 to avoid combining medicines from two classes of RAS-blocking agents (ACE inhibitors, ARBs, or aliskiren) for the treatment of hypertension (Medicines and Healthcare Regulatory Authority [MHRA], 2014).

Stroke

Hypertension is the most important risk factor for stroke in patients with or without previous stroke. There is increasing evidence that in those with a previous stroke, blood pressure reduction reduces the risk of stroke recurrence as well as other cardiovascular events. The PROGRESS study, although clearly demonstrating a benefit of lowering blood pressure in patients with cerebrovascular disease, only demonstrated benefit in those whose blood pressure was greater than 140 mmHg on entry or who were already on antihypertensives. The size of benefit was proportional to the size of the blood pressure reduction. The combination of perindopril and indapamide lowered systolic blood pressure by 12.3 mmHg and stroke incidence by an impressive 43%, whereas perindopril alone was associated with a small drop in systolic blood pressure and no reduction in stroke risk (PROGRESS Collaborative Group, 2001). On treatment, blood pressure in the actively treated group was 132 mmHg systolic.

In the Secondary Prevention of Small Subcortical Strokes (SPS3) trial, targeting a systolic blood pressure of below 130 mmHg in patients with recent lacunar stroke, reductions in the rate of all stroke, disabling or fatal stroke and the composite outcome of myocardial infarction or vascular death were not significant, but the rate of cerebral haemorrhage was reduced, and the lower target was well tolerated (SPS Study Group, 2013). A meta-analysis of 123 studies and 613,815 subjects found that blood-pressure-lowering treatment significantly reduced cardiovascular events and death in proportion to the magnitude of blood pressure reduction achieved, with no differences in the proportional benefits between trials with lower (below 130 mmHg) or higher systolic BP at baseline (Ettehad et al., 2016). Overall, a 10-mmHg reduction in systolic BP reduced the risk of cardiovascular disease by 20% and stroke by 27%.

The UK Royal College of Physicians national clinical guideline for stroke (Intercollegiate Stroke Working Party, 2016) recommends that patients post-stroke should be treated to achieve a clinic systolic blood pressure below 130 mmHg, except for people with severe bilateral carotid artery stenosis, for whom a systolic blood pressure target of 140–150 mmHg is appropriate.

Treatment of hypertension in the setting of acute stroke has been a subject of much debate. Blood pressure naturally rises then falls in the days and hours following acute stroke, and some

have argued that elevated levels are necessary to maintain brain circulation due to the failure of cerebral autoregulatory mechanisms around the time of stroke. The theory that lowering blood pressure could reduce cerebral perfusion due to a lack of the usual autoregulatory mechanisms is counterweighted by the potential for further damage due to cerebral oedema. There are no large-scale clinical trials to guide treatment, and national guidance from the UK ([Intercollegiate Stroke Working Party, 2016](#)) currently only recommends lowering blood pressure in the setting of acute ischaemic stroke if there is an indication for emergency treatment, such as:

- systolic blood pressure above 185 mmHg or diastolic blood pressure above 110 mmHg when the patient is otherwise eligible for thrombolysis,
- hypertensive encephalopathy,
- hypertensive nephropathy,
- hypertensive cardiac failure or myocardial infarction,
- aortic dissection,
- pre-eclampsia or eclampsia.

In patients with intracerebral haemorrhage, acute reduction of blood pressure has also been demonstrated to be feasible and probably safe, with reduced haematoma growth in the actively treated group ([Anderson et al., 2008](#)).

Following the acute phase of treatment, patients with acute stroke admitted on antihypertensive medication should resume oral treatment once they are medically stable and as soon as they can swallow medication safely. For newly identified hypertension, blood-pressure-lowering treatment for people with stroke should be initiated before the transfer of care out of hospital or at 2 weeks, whichever is the soonest.

Pregnancy

An increased blood pressure before 20 weeks of gestation usually indicates pre-existing chronic hypertension that may not have been previously diagnosed. As in all younger hypertensive patients, a careful assessment is needed to exclude possible secondary causes, although radiological and radionuclide investigations should usually be deferred until after pregnancy. Hypertension diagnosed after 20 weeks of gestation may also indicate chronic hypertension, which may have been masked during early pregnancy by the fall in blood pressure that occurs at that time. Patients with elevated blood pressure in pregnancy are at increased risk of pre-eclampsia and intrauterine growth retardation. They need frequent checks of their blood pressure, urinalysis and fetal growth. Pre-eclampsia is diagnosed when the blood pressure increases by 30/15 mmHg from measurements obtained in early pregnancy or if the diastolic blood pressure exceeds 110 mmHg and proteinuria is present. There is general consensus that blood pressure should be treated with drugs if it exceeds 150/100 mmHg ([NICE, 2010](#)), although some clinicians use a lower threshold, for example, 140/90 mmHg. Methyl dopa is the most suitable drug choice for use in pregnancy because of its long-term safety record. Calcium channel blockers, hydralazine and labetalol are also used. β -Blockers, particularly atenolol, are used less often because they are associated with intrauterine growth retardation. Although diuretics reduce the incidence of pre-eclampsia, they are little used in pregnancy because of

concerns about decreasing maternal blood volume. ACE inhibitors and ARBs are contraindicated because they are associated with oligohydramnios, renal failure and intrauterine death.

Meta-analysis of trials suggests that antihypertensive drugs reduce the risk of progression to severe hypertension and reduce hospital admissions, although excessive blood pressure reduction may reduce fetal growth.

Oral contraceptives

Use of combined oral contraceptives results, on average, in an increase of 5/3 mmHg in blood pressure. However, severe hypertension can occur in a small proportion of recipients months or years into treatment. Progesterone-only preparations do not cause hypertension very often but are less effective for contraception, especially in younger women. Combined oral contraceptives are not absolutely contraindicated in hypertension unless other risk factors for cardiovascular disease, such as smoking, are present.

Hormone replacement therapy

There is little evidence that hormone replacement therapy is associated with an increase in blood pressure, and women with hypertension should not be denied access to these agents if there is an appropriate indication. Controversy remains regarding whether hormone replacement therapy reduces or increases the risk of CV events overall. Large increases in blood pressure have occasionally been reported in individuals, and it is important to monitor blood pressure during the first few weeks of therapy and every 6 months thereafter. In women with resistant hypertension, during treatment with hormone replacement therapy, the effectiveness of discontinuing hormone replacement should be assessed.

A list of the indications and contraindications to the various antihypertensive agents can be found in [Table 19.7](#).

Ancillary drug treatment

Aspirin

The use of aspirin reduces cardiovascular events at the expense of an increase in gastro-intestinal complications, and it is no longer recommended for primary prevention of cardiovascular events. Its use in hypertensive patients should be restricted to those who have evidence of established vascular disease.

Lipid-lowering therapy

Guidelines clearly support the use of statins in all patients requiring secondary prevention of CVD. In the absence of established CV disease, the decision to initiate statin therapy should be based on the results of a cardiovascular risk assessment using an approved risk calculator, such as QRisk. NICE guidance recommends that statins should be considered in patients with a CV risk greater than 10% over 10 years, after other modifiable risk factors have been addressed ([NICE, 2014b, 2014c](#)).

Table 19.7 Use of antihypertensive drugs adapted from British Hypertension Society guidelines

Class	Indications	Contraindications
Diuretics	Elderly ISH Heart failure Secondary stroke prevention	Gout
β -Blockers	Myocardial infarction Angina (Heart failure)	Asthma/chronic obstructive pulmonary disease Heart block (Heart failure) (Dyslipidaemia) (Peripheral vascular disease) (Diabetes, except with coronary heart disease)
Calcium antagonists: dihydropyridine	Elderly ISH (Elderly) (Angina)	
Calcium antagonists (rate limiting)	Angina (Myocardial infarction)	Combination with β -blocker (Heart block) (Heart failure)
ACE inhibitors	Heart failure Left ventricular dysfunction Type 1 diabetic nephropathy Secondary stroke prevention (Chronic renal disease) (Type 2 diabetic nephropathy) (Proteinuric renal disease)	Pregnancy Renovascular disease (Renal impairment) (Peripheral vascular disease)
α -Blockers	Benign prostatic hypertrophy (Dyslipidaemia)	Urinary incontinence (Postural hypotension) (Heart failure)
Angiotensin receptor blockers	ACE inhibitor intolerance Type 2 diabetic nephropathy Hypertension with LVH Heart failure in ACE inhibitor-intolerant subjects Post-MI (LV dysfunction post-MI) (Intolerance of other antihypertensive drugs) (Proteinuric renal disease) (Chronic renal failure) (Heart failure)	As ACE inhibitors
Centrally acting vasodilators	Pregnancy (methyldopa only) Resistant hypertension unresponsive to first-line therapy	
Direct-acting vasodilators	Resistant hypertension, unresponsive to first-line therapy	

Note: Strong indications and contraindications are shown. Text in parentheses indicates weak/possible indications or contraindications.
ACE, Angiotensin-converting enzyme; ISH, isolated systolic hypertension; LV, left ventricular; LVH, left ventricular hypertrophy; MI, myocardial infarction.

Case studies

Case 19.1

Mrs PP, a 55-year-old woman of African Caribbean origin, is found to have consistently elevated blood pressure over several weeks; her lowest reading was 155/98 mmHg. She is overweight and has

diabetes and is being treated with metformin. Her renal function and urinalysis are both normal.

Questions

1. Should Mrs PP be initiated on drug therapy for her hypertension?
2. If her hypertension was treated with drugs, which agents should be offered and in what order?

Answers

1. Provided Mrs PP's blood pressure has been measured accurately over several weeks, it demonstrates stage 1 hypertension. It is important to ensure that an appropriately sized blood pressure cuff is being used, in view of her obesity. She should be treated with both lifestyle advice and drug therapy because she also has diabetes. Restriction of salt intake may be particularly helpful in people of black African or Caribbean family origin, and weight reduction would benefit her hypertension and diabetes.
2. **NICE (2015b)** guidance recommends that first-line antihypertensive drug treatment for a person of African or Caribbean family origin should be an ACE inhibitor plus either a diuretic or a calcium channel blocker. This conflicts with the recommendation in the 2011 NICE guideline, which suggests that ARBs are preferred to ACE inhibitors in people of black African or Caribbean family origin, but the recommendation is based on the greater wealth of clinical trial data to support ACE inhibitors in people with diabetes. Calcium channel blockers do not have adverse metabolic effects and are effective in people of this origin and would, therefore, be an appropriate choice. If blood pressure remains uncontrolled, the addition of either diuretic or CCB should be considered (whichever was not initiated at step 1). Tight blood pressure control is important, and if blood pressure is not controlled with three agents, an α -blocker, β -blocker or potassium-sparing diuretic could be considered for addition at this stage.

Case 19.2

Mr PT, a 35-year-old man, is overweight and has a blood pressure of 178/108 mmHg. He smokes 25 cigarettes daily and drinks 28 units of alcohol per week. He has a sedentary occupation. He eats excessive quantities of saturated fat and salt.

Mr PT subsequently stopped smoking and lost some weight but remained hypertensive. He was treated with atenolol 50 mg daily. His blood pressure fell to 136/84 mmHg, but he developed tiredness and bradycardia and complained of erectile impotence.

Questions

1. How should Mr PT be managed?
2. What are the treatment options for Mr PT?

Answers

1. Since Mr PT is a young man, his absolute risk of cardiovascular events is likely to be low, at least for the time being; however, this should be confirmed using QRisk. His total cholesterol and high-density lipoprotein (HDL) cholesterol levels, as well as height and weight, will be needed to accurately assess his risk. Mr PT has several cardiovascular risk factors that need to be addressed, including his sedentary lifestyle and his smoking. Non-pharmacological methods have the potential of reducing his blood pressure considerably, including dietary modification, weight loss, and reduced salt intake. He is unlikely to qualify for lipid-lowering therapy at this point because of his young age and presumed low cardiovascular risk. Because he has stage 2 hypertension, drug treatment should be initiated in parallel with lifestyle advice.
2. β -Blockers are no longer recommended for the first-line treatment of hypertension, and Mr PT is complaining of significant adverse effects, which may affect adherence. In line with guidance and to address his adverse effects, he should be changed to a drug of a different class such as an ACE inhibitor, in view of his age (**NICE, 2011**). This is likely to be more effective for blood pressure lowering than

a calcium channel blocker or diuretic. Other drugs could be added or substituted if Mr PT was intolerant to initial therapy or it did not reduce his blood pressure to target levels; with calcium channel blocker recommended at step 2 and the addition of a thiazide type diuretic at step 3 (although these can also cause impotence).

Case 19.3

A 24-year-old woman, Ms SR, with a family history of hypertension is prescribed an oral contraceptive. Six months after starting this, she is noted to have a blood pressure of 148/96 mmHg.

Question

How should Ms SR be managed?

Answer

If Ms SR's blood pressure is consistently raised, she may have either essential hypertension or hypertension induced by the oral contraceptive (secondary hypertension) or a combination. Her blood pressure may fall if her oral contraceptive is discontinued. Ms SR will, however, need advice on adequate contraceptive methods. A progesterone-only preparation would be one possibility. She would need careful counselling about the methods available and how successful they are. If her blood pressure remained elevated after discontinuing her oral contraception, she is likely to have underlying hypertension. This may be essential in nature, in view of the family history; however, because of her age, Ms SR should undergo some investigations to exclude possible secondary causes of hypertension. She is at low risk of complications, and there is no urgency to consider drug treatment. If there is a strong wish to use combined oral contraception, it would be important to control other risk factors as far as possible and to consider drug treatment for her hypertension.

Case 19.4

Mrs GJ, a 73-year-old woman, has a long-standing history of hypertension and intolerance to antihypertensive drugs. Bendroflumethiazide was associated with acute attacks of gout, she developed breathlessness and wheezing while taking bisoprolol, amlodipine caused flushing and headache and doxazosin was associated with intolerable postural hypotension. Four weeks earlier she had been started on enalapril but then complained of a dry, persistent cough. Her blood chemistry has remained normal.

Questions

1. Is Mrs GJ's cough likely to be an adverse effect of enalapril?
2. What other options are available for controlling her blood pressure?

Answers

1. Yes, a dry cough is a common adverse effect of ACE inhibitors. It affects approximately 10–20% of recipients and is more common in women. Some patients are able to tolerate the symptom, but in many, the drug has to be discontinued.
2. Angiotensin receptor blockers can be used in patients intolerant of ACE inhibitors due to cough. They are unlikely to produce this symptom because they do not inhibit the metabolism of

pulmonary bradykinin. Centrally acting agents such as methyldopa or moxonidine could also be considered. However, these are not well tolerated, and side effects are quite likely in this patient. A non-dihydropyridine calcium channel blocker such as diltiazem or verapamil is another alternative. Measurement of plasma uric acid could also be considered followed by prophylactic treatment with allopurinol before introducing a diuretic. Alternatively, a trial of spironolactone could be considered, although renal function will need careful monitoring.

Case 19.5

Mrs KB, a 23-year-old woman, has a normal blood pressure (118/82 mmHg) when reviewed at 8 weeks of pregnancy. In the 24th week of pregnancy, she is reviewed by her midwife and found to have a blood pressure of 148/96 mmHg. Urinalysis is normal.

Questions

1. What is the likely diagnosis?
2. What complications does Mrs KB's high blood pressure place her at increased risk of?
3. Should she receive drug treatment? If so, with which drug, and if not, how should she be managed?

Answers

1. Mrs KB may have gestation-induced hypertension or chronic hypertension that had previously been masked by the fall in blood pressure that happens in early pregnancy.
2. She is at increased risk of pre-eclampsia and intrauterine growth retardation.
3. There are differences of opinion between specialists as to whether blood pressure should be treated at this level during pregnancy. In favour of treatment is the substantial rise over the earlier blood pressure recording. Some specialists would not treat unless the blood pressure was greater than 170/110 mmHg or other complications were present, but NICE (2010) recommends intervention if the BP is greater than 150/100 mmHg. If Mrs KB was treated, methyldopa would be a suitable choice. In any event, Mrs KB requires close monitoring of her blood pressure, urinalysis and fetal growth.

Case 19.6

An elderly patient, Mr GD, comes to the pharmacy with a prescription for the following medications: salbutamol inhaler 200 micrograms as required, beclometasone inhaler 200 micrograms twice daily, bendroflumethiazide 2.5 mg daily, modified release diltiazem 180 mg once daily and atenolol 50 mg daily. The atenolol was being started by Mr GD's primary care doctor, apparently because of inadequate blood pressure control.

Question

What action should the pharmacist take?

Answer

There are three reasons to be concerned about the addition of atenolol to Mr GD's drug regimen. First, there is a potentially hazardous interaction with diltiazem, which may result in severe bradycardia or heart block. Second, Mr GD is receiving treatment for obstructive

airways disease, and this may be worsened by the atenolol. Third, there is increasing evidence to demonstrate that the combination of a thiazide and a β -blocker increases the risk of developing diabetes. The prescription should be discussed with the prescriber. The addition of an ACE inhibitor or ARB would be a suitable alternative in line with NICE (2011) guidance.

Case 19.7

A patient, Mr AG, is admitted to hospital with a stroke. A CT scan of the brain shows a cerebral infarct. The patient's blood pressure is 178/102 mmHg and remains at this level over the first 6 hours after admission to the ward.

Question

Should Mr AG be prescribed antihypertensive medication?

Answer

There is no good evidence that antihypertensive drug treatment is beneficial in the early stages of acute stroke, and there is a risk that lowering blood pressure may compromise cerebral perfusion further. However, in the longer-term, blood pressure reduction is valuable for preventing further strokes and other cardiovascular events. It would be appropriate to monitor Mr AG's blood pressure and start treatment after a few days if it remains persistently elevated. A thiazide diuretic and/or ACE inhibitor are commonly used under these circumstances, following the demonstration of benefit in the PROGRESS study (PROGRESS Collaborative Group, 2001).

Case 19.8

Mr TH, a 67-year-old man, has been treated for hypertension with atenolol 50 mg daily for several years. He feels well, and his blood pressure is controlled. Mr TH has read an article in the paper that suggests atenolol is not considered the most suitable drug for treating high blood pressure and enquires about changing his prescription.

Question

Should an alteration to Mr TH's treatment be recommended?

Answer

There is increasing evidence that β -blockers, including atenolol, may be less effective at preventing cardiovascular events, especially stroke, than other drugs and are associated with a higher risk of development of diabetes, especially if used in combination with thiazide diuretics. They are also less effective at reducing blood pressure in older people. However, if Mr TH's blood pressure is well controlled and the treatment suits him, there is no strong reason to change his medication unless he is at particular risk of diabetes.

Case 19.9

Mr AB, a 58-year-old man, is noted to have high blood pressure by his primary care doctor. There is no evidence of end-organ damage, and he has no other cardiovascular risk factors. The blood

pressure remains greater than 160/100 mmHg each time it is checked in the surgery over several weeks, in spite of salt and alcohol reduction. Mr AB buys a wrist blood pressure monitor at a pharmacy and takes several readings at home. These are all below 130/75 mmHg.

Question

What advice should Mr AB be given about the need for drug treatment?

Answer

Mr AB may have 'white-coat' hypertension. Because this is associated with a lower risk than sustained hypertension, he may not need drug treatment. However, before making this judgment, it is important to check that his machine is accurate. This can be done by comparing readings with a validated machine or by checking to see if the make of the blood pressure monitor has been verified as accurate by the British Hypertension Society.

20 Coronary Heart Disease

Duncan McRobbie and Imran Hafiz

Key points

- Coronary heart disease (CHD) is common, often fatal and frequently preventable.
- High dietary fat, smoking and sedentary lifestyle are risk factors for CHD and require modification if present.
- Hypertension, hypercholesterolaemia, diabetes mellitus, obesity and personal stress are also risk factors and require optimal management.
- Stable angina should be managed with nitrates for pain relief and β -blockers, unless contraindicated, for long-term prophylaxis. Where β -blockers are inappropriate, the use of calcium channel blockers and/or nitrates may be considered.
- Acute coronary syndromes arise from unstable atheromatous plaques and may be classified as to whether there is ST-elevation myocardial infarction (STEMI) or non-ST-elevation myocardial infarction (NSTEMI).
- ST elevation on the electrocardiogram (ECG) indicates an occluded coronary artery and is used to determine treatment with fibrinolysis or primary angioplasty.
- Patients with NSTEMI may have experienced myocardial damage, are at increased risk of death and may benefit from a glycoprotein IIb/IIIa inhibitor.

Coronary heart disease (CHD), sometimes described as coronary artery disease (CAD) or ischaemic heart disease (IHD), is a condition in which the vascular supply to the heart is impeded by atheroma, thrombosis or spasm of coronary arteries. This may impair the supply of oxygenated blood to cardiac tissue sufficiently to cause myocardial ischaemia which, if severe or prolonged, may cause the death of cardiac muscle cells. Similarities in the development of atheromatous plaques in other vasculature, in particular the carotid arteries, with the resultant cerebral ischaemia has resulted in the term cardiovascular disease (CVD) being adopted to incorporate CHD, cerebrovascular disease and peripheral vascular disease.

Myocardial ischaemia occurs when the oxygen demand exceeds myocardial oxygen supply. The resultant ischaemic myocardium releases adenosine, the main mediator of chest pain, by stimulating the A1 receptors located on the cardiac nerve endings. Myocardial ischaemia may be 'silent' if the duration is of insufficient length, the afferent cardiac nerves are damaged (as with diabetics) or there is inhibition of the pain at the spinal or supraspinal level.

Factors increasing myocardial oxygen demand often precipitate ischaemic episodes and are commonly associated with increased work rate (heart rate) and increased workload (force of contractility). Less commonly, myocardial ischaemia can also arise if oxygen demand is abnormally increased, as may occur in patients with thyrotoxicosis or severe ventricular hypertrophy due to hypertension. Myocardial oxygen supply is dependent on the luminal cross-sectional area of the coronary artery and coronary arteriolar tone. Atheromatous plaques decrease the lumen diameter and, when extensive, reduce the ability of the coronary artery to dilate in response to increased myocardial oxygen demand. Ischaemia may also occur when the oxygen-carrying capacity of blood is impaired, as in iron-deficiency anaemia, or when the circulatory volume is depleted.

Epidemiology

An estimated 17.5 million people die from CVD worldwide each year, accounting for almost one-third of all deaths ([World Health Organization, 2017](#)). In the UK, just more than 150,000 people die from CVD each year, with CHD accounting for almost a half of these ([British Heart Foundation, 2017](#)). About 25% of premature deaths (<75 years old) in men and 17% of premature deaths in women result from CVD.

The epidemiology of CHD has been studied extensively, and risk factors for developing CHD are now well described. The absence of established risk factors does not guarantee freedom from CHD for any individual, and some individuals with several major risk factors seem perversely healthy. Nonetheless, there is evidence that in developed countries, education and publicity about the major risk factors have led to changes in social habits, particularly with respect to a reduction in smoking and fat consumption, and this has contributed to a decrease in the incidence of CHD.

The UK has seen a steady decline in deaths from CVD. Since the early 1960s the number of deaths has more than halved ([British Heart Foundation, 2017](#)). A study has indicated that both reductions in major risk factors and improvements in treatment have contributed to this reduction ([Unal et al., 2004](#)).

The improvement in deaths from CHD has been chiefly among those with higher incomes; however, the less prosperous social classes continue to have almost unchanged levels of CHD.

Better treatment has also contributed to a decrease in cardiac mortality, although CHD still accounts for some 70,000 deaths in the UK each year (British Heart Foundation, 2017), including 70% of sudden natural deaths, 14% of male deaths and 9% of female deaths. In the UK, CHD is the leading cause of death in men between 50 and 79 years old (second to lung cancer in women) (Office of National Statistics, 2015). In the over-80s, Alzheimer's disease and dementia are the leading causes of death in both men and women, followed by CHD in both groups. In the UK, in comparison with Caucasians, people of South Asian descent have a higher death rate from CHD, potentially due to a combination of genetic and environmental factors, including increased prevalence of metabolic syndrome and abdominal obesity, which increase the risk of diabetes and premature atherosclerosis. African Caribbeans and West Africans in the UK have a lower rate of CHD mortality, potentially explained by low levels of very low-density lipoprotein (VLDL), small dense LDL, and triglycerides.

Prevalence

In the UK, 2.3 million people have CHD, more than 60% of whom are male (British Heart Foundation, 2017). It has a prevalence of 5% in men and 3% in women. A quarter of men aged 55–74 years have evidence of CHD, and this proportion increases with age. Every year nearly 200,000 people suffer a myocardial infarction in the UK, of whom 70% survive. There are currently 915,000 people who have survived a myocardial infarction.

Mortality increases with age and is probably not due to a particular age-related factor but to the cumulative effect of risk factors that lead to atheroma and thrombosis and hence to CHD. Whilst the death rates for CHD in the UK have fallen (British Heart Foundation, 2017), the number of people living with CHD is increasing because of the ageing population.

Women appear less susceptible to CHD than men, although they seem to lose this protection after menopause, presumably because of hormonal changes. Race has not proved to be a clear risk factor because the prevalence of CHD seems to depend much more strongly on location and lifestyle than on ethnic origin or place of birth. It has been shown that lower social or economic class is associated with increased obesity, poor cholesterol indicators, higher blood pressure and higher C-reactive protein (CRP) measurements (an indicator of inflammatory activity).

Risk factors

Traditionally, the main potentially modifiable risk factors for CHD have been considered to be hypertension, cigarette smoking, raised serum cholesterol and diabetes. More recently psychological stress and abdominal obesity have gained increased prominence (Box 20.1). Patients with a combination of all these risk factors are at risk of suffering a myocardial infarction some 500 times greater than individuals without any of the risk factors. Stopping smoking, moderating alcohol intake, regular exercise and consumption of fresh fruit and vegetables were associated independently and additively with a reduction in the risk of having a myocardial infarction.

Box 20.1 Factors that increase or decrease the risk of developing coronary heart disease

Factors that increase the risk of CHD

- Cigarette smoking
- Raised serum cholesterol
- Hypertension
- Diabetes
- Abdominal obesity
- Increased personal stress

Factors that decrease the risk of CHD

- Regular consumption of fresh fruit and vegetables
- Regular exercise
- Moderate alcohol consumption
- Modification of factors that increase the risk of CHD

CHD, Coronary heart disease.

Diabetes mellitus is a positive risk factor for CHD in developed countries with high levels of CHD. Insulin resistance, as defined by high fasting insulin concentrations, is an independent risk factor for CHD in men. In the UK, the mortality rates from CHD is higher for people with diabetes.

Although unusual physical exertion is associated with an increased risk of infarction, an active lifestyle that includes regular, moderate exercise is beneficial; however, the optimum level has not been determined, and its beneficial effect appears to be readily overwhelmed by the presence of other risk factors. A family history of CHD is a positive risk factor, independent of diet and other risk factors. Hostility, anxiety and depression are associated with increased CHD and death, especially after a myocardial infarction.

Epidemiological studies have shown associations between CHD and prior infections with several common micro-organisms, including *Chlamydia pneumoniae* and *Helicobacter pylori*, but a causal connection has not been found. The influence of fetal and infant growth conditions, and their interaction with social conditions in childhood and adult life, has been debated strongly for decades, but it is clear that lower socioeconomic status and being underweight in very early life are linked to higher incidences of CHD.

Aetiology

The vast majority of CHD occurs in patients with atherosclerosis of the coronary arteries (Fig. 20.1) that starts before adulthood. The cause of spontaneous atherosclerosis is unclear, although it is thought that in the presence of hypercholesterolaemia, a non-denuding form of injury occurs to the endothelial lining of coronary arteries and other vessels. This injury is followed by subendothelial migration of monocytes and the accumulation of fatty streaks containing lipid-rich macrophages and T-cells. Almost all adults, and 50% of children aged 11–14 years, have fatty streaks in their coronary arteries. Thereafter, there is migration and proliferation of smooth muscle cells into the intima, with further lipid deposition. The smooth muscle cells, together with fibroblasts, synthesise and secrete collagen, proteoglycans, elastin and glycoproteins that make up a fibrous cap surrounding cells

Fig. 20.1 Main coronary arteries.

and necrotic tissue, together called a plaque. The presence of atherosclerotic plaques results in narrowing of vessels, reduction in blood flow and a decrease in the ability of the coronary vasculature to dilate. This may manifest as angina. Associated with the plaque rupture is a loss of endothelium. This can serve as a stimulus for the formation of a thrombus and result in more acute manifestations of CHD, including unstable angina (UA) and myocardial infarction. Plaque rupture caused by physical stresses or plaque erosion may precipitate an acute reaction. Other pathological processes are probably involved, including endothelial dysfunction, which alters the fibrin–fibrinolysis balance and the vasoconstriction–vasodilation balance. There is interest in the role of statins and angiotensin-converting enzyme (ACE) inhibitors in modifying endothelial function.

There is also great interest in the role of inflammation, especially in acute episodes. At postmortem, many plaques are found to contain inflammatory cells, and inflammatory damage is found at the sites of plaque rupture.

Measurement of acute phase inflammatory reactions, such as fibrinogen and CRP, has a predictive association with coronary events. High-sensitivity CRP assays have been used in populations without acute illness to stratify individuals into high-, medium- and low-risk groups. In patients with other risk factors, however, CRP adds little prognostic information. CRP is produced by atheroma, in addition to the major producer, which is the liver, and is an inflammatory agent as well as a marker of inflammation. Evidence is emerging that drug therapy that reduces CRP in otherwise healthy individuals reduces the incidence of major cardiac events (Ridker et al., 2008).

Oxidative stress that involves the uncontrolled production of reactive oxygen species (ROS) or a reduction in antioxidant species has been linked in the laboratory to several aspects of cardiovascular pathogenesis including endothelial malfunction, lipid metabolism, atheroma formation and plaque rupture, but the clinical importance is unclear. The use of antioxidants has been disappointingly unsuccessful, but there is interest in peroxisome proliferator-activated receptor (PPAR) agonists that modify ROS production; some of these are already in use for treating diabetes

Table 20.1 Effect of interventions on risk of myocardial infarction

Intervention	Control	Benefit of intervention
Stopping smoking for ≥5 years	Current smokers	50–70% lower risk
Reducing serum cholesterol		2% lower risk of each 1% reduction in cholesterol
Treatment of hypertension		2–3% lower risk of each 1-mmHg decrease in diastolic pressure
Active lifestyle	Sedentary lifestyle	45% lower risk
Mild to moderate alcohol consumption (approx. 1 unit/day)	Total abstainers	25–45% lower risk
Low-dose aspirin	Non-users	33% lower risk in men
Postmenopausal oestrogen replacement	Non-users	44% lower risk
The quality of data associated with these interventions varies greatly, and figures may not apply to all patient groups.		

and are associated with favourable changes in many metabolic markers for CVD. Other agents that reduce ROS production include statins and drugs that reduce angiotensin production.

Modification of risk factors

Common to all stages of CHD treatment is the need to reduce risk factors (Table 20.1). The patient needs to appreciate the value of the proposed strategy and to be committed to a plan for changing their lifestyle and habits, which may not be easy to achieve after years of smoking or eating a particular diet. Preventing CHD is important but neither instant nor spectacular. It may require many sessions of counselling over several years to initiate and maintain healthy habits. It may also involve persuasion of patients to continue taking medication for asymptomatic disorders such as hypertension or hypercholesterolaemia.

National campaigns to encourage healthy eating or exercise are expensive, as is the long-term medical treatment of hypertension or hypercholesterolaemia, and such strategies must have the backing of governments to succeed. It has been argued that community-wide campaigns on cholesterol reduction have had measurable benefits in Finland, the USA and elsewhere, at least in high-risk, well-educated and affluent groups. It follows that the next challenge is to extend that success to poorer, ethnically diverse groups and to those portions of the population with mild to moderate risk.

National campaigns to reduce smoking, either by raising public awareness of the risks or by legislation that prohibits smoking in enclosed public places and workplaces, on public

transport and in vehicles used for work, have reduced the number of smokers in the UK to an all-time low (although 17% of adults still smoke).

For every individual there is a need to act against the causative factors of CHD. Thus, attempts should be made to control hypertension, heart failure, arrhythmias, hypercholesterolaemia, obesity, diabetes mellitus, thyroid disease, anaemia and cardiac valve disorders. Apart from medication, these will require careful attention to diet and exercise and will necessitate smoking cessation. Cardiac rehabilitation classes and exercise programmes improve many risk factors, including obesity, lipid indices, insulin resistance, psychological state and lifestyle. They also impact on morbidity and mortality.

The role of antioxidants and hormone replacement therapy in preventing and treating coronary disease has been debated. However, a randomised clinical trial of antioxidant vitamins and/or hormone replacement therapy suggested that these agents are not of benefit and may indeed result in higher rates of cardiovascular events (Waters et al., 2002).

Clinical syndromes

The primary clinical manifestation of CHD is chest pain. Chest pain arising from stable coronary atheromatous disease leads to stable angina and normally arises when narrowing of the coronary artery lumen exceeds 50% of the original luminal diameter. Stable angina is characterised by chest pain and breathlessness on exertion; symptoms are relieved promptly by rest.

A stable coronary atheromatous plaque may become unstable as a result of either plaque erosion or rupture. Exposure of the subendothelial lipid and collagen stimulates the formation of thrombus, which causes sudden narrowing of the vessel. The spectrum of clinical outcomes that results is grouped under the term acute coronary syndrome (ACS) and is characterised by chest pain of increasing severity either on minimal exertion or, more commonly, at rest. These patients are at high risk of myocardial infarction and death and require prompt hospitalisation. Many aspects of the treatment of stable angina and ACS are similar, but there is a much greater urgency and intensity in the management of ACS.

Stable angina

Stable angina is a clinical syndrome characterised by discomfort in the chest, jaw, shoulder, back, or arms, typically elicited by exertion or emotional stress and relieved by rest or nitroglycerin. Characteristically, the discomfort (it is often not described by the patient as a pain) occurs after a predictable level of exertion, classically when climbing hills or stairs, and resolves within a few minutes on resting. The [Canadian Cardiovascular Society \(1976\)](#) classification is often used to measure the severity of the angina ([Table 20.2](#)). Unfortunately, the clinical manifestations of angina are very variable. Many patients mistake the discomfort for indigestion. Some patients, particularly diabetics and the elderly, may not experience pain at all but present with breathlessness or fatigue; this is termed silent ischaemia.

Table 20.2 Classification of angina severity according to the Canadian Cardiovascular Society (1976)

Class I	Ordinary activity does not cause angina, such as walking and climbing stairs.
Class II	Slight limitation of ordinary activity
Class III	Marked limitation of ordinary physical activity
Class IV	Inability to carry on any physical activity without discomfort

Further investigations are needed to confirm the diagnosis and assess the need for intervention. The resting electrocardiogram (ECG) is normal in more than half of patients with angina. However, an abnormal ECG substantially increases the probability of coronary disease; in particular, it may show signs of previous myocardial infarction. Noninvasive testing is helpful. Exercise testing is useful both in confirming the diagnosis and in giving a guide to prognosis. Alternatives such as myocardial scintigraphy (isotope scanning) and stress echocardiography (ultrasound) provide similar information.

Coronary angiography is regarded as the gold standard for the assessment of CHD and involves the passage of a catheter through the arterial circulation and the injection of radio-opaque contrast media into the coronary arteries. The X-ray images obtained permit confirmation of the diagnosis, aid assessment of prognosis and guide therapy, particularly with regard to suitability for angioplasty and coronary artery bypass grafting.

Noninvasive techniques, including magnetic resonance imaging (MRI) and multi-slice computerised tomography (CT) scanning, are being developed and tested as alternatives to angiography.

Treatment of stable angina is based on two principles:

- improve prognosis by preventing myocardial infarction and death,
- relieve or prevent symptoms.

Pharmacological therapy can be considered a viable alternative to invasive strategies, providing similar results without the complications associated with percutaneous coronary intervention (PCI). An algorithm for addressing both of these principles is outlined in [Fig. 20.2](#). In addition, diabetes, hypertension and Legislation under the Health Act 2006, which prohibits smoking in enclosed public places and workplaces, on public transport and in vehicles used for work in patients with stable angina should be well controlled. Smoking cessation, without or with pharmacological support, and weight loss should be attempted.

Treatment to reduce risk

One of the major complications arising from atheromatous plaque is thrombus formation. This causes an increase in plaque size and may result in myocardial infarction. Antiplatelet agents, in particular aspirin, are effective in preventing platelet activation and thus thrombus formation. Aspirin is of proven benefit in all forms of established CHD, although the risk/benefit ratio in people at risk of CHD is less clear.

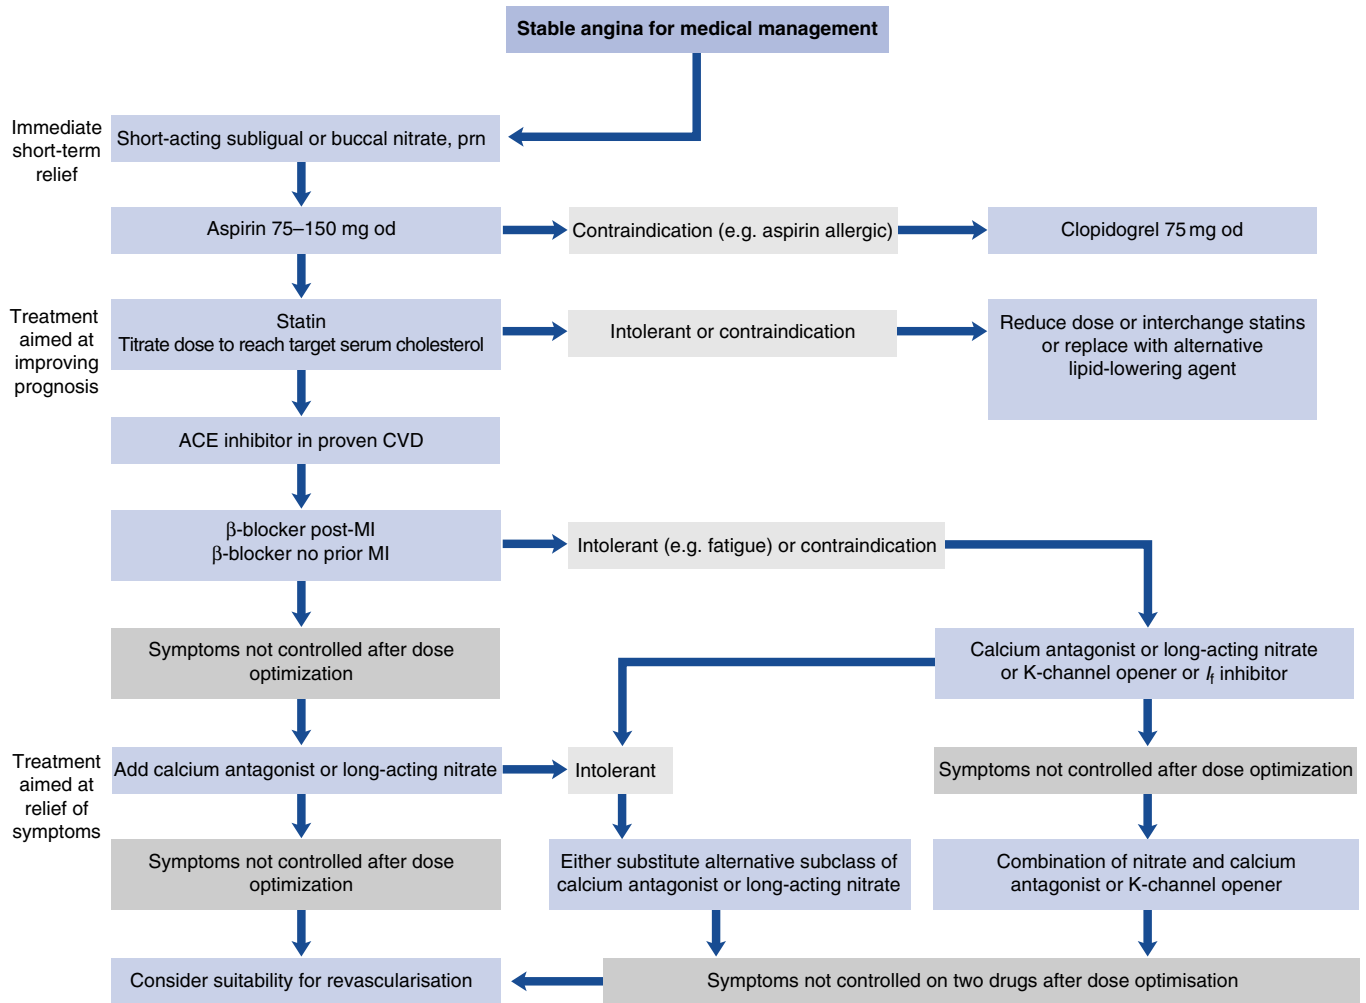

Fig. 20.2 Algorithm for the medical management of stable angina.

CVD, Cardiovascular disease; MI, myocardial infarction; od, once a day; prn, when required. (Adapted from Fox et al., 2006.)

Aspirin. Aspirin acts via irreversible inhibition of platelet cyclooxygenase 1 (COX-1) and thus thromboxane production, which is normally complete with chronic dosing of 75 mg/day. This antiplatelet action is apparent within an hour of taking a dose of 300 mg. The effect on platelets lasts for the lifetime of the platelet, around 8–10 days.

The optimal maintenance dose seems to be 75–150 mg/day, with lower doses having limited cardiac risk protection and higher doses increasing the risk of gastro-intestinal side effects. Dyspepsia is relatively common in patients taking aspirin, and patients should be advised to take the medicine with or immediately after food. Enteric-coated preparations are no safer, and patients with ongoing symptoms of dyspepsia may require concomitant acid suppression with a proton pump inhibitor or should be switched to clopidogrel. Adverse reactions to aspirin include allergy, including bronchospasm. The benefits and risks of using aspirin in patients with asthma or a previous history of gastro-intestinal bleeding need to be carefully considered.

Clopidogrel. Clopidogrel inhibits adenosine diphosphate (ADP) activation of platelets and is useful as an alternative to

aspirin in patients who are allergic or cannot tolerate aspirin. Data from one major trial (CAPRIE Steering Committee, 1996) indicate that clopidogrel is at least as effective as aspirin in patients with stable coronary disease. The usual dose is 300 mg once, then 75 mg daily. Although less likely to cause gastric erosion and ulceration, gastro-intestinal bleeding is still a major complication of clopidogrel therapy. There is evidence that the combination of a proton pump inhibitor and aspirin is as effective as using clopidogrel alone in patients with a history of upper gastro-intestinal bleeding.

COX-2 inhibitors. The analgesic and anti-inflammatory action of non-steroidal anti-inflammatory drugs (NSAIDs) is believed to depend mainly on their inhibition of COX-2, and the unwanted gastro-intestinal effects of NSAIDs on their inhibition of COX-1. COX-2 inhibition reduces the production of prostacyclin, which has vasodilatory and platelet-inhibiting effects. Studies have raised concern about the cardiovascular safety of NSAIDs. Initially, the concern was focussed on the selective cyclo-oxygenase-2 inhibitors and a link to an increased cardiovascular risk. Evidence has shown the more traditional nonselective NSAIDs increase cardiovascular risk in both patients with

established CVD and in the healthy population (Fosbøl et al., 2010). NSAIDs with high COX-2 specificity increase the risk of myocardial infarction and should be avoided where possible in patients with stable angina.

Angiotensin-converting enzyme inhibitors

ACE inhibitors are established treatments for hypertension and heart failure and have proven beneficial post-myocardial infarction. In addition to the vasodilation caused by inhibiting the production of angiotensin II, ACE inhibitors have anti-inflammatory, antithrombotic and antiproliferative properties. Some of these effects are mediated by actions on vascular endothelium and might be expected to be of benefit in all patients with CHD. ACE inhibitors also reduce the production of ROS.

The use of ACE inhibitors in patients without myocardial infarction or left ventricular damage is based on two trials: the HOPE study (Yusuf et al., 2000), which studied ramipril, and the EUROPA (2003) study, which used perindopril. These trials also identified an incidental delay in the onset of diabetes mellitus in susceptible individuals, which may be of long-term benefit to them. The HOPE study (Yusuf et al., 2000), a secondary prevention trial, investigated the effect of an ACE inhibitor on patients older than 55 years who had known atherosclerotic disease or diabetes plus one other cardiovascular risk factor. The use of ramipril decreased the combined endpoint of stroke, myocardial infarction or cardiovascular death by approximately 22%. The benefits were independent of blood pressure reduction. This has major implications for the management of CHD patients, both for the decision to treat all and the choice of treatment. At present the use of ACE inhibitors in patients with coronary disease and at least one additional risk factor, but without myocardial infarction, has general acceptance and is recommended in European guidelines (Montalescot et al., 2013).

Statins

Studies have repeatedly demonstrated the benefit of reducing cholesterol, especially low-density lipoprotein-cholesterol (LDL-C), in patients with CHD.

Earlier studies focused on patients with 'elevated' cholesterol, but all patients with coronary risk factors benefit from reduction of their serum cholesterol level. It is now clear that there is no 'safe' level of cholesterol for patients with CHD and that there is a continuum of risk down to very low cholesterol levels. Levels of LDL-C of less than 1.8 mmol/L used to be recommended for patients with established CVD, but a 40% reduction in non-HDL cholesterol from baseline is now recommended (National Institute for Health and Care Excellence [NICE], 2014a). Statins should be prescribed alongside lifestyle advice for both primary prevention of CVD and in those with established CVD (see Chapter 24 for more detail).

In addition to cholesterol-lowering properties, statins also have antithrombotic, anti-inflammatory and antiproliferative properties. They are also important in restoring normal endothelial function and inhibit the production of ROS in the

vessel wall. There is some evidence that patients with elevated levels of CRP have better outcomes with statin therapy, even if cholesterol levels are not raised. Most patients with stable angina will be on statins for their cholesterol-lowering effects. It is important, however, to recognise that these drugs may have beneficial effects independent of cholesterol lowering, and this makes them valuable even in patients with 'normal' cholesterol levels.

Symptom relief and prevention

In stable angina, much of the drug treatment is directed towards decreasing the workload of the heart and, to a lesser extent, improving coronary blood supply; this provides symptomatic relief and improves prognosis. Therapy to decrease workload is targeted at both decreasing afterload and controlling heart rate. Evidence suggests a prognostic benefit when the resting heart rate is controlled below 70 beats/min (Fox et al., 2008). Drug treatment is initiated in a stepwise fashion according to symptom relief and side effects. Some patients will require a number of anti-anginal medicines to control their angina symptoms.

β -Blockers

β -Blockers are now considered first-line agents in the management of angina. β -Blockers reduce mortality in both patients who have suffered a previous myocardial infarction and in those with heart failure. They reduce myocardial oxygen demand by blocking β -adrenergic receptors, thereby decreasing the heart rate and force of left ventricular contraction and lowering blood pressure. The decreased heart rate not only reduces the energy demand on the heart but also permits better perfusion of the subendocardium by the coronary circulation. β -Blockers may also reduce energy-demanding supraventricular or atrial arrhythmias and counteract the cardiac effects of hyperthyroidism or pheochromocytoma.

β -Blockers are particularly useful in exertional angina. Patients treated optimally should have a resting heart rate of around 60 beats/min. Although many patients may dislike the side effects of β -blockers, they should be urged to continue wherever reasonable. β -Blockers should be used with caution in patients with diabetes because the production of insulin is under adrenergic system control, and thus their concomitant use may worsen glucose control. β -Blockers can also mask the symptoms of hypoglycaemia and patients in whom the combination is considered of value should be warned of this; however, most clinicians now believe that the benefits of taking β -blockers, even in diabetics, outweigh the risks, and they are frequently prescribed.

Although β -blockers are widely used, their tendency to cause bronchospasm and peripheral vascular spasm means that they are contraindicated in patients with asthma and used with caution in chronic obstructive pulmonary disease and peripheral vascular disease as well as in acute heart failure and bradycardia.

Cardioselective agents such as atenolol, bisoprolol and metoprolol are preferred because of their reduced tendency to cause bronchoconstriction, but no β -blocker is completely specific for the heart. Agents with low lipophilicity, for example, atenolol, penetrate the central nervous system (CNS) to a lesser extent

Table 20.3 Properties and pharmacokinetics of β -blockers

	Blockade	Lipophilicity	ISA	Oral absorption	Elimination
Acebutolol	β_1 (some β_2)	+	+	90% ^a	Active metabolite ($t_{1/2}$ 11–13 h, renal) Gut 50%, $t_{1/2}$ 3–4 h
Atenolol	β_1	–	–	50%	Renal $t_{1/2}$ 5–7 h
Betaxolol	β_1	+	–	100%	Hepatic + renal $t_{1/2}$ 15 h
Bisoprolol	β_1	+	–	90%	Hepatic + renal $t_{1/2}$ 10–12 h
Carteolol	$\beta_1 \beta_2$	–	++	80%	Hepatic + renal $t_{1/2}$ 3–7 h
Carvedilol	$\beta_1 \beta_2 \alpha_1$	+	–	80% ^a	Hepatic + renal $t_{1/2}$ 4–8 h
Celiprolol	$\beta_1 \alpha_2$	–	β_2+	30–70%	Renal + gut $t_{1/2}$ 5–6 h
Esmolol	β_1	–	–	i.v.	Blood enzymes $t_{1/2}$ 9 min
Labetalol	$\beta_1 \beta_2 \alpha_1$	–	–	100% ^a	Hepatic $t_{1/2}$ 6–8 h
Metoprolol	β_1	+	–	95% ^a	Hepatic $t_{1/2}$ 3–4 h
Nadolol	$\beta_1 \beta_2$	–	–	30%	Renal $t_{1/2}$ 16–18 h
Nebivolol	β_1	+	–	12–96% ^b	Hepatic $t_{1/2}$ 8–27 h ^b
Oxprenolol	$\beta_1 \beta_2$	+	++	90% ^a	Hepatic + $t_{1/2}$ 1–2 h
Pindolol	$\beta_1 \beta_2$	+	+++	90%	Hepatic + renal $t_{1/2}$ 3–4 h
Propranolol	$\beta_1 \beta_2$	+	–	90% ^a	Hepatic $t_{1/2}$ 3–6 h
Sotalol	$\beta_1 \beta_2$	–	–	70%	Renal $t_{1/2}$ 15–17 h
Timolol	$\beta_1 \beta_2$	+	–	90% ^a	Hepatic + renal $t_{1/2}$ 3–4 h

^aExtensive first-pass metabolism may result in a significant decrease in bioavailability.

All figures are approximate and subject to interpatient variability. Therapeutic ranges are not well defined.
ISA, Intrinsic sympathomimetic activity; i.v., intravenous; $t_{1/2}$, elimination half-life.

than others, and do not so readily cause the nightmares, hallucinations and depression that are sometimes found with lipophilic agents, for example, propranolol and metoprolol, which should not be used in patients with psychiatric disorders. CNS-mediated fatigue or lethargy is found in some patients with all β -blockers, although it must be distinguished from that of myocardial suppression. β -Blockers should not be stopped abruptly for fear of precipitating angina through rebound receptor hypersensitivity. They should be avoided in the rare Prinzmetal's angina where coronary spasm is a major factor.

All β -blockers tend to reduce renal blood flow, but this is only important in renal impairment. Drugs eliminated by the kidney (Table 20.3) may need to be given at lower doses in the renally impaired or in the elderly, who are particularly susceptible to the CNS-mediated lassitude. Drugs eliminated by the liver have a number of theoretical interactions with other agents that affect liver blood flow or metabolic rate, but these are rarely of clinical significance because the dose should be titrated to the effect.

Likewise, although there is theoretical support for the use of agents with high intrinsic sympathomimetic activity (ISA) to reduce the incidence or severity of drug-induced heart failure, there is no β -blocker that is free from this problem, and clinical trials of drugs with ISA have generally failed to show any extra benefit.

Calcium channel blockers

Calcium channel blockers (CCBs) act on a variety of smooth muscle and cardiac tissues, and there are a large number of agents that have differing specificities for different body tissues.

Although short-acting dihydropyridine CCBs have been implicated in the exacerbation of angina due to the phenomenon of 'coronary steal', longer-acting dihydropyridines, for example, amlodipine and felodipine, or longer-acting formulations, for example, nifedipine LA, have demonstrated symptom-relieving potential similar to β -blockers. Dihydropyridines have no effect

on the conducting tissues and are effective arterial dilators, decreasing afterload and improving coronary perfusion but also causing flushing, headaches and reflex tachycardia. This may be overcome by combination with a β -blocker. The use of dihydropyridines in angina is based on efficacy in trials that have used surrogate markers such as exercise tolerance rather than mortality as the endpoint.

CCBs with myocardial rate control as well as vasodilatory properties, for example, diltiazem, and those with predominantly rate-controlling effects, for example, verapamil, have also been shown to improve symptom control, reduce the frequency of anginal attacks and increase exercise tolerance. They should be avoided in patients with compromised left ventricular function and conduction abnormalities. Verapamil and diltiazem are suitable for rate-control patients in whom β -blockers are contraindicated on the grounds of respiratory or peripheral vascular disease. They should be used with caution in patients already receiving β -blockers because bradycardia and heart block have been reported with this combination.

CCBs have a particular role in the management of Prinzmetal's (variant) angina, which is thought to be due to coronary artery spasm.

Nitrates

Organic nitrates are valuable in angina because they dilate veins and thereby decrease preload, dilate arteries to a lesser extent, thereby decreasing afterload, and promote flow in collateral coronary vessels, diverting blood from the epicardium to the endocardium. They are available in many forms, but all relax vascular smooth muscle by releasing nitric oxide (formerly known as endothelium-derived relaxing factor), which acts via cyclic GMP. The production of nitric oxide from nitrates is probably mediated by intracellular thiols, and it has been observed that when tolerance to the action of nitrates occurs, a thiol donor (such as *N*-acetylcysteine) may partially restore the effectiveness of the nitrate. Antioxidants such as vitamin C have also been used. Although clinical trials have not established any mortality gain from the use of oral nitrate preparations, their role in providing symptom relief is well established.

Tolerance is one of the main limitations to the use of nitrates. This develops rapidly, and a 'nitrate-free' period of a few hours in each 24-hour period is beneficial in maintaining the effectiveness of treatment. The nitrate-free period should coincide with the period of lowest risk of infarction, usually night time, and not early morning, the period with the highest risk. Many patients receiving short-acting nitrates two or three times a day would do well to have their doses between 7 a.m. and 6 p.m. (say, 8 a.m. and 2 p.m. for isosorbide mononitrate). This is generally not practised in unstable angina where there is no low-risk period; continuous dosing is used, with doses increased if tolerance develops.

There are many nitrate preparations available, including intravenous infusions, conventional or slow-release tablets and capsules, transdermal patches, sublingual tablets and sprays and adhesive buccal tablets. Slow-release preparations and transdermal patches are expensive and do not generally offer such flexible dosing regimens as short-acting tablets. Sustained-release tablets do not release the drug over the whole 24-hour period, producing a 'nitrate free period', whereas patches need to be

removed for a few hours each day. Buccal tablets are expensive and offer no real therapeutic advantage in regular therapy. Like sublingual sprays and tablets, however, they have a rapid onset of action, and the drug bypasses the liver, which has an extensive first-pass metabolic effect on oral nitrates. The sublingual preparations, whether sprays or suckable or chewable tablets, are used for the prevention or relief of acute attacks of pain but may elicit the two principal side effects of nitrates: hypotension with dizziness and fainting, and a throbbing headache. To minimise these effects, patients should be advised to sit down, rather than lie or stand, when taking short-acting nitrates, and to spit out or swallow the tablet once the angina is relieved. Sublingual glyceryl trinitrate (GTN) tablets have a very short shelf-life on exposure to air and need to be stored carefully and replaced frequently. As a consequence, they are now little used. All nitrates may induce tachycardia.

Three main nitrates are used: GTN (mainly for sublingual, buccal, transdermal and intravenous routes), isosorbide dinitrate and isosorbide mononitrate. All are effective if given in appropriate doses at suitable dose intervals (Table 20.4). Because isosorbide dinitrate is metabolised to the mononitrate, there is a preference for using the more predictable mononitrate, but this is not a significant clinical factor. A more relevant feature may be that whereas the dinitrate is usually given three or four times a day, the mononitrate is given once or twice a day. Slow-release preparations exist for both drugs.

Nicorandil

Nicorandil is a compound that exhibits the properties of a nitrate but which also activates adenosine triphosphate (ATP)-dependent potassium channels. The IONA Study Group (2002) compared nicorandil with placebo as 'add-on' treatment in 5126 high-risk patients with stable angina. The main benefit for patients in the nicorandil group was a reduction in unplanned admission to hospital with chest pain. The study did not discuss when to add nicorandil to combinations of antianginals such as β -blockers, CCBs and long-acting nitrates. There is a theoretical benefit from these agents in their action to promote ischaemic preconditioning. This phenomenon is seen when myocardial tissue is exposed to a period of ischaemia before sustained coronary artery occlusion. Prior exposure to ischaemia renders the myocardial tissue more resistant to permanent damage. This mechanism is mimicked by the action of nicorandil.

Ivabradine

Ivabradine represents a class of antianginal agents which block the I_f current. I_f is a mixed Na^+ - K^+ inward current activated by hyperpolarisation and modulated by the autonomic nervous system. This regulates pacemaker activity in the sinoatrial node and controls heart rate. Inhibition, therefore, reduces heart rate without affecting the force of contraction. Ivabradine is similar in efficacy to atenolol and CCBs and may be of particular use in patients in whom β -blockers are contraindicated. The most frequent adverse drug reactions are dose-dependent transient visual symptoms that manifest as enhanced brightness commonly associated with abrupt changes in light intensity. They may be related to the action of ivabradine at hyperpolarisation-activated, cyclic

Table 20.4 Properties of commonly used nitrates

Drug	Speed of onset	Duration of action	Notes
GTN			
Intravenous	Immediate	Duration of infusion	
Transdermal	30 min	Designed to release drug steadily for 24 h	Tolerance develops if applied continuously
SR tablets and capsules	Slow	8–12 h	
Sublingual tablets	Rapid (1–4 min)	<30 min	Inactivated if swallowed Less effective if dry mouth
Spray	Rapid (1–4 min)	<30 min	
Buccal tablets	Rapid (1–4 min)	4–8 h	Nearly as rapid in onset as sublingual tablets
Isosorbide dinitrate			
SR tablets	Similar to GTN		
Intravenous	Similar to GTN		
Sublingual	Slightly slower than GTN	As for GTN	
Chewable tablets	2–5 min	2–4 h	Less prone to cause headaches than sublingual tablets
Oral tablets	30–40 min	4–8 h	
Isosorbide mononitrate			
Oral tablets	30–40 min	6–12 h	
SR tablets or capsules	Slow	12–24 h	Some brands claim a nitrate-free period if given once daily

GTN, Glyceryl trinitrate; SR, sustained-release.

nucleotide-gated cation current channels present in the retina. Visual symptoms may resolve spontaneously during therapy or after drug discontinuation.

Ranolazine

Ranolazine, a selective inhibitor of late sodium influx, attenuates the abnormalities of ventricular repolarisation and contractility associated with ischaemia. It has been shown to increase exercise tolerance, reduce anginal episodes and reduce the use of GTN. Side effects include dizziness, constipation, nausea, and the potential for prolongation of the QTc interval. Ranolazine seems to be a safe addition to current traditional drugs for chronic stable angina, especially in aggressive multidrug regimens.

Acute coronary syndrome

Definition and cause

The group of conditions referred to as ACS often present with similar symptoms of chest pain which is not, or only partially, relieved by GTN. These conditions include acute

myocardial infarction (AMI), unstable angina (UA) and non-ST-elevation myocardial infarction (NSTEMI). AMI with persistent ST-segment elevation on the ECG usually develops Q waves, indicating transmural infarction. UA and NSTEMI present without persistent ST-segment elevation and are managed differently, although a similar early diagnostic and therapeutic approach is employed. All patients with ACS should be admitted to hospital for evaluation, risk stratification and treatment. The spectrum of ACS is described in Fig. 20.3.

ACS arises from the rupture of an unstable atheromatous plaque. This exposes the cholesterol-rich plaque in the intima to the blood, initiating platelet activation and eventual thrombus formation. The volume of the eventual thrombus and the time the vessel is occluded determine the degree of myocardial necrosis that occurs. The major difference in approach to these patients arises from whether the coronary artery involved is felt to be occluded or open.

Patients with an occluded coronary artery suffer myocardial damage, the extent of which is determined by the duration and site of the occlusion. The primary strategy for these patients is the restoration of coronary flow with either a fibrinolytic agent or primary angioplasty. If the coronary artery is

Fig. 20.3 The spectrum of acute coronary syndrome (Thygesen et al., 2007).

ECG, Electrocardiogram; NSTEMI, non-ST-elevation myocardial infarction; STEMI, ST elevation myocardial infarction.

patient, then fibrinolysis is unnecessary and probably harmful, although angioplasty may still be appropriate. When the vessel is open, for both groups, patient management focuses on the unstable coronary plaque and is, therefore, fundamentally similar.

Troponins (troponin I or troponin T) are cardiac muscle proteins that are released after myocardial cell damage and are highly sensitive and specific for myocardial infarction. They are useful in diagnosing patients with ACS and for predicting response to drug therapy; they are now key to the management of these patients and have replaced cardiac enzymes such as creatinine kinase (CK), aspartate transaminase (AST) and lactate dehydrogenase (LDH).

Diagnostic criteria for AMI have changed to incorporate the increasing availability of new diagnostic techniques with traditional symptoms and ECG changes. The following criteria for AMI, agreed by the European Society of Cardiology (Steg et al., 2012) rely on the rise of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit, together with evidence of myocardial ischaemia characterised by at least one of the following symptoms:

- ECG changes indicative of new ischaemia: new ST changes (STEMI or new left bundle branch block [LBBB]),
- development of pathological Q waves in the ECG,
- image evidence of new loss of viable myocardium or new regional wall motion abnormality.

Mortality rates of patients with presumed myocardial infarction or ACS in the first month is approximately 30%, and of these deaths, about half occur within the first 2 hours. The prognosis of an individual who has suffered a STEMI and receives hospital treatment has improved since the widespread use of thrombolytic therapy and primary percutaneous intervention.

The most dangerous time after a myocardial infarction is the first few hours when ventricular fibrillation (VF) is most likely to occur.

Patients without persistent ST elevation on the ECG may still have experienced myocardial damage due to the temporary occlusion of the vessel or emboli from the plaque-related thrombus blocking smaller distal vessels and will have raised levels of troponin. These patients have had a NSTEMI. The long-term prognosis in NSTEMI is similar to that of STEMI. The early adverse event rate is lower, but these patients are more likely to suffer death, recurrent myocardial infarction or recurrent ischaemia after hospital discharge than patients with STEMI. More emphasis is now placed on improving the treatment of patients with NSTEMI than was previously the case. Patients without ST elevation and without a rise in troponin or cardiac enzymes are defined as having UA.

The Global Registry of Acute Coronary Events (GRACE; available at <http://www.gracescore.org>) is an international registry which has enrolled patients with ACS (UA, NSTEMI and STEMI) since 1999. The registry indicates a similar incidence of UA, NSTEMI and STEMI. The GRACE 2.0 risk calculator (available via <http://www.gracescore.org>) provides a direct estimation of mortality while in hospital, at 6 months, 1 year and at 3 years. The combined risk of death or myocardial infarction at 1 year is also provided. Variables used in the GRACE 2.0 risk calculation include age, systolic blood pressure, pulse rate, serum creatinine, Killip class at presentation, cardiac arrest at admission, elevated cardiac biomarkers and ST deviation (Roffi et al., 2016).

The classification of ACS based on ECG findings and measurement of troponin is shown in Fig. 20.4.

Treatment of ST-elevation myocardial infarction

Treatment of STEMI may be divided into four categories:

- provide immediate care to alleviate pain, prevent deterioration and improve cardiac function;
- restore coronary flow and myocardial tissue perfusion;
- manage complications, notably heart failure and arrhythmias;
- prevent further infarction or death (secondary prophylaxis).

The management of heart failure and arrhythmias is covered more extensively in Chapters 21 and 22, respectively, and will not be discussed here. The remaining therapeutic aims are to relieve pain, return patency to the coronary arteries, minimise infarct size, provide prophylaxis to arrhythmias and institute secondary prevention.

Immediate care to alleviate pain, prevent deterioration and improve cardiac function

Pain relief. Patients with suspected STEMI should receive sublingual GTN under the tongue, and intravenous access should be established immediately. If sublingual GTN fails to relieve the chest pain, intravenous morphine may be administered together with an antiemetic such as prochlorperazine or metoclopramide. There is no benefit in leaving a patient in pain while the diagnosis is considered. Pain is associated

Fig. 20.4 Classification of acute coronary syndrome based on electrocardiogram (ECG) and measurement of troponins.

with sympathetic activation, which causes vasoconstriction, increases the workload of the heart and can exacerbate the underlying condition. Oxygen should only be administered in cases of hypoxaemia or respiratory distress; a recent trial has demonstrated the potential of harm if used in normoxaemic patients (Stub et al., 2015).

Antiplatelet therapy. An aspirin tablet (300–325 mg) chewed as soon as possible after the infarct and followed by a daily dose of 75 mg for at least 1 month has been shown to reduce mortality and morbidity. The reduction in mortality is additional to that obtained from thrombolytic therapy (Table 20.5). Current recommendations state aspirin should be taken indefinitely (Ibanez et al., 2018). Clopidogrel, a P2Y₁₂ inhibitor given in addition to aspirin, can further improve coronary artery blood flow, but the additional absolute reduction in mortality is small, at approximately 0.4% (Sabatine et al., 2005). Clopidogrel is a prodrug that undergoes a two-step metabolic activation process within the body. This alongside its variable absorption results in a delayed response and increases inter-patient variability. The newer P2Y₁₂ inhibitors, prasugrel (another thienopyridine) and ticagrelor (an acyclopentyl-triazolo-pyrimidine), offer a quicker onset of action and less interpatient variability, with an absolute risk reduction of 2% (Lindholm et al., 2014; Montalescot et al., 2009). Cangrelor, an intravenous P2Y₁₂ inhibitor, has most recently been licensed in the UK, but its role in therapy is still to be ascertained.

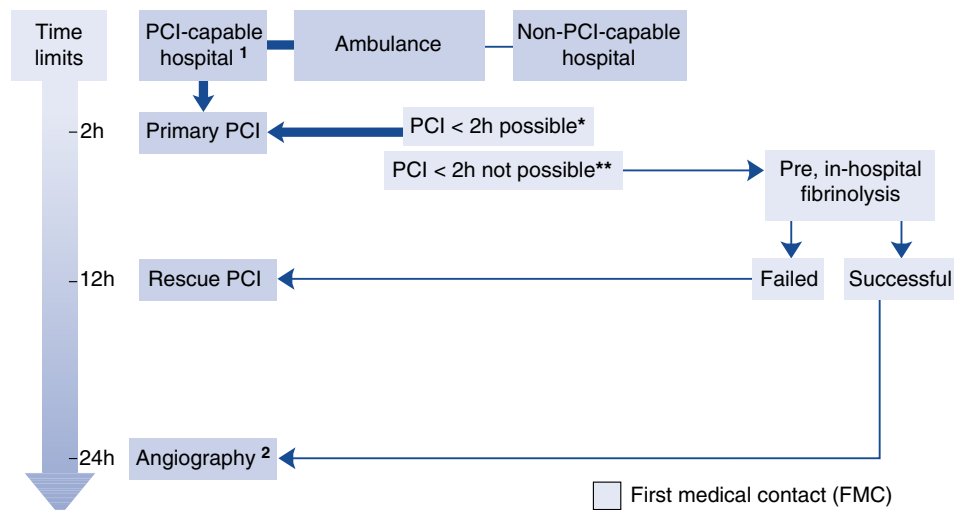

Table 20.5 Vascular deaths at 35 days in the ISIS-2 (1990) study

Placebo	13.2%
Aspirin	10.7%
Streptokinase	10.4%
Aspirin + streptokinase	8.0%

Restoring coronary flow and myocardial tissue perfusion

In patients with STEMI, early restoration of coronary artery patency results in an improved outcome. The timing of treatment is vital because myocardial damage after the onset of an acute ischaemic episode is progressive, and there are pathological data to suggest it is irreversible beyond 6 hours. Hospitals need to maintain fast-track systems to ensure maximum benefit, although there is still some worthwhile benefit up to 12 hours after infarction.

Treatment within 1 hour has been found to be particularly advantageous, although difficult to achieve, for logistical reasons, in anyone who has an infarct outside hospital. Prioritisation of ambulances to emergency calls for chest pain and appropriately equipped paramedics or primary care doctors administering fibrinolytics out of hospital have all helped reduce delay

- * Time FMC to first balloon inflation must be shorter than 90 min in patients presenting early (<2 h after symptom onset), with large amount of viable myocardium and low risk of bleeding
- ** If PCI is not possible <2 h of FMC, start fibrinolytic therapy as soon as possible
- ¹ 24/7 service
- ² Not earlier than 3 h after starting fibrinolysis
- PCI, Percutaneous coronary intervention

Fig. 20.5 Reperfusion strategies. The thick arrow (dark blue) indicates the preferred strategy (Van de Werf, 2008).

Table 20.6 Fibrinolytic agents (thrombolytics)

	Fibrin specificity	Elimination	Half-life (minute)	Dosing	Antigenic	Mode of action
Streptokinase		Hepatic	18–23	1 h infusion	Yes	Activator complex
Alteplase	++	Hepatic	3–8	Bolus + 90 min infusion	No	Direct
Retepase	+	Renal	15–18	Two boluses	No	Direct
Tenecteplase	+++	Hepatic	20–28	One bolus	No	Direct

in fibrinolysis administration. Increased numbers of and direct access to hospitals offering primary angioplasty sites have further reduced the time to myocardial reperfusion. Current reperfusion strategies are outlined in Fig. 20.5.

Fibrinolytics. Fibrinolytic agents (Table 20.6) have transformed the management of these patients by substantially improving coronary artery patency rates, which has translated into a 25% relative reduction in mortality. The risk of haemorrhagic stroke (around 1%) (Ibanez et al., 2018) and a failure to adequately reperfuse the affected myocardium have remained despite advances in fibrinolytics.

Percutaneous coronary intervention. Percutaneous coronary intervention (PCI) involves the passing of a catheter via the femoral or radial artery and aorta into the coronary vasculature under radio-contrast guidance. Inflation of a balloon at the end of the catheter in the area of the atheromatous plaques opens the

lumen of the artery. For patients undergoing PCI, there is a small risk of death, myocardial infarction and long-term restenosis. This is reduced by insertion of a coronary artery stent and the use of pre- and peri-procedural antiplatelet therapy. Over the last 10 years the proportion of patients undergoing PCI and stent insertion has accounted for more than 95% of all PCI procedures.

The introduction of primary PCI (angioplasty and/or stent insertion without prior or concomitant fibrinolytic therapy) has demonstrated superiority to fibrinolysis when it can be performed expeditiously by an experienced team in a hospital with an established 24-hour-a-day interventional programme. In this context, primary angioplasty is better than fibrinolysis at reducing the overall short-term death, non-fatal reinfarction and stroke. The target for time from first medical contact to first balloon inflation should be less than 2 hours. If the delay to angioplasty is likely to be longer than 2 hours, facilitated PCI can be undertaken.

Table 20.7 Key features and differences of the oral P2Y₁₂ Inhibitors

	Clopidogrel	Prasugrel	Ticagrelor
Class	Thienopyridine	Thienopyridine	Acyclopentyl-triazolo-pyrimidine
Loading dose	300–600 mg	60 mg	180 mg
Maintenance dose	75 mg daily	5–10 mg daily	90 mg twice daily
Activation	Prodrug with variable metabolic activation	Prodrug with predictable metabolic activation	Active drug
Binding	Irreversible	Irreversible	Reversible
Onset	2–6 h	30 min	30 min
Duration of effect	3–10 days	7–10 days	3–5 days

Facilitated PCI involves the use of a fibrinolytic to achieve reperfusion before a planned PCI. This approach allows the clinical team to bridge an anticipated delay in undertaking a PCI.

Rescue PCI is performed on coronary arteries which remain occluded despite attempts at fibrinolysis. It has better outcomes than repeated fibrinolytic therapy or conservative management.

PCIs encompass various invasive procedures to improve myocardial blood delivery by opening up the blood vessels. PCIs open stenosed coronary vessels and are less invasive than coronary bypass surgery, where the coronary vessels are replaced.

A percutaneous (through the skin) transluminal (through the lumen of the blood vessels) coronary (into the heart) angioplasty (surgery or repair of the blood vessels) (PTCA) was first carried out on a conscious patient in 1977. Now more than 2 million people a year undergo PCIs. The procedure is less invasive than coronary artery bypass graft (CABG) surgery.

Antiplatelet and anticoagulant therapy. After stent insertion, there is a short-term risk of thrombus formation until the endothelial lining of the blood vessel has been re-established. The combination of aspirin and a P2Y₁₂ inhibitor has been shown to reduce the risk of myocardial infarction and need for reperfusion therapy and decrease the length of hospital stay. Patients undergoing primary PCI should receive aspirin and an oral P2Y₁₂ inhibitor as early as possible. In comparison to clopidogrel, prasugrel has less metabolic activation steps and a faster and more reliable onset of antiplatelet action. In combination with aspirin, in the UK it is recommended as an option for preventing atherothrombotic events in adults with acute coronary syndrome having primary or delayed percutaneous coronary intervention (NICE, 2014b). Ticagrelor does not require metabolic activation and has a faster and more reliable onset of antiplatelet action. In combination with aspirin, in the UK it is recommended (NICE, 2011) in the following individuals:

- those with STEMI who are to be treated with percutaneous coronary intervention,
- those with NSTEMI or unstable angina.

Most centres are now using the newer P2Y₁₂ inhibitors due to their favourable properties (Table 20.7).

Heparin is routinely administered during the PCI procedure and is titrated to maintain an activated clotting time (ACT) of 250–350 seconds. Glycoprotein IIb/IIIa receptor antagonists, particularly abciximab, have been shown to reduce mortality if used during the procedure. These are used in combination with heparin, and a lower ACT (200–250 seconds) is targeted to reduce bleeding complications. Bivalirudin, a direct thrombin inhibitor, has demonstrated less bleeding compared with abciximab and may be useful in those at risk of increased bleeding.

Much of the evidence for the use of glycoprotein IIb/IIIa receptor antagonists was accumulated before high-dose clopidogrel or more potent antiplatelets were in routine practice. Current recommendations are that in the setting of dual-antiplatelet therapy with unfractionated heparin or bivalirudin as the anticoagulant, glycoprotein IIb/IIIa receptor antagonists can be useful at the time of primary PCI for bailout (intraprocedure thrombus formation, slow flow, threatened vessel closure) but cannot be recommended as routine therapy (Ibanez et al., 2018).

Intracoronary administration of vasodilators such as adenosine, verapamil, nicorandil, papaverine, and nitroprusside during and after primary PCI has been shown to improve flow in the infarct-related coronary artery and myocardial perfusion, and/or to reduce infarct size, but large prospective randomised trials with hard clinical outcomes are missing.

Fibrinolytics. Fibrinolytic agents fall into two categories: fibrin specific (alteplase, tenecteplase and reteplase) and fibrin nonspecific (streptokinase). There are theoretical advantages for the fibrin-specific agents, which are superior in terms of achieving coronary artery patency in angiographic studies, and these are therefore recommended in current guidance (Ibanez et al., 2018). Fast injection of fibrin-specific agents is better than slower infusion of streptokinase, especially in younger patients with anterior infarcts. Tenecteplase and reteplase have the advantage that they can be administered by bolus injection, which facilitates pre-hospital administration and reduces errors.

Patients receiving alteplase also receive a 5000-unit heparin bolus followed by a 48-hour infusion adjusted to maintain the activated partial thromboplastin time (APTT) in the therapeutic

range. Intravenous enoxaparin followed by subcutaneous injections may be an alternative. Heparin has not been compared with a placebo in trials of tenecteplase or reteplase, but it is standard practice to use heparin with these agents. Heparin has no advantage in addition to streptokinase, which has a longer-lasting and less specific fibrinolytic action.

A low dose of fondaparinux, a synthetic, indirect anti-Xa agent, has been found to be superior to placebo or heparin in preventing death and reinfarction in patients who received fibrinolytic therapy (OASIS-6 Trial Group, 2006).

Bivalirudin, a direct thrombin inhibitor, reduces reinfarction rates compared with heparin when given with streptokinase but has not been studied with fibrin-specific agents. This combination resulted in a nonsignificant increase in noncerebral bleeding complications (HERO-2 Trial Investigators, 2001).

Trials using various dosing combinations of glycoprotein IIb/IIIa inhibitors with newer fibrinolytic agents have not found a regimen that increases overall survival (Menon et al., 2004).

All fibrinolytics cause haemorrhage, which may present as a stroke or a gastro-intestinal bleed, and there is an increased risk with regimens that use intravenous heparin. Recent strokes, bleeds, pregnancy and surgery are contraindications to fibrinolysis. Streptokinase induces cross-reacting antibodies which reduce its potency and may cause an anaphylactoid response. Patients with exposure to streptokinase, or with a history of rheumatic fever or recent streptococcal infection, should not receive the drug. The use of hydrocortisone to reduce allergic responses has fallen out of favour, but patients should be carefully observed for hypotension during the administration of streptokinase.

Old age is no longer considered to be a contraindication to fibrinolysis. Although the risks are greater, the benefit is also greater, but the doses of alteplase and tenecteplase need to be adjusted for body weight.

All the major trials have used specific ECG criteria for entry, usually ST elevation in adjacent leads or LBBB, and eliminated patients with major contraindications to fibrinolysis (Box 20.2). Confusion often arises about the term 'relative contraindication'. For example, systolic hypertension is common in AMI, so most protocols recommend lowering the blood pressure with either a β -blocker or intravenous nitrates before commencing fibrinolysis. An increasing number of patients are on warfarin, and this again is regarded as a relative contraindication to fibrinolysis; thresholds for the use of fibrinolysis in patients on warfarin vary from an international normalised ratio (INR) of 2 to 2.4. The use of fibrinolytic therapy in patients with relative contraindications should take into account both the site and size of the myocardial infarction. For example, in patients with a large anterior myocardial infarction the benefits of fibrinolysis may outweigh its risk. In patients in whom there is a serious concern regarding bleeding after fibrinolysis, primary angioplasty should be considered.

Management of complications

Heart failure. Heart failure during the acute phase of STEMI is associated with a poor short- and long-term prognosis. It should be managed with oxygen, intravenous furosemide and nitrates.

Box 20.2 Contraindications to fibrinolysis (Van de Werf et al., 2008)

Absolute contraindications

- Haemorrhagic stroke of unknown origin at any time
- Ischaemic stroke in preceding 6 months
- Central nervous system damage or neoplasms
- Recent major trauma/surgery/head injury (within preceding 3 weeks)
- Gastro-intestinal bleed within the last month
- Known bleeding disorder
- Non-compressible punctures
- Aortic dissection

Relative contraindications

- Transient ischaemic attack in preceding 6 months
- Oral anticoagulant therapy
- Pregnancy or within 1 week postpartum
- Advanced liver disease
- Active peptic ulcer
- Infective endocarditis
- Traumatic resuscitation
- Refractory hypertension (systolic blood pressure >180 mmHg)

More severe failure or cardiogenic shock (tissue hypoperfusion resulting from cardiac failure with symptoms of hypotension, peripheral vasoconstriction, diminished pulses, decreased urine output and decreased mental status) should be treated with inotropes and/or intra-aortic balloon pumps to maintain the systolic blood pressure greater than 90 mmHg. Invasive monitoring may be required.

Arrhythmias. Life-threatening arrhythmias such as ventricular tachycardia, sustained VF or atrio-ventricular block occur in about one-fifth of patients presenting with a STEMI, although this is decreasing due to early reperfusion therapy. β -Blockers have been the subject of many studies because of their anti-arrhythmic potential and because they permit increased subendocardial perfusion. In studies undertaken before the widespread use of fibrinolytics, the early administration of an intravenous β -blocker was shown to limit infarct size and reduce mortality from early cardiac events. A post hoc analysis of the use of atenolol in the GUSTO-I trial and a systematic review (Freemantle et al., 1999) did not support the routine, early intravenous use of β -blockers; therefore, oral β -blockers are started within 24 hours of the event. If a β -blocker is contraindicated because of respiratory or vascular disorders, verapamil may be used because it has been shown to reduce late mortality and reinfarction in patients without heart failure, although it shows no benefit when given immediately after an infarct. Diltiazem is less effective but may be used as an alternative. This is clearly not a class effect; other calcium channel blockers have produced different results, and nifedipine increases mortality in patients after a myocardial infarction.

Initially, magnesium infusions looked promising when given early after infarction. However, in large trials (ISIS-4, 1995), no reductions in mortality were found, making the routine use of magnesium inappropriate. Magnesium infusions are used, however, to correct low serum magnesium levels if cardiac arrhythmias are present.

Sinus bradycardia and heart block may also occur after a myocardial infarction, and patients may require temporary or permanent pacemaker insertion.

Blood glucose. Patients with a myocardial infarction are often found to have high serum and urinary glucose levels, usually described as a stress response. The CREATE-ECLA trial (Mehta et al., 2005) studied more than 20,000 patients and showed a neutral effect of insulin on mortality, cardiac arrest and cardiogenic shock. Current guidelines do not support the routine use of insulin in STEMI in patients not previously known to be diabetic.

Up to 20% of patients who have a myocardial infarction have diabetes. Moreover, diabetic patients are known to do poorly after infarction, with almost double the mortality rate of non-diabetics. In these patients, an intensive insulin regimen, both during admission and for 3 months after, was found to save lives (Malmberg, 1997). However, the follow-up study (Malmberg et al., 2005) did not show any mortality benefit from intensive insulin therapy compared with standard therapy. In patients with diabetes, it appears reasonable, however, to continue to control blood glucose levels within the normal range immediately post-infarct.

Prevention of further infarction or death (secondary prophylaxis)

Lipid-lowering agents. Reduction of cholesterol through diet and use of lipid-lowering agents is effective at reducing subsequent mortality and morbidity in patients with established CHD. Levels of LDL-C of less than 1.8 mmol/L used to be recommended for patients with established CVD, but a 40% reduction in non-HDL cholesterol from baseline is now recommended (NICE, 2014a). In patients with AMI or high-risk NSTEMI, there was a reduction in the combination end point of death, myocardial infarction, or documented UA requiring hospitalisation, revascularisation or stroke when patients were treated with high-intensity statin therapy (atorvastatin 80 mg daily) compared with standard statin therapy (Cannon et al., 2004). A meta-analysis of studies (Josan et al., 2008) reaffirmed the benefit of high-intensity statin therapy especially in those patients with ACS. An additional finding of particular interest was that the results were significant for the high-intensity treatment arms despite approximately half of patients not achieving LDL-C of less than 2 mmol/L.

β -Blockers. Long-term use of a β -blocker is recommended to decrease mortality in patients in whom there is no contraindication (Ibanez et al., 2018). β -Blockade should be avoided in individuals with heart block, bradycardia and asthma and used with caution in individuals with chronic obstructive pulmonary disease or peripheral vascular disease. One large cohort study compared low and high doses of β -blockers with no therapy and found benefit in all treated patients, with similar survival rates but a lower heart failure rate in the low-dose group (Rochon et al., 2000).

Angiotensin-converting enzyme inhibitors. Various doses and durations of ACE inhibitors have proved beneficial in reducing the incidence of heart failure and mortality. In all but the earliest trials, patients were given an ACE inhibitor for 4–6 weeks,

Table 20.8 Relative benefits of treating 1000 patients for myocardial infarction

Intervention	Events prevented
Intravenous β -adrenoceptor blocker	6 deaths
ACE inhibitor	6 deaths
Aspirin	20–25 deaths
Streptokinase (in hospital)	20–25 deaths
Alteplase (in hospital)	35 deaths
Streptokinase (before hospital)	35–40 deaths
Fibrinolysis 4½–1 h earlier	15 deaths
Long-term aspirin	16 deaths/MI/strokes
Long-term β -blockade	18 deaths/MI
Long-term ACE inhibitor	21–45 deaths/MI
10% reduction in serum cholesterol	7 deaths/MI
Stopping smoking	27 deaths

ACE, Angiotensin-converting enzyme; MI, myocardial infarction. Adapted from McMurray and Rankin (1994).

and treatment continued in patients with signs or symptoms of heart failure or left ventricular dysfunction. The HOPE study (Yusuf et al., 2000) found that ramipril improved survival in all groups of patients with CHD, and this has led clinicians to continue ACE inhibitors in all patients with a myocardial infarction older than 55 years and in younger patients with evidence of left ventricular dysfunction. Contraindications to their use include hypotension and intractable cough.

There is considerable interest in focusing on the possible benefits of combining ACE inhibition with angiotensin II receptor blockers. Angiotensin receptor blockade alone does not cause the accumulation of bradykinins which may be part of the benefit of using ACE inhibitors. Clinical trials (OPTIMAAL Study Group, 2002; VALIANT Investigators, 2003) have failed to find a benefit over ACE inhibition. Nonetheless, angiotensin receptor blockers are probably suitable in patients who cannot tolerate an ACE inhibitor. The relative benefits of ACE inhibitors and other treatments are shown in Table 20.8.

Eplerenone. In patients with heart failure post-AMI, in the EPHEBUS Trial (Pitt et al., 2003) an improvement in survival and decreased cardiovascular mortality and hospitalisation was seen in those taking the aldosterone antagonist eplerenone. Serious hyperkalemia occurred more frequently in the eplerenone arm, and monitoring of serum potassium is warranted when used in practice.

Antidepressants. Anxiety is almost inevitable, and a quarter of patients who have suffered a myocardial infarction subsequently experience marked depression. Post-myocardial infarction depression is associated with poor medication compliance,

a lower quality-of-life score and a fourfold increase in mortality (Januzzi et al., 2000). Antidepressant treatments have not been subjected to formal trials, but it seems reasonable to try to reduce the depression. There is concern about the potential for older antidepressants, such as tricyclic antidepressants, to increase the QT interval and cause arrhythmias. Newer antidepressants are less prone to cause these arrhythmias, and selective serotonin receptor inhibitors (SSRIs) are preferred.

Rehabilitation programmes which include some measure of social interaction, physical activity and education are also of proven benefit. Although psychological stress clearly worsens outcomes, stress reduction interventions have not been tested and proven to work independently of other measures.

Nitrates. Studies on nitrates in myocardial infarction were mostly completed before fibrinolysis was widely used. Nitrates improve collateral blood flow and aid reperfusion, thus limiting infarct size and preserving functional tissue. ISIS-4 (1995) and GISSI-3 (1994) demonstrated that nitrates did not confer a survival advantage in patients receiving fibrinolysis. Sublingual nitrates may be given for immediate pain relief, and the use of intravenous or buccal nitrates can be considered in patients whose infarction pain does not resolve rapidly or who develop ventricular failure.

Anticoagulants and antiplatelets. Anticoagulation with warfarin is not generally recommended after a myocardial infarction, despite promising results in trials that have practised exceptionally good anticoagulant monitoring. This is partly because of the success of antiplatelet therapy with aspirin. Aspirin does not have the same need for expensive and time-consuming follow-up and monitoring as warfarin and is associated with fewer drug interactions. The P2Y₁₂ inhibitors (clopidogrel, prasugrel and ticagrelor) have been shown to be beneficial, when combined with aspirin, in patients who have had a myocardial infarction. As the number of patients who receive a stent increases, dual antiplatelet therapy (DAPT) with aspirin and a P2Y₁₂ inhibitor is more common. The duration of DAPT therapy has been the topic of much debate, with most guidelines recommending 12-month therapy, but this is reduced in patients at a high risk of bleeding and increased in those with a heightened risk of reinfarction. A lower dose of ticagrelor (60 mg twice daily) given after the initial year of DAPT has demonstrated a reduction in CVD-associated death (Bonaca et al., 2015).

A low dose of the direct acting oral anticoagulant (DOAC) rivaroxaban (2.5 mg twice daily) combined with aspirin and clopidogrel or aspirin alone has demonstrated a reduction in atherothrombotic events in individuals post-ACS (Mega et al., 2012). Higher doses were found to increase the risk of bleeding.

For patients who require long-term oral anticoagulation, either with warfarin or a DOAC, for other therapeutic indications (e.g., stroke prevention in atrial fibrillation or treatment of venous thromboembolism) in addition to dual antiplatelet therapy, a combination which minimises bleeding risk should be considered. Evidence currently favours DAPT (with aspirin and clopidogrel) for a shorter period (followed by clopidogrel alone for up to 12 months) with the lowest recommended therapeutic dose of oral anticoagulant. The use of prasugrel or

ticagrelor as part of triple therapy should be avoided unless there is a clear need for these agents (Kirchhof et al., 2016).

Treatment of non-ST-elevation acute coronary syndromes

ACS without ST elevation is classified as either UA or NSTEMI. UA is defined as angina that occurs at rest or with minimal exertion, new (within 1 month) onset of severe angina, or worsening of previously stable angina. NSTEMI (or non-Q wave MI) is the more severe manifestation of ACS.

Patients with NSTEMI may be treated either with an interventional strategy, where all patients undergo angiography and PCI after admission, or conservatively, where they undergo angiography and intervention only if they remain unstable or have a positive exercise test. Initial trials of early intervention did not demonstrate any benefit, but with the advent of advanced angioplasty techniques using stents and adjuvant drug therapies including clopidogrel and glycoprotein IIb/IIIa antagonists, there appears to be a clear advantage for an interventional strategy in high-risk patients (Fox et al., 2005).

Patients presenting with UA/NSTEMI can be classified into three categories of risk (low, intermediate and high), depending on their risk of death or likelihood of developing an AMI. High-risk patients (those with ST-segment changes during chest pain, chest pain within 48 hours, troponin T-positive patients and those presenting already on intensive anti-anginal therapy) can be effectively managed with aggressive medical and interventional therapy. This results in fewer individuals progressing to AMI.

Various pharmacological agents such as antithrombin and antiplatelet drugs, and coronary revascularisation (particularly PCI) have been shown to improve the outcome of patients with UA or NSTEMI. These interventions are known to be associated with some treatment hazards, particularly bleeding complications. The risks must be balanced against potential treatment benefits for each individual patient. This balance is influenced by the patient's estimated risk of an adverse cardiovascular outcome as a consequence of the ACS. The absolute magnitude of benefit from an intervention is generally greatest in those at highest risk. A confounding issue is that treatment hazards, such as bleeding complications, are often also greatest in those at highest risk of an ischaemic event.

Measures of risk can be derived from the clinical assessment of a patient and the use of a formal risk scoring system, such as the GRACE, PURSUIT, PREDICT or TIMI scores. Scores based on clinical trial data generally exclude patients who are at high risk of an adverse cardiovascular outcome such as the elderly, or those with renal or heart failure. As a consequence, the evidence for clinical and cost-effectiveness of therapeutic interventions is confined to patients at lower to intermediate levels of risk. Risk score based on registry data (e.g. GRACE) may provide a more realistic estimation of risk.

In patients with NSTEMI, the immediate administration of 300 mg aspirin can reduce mortality or subsequent myocardial infarction by 50%. Risk stratification according to a recognised tool should be used to guide the subsequent choice of pharmacological and/or surgical intervention. The exclusion of STEMI and

Fig. 20.6 Schematic representation of mechanism of action of glycoprotein IIb/IIIa inhibitors.

confirmation of NSTEMI is important, as the use of fibrinolysis in NSTEMI confers no benefit and merely increases the risk of bleeding. In patients with NSTEMI, the preferred treatment normally involves a combination of antiplatelet agents to reduce the formation of a thrombus.

Antiplatelet and anticoagulant drugs

The current range of antiplatelet and anticoagulant drugs available for the reduction of thrombotic events in ACS leads to the potential for a large number of combinations. In all cases, the benefit of reducing thrombotic events must be balanced against the potential for an increased risk of bleeding.

In the early 1990s, unfractionated heparin combined with aspirin showed a reduction in death and subsequent myocardial infarction compared with aspirin alone. The use of the low-molecular-weight heparin (LMWH), enoxaparin, subsequently demonstrated superiority over unfractionated heparin, with both usually continued for 48 hours, or until chest pain resolves or patient is discharged. Both groups of drugs were tested in the era before PCI became part of routine practice.

The **CURE study (2001)** showed that clopidogrel, given as a loading dose of 300 mg followed by 75 mg daily in combination with aspirin and heparin, reduced the combined end point of death, myocardial infarction and revascularisation in all patients with NSTEMI. Clopidogrel needs to be continued for 12 months but should be stopped 5–7 days before any major surgery to reduce the risk of bleeding.

Because PCI has become more routine as part of the management of high-risk NSTEMI patients, more aggressive antiplatelet treatment has been required to reduce both peri-procedural and post-procedural thromboembolic complications.

Expression of glycoprotein IIb/IIIa is one of the final steps in the platelet aggregation cascade. Inhibiting these receptors has been a strategy before, and during, PCI for some time. Glycoprotein IIb/IIIa inhibitors bind to the IIb/IIIa receptors on platelets (**Fig. 20.6**)

and prevent cross-linking of platelets by fibrinogen. There are three classes of these agents: murine-human chimeric antibodies, (e.g. abciximab); synthetic peptides (e.g. eptifibatid); and non-peptide synthetics (e.g. tirofiban). Oral agents are ineffective, and the murine-human chimeric antibodies appear to be effective only in the context of PCI.

In high-risk patients undergoing PCI and receiving background heparin, triple antiplatelet therapy (aspirin, clopidogrel and a glycoprotein IIb/IIIa inhibitors) has been shown to be superior to standard dose dual-antiplatelet therapy (aspirin and clopidogrel), particularly in troponin-positive individuals (**Kastrati et al., 2006**). However, much of this evidence was generated before the introduction of higher doses of clopidogrel or the newer, more potent oral antiplatelet agents.

There is no clear benefit to giving glycoprotein IIb/IIIa inhibitors more than 4 hours before PCI ('upstream') compared with waiting until immediately before or during the procedure ('deferred' or 'downstream') (**Stone et al., 2007**).

Currently, all patients with a likely or definite diagnosis of NSTEMI should receive a loading dose of aspirin 300 mg (see **Fig. 20.7**). Patients undergoing PCI intervention should have a higher loading dose of 600 mg of clopidogrel or 60 mg of prasugrel, unless contraindicated, to reduce events during and after PCI. Clopidogrel is often given as 300 mg on admission and a further 300 mg when the decision to intervene is made. Patients who are not planned for intervention should receive a lower loading dose of clopidogrel 300 mg. Prasugrel, with its faster time to maximum effect, has demonstrated some benefit but routine use is not recommended (**NICE, 2014b**). Ticagrelor is a suitable alternative, and a loading dose of 180 mg can be given in those already loaded on clopidogrel.

All patients should receive heparin; bivalirudin or fondaparinux are suitable alternatives in combination with aspirin and clopidogrel. Unfractionated heparin is preferred for patients with compromised renal function. Fondaparinux, a synthetic pentasaccharide factor Xa inhibitor which has predictable and

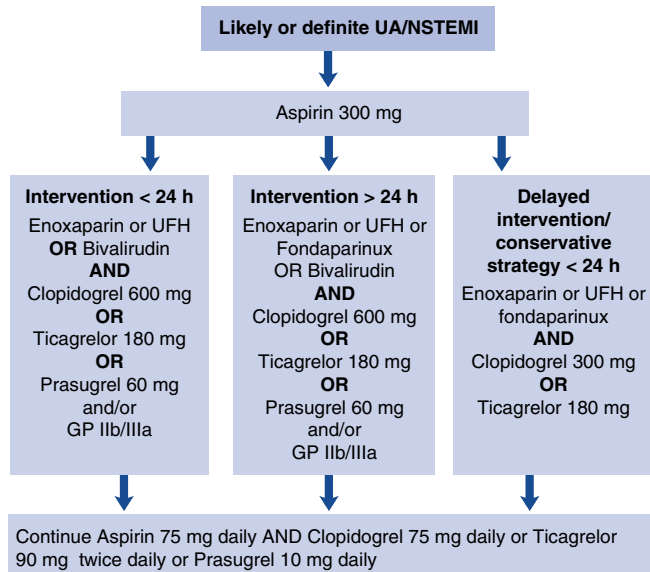

Fig. 20.7 Treatment options for patients with likely or definite unstable angina (UA) or non-ST-elevation myocardial infarction (NSTEMI) in relation to time of percutaneous coronary intervention (PCI) intervention. UFH, Unfractionated heparin.

sustained anticoagulation with fixed dose, once-a-day subcutaneous administration, causes less bleeding than enoxaparin, an LMWH. Concerns over catheter-related thrombus mean it should not be considered if patients are planned for PCI within 24 hours of chest pain. Bivalirudin is a synthetic analogue of hirudin that binds reversibly to thrombin and inhibits clot-bound thrombin.

The decision to use glycoprotein IIb/IIIa inhibitors is dependent on the centre and operator and whether the planned intervention for the patient is to be surgical or pharmacological. The introduction of higher loading doses of clopidogrel and more potent oral agents, as well as an increased focus on the bleeding risks associated with combination therapy, has reduced the use of these agents in many centres.

The recommendation of an anticoagulant regimen has become more complicated by a number of new choices suggested by contemporary trials, some of which do not provide adequate comparative information for common practice settings (see section in previous STEMI discussion).

Anti-ischaemic drugs

The use of both β -blockers and nitrates in the management of patients with NSTEMI is based on studies of their use in stable angina and AMI. Their use is, however, well established and based on a firm pathophysiological and pharmacological rationale.

Statins

High-intensity statins have been shown to benefit patients when given early in ACS. They are usually started on admission if the diagnosis of CHD is definite, independent of the patient's cholesterol level. Treatment should aim to achieve a 40% reduction in non-HDL cholesterol from baseline.

Patient care

Patients with CHD range from those who have investigational evidence of CHD but no symptoms to those who have major pain and exercise limitation. All need encouragement in adhering to preventive measures, including diet, exercise and smoking cessation. Patients need to be able to discuss concerns about their health.

Exercise must be tailored according to the patient's threshold for angina, aiming for moderate- to vigorous-intensity aerobic exercise training three or more times a week and for 30 minutes per session. In general, although some patients are too cavalier, most are likely to err on the cautious side and may need to be encouraged to do more. Many centres now run cardiac rehabilitation classes to encourage patients to exercise and adopt a suitable lifestyle.

There are simple treatments and important lifestyle changes that can reduce cardiovascular risk and slow or even reverse the progression of established coronary disease. The most important of these to address is smoking cessation. The risk of CHD is two to four times higher in heavy smokers (those who smoke at least 20 cigarettes/day) than in those who do not smoke. Other reports estimate the age-adjusted risk of smokers of more than 25 cigarettes/day is 5–21 times that of non-smokers. Smokers should be encouraged to quit. Within months of stopping smoking, CHD risk begins to decline. Within 5 years of smoking cessation, the risk decreases to approximately the level found in people who have never smoked, regardless of the amount smoked, duration of the habit and the age at cessation. The use of nicotine replacement therapy almost doubles a smokers' chance of successfully stopping smoking (18% vs. 11%). All patients who smoke should be offered advice on cessation and encouraged to attend specialist smokers' clinics to further improve their chance of quitting.

Patient beliefs about medicines and medication-taking behaviour (and therefore adherence) are also important determinants of outcome and are influenced by many factors. These can largely be divided into beliefs about the importance of the medicine and concerns about the medicine's harmful effects. To ensure the patient's concordance with medication regimens, it is necessary to address each individual patient's beliefs and concerns. One approach to counselling patients with CHD may be to divide the medication prescribed into those used to reduce the risk of heart attacks and death and those for symptom control. Key points to be discussed will relate to side effects and what to do if they occur, the need to continue medication until told otherwise and ensuring they do not run out of medication. Patients should be encouraged to identify their concerns, and these should be addressed as openly and honestly as possible.

Patients also need up-to-date advice when faced with difficult choices regarding medical treatment, angiographic procedures or surgery. Patients have good reason to be anxious at times, but some patients restrict their activities unnecessarily out of fear of angina and infarction.

Some of the common therapeutic problems encountered in the management of CHD are described in [Table 20.9](#).

Table 20.9 Common therapeutic problems in coronary heart disease

Problem	Comment
Used incorrectly, nitrates may cause hypotensive episodes or collapse.	Advise to sit down when using nitrate sprays or sublingual tablets.
A daily nitrate-free period is required to maintain efficacy of nitrates.	Avoid long-acting preparations and prescribe asymmetrically (e.g. 8 a.m. and 2 p.m.).
NSAIDs are associated with renal failure when given with ACE inhibitors.	Advise patients to use paracetamol as their analgesic of choice.
Speed is essential when patients need fibrinolytic drugs after infarction.	Arrange emergency admission to hospital where fast-track systems should exist.
Aspirin may cause gastro-intestinal bleeding.	Advise on taking with food and water. Consider use of prophylactic agents in high-risk patients.
β -Blockers are often considered unpleasant to take.	Encourage patient to use regularly. Change the time of day. Consider a vasodilator if cold extremities are a problem. Consider verapamil or diltiazem.
β -Blockers are contraindicated in asthma.	Consider verapamil or diltiazem. Pay strict attention to other treatments and removal of precipitating factors.
Patients often receive multiple drugs for prophylaxis and for treatment of co-existing disorders.	Use once-daily preparations, dosing aids and intensive social and educational support. Avoid all unnecessary drugs.
ACE inhibitors are contraindicated in pregnancy, especially the first trimester.	Advise women of child-bearing years to avoid conception or seek specialist advice first.

ACE, Angiotensin-converting enzyme; NSAID, non-steroidal anti-inflammatory drug.

Case studies

Case 20.1

A 55-year-old man, Mr HG, presents to his primary care doctor complaining of tightness in his chest when he digs the garden. It eases when he has a rest. On investigation, Mr HG has a raised serum glucose concentration and is considered to be a newly diagnosed non-insulin-dependent type II diabetic.

Question

What cardiovascular investigations and treatments should Mr HG receive?

Answer

Mr HG's blood pressure and ECG should be checked, and he should be examined for signs of hypertensive or diabetic target organ damage, including albuminuria. His serum lipid profile should be measured.

Mr HG should receive GTN spray or sublingual tablets for the chest symptoms that are almost certainly angina. He should take aspirin 75 mg daily. Prescribers would give a statin in almost all diabetic CHD patients and likewise an ACE inhibitor (unless there is a contraindication). Certainly, any hypertension should be

treated aggressively so that the diastolic pressure is less than 80 mmHg. A β -blocker may also be useful to control blood pressure and prevent further episodes of angina, but many prescribers would wait until there was evidence of failure of the other therapies. In view of Mr HG's relatively young age, a referral to a cardiologist for possible angiography should be considered. Dietary advice and help stop smoking, if needed, should be given. Diabetic treatments should be given (see [Chapter 45](#) diabetes).

Case 20.2

The following patients are admitted for treatment of myocardial infarction:

1. A patient with asthma
2. A man previously treated for infarction

Question

What considerations are there for standard treatment in these two patients?

Answers

Standard treatment for myocardial infarction includes the use of aspirin (or dual antiplatelet therapy if a PCI was performed), lipid lowering with a statin, rate control with a β -blocker and the prevention of cardiac remodeling with an ACE inhibitor. Treatment of

further chest pain should be with GTN for acute chest pain and anti-anginals (long-acting nitrates or amlodipine) for ongoing chest pain.

1. A patient with asthma should not receive a β -blocker without careful consideration and supervision because of the risk of bronchoconstriction; there is also a small risk of bronchoconstriction with aspirin.
2. A previous infarct may have been treated with streptokinase, and a repeat dose within 12 months should be avoided because of the build-up of antibodies to the initial dose rendering subsequent doses ineffective. Tissue plasminogen activator should be used instead. Consideration of patient adherence to previously prescribed medicines should be assured.

Case 20.3

A patient, Mr TD, with rheumatoid disease, treated with naproxen, has CHD.

Question

Is there any benefit or harm in adding aspirin to Mr TD's treatment?

Answer

A recent meta-analysis of the major randomised controlled trials on the effect of NSAIDs has concluded that, except for naproxen, NSAIDs used commonly in clinical practice are associated with increased risk of AMI at high doses or in patients previously diagnosed with coronary heart disease. For diclofenac and rofecoxib, the risk is elevated for both low and high doses (Varas-Lorenzo, 2013).

Aspirin is more beneficial than any other non-steroidal anti-inflammatory agent in modifying platelet activity and reducing mortality and morbidity in CHD. There is an increased risk of gastro-intestinal bleeding if two agents are given, but this should not be a major consideration at low doses of aspirin. There is some evidence, however, that some NSAIDs interfere with the action of aspirin by blocking access to the active site on the COX-1 enzyme. Such agents should be avoided. Diclofenac does not block the receptor, and ibuprofen has a short action and is acceptable if given 2 hours after the daily dose of aspirin.

Case 20.4

A patient, Ms LV, who has recently been started on aspirin and ticagrelor post-PCI with a drug-eluting stent (after an ACS), has been diagnosed a left ventricular thrombus.

Question

What changes to her medication therapy are required?

Answer

Left ventricular thrombi commonly develop in patients with severe left ventricular dysfunction. Treatment will require full anticoagulation for at least 3–6 months to allow the clot to disperse. Although the combination of aspirin and ticagrelor produces better outcomes than aspirin and clopidogrel, there is a bleeding risk associated with adding full-dose anticoagulation. Recent European

Society of Cardiology (ESC) guidelines (Roffi et al., 2016) do not recommend using ticagrelor or prasugrel with full anticoagulation post-PCI.

The recommended option would be to commence warfarin (bridged with parenteral anticoagulation; e.g. LMWH) and switch ticagrelor to clopidogrel 75 mg once daily. The duration of triple therapy (i.e. aspirin, clopidogrel and warfarin) should be minimised based on several factors, balancing the risk of atherothrombosis and bleeding.

Case 20.5

A patient with angioedema, Ms MJ, who is allergic to aspirin, has suffered a STEMI.

Question

What antiplatelet therapy would you recommend for Ms MJ post-PCI?

Answer

Due to the lack of research in patients with aspirin allergy, there is currently no dual antiplatelet regimen recommended post-PCI without aspirin. Options include the following:

- Allergy desensitisation to aspirin – a rapid desensitisation protocol has been described in the literature and can be performed in the cardiac laboratory within 2 hours before/after PCI.
- Single antiplatelet agent – this is an option, with a greater preference for the newer agents (prasugrel or ticagrelor). There is no evidence to suggest the combination of prasugrel and ticagrelor would be beneficial because both act on the ADP-receptor, potentially competing for the same site.
- Anticoagulation with clopidogrel – if there is another reason to anticoagulate (e.g. the presence of atrial fibrillation), then the combination of warfarin or DOAC with clopidogrel is a treatment option.

Case 20.6

A patient with angina, Mr WF, has just been started on ranolazine.

Question

What drug interactions do you need to consider before starting therapy?

Answer

Before commencing any drug therapy, there are two types of effects that need to be considered: pharmacokinetic and pharmacodynamic interactions.

With respect to pharmacokinetic effects, ranolazine is metabolised by the cytochrome P450 3A4 isoenzyme (CYP3A4), resulting in a range of drug interactions. Plasma levels are increased by CYP3A4 inhibitors (e.g. diltiazem, verapamil, macrolide antibiotics, grapefruit juice). Ranolazine clearance is also reduced by renal and hepatic impairment; thus, dose adjustments may be required.

Pharmacodynamically, ranolazine may increase the risk of arrhythmias by prolonging the QTc. It should be avoided in patients with prolonged-QT and used with caution with other QT-prolonging medication (e.g. fluconazole and erythromycin).

21 Chronic Heart Failure

John McAnaw and Tobias Dreischulte

Key points

- Heart failure is a common condition that affects the quality of life, causing fatigue, breathlessness and oedema. It often has a poor prognosis.
- Heart failure is a maladaptive condition with haemodynamic and neurohormonal disturbances. Increased understanding of its pathophysiology and the strength of the evidence base allow a rational approach to therapeutic management.
- The aims of drug treatment are to control symptoms and improve survival. By slowing disease progression, the aim is to maintain quality of life.
- Angiotensin-converting enzyme (ACE) inhibitors, β -blockers and mineralocorticoid receptor antagonists are first-line options in treating patients with systolic dysfunction.
- Angiotensin II receptor blockers (ARBs) are an alternative choice in patients intolerant of or resistant to ACE inhibitors or mineralocorticoid receptor antagonist therapy.
- Diuretics are used for symptomatic management of heart failure and are combined with other agents in the treatment of systolic dysfunction.
- The use of sacubitril/valsartan should be considered under specialist advice in patients with systolic dysfunction who have ongoing symptoms of heart failure despite optimal therapy.
- Ivabradine should be considered under specialist advice in patients with systolic dysfunction who have had a hospital admission for heart failure in the preceding 12 months but have stabilised on standard therapy for at least 4 weeks.
- Digoxin may still have a role in improving symptoms and reducing the rate of hospitalisation for patients with heart failure in sinus rhythm, but it has not been demonstrated to affect mortality. The combination of hydralazine and nitrate may still have a place for specific patients on the advice of a specialist.
- Heart failure is a condition in which integration of pharmaceutical care within multidisciplinary models of patient care can improve clinical outcomes for patients and contribute to the continuity of care.

Chronic heart failure results from a deficiency in the heart's function as a pump, where the delivery of blood, and therefore oxygen and nutrients, becomes inadequate for the needs of the tissues. Chronic heart failure is a complex condition associated with a number of symptoms arising from defects in left ventricular filling and/or emptying, of which shortness of breath (exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea), fatigue and ankle swelling are the most common. The symptoms of heart failure are due to inadequate tissue perfusion,

venous congestion and disturbed water and electrolyte balance. Impairment of renal function, and the associated water retention, adds to the burden placed on the heart. In chronic heart failure, the physiological mechanisms that aim to maintain adequate tissue perfusion become counterproductive and contribute to the progressive nature of the condition.

Treatment is aimed at improving left ventricular function, controlling the secondary effects that lead to the occurrence of symptoms and delaying disease progression. Drug therapy is indicated in all patients with heart failure to control symptoms (where present), improve quality of life and prolong survival. Patients with heart failure usually have their functional status assessed and categorised using the New York Heart Association (NYHA) classification system shown in [Table 21.1](#).

Epidemiology

Chronic heart failure is a common condition, affecting about 2% of the adult population ([Metra and Teerlink, 2017](#)). Prevalence increases with age; less than 2% of people younger than 60 years of age to greater than 10% in those aged 75 years or older. Heart failure accounts for 5% of adult emergency medical admissions to hospital ([National Institute for Health and Care Excellence \[NICE\], 2010](#)). There is a loss of cardiac reserve with age, and heart failure may often complicate the presence of other conditions in the elderly.

Heart failure is a progressive condition with complex possible causes, and mortality varies according to aetiology and severity. The variable prognosis is represented by a median survival of about 5 years after diagnosis. The prognosis can be predicted according to the severity of the disease, with an overall annual mortality rate for patients with stable heart failure estimated at 6–7%, up to 25% or more in patients admitted to hospital with acute heart failure ([Metra and Teerlink, 2017](#)). Main causes of death are progressive pump failure, sudden cardiac death and recurrent myocardial infarction (MI).

Aetiology

Heart failure may be a consequence of MI, but as a chronic condition, it is often gradual in onset with symptoms arising

Table 21.1 New York Heart Association classification of functional status of the patient with heart failure

I	No symptoms with ordinary physical activity (such as walking or climbing stairs)
II	Slight limitation with dyspnoea on moderate to severe exertion (climbing stairs or walking uphill)
III	Marked limitation of activity, less than ordinary activity causes dyspnoea (restricting walking distance and limiting climbing to one flight of stairs)
IV	Severe disability, dyspnoea at rest (unable to carry on physical activity without discomfort)

Adapted from the [Criteria Committee of the New York Heart Association \(1994\)](#).

insidiously and without any specific cause over a number of years. The common underlying aetiologies in patients with heart failure are coronary artery disease and hypertension. The appropriate management of these predisposing conditions is also an important consideration in controlling heart failure in the community. Identifiable causes of heart failure include aortic stenosis, cardiomyopathy, mechanical defects such as cardiac valvular dysfunction, hyperthyroidism and severe anaemia. Conditions that place increased demands on the heart can create a shortfall in cardiac output and lead to intermittent exacerbation of symptoms. Symptoms of heart failure may occur as a consequence of hyperthyroidism, where the tissues place a greater metabolic demand, or severe anaemia, where there is an increased circulatory demand on the heart. Cardiac output may also be compromised by bradycardia or tachycardia, or by a sustained arrhythmia such as that experienced by patients in atrial fibrillation.

Atrial fibrillation often accompanies hyperthyroidism and mitral valve disease, where a rapid and irregular ventricular response can compromise cardiac efficiency. Improved management of the underlying causes, where appropriate, may alleviate the symptoms of heart failure, whereas the presence of mechanical defects may require the surgical insertion of prosthetic valve(s). Although around 50% of patients with heart failure have significant left ventricular systolic dysfunction, the other half comprises patients who have either a normal or insignificantly reduced left ventricular ejection fraction (EF). However, there is no consensus on the threshold for compromised EF, and assessment of each patient relies mainly on clinical symptoms. These patients are referred to as having heart failure with preserved left ventricular ejection fraction (HFPEF). Most of the available evidence from clinical trials regarding the pharmacological treatment of heart failure to date relates to those patients with heart failure due to left ventricular systolic dysfunction. Clinical symptomatic description of chronic heart failure is mild, moderate or severe heart failure. ‘Mild’ is used for patients who are mobile with no important limitations of dyspnoea or fatigue, ‘severe’ for patients who are markedly symptomatic in terms of exercise intolerance and ‘moderate’ for those with restrictions in

between. Trials tend to formalise these categories into NYHA Categories I–IV ([Table 21.1](#)).

Pathophysiology

In health, cardiac output at rest is approximately 5 L/min with a mean heart rate of 70 beats/min and stroke volume of 70 mL. Because the filled ventricle has a normal volume of 130 mL, the fraction ejected is more than 50% of the ventricular contents, with the remaining (residual) volume being approximately 60 mL. In left ventricular systolic dysfunction, the EF is reduced to less than 45%, and symptoms are common when the fraction is less than 35%, although some patients with a low EF can remain asymptomatic. When the EF falls below 10%, patients have the added risk of thrombus formation within the left ventricle, and in most cases anticoagulation with warfarin is indicated.

Left ventricular systolic dysfunction can result from cardiac injury, such as MI, or by exposure of the heart muscle to mechanical stress, such as long-standing hypertension. This may result in defects in systolic contraction, diastolic relaxation or both. Systolic dysfunction arises from impaired contractility and is reflected in a low EF and cardiac dilation. Diastolic dysfunction arises from impairment of the filling process. Diastolic filling is affected by the rate of venous return, and normal filling requires active diastolic expansion of the ventricular volume. The tension on the ventricular wall at the end of diastole is called the preload and is related to the volume of blood available to be pumped. That tension contributes to the degree of stretch on the myocardium. In diastolic dysfunction, there is impaired relaxation or reduced compliance of the left ventricle during diastole, and therefore less additional blood is accommodated. In pure diastolic dysfunction, the EF can be normal, but cardiac dilation is absent. Sustained diastolic dysfunction, which is a feature in a minority of patients with heart failure, may lead to systolic dysfunction associated with disease progression and left ventricular remodelling (structural changes and/or deterioration).

During systolic contraction, the tension on the ventricular wall is determined by the degree of resistance to outflow at the exit valve and that within the arterial tree, that is, the systemic vascular resistance. Arterial hypertension, aortic narrowing and disorders of the aortic valve increase the afterload on the heart by increasing the resistance against which the contraction of the ventricle must work. The result is an increased residual volume and consequently an increased preload as the ventricle overfills and produces greater tension on the ventricular wall. In the normal heart, a compensatory increase in performance occurs as the stretched myocardium responds through an increased elastic recoil. In the failing heart, this property of cardiac muscle recoiling under stretch is diminished, with the consequence that the heart dilates abnormally to accommodate the increased ventricular load. With continued dilation of the heart, the elastic recoil property can become much reduced. Failure of the heart to handle the increasing ventricular load leads to pulmonary and systemic venous congestion. At the same time, the increased tension on

the ventricular wall in heart failure raises myocardial oxygen requirements, which increases the risk of an episode of myocardial ischaemia or arrhythmias.

The failing heart may show cardiac enlargement due to dilation, which is reversible with successful treatment. An irreversible increase in cardiac muscle mass, cardiac hypertrophy, occurs with progression of heart failure and is a consequence of long-standing hypertension. Although hypertrophy may initially alleviate heart failure, the increased mass is pathologically significant because it ultimately increases the demands on the heart and oxygen consumption.

A reflex sympathetic discharge caused by the diminished tissue perfusion in heart failure exposes the heart to catecholamines where positive inotropic and chronotropic effects help sustain cardiac output and produce a tachycardia. Arterial constriction diverts blood to the organs from the skin and gastro-intestinal tract but overall raises systemic vascular resistance and increases the afterload on the heart.

Reduced renal perfusion due to heart failure leads to increased renin release from the glomerulus in the kidney. Circulating renin raises blood pressure through the formation of angiotensin I and angiotensin II, a potent vasoconstrictor, and renin also prompts adrenal aldosterone release. Aldosterone retains salt and water at the distal renal tubule and so expands blood volume and increases preload. Arginine vasopressin released from the posterior pituitary in response to hypoperfusion adds to the systemic vasoconstriction and has an antidiuretic effect by retaining water at the renal collecting duct.

These secondary effects become increasingly detrimental to cardiac function as heart failure progresses because the vasoconstriction adds to the afterload, and the expanded blood volume adds to the preload. The expanded blood volume promotes the atrial myocytes to release a natural vasodilator, atrial natriuretic peptide (ANP), to attenuate the increased preload.

The compensatory mechanisms for the maintenance of the circulation eventually become overwhelmed and are ultimately highly counterproductive, leading to the emergence and progression of clinical signs and symptoms of heart failure. The long-term consequences are that the myocardium of the failing heart undergoes biochemical and histological changes that lead to remodelling of the left ventricle, which further complicates disease progression. In those patients where the condition is severe and has progressed to an end stage, heart transplantation may be the only remaining treatment option.

Clinical manifestations

The reduced cardiac output, impaired oxygenation and diminished blood supply to muscles cause fatigue. Shortness of breath occurs on exertion (dyspnoea) or on lying (orthopnoea). When the patient lies down, the postural change causes abdominal pressure on the diaphragm which redistributes oedema to the lungs, leading to breathlessness. At night the pulmonary symptoms give rise to cough, and an increase in urine production prompts micturition (nocturia), which adds to the sleep

Table 21.2 Clinical manifestations of heart failure

Venous (congestion)	Cardiac (cardiomegaly)	Arterial (peripheral hypoperfusion)
Dyspnoea	Dilation	Fatigue
Oedema	Tachycardia	Pallor
Hypoxia	Regurgitation	Renal impairment
Hepatomegaly	Cardiomyopathy	Confusion
Raised venous pressure	Ischaemia, arrhythmia	Circulatory failure

disturbance. The patient can be inclined to waken at night as gradual accumulation of fluid in the lungs may eventually provoke regular attacks of gasping (paroxysmal nocturnal dyspnoea). Characteristically, the patient describes the need to sit or stand up to seek fresh air and often describes a need to be propped up by three or more pillows to remedy the sleep disturbances that are due to fluid accumulation.

Patients with heart failure may appear pale and their hands cold and sweaty. Reduced blood supply to the brain and kidney can cause confusion and contribute to renal failure, respectively. Hepatomegaly occurs from congestion of the gastro-intestinal tract, which is accompanied by abdominal distension, anorexia, nausea and abdominal pain. Oedema affects the lungs, ankles and abdomen. Signs of oedema in the lungs include crepitations heard at the lung bases. In acute heart failure, symptoms of pulmonary oedema are prominent and may be life-threatening. The sputum may be frothy and tinged red from the leakage of fluid and blood from the capillaries. Severe dyspnoea may be complicated by cyanosis and shock. [Table 21.2](#) presents the clinical manifestations of heart failure.

Investigations

Patients with chronic heart failure are diagnosed and monitored on the basis of signs and symptoms from physical examination, history and an exercise tolerance test. On physical examination of the patient, a lateral and downwards displacement of the apex beat can be identified as evidence of cardiac enlargement. Additional third and/or fourth heart sounds are typical of heart failure and arise from valvular dysfunction. Venous congestion can be demonstrated in the jugular vein of the upright, reclining patient by an elevated jugular venous pressure (JVP), which reflects the central venous pressure. The JVP is measured by noting the visible distension above the sternum and may be accentuated in heart failure by the application of abdominal compression in the reclining patient. Confirmation of heart failure, however, should not be based on symptom assessment alone.

After clinical examination, patients should have their brain-type natriuretic peptide (BNP) and N-terminal (NT) proBNP (BNP/NT-proBNP) measured and then have an

Table 21.3 Investigations performed to confirm a diagnosis of heart failure

Investigation	Comment
Blood test	The following assessments are usually performed: <ul style="list-style-type: none"> • Urinalysis • Serum creatinine and urea to assess renal function • Full blood count to investigate possibility of anaemia • Thyroid function tests to investigate possibility of thyrotoxicosis • Serum BNP or NT pro-BNP to indicate whether echocardiography is necessary • Fasting blood glucose to investigate possibility of diabetes mellitus
12-Lead electrocardiogram	A normal ECG along with low BNP/NT-ProBNP levels usually excludes the presence of left ventricular systolic dysfunction. An abnormal ECG will require further investigation including echocardiography
Chest radiograph	A chest radiograph (X-ray) is performed to look for an enlarged cardiac shadow and consolidation in the lungs
Echocardiography	An echocardiogram is used to confirm the diagnosis of heart failure and any underlying causes, e.g. valvular heart disease
BNP or NT pro-BNP, brain-type natriuretic peptide (BNP) and N-terminal (NT) proBNP; ECG, electrocardiogram.	

electrocardiogram (ECG) taken. If BNP/NT-proBNP level is found to be low and the ECG result is normal, it is unlikely that the patient has heart failure. Therefore, another underlying cause for the symptoms should be considered. If a raised BNP/NT-proBNP level is found or the patient's ECG is abnormal, then the patient should be referred for echocardiography. Echocardiography is important when investigating patients with a suspected diagnosis of heart failure. An echocardiogram allows visualisation of the heart in real time and will identify whether heart failure is due to systolic dysfunction, diastolic dysfunction or heart valve defects. [Table 21.3](#) shows the investigations that are routinely performed in the assessment of heart failure symptoms.

Treatment of heart failure

Until the 1980s, pharmacotherapy was driven by the aim to control symptoms, when diuretics and digoxin were the mainstays of treatment. Although relieving the symptoms of heart failure remains decisive in improving a patient's quality of life, a better understanding of the underlying pathophysiology has led to major advances in the pharmacological treatment of heart failure. With the introduction of angiotensin-converting enzyme (ACE) inhibitors, β -blockers, angiotensin II receptor

blockers (ARBs) and mineralocorticoid receptor antagonists (MRAs), delaying disease progression and ultimately improving survival have become realistic goals of therapy. An outline of the site of action of the various drugs is schematically presented in [Fig. 21.1](#).

In heart failure patients with comorbid conditions known to contribute to heart failure, such as hyperthyroidism, anaemia, atrial fibrillation and valvular heart disease, attention must be given to ensuring these underlying contributing factors are well controlled. Patients with atrial fibrillation may be candidates for electrocardioversion. Tachycardia from atrial fibrillation usually requires control of the ventricular rate through suppression of atrioventricular node conduction. In patients with heart failure, the use of β -blockers or digoxin are options in such circumstances. In these patients, the use of an anticoagulant may be necessary and should be based on an assessment of stroke risk.

In patients with heart failure and preserved EF, diuretics are commonly used for symptom control. However, the use of all other agents of proven benefit in treating heart failure due to left ventricular systolic dysfunction is currently not supported by an evidence base.

There is consensus that all patients with left ventricular systolic dysfunction should be treated with an ACE inhibitor in the absence of intolerance or contraindications ([Scottish Intercollegiate Guidelines Network \[SIGN\], 2016](#)). The evidence base for treatment clearly shows that use of an ACE inhibitor in patients with heart failure due to left ventricular systolic dysfunction leads to an improvement in symptoms and reduction in mortality. Beneficial effects on morbidity and mortality have also been shown for the use of ARBs, β -blockers, mineralocorticoid receptor antagonists and hydralazine/nitrate combinations when used in the treatment of chronic heart failure. Digoxin has been shown to improve morbidity and reduce the number of hospital admissions in patients with heart failure, although its effect on mortality has not been demonstrated. [Table 21.4](#) describes the treatment of acute heart failure in the hospital setting, and [Table 21.5](#) highlights the possible treatment options for patients with chronic heart failure due to left ventricular systolic dysfunction.

The selection of adjunctive therapy beyond the use of ACE inhibitor, β -blocker and mineralocorticoid receptor antagonist therapy is largely dependent on the nature of the patient and the preference of the heart failure specialist involved in the patient's care. It is accepted that there is a limit as to how many agents any one patient can tolerate; therefore, the selection of drug therapy will probably be tailored to each individual patient, meaning that treatment plans will vary.

Diuretics

In chronic heart failure, diuretics are used to relieve pulmonary and peripheral oedema by increasing sodium and chloride excretion through blockade of sodium re-absorption in the renal tubule. Normally, in the proximal tubule, about 70% of sodium is reabsorbed along with water. In mild heart failure, either a thiazide or more often a loop diuretic is chosen depending on the severity of the symptoms experienced by the patient

Fig. 21.1 Schematic representation of the physiological response to reduced cardiac output and arterial pressure, and where heart failure drugs act.

Table 21.4 Treatment of acute heart failure due to left ventricular systolic dysfunction in patients requiring hospitalisation	
Problem	Drug therapy indicated
Anxiety	Use of opiates to reduce anxiety and reduce preload through venodilation might be considered for some patients, although routine use should be avoided due to a potentially increased risk of mortality.
Breathlessness	High-flow oxygen (60–100%) may be required in conjunction with i.v. furosemide as either direct injection or 24-h infusion (5–10 mg/h). GTN may be considered to help relieve pulmonary congestion.
Arrhythmia	Digoxin is useful in the control of atrial fibrillation. Amiodarone is the drug of choice in ventricular arrhythmias.
Expansion of blood volume after blood transfusion	An elevation in preload, such as can occur acutely by the expansion of blood volume after a transfusion, can exacerbate the degree of systolic dysfunction. Therefore, it is necessary to continue or increase diuretic dosage during this time.

GTN, glyceryl trinitrate; i.v., intravenous.

and the degree of diuresis required. Thiazides are described as ‘low-ceiling agents’ because maximum diuresis occurs at low doses, and they act mainly on the cortical diluting segment (the point of merger of the ascending limb with the distal renal tubule), at which 5–10% of sodium is normally removed. Although thiazides have some action at this site, they fail to produce a marked diuresis because a compensatory increase in sodium re-absorption occurs in the loop of Henle, and consequently thiazides are ineffective in patients with moderate to severe renal impairment (eGFR <30 mL/min/1.73 m²) or persisting symptoms. Additionally, doses above the equivalent of bendroflumethiazide 5 mg have an increased risk of adverse metabolic effects with no additional symptomatic benefit. Thiazides are, therefore, now rarely used as sole diuretic therapy and are reserved for cases where the degree of fluid retention is very mild, renal function is not compromised or as an adjunct to loop diuretics.

Loop diuretics are indicated in the majority of symptomatic patients, and most patients will be prescribed one of either furosemide, bumetanide or torasemide in preference to a thiazide. These agents are known as ‘high-ceiling agents’ because their blockade of sodium re-absorption in the loop of Henle continues with increased dose. They have a shorter duration of action (average 4–6 hours) compared with thiazides (average 12–24 hours), and they produce less hypokalaemia. In high doses, however, their intensity of action may produce hypovolaemia with risk of postural hypotension, worsening of symptoms and renal failure. In practice, high doses of furosemide (up to 500 mg/day) may be required to control oedema in patients with poor renal function. In the acute situation, doses of loop diuretics are titrated to produce a weight loss of 0.5–1 kg/day.

Table 21.5 Outline of the treatment options for patients with chronic heart failure due to left ventricular systolic dysfunction

NYHA	Drug therapy options
I	Asymptomatic patients with a reduced ejection fraction Angiotensin-converting enzyme inhibitor (or ARB if intolerant)
II–IV	Patients with symptoms of heart failure and reduced ejection fraction ACE inhibitor (or ARB if intolerant) β-Blocker MRA (or ARB if NYHA II–III and intolerant of MRA) Diuretic (where dyspnoea and/or oedema present)
II–IV	Additional options where specialist advice required before use Angiotensin receptor/neprilysin inhibitor (only where ongoing symptoms despite optimal therapy; requires stopping both ACE inhibitor and/or ARB) Ivabradine (only if sinus rhythm heart rate ≥75 beats/min and maximum tolerated β-blocker dose reached) Digoxin (only in sinus rhythm if patient still symptomatic despite optimal therapy) Hydralazine/isosorbide dinitrate (only where ACE inhibitor or ARB intolerant due to renal dysfunction or raised potassium, or where the patient is African-American and NYHA III–IV)

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; MRA, mineralocorticoid receptor antagonist; NYHA, New York Heart Association.

In longer-term use, patients with heart failure frequently develop some resistance to the effects of loop diuretic due to a compensatory rebound in sodium retention. In this situation, a combination of thiazide and loop diuretics has been shown to have a synergistic effect, even in patients with reduced renal function. In the UK, metolazone is also used as an adjunct to augment the effects of loop diuretics. The potentially profound diuresis produced by such a combination poses serious risks, such as dehydration and hypotension, and patients who are prescribed metolazone in addition to an existing loop diuretic must be carefully monitored. In practice, patients with oedema treated with loop diuretics may best be treated using a degree of self-management. Some patients are instructed to make upwards adjustment of loop diuretic dose or to add metolazone therapy on particular days, for example, when they self-record a gain of 2 kg or more in their body weight over a short period of time.

Diuretics also have a mild vasodilator effect that helps improve cardiac function, and the intravenous use of loop diuretics reduces preload acutely by locally relieving pulmonary congestion before the onset of the diuretic effect. Effective diuretic therapy is demonstrated by the normalisation of filling pressure. Therefore,

continued elevation of the JVP suggests a need for more diuretic unless otherwise contraindicated. The administration rate of intravenous furosemide should not usually exceed 4 mg/min because it can cause ototoxicity when administered more rapidly.

Details of diuretic therapy used in left ventricular systolic dysfunction are summarised in [Table 21.6](#).

Angiotensin-converting enzyme inhibitors

ACE inhibitors are indicated as first-line treatment for all grades of heart failure due to left ventricular systolic dysfunction, including those patients who are asymptomatic. These agents exert their effects by reducing both the preload and afterload on the heart, thereby increasing cardiac output.

ACE inhibitors act on the renin–angiotensin–aldosterone system, and they reduce afterload by reducing the formation of angiotensin II, a potent vasoconstrictor in the arterial system. These drugs also have an indirect effect on sodium and water retention by inhibiting the release of aldosterone and vasopressin, thereby reducing venous congestion and preload. The increase in cardiac output leads to an improvement in renal perfusion, which further helps alleviate oedema. ACE inhibitors also potentiate the vasodilator bradykinin and may intervene locally on ACE in cardiac and renal tissues.

ACE inhibitors are generally well tolerated by most patients and have been shown to improve the quality of life and survival in patients with mild-to-severe systolic dysfunction ([CONSENSUS I, 1987](#); [CONSENSUS II, 1992](#); [SOLVD-P, 1992](#); [SOLVD-T, 1991](#); [V-HeFT II, 1991](#)), including those patients who have experienced an MI ([AIRE, 1993](#); [SAVE, 1992](#); [TRACE, 1995](#)). When an ACE inhibitor is prescribed, it is important to ensure that the dose is started low and increased gradually, paying close attention to renal function and electrolyte balance. The dose should be titrated to achieve the target dose that has been associated with long-term benefits shown in clinical trials or (if not possible) the maximum tolerable dose. There is some evidence to suggest that high doses of ACE inhibitor are more effective than low doses in relation to reduction in mortality, although it is uncertain whether this is a general class effect ([ATLAS, 1999](#)). In clinical practice, it is possible that some patients may be treated with ACE inhibitors at doses lower than those used in clinical trials. As a consequence, actual outcomes in heart failure treatment may not be as good as expected from the trial findings.

The introduction of an ACE inhibitor may produce hypotension, which is most pronounced after the first dose and is sometimes severe. Patients at risk include those already on high doses of loop diuretics, where the diuretics cannot be stopped or reduced beforehand, and patients who may have a low-circulating fluid volume (due to dehydration) and an activated renin–angiotensin system. Hypotension can also occur where the ACE inhibitor has been initiated at too high a dose or where the dose has been increased too quickly after initiation. In the primary care setting, treatment must be started with a low dose, which is usually administered at bedtime. In patients at particular risk of hypotension, a test dose of the shorter-acting agent captopril can be given to assess suitability for treatment

Table 21.6 Diuretics and mineralocorticoid receptor antagonists used in the treatment of patients with heart failure with reduced ejection fraction

Class and agent	Onset and duration of effect		Comment
Thiazide and related	Oral		
Bendroflumethiazide	Onset 1–2 h Duration 12–18 h		Thiazides are effective in the treatment of sodium and water retention, although there is generally a loss of action in renal failure (GFR <30 mL/min). Metolazone has an intense action when added to a loop diuretic and is effective at low GFR.
Metolazone	Onset 1–2 h Duration 12–24 h		
Loop	Oral	Parenteral	
Furosemide	Onset 0.5–1 h Duration 4–6 h	Onset 5 min Duration 2 h	Loop diuretics are preferred in the treatment of sodium and water retention where renal dysfunction is evident or more severe grades of heart failure present. Agents can be given orally or by infusion, and all are effective at low GFR.
Bumetanide	As above	As above	
Torsemide	Onset <1 h Duration <8 h	Onset 10 min Duration <8 h	
Mineralocorticoid receptor antagonist	Oral		
Spirolactone	Onset 7 h Duration 24 h		Mineralocorticoid receptor antagonists can improve symptoms and survival when given as an adjunct to ACE inhibitor and β -blocker therapy. Spirolactone has a recommended starting dose of 25 mg daily (or on alternate days), with a target dose of 25–50 mg daily. With eplerenone, a starting dose of 25 mg daily is given, titrating up to a target dose of 50 mg daily.
Eplerenone	Steady-state within 2 days		

ACE, Angiotensin-converting enzyme; GFR, glomerular filtration rate.

before commencing long-term treatment with a preferred ACE inhibitor. Once it has been established that the ACE inhibitor can be initiated safely, the preferred option would be to switch to a longer-acting agent with once- or twice-daily dosing, starting with a low dose that would be gradually titrated upwards to the recommended target (Table 21.7). Monitoring of fluid balance, blood biochemistry and blood pressure is an essential safety check during initiation and titration of ACE inhibitor therapy.

One of the most common adverse effects seen with ACE inhibitors is a dry cough. However, because a cough can occur naturally in patients with heart failure, it is sometimes difficult to determine the true cause. ACE inhibitor therapy can also compromise renal function, although in patients in whom there is a reduction in renal perfusion due to worsening heart failure or hypovolaemia, renal dysfunction can also occur. Therefore, there are a number of instances where ACE inhibitor intolerance can be misdiagnosed in practice. Where ACE inhibitor intolerance is suspected, patients can usually be successfully rechallenged with an ACE inhibitor once their heart failure is more stable, although careful monitoring of the

patient should be undertaken during initiation and subsequent dose titration. If the increase in the patient's serum creatinine is greater than 100% from baseline, the ACE inhibitor should be stopped, intolerance confirmed and specialist advice sought. Where the increase from baseline is 50–100%, the ACE inhibitor dose should be halved and serum creatinine concentration rechecked after 1–2 weeks. If renal function is stable and no cough or other adverse effects are reported, therapy should be continued. Where the problem persists, an alternative treatment option might be required. For example, an ARB will have similar benefits for morbidity and mortality, but there is a possibility of similar adverse effects on blood pressure and renal function. Alternatively, a mineralocorticoid receptor antagonist could be used.

ACE inhibitors are potentially hazardous in patients with pre-existing renal disease because blockade of the renin–angiotensin system may lead to reversible deterioration of renal function. In particular, ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis, in whom the renin–angiotensin system is highly activated to maintain renal perfusion. Because most ACE inhibitors or their active metabolites rely

on elimination via the kidney, the risk of other forms of dose-related toxicity is also increased in the presence of renal failure. Fosinopril, which is partially excreted by metabolism, may be the preferred agent in patients with renal failure. ACE inhibitors

are also contraindicated in patients with severe aortic stenosis because their use can result in a markedly reduced cardiac output due to decreased filling pressure within the left ventricle. [Table 21.7](#) summarises the activity and use of ACE inhibitors.

Table 21.7 Vasodilators used in the treatment of heart failure

	Dose	Frequency	Half-life (h)	Comment
ACE inhibitors				
Captopril	Target: 50 mg Start: 6.25 mg	Three times daily	8	First-dose hypotension may occur. May worsen renal failure. Adjust dose in renal failure. Hypokalaemia, cough, taste disturbance and hypersensitivity may occur, particularly with captopril. ACE inhibitors have been shown to improve survival, with starting and target dose for those agents used in clinical trials highlighted.
Enalapril	Target: 10-20 mg Start: 2.5 mg	Twice daily	11	
Fosinopril	Target: 40 mg Start: 10 mg	Once daily	11-14	
Lisinopril	Target: 20-35 mg Start: 2.5-5 mg	Once daily	12	
Perindopril	Target: 4 mg Start: 2 mg	Once daily	25	
Quinapril	Target: 10-20 mg Start: 2.5 mg	Once daily (or divided dose)	2-3	
Ramipril	Target: 10 mg Start: 2.5 mg	Once daily (or divided dose)	13-17	
Trandolapril	Target: 4 mg Start: 0.5 mg	Once daily	16-24	
B-Blocker				
Bisoprolol	Target: 10 mg Start: 1.25 mg	Once daily	10-12	May initially exacerbate symptoms, but if initiated at low dose and slowly titrated, can improve long-term survival, even in elderly patients with heart failure. Half-life of nebivolol can be 3-5 times longer in slow metabolisers.
Carvedilol	Target: 25-50 mg Start: 3.125 mg	Twice daily	6-10	
Nebivolol	Target: 10 mg Start: 1.25 mg	Once daily	10	
Angiotensin II receptor blocker				
Losartan	Target: up to 150 mg Start: 12.5 mg	Once daily	6-9	Comparable effectiveness to ACE inhibitor in patients with ACE inhibitor intolerance, although similar effect on renal function and blood pressure. Evidence suggests improved survival when ARB used as adjunctive therapy. However, increased potential for deterioration in renal function and/or hyperkalaemia
Candesartan	Target: 32 mg Start: 4-8 mg	Once daily	9	
Valsartan	Target: 160 mg Start: 40 mg	Twice daily	9	
Angiotensin II receptor/ Neprilysin inhibitors				
	Oral			
Sacubitril/Valsartan	Target: 96/104 mg Start: 24/26 mg to 49/51 mg	Twice daily	1.4-10	Comparable effectiveness to ACE inhibitor regarding survival and hospitalisation for heart failure. If patient on an ACE inhibitor or ARB, this must be stopped 36h before initiation to minimise the risk of angioedema. During titration the dose should be doubled at 2-4 weekly intervals until target reached, with patients who have moderate renal impairment or systolic blood pressure \geq 100-110mmHg starting on the lower starting dose.

Table 21.7 Vasodilators used in the treatment of heart failure—cont'd

	Dose	Frequency	Half-life (h)	Comment
Hydralazine				
	Target: 50-75mg Start: 25mg	Three to four times daily	2-3	Has a direct action on arteries. Tolerance occurs. May cause drug-induced lupus and sodium retention. Used in combination with oral nitrates.
Nitrates				
Isosorbide dinitrate	Target: 40-160mg	Daily in divided doses	1	High doses of Isosorbide dinitrate needed and may require up to 240mg daily in divided doses. With isosorbide mononitrate, up to 120mg daily in divided doses may be required. Tolerance can be prevented by nitrate-free period of >8 hours. Protective against cardiac ischaemia. Used in combination with hydralazine.
Isosorbide mononitrate	Target: variable Start: 10mg	Twice daily	5	
ARB, angiotensin receptor blocker; ACE, angiotensin-converting enzyme.				

Angiotensin II receptor blockers

Although comparisons of ACE inhibitors and ARBs have shown similar benefits on morbidity and heart failure mortality, only ACE inhibitors have been shown to have positive effects on all-cause mortality. ARBs should, therefore, not be used instead of ACE inhibitors, unless the patient experiences intolerable side effects.

The use of ARBs as an adjunct to ACE inhibitor and β -blocker therapy has been associated with significant reductions in cardiovascular events and hospitalisation rate (CHARM Added, 2003). Although this finding is encouraging, the impact on mortality alone remains inconsistent, and there is no clear consensus on when to use an ARB as adjunctive therapy. In studies involving patients unable to tolerate an ACE inhibitor, ARBs have been shown to be comparable to ACE inhibitors in reducing the risk of cardiovascular death and rate of hospitalisation and in the control of symptoms in heart failure patients (CHARM Alternative, 2003; Val-HeFT, 2002). Therefore, ARBs are recommended for use as an alternative to ACE inhibitor therapy where intolerance has been confirmed. It is important to note that in patients who have renal failure secondary to ACE inhibitors, switching to an ARB is of no theoretical or practical benefit because similar adverse effects are likely.

β -Blockers

Formerly, β -blockers have been contraindicated in patients with heart failure. However, the sympathetic neurohormonal overactivity that occurs in response to the failing heart has been identified as a decisive factor in the progression of ventricular dysfunction. Consequently, β -blockers have been tested in a number of clinical trials. There is now substantial evidence that β -blockers reduce mortality among patients with mild-to-moderate symptomatic heart failure (ANZ Carvedilol, 1997; CAPRICORN, 2001; CIBIS II, 1999; MERIT-HF, 1999; US Carvedilol, 1996;) and those with severe heart failure (COPERNICUS, 2001). This beneficial effect

also extends to the elderly heart failure population (SENIORS, 2005).

The use of β -blockers is, therefore, recommended for all patients with symptoms of heart failure due to left ventricular systolic dysfunction, irrespective of age and the degree of dysfunction. However, due to their negative inotropic effects, β -blockers should only be initiated when the patient's condition is stable. There is insufficient evidence for a class effect to be assumed illustrated by the fact that in one trial, metoprolol tartrate was found to be inferior to carvedilol (COMET, 2003). Currently, nebivolol, bisoprolol and carvedilol are the only licensed β -blockers for the treatment of heart failure in the UK.

It is likely that patients will experience a worsening of symptoms during initiation of therapy, and therefore, patients are started on very low doses of β -blocker (e.g. carvedilol 3.125 mg daily), with careful titration occurring over a number of weeks or months with careful monitoring. The goal is to titrate the dose towards those used in clinical trials that have been associated with morbidity and mortality benefits (carvedilol 25–50 mg daily). Table 21.7 summarises the activity and use of β -blockers in heart failure.

Despite the demonstrated benefits, there is ongoing concern that certain subgroups of patients with heart failure continue to be undertreated with β -blockers. These groups include patients with chronic obstructive pulmonary disease (COPD), peripheral vascular disease, diabetes mellitus and erectile dysfunction and older adults. With the exception of patients with reversible pulmonary disease, who have typically been excluded from β -blocker trials (CIBIS II, 1999; MERIT-HF, 1999), there is now sufficient evidence to justify the use of β -blockers licensed for heart failure in these patients. In addition, a systematic review of trials on cardio-selective β -blockers found no clinically significant adverse respiratory effects in patients with reversible COPD, although it would be prudent to use these agents in such patients with caution and with appropriate monitoring in place (Salpeter et al. 2005).

Mineralocorticoid receptor antagonists

The use of MRAs as an adjunct to standard treatment has been shown to reduce morbidity and mortality in patients with heart failure. Spironolactone has been shown to reduce mortality and hospitalisation rates in patients with moderate to severe heart failure (RALES, 1999). The use of eplerenone has also been shown to be associated with similar benefits in early post-MI patients with symptomatic heart failure or early post-MI diabetic patients with asymptomatic heart failure (EMPHASIS-HF, 2011; EPHEBUS, 2003).

Aldosterone can cause sodium and water retention, sympathetic activation and parasympathetic inhibition, all of which are associated with harmful effects in the patient with heart failure. Aldosterone antagonists counteract these effects by directly antagonising the activity of aldosterone, providing a more complete blockade of the renin–angiotensin–aldosterone system when used in conjunction with an ACE inhibitor. Although the combination of spironolactone (at a dose of 50 mg daily or more) and an ACE inhibitor is associated with an increased risk of developing hyperkalaemia, the use of a 25 mg daily dose has been shown to have little effect on serum potassium and provides a significant reduction in mortality. The use of spironolactone is, however, contraindicated in those patients with a serum potassium >5.5 mmol/L or serum creatinine >200 mmol/L. With eplerenone, similar contraindications exist, and therefore close monitoring of blood biochemistry and renal function must be undertaken for the use of either agent. The activity and use of spironolactone and eplerenone are summarised in Table 21.5.

Currently, there is no evidence available regarding the effectiveness and safety of combining an ACE inhibitor, ARB and a mineralocorticoid receptor antagonist, and therefore it is recommended that this combination is avoided until more information about this particular combination becomes available.

Sacubitril

Sacubitril is a neprilysin inhibitor, a new class of medicine with a unique mechanism of action. Neprilysin breaks down endogenous vasoactive peptides (e.g. natriuretic peptides, bradykinin), meaning that neprilysin inhibition elevates plasma levels of these peptides, which in turn offset the activation of the renin–angiotensin–aldosterone system and its negative consequences on symptom control and disease progression in heart failure (see Fig. 21.1).

Replacing ACE inhibitor therapy in suitable patients with the combination of the neprilysin inhibitor, sacubitril, and the ARB valsartan has been shown to reduce cardiovascular mortality and hospital admissions for heart failure in patients who are poorly controlled under treatment with an ACE inhibitor (or ARB), β -blockers and/or mineralocorticoid receptor antagonist (PARADIGM-HF, 2014). Patients shown to benefit are those with moderate to severe heart failure who have either markedly elevated plasma BNP levels or previous hospital admission for heart failure.

Because both ACE inhibitors and sacubitril inhibit the breakdown of bradykinin, there is an increased risk of angioedema with overlapping use of these agents, and therefore it is recommended

that ACE inhibitor is stopped at least 36 hours before initiating sacubitril/valsartan. There is also a higher risk of symptomatic hypotension with sacubitril/valsartan than with ACE inhibitors or ARBs alone, and with limited post-marketing experience to date, it is currently recommended that specialist advice is sought before treatment with sacubitril/valsartan is initiated.

Ivabradine

Ivabradine is a new type of medicine that reduces the pacemaker activity of the sinoatrial node. As with β -blockers, ivabradine reduces the heart rate, but in contrast to β -blockers, it lacks negative inotropic effects, which has obvious advantages in patients with heart failure. However, a disadvantage is that it only slows the heart rate when the heart rhythm is driven by the sinoatrial node (sinus rhythm).

The use of ivabradine in heart failure is supported by trial evidence showing that it reduces heart failure deaths and hospitalisation due to heart failure when added to usual care of patients with moderate to severe heart failure (SHIFT, 2010). It is recommended for use in patients who have had a hospital admission for heart failure in the preceding 12 months but have stabilised on standard therapy for at least 4 weeks. Due to the risk of severe bradycardia with the combined use of β -blockers and ivabradine, it is recommended that patients have a sinus rhythm heart rate ≥ 75 beats/min despite maximum tolerated doses of β -blockers, and specialist advice should be sought before choosing to initiate ivabradine.

Digoxin

There is evidence to show that when digoxin has been used to treat heart failure in patients in sinus rhythm, as an adjunct to ACE inhibitor and diuretic therapy, worsening of symptoms occurs on withdrawal of digoxin (PROVED, 1993; RADIANCE, 1993). Although the use of digoxin in heart failure in patients in sinus rhythm has no measurable impact on mortality, it reduces the number of hospital admissions (DIG, 1997). Consequently, digoxin is currently recommended for use as add-on therapy at low doses in patients with moderate to severe heart failure who remain symptomatic despite adequate doses of ACE inhibitor, β -blocker and diuretic treatment. Due to the lack of effect on mortality, it is unlikely that digoxin would be considered before the other adjunctive therapies available.

Digoxin is a positive inotropic agent and acts by increasing the availability of calcium within the myocardial cell through an inhibition of sodium extrusion, thereby increasing sodium–calcium exchange and leading to enhanced contractility of cardiac muscle. Digoxin increases cardiac output in patients with co-existing atrial fibrillation by suppressing atrioventricular conduction and controlling the ventricular rate. In patients with atrial fibrillation, the serum digoxin concentration usually needs to be at the higher end of the reference range (0.8–2 micrograms/L) or beyond to control the arrhythmia. However, a high serum digoxin concentration is not necessarily required to achieve an inotropic effect in patients in sinus rhythm. Digoxin is also associated with both vagal stimulation and a reduction in sympathetic nerve activity, and these may play important roles in the symptomatic benefits

experienced by those patients in sinus rhythm receiving lower doses. In practice, the dose prescribed will be judged appropriate by the clinical response expressed as relief of symptoms and control of ventricular rate. Routine monitoring of serum digoxin concentrations in the pharmaceutical care of the patient is not recommended, other than to confirm or exclude digoxin toxicity or investigate issues around patient adherence.

Digoxin treatment is potentially hazardous due to its low therapeutic index, and so all patients receiving this drug should be regularly reviewed to exclude clinical signs or symptoms of adverse effects. Digoxin may cause bradycardia and lead to potentially fatal cardiac arrhythmias. Other symptoms associated with digoxin toxicity include nausea, vomiting, confusion and visual disturbances. Digoxin toxicity is more pronounced in the presence of metabolic or electrolyte disturbances and in patients with cardiac ischaemia. Those patients who develop hypokalaemia, hypomagnesaemia, hypercalcaemia, alkalosis, hypothyroidism or hypoxia are at particular risk of toxicity. Treatment may be required to restore serum potassium, and in emergency situations, intravenous digoxin-specific antibody fragments can be used to treat life-threatening digoxin toxicity. [Table 21.8](#) summarises the activity and use of digoxin.

Nitrates/hydralazine

Nitrates exert their effects in heart failure predominantly on the venous system, where they cause venodilation, thereby reducing the symptoms of pulmonary congestion. The preferred use of nitrates is in combination with an arterial vasodilator such as hydralazine, which reduces the afterload, to achieve a balanced effect on the venous and arterial circulation. The combined effects of these two drugs lead to an increase in cardiac output, and there is evidence to show the combination is effective and associated with a reduction in mortality in patients with

heart failure ([V-HeFT I, 1986](#)). Although the combination can improve survival, the reduction in mortality is much smaller than that seen with ACE inhibitors ([V-HeFT II, 1991](#)), especially in the white population. The combination has been shown to reduce mortality, heart failure hospitalisation rates and quality of life in patients of African descent, when added as an adjunct to optimum medical therapy ([A-HeFT, 2004](#)), and this benefit is sustained ([A-HeFT, 2007](#)).

The evidence supports the use of hydralazine 300 mg daily with isosorbide dinitrate (ISDN) 160 mg daily (although in practice an equivalent dose of isosorbide mononitrate, ISMN, is often used). Since the emergence of ACE inhibitors, with their superior effects on morbidity and mortality, the combination has mainly been reserved for patients unable to tolerate or with a contraindication to ACE inhibitor therapy or for those patients of African descent.

Organic nitrate vasodilators work by interacting with sulphhydryl groups found in the vascular tissue. Nitric oxide is released from the nitrate compound, and this in turn activates soluble guanylate cyclase in vascular smooth muscle, leading to the vasodilatory effect. Plasma nitric oxide concentrations are not clearly related to pharmacological effects because of their indirect action on the vasculature. Depletion of tissue sulphhydryl groupings can occur during continued treatment with nitrates and is partly responsible for the development of tolerance in patients with sustained exposure to high nitrate doses. Restoration of sulphhydryl groupings occurs within hours of treatment being interrupted; therefore, nitrate tolerance can be prevented by the use of an asymmetrical dosing regimen to ensure that the patient experiences a daily nitrate-free period of more than 8 hours.

In the acute setting, glyceryl trinitrate (GTN) might be administered intravenously, along with a loop diuretic, to patients with heart failure and concomitant myocardial ischaemia. When using

Table 21.8 Inotropic agents used in the treatment of heart failure

Class and agent	Pharmacological half-life	Comment
Cardiac glycosides		
Digoxin	39 h	In renal failure, half-life of digoxin is prolonged. Dosage individualisation required. Serum drug concentration monitoring used to confirm or exclude toxicity or effectiveness. Dose of digitoxin unaffected by renal failure. CNS, visual and GI symptoms linked to digoxin toxicity. No benefit in terms of mortality, but use associated with improved symptoms and reduced hospitalisation for heart failure. Beneficial in AF, although risk of arrhythmias with high doses. If given i.v., must be administered slowly (20 min) to avoid cardiac ischaemia.
Digitoxin	5–8 days	
Phosphodiesterase inhibitors		
Enoximone	4.2 h	Used only in severe heart failure as adjunctive therapy. Associated with arrhythmias and increased mortality with chronic use.
Milrinone	2.4 h	
Sympathomimetics		
Dopexamine	6–7 min	Continuous i.v. use only and should be used with caution in acute heart failure. Generally given in lower doses and titrated up with close monitoring in critical care setting. Dopamine and dobutamine may also be useful agents where appropriate.

AF, Atrial fibrillation; CNS, central nervous system; GI, gastro-intestinal; i.v., intravenous.

this route of administration, it is important that a Teflon-coated catheter is used to avoid adsorption of the GTN onto the intravenous line, and blood pressure is closely monitored.

ISDN can be given orally and is completely absorbed; however, only 25% of a given dose appears as ISDN in serum, with 60% of an oral dose being rapidly converted to ISMN. ISMN is longer acting, and therefore most of the accumulated effects of a dose of ISDN are attributable to the 5-isosorbide mononitrate metabolite. Consequently, a 20 mg dose of ISDN is approximately equivalent to a 10 mg dose of ISMN. In practice, nitrate preparations are usually given orally in the form of ISMN (see Table 21.7).

Hydralazine has a direct action on arteriolar smooth muscle to produce arterial vasodilation. Its use is associated with the risk of causing drug-induced systemic lupus erythematosus (SLE). SLE is an uncommon multisystem connective tissue disorder that is more likely to occur in patients classified as slow acetylators of hydralazine, which accounts for almost half the UK population.

Inotropic/Vasopressor agents

The use of inotropic/vasopressor agents (except digoxin) is almost exclusively limited to hospital practice, where acute heart failure with potentially reversible cardiogenic shock may require the use of agents such as the sympathomimetic dopexamine in an intravenous continuous infusion. They may be used to address persisting hypotension and hypoperfusion in the critical care setting. These agents have inotrope-vasodilator effects that differ according to their action on α , β_1 , β_2 and dopamine receptors. Dopexamine acts on β_2 adrenoceptors in cardiac muscle with a lesser effect on peripheral dopamine receptors, which together produces a positive inotropic effect and an increase in renal perfusion (see Table 21.8). Generally, inotropes would only be used where there is hypotension or hypoperfusion. Tolerance to sympathomimetic inotropic agents may develop on prolonged administration, particularly in patients with underlying ischaemia, and is also associated with a risk of precipitating arrhythmias.

Noradrenaline (norepinephrine) is an α -adrenoreceptor agonist; its vasoconstrictor action limits its usefulness in severely hypotensive patients such as those in septic shock. Adrenaline (epinephrine) has β_1 -, β_2 - and α -adrenoreceptor agonist effects and is used in patients with low vascular resistance. However, it is more arrhythmogenic than dobutamine and should be used with caution.

Phosphodiesterase inhibitors are rarely used in clinical practice as a consequence of trials showing an increased risk of mortality (PROMISE, 1991) and there being little evidence to date to show they improve prognosis or survival (Tang et al, 2015).

Other agents

Direct-acting vasodilators such as sodium nitroprusside are rarely used.

Patients with coronary heart disease may be candidates for calcium-blocking antianginal vasodilators. However, some of these agents can exacerbate co-existing heart failure because

their negative inotropic effects offset the potentially beneficial arterial vasodilation. Amlodipine and felodipine have a more selective action on vascular tissue and, therefore, a less pronounced effect on cardiac contractility than other calcium antagonists and should be the agents of choice where appropriate.

In hospitalised patients in whom compromised respiratory function remains despite medical management of heart failure, the treatment options include mechanical ventilation, continuous positive airway pressure ventilation and the use of intra-aortic balloon pumping.

Guidelines

Several groups have produced evidence-based consensus clinical guidelines for the management of chronic heart failure. The focus of the various guidelines tends to be on chronic medication use (European Society of Cardiology, 2016; NICE, 2010; ACC/AHA/HFSA, 2016; SIGN, 2016). All guidelines confirm that ACE inhibitors should be given to all patients with all grades of heart failure, whether symptomatic or asymptomatic, in the absence of contraindication or intolerance.

In patients intolerant of ACE inhibitors, the preferred alternative is an ARB. However, it should be remembered that where ACE inhibitor intolerance is due to renal dysfunction, hypotension or hyperkalaemia, similar effects could be expected with an ARB. For patients with symptomatic heart failure, a loop diuretic is usually recommended to treat oedema and control symptoms. In heart failure patients who are still symptomatic despite being on optimum therapy (ACE inhibitor, β -blocker, mineralocorticoid receptor antagonist with/without a diuretic), the use of adjunctive therapies is recommended, which can include sacubitril/valsartan, ivabradine, hydralazine/nitrate combination and digoxin where the patient is still in sinus rhythm.

There is also debate as to whether diastolic dysfunction is a true diagnosis. The cause of 'apparent' heart failure symptoms can in many cases be attributed to another disease/condition such as respiratory disease, obesity or ischaemic heart disease. However, there may also be some patients in whom the cause of heart failure symptoms remains uncertain. Therefore, specific recommendations for the drug treatment of diastolic heart failure are still lacking.

Patient care

Heart failure remains poorly understood by the general public, among whom only 3% were able to identify the condition when presented with a list of typical symptoms. Patients with heart failure are often elderly and often include patients with comorbidity such as coronary heart disease and hypertension. Other complications include renal impairment, polypharmacy and variable adherence to prescribed medication regimens. Where renal function is compromised, careful attention to dosage selection is required for drugs excreted largely unchanged in the urine. Patients with heart failure are at particular risk of fluid or electrolyte imbalance, adverse effects and drug interactions. Consequently, careful

monitoring is indicated to help detect problems associated with suboptimal drug therapy, unwanted drug effects and poor patient adherence.

A number of therapeutic problems may be encountered by the patient with heart failure. Notably, heart failure often complicates other serious illness and is a common cause of hospital admission. In addition to monitoring clinical signs and symptoms in the acute setting, there should be monitoring of fluid and electrolyte balance, assessment of renal and hepatic function, and performance of chest radiograph, electrocardiograph and haemodynamic measurements where appropriate.

Patient education and self-monitoring

The patient must be in a position to understand the need for treatment and the benefits and risks offered by prescribed medication before concordance with a treatment plan can be achieved. Appropriate patient education is necessary to encourage an understanding of the condition and inform patients of the extent of the condition and how prescribed drug treatment will work and affect their daily lives. It is also important to encourage them to be an active participant in their care where appropriate. Specific advice should be given to reinforce the timing of doses and how each medication should be taken. Patients also need to be advised of potentially troublesome symptoms that may occur with the medication and whether such effects are avoidable, self-limiting or a cause for concern.

Patients should be made aware that diuretics will increase urine production and that doses are usually timed for the morning to avoid inconvenience during the rest of the day or overnight. However, there are cases where patients are advised that they can alter the timing of the dose(s) if required to suit their lifestyle or social commitments, with the agreement of their doctor. There are also some patients who use a flexible diuretic dosing regimen, where they can take an extra dose of diuretic in response to worsening signs or symptoms as part of an agreed self-management protocol. To use such a regimen, the patient has to monitor and record his or her weight on a daily basis, have clear instructions to take an extra dose of diuretic when a notable increase in weight is detected as a result of fluid retention and know when to seek medical attention.

Patients with heart failure are at an increased risk of acute kidney injury when experiencing intercurrent illness that can cause dehydration (e.g. diarrhoea, vomiting, bacterial or viral infections) as a result of their condition and the medicines they are taking. In dehydration, the reduced cardiac output is further exacerbated by a loss in circulating blood volume, leading to reduced renal perfusion. In this situation the renin–angiotensin–aldosterone system is normally activated to maintain renal blood flow, but the use of ACE inhibitors, ARBs and/or MRAs in patients with heart failure offsets this compensatory mechanism. It is therefore important that patients and carers are made aware of the potential harms of continuing to take these medicines when acutely ill. In Scotland, a ‘Medicine Sick Day Rules’ card has been introduced that lists those problematic medicines that patients should stop

for 24–48 hours when they experience a dehydrating illness (<http://ihub.scot/spsp/primary-care/medicine-sick-day-rules-card/>).

It is also important for patients to be aware of signs and symptoms of drug toxicity with medicines such as digoxin (e.g. anorexia, diarrhoea, nausea and vomiting), and to be aware of the action to be taken should these symptoms occur.

Timing of doses is also important. If a nitrate regimen is being used, then patients must be made aware that the last dose of the nitrate should be taken in mid- to late afternoon to ensure that a nitrate-free period occurs overnight, thus reducing the risk of nitrate tolerance. However, patients with prominent nocturnal symptoms require separate consideration. Where β -blockers are introduced, it is important that the patient is aware of the need for gradual dose titration due to the risk of the medication aggravating heart failure symptoms. Certain medicines for the treatment of minor ailments that are available for purchase over the counter without a prescription can aggravate heart failure, such as ibuprofen, anti-histamines and effervescent formulations. It is important that patients know what action to take if their symptoms become progressively worse and whom to contact when necessary for advice. Table 21.9 provides a general patient education and self-monitoring checklist, highlighting the typical areas where advice should be given.

Monitoring effectiveness of drug treatment

Therapeutic effectiveness is confirmed by assessing the patient for improvements in reported symptoms, such as shortness of breath and oedema, and for noticeable changes in exercise tolerance. Oedema is often visible and remarked upon by patients, especially in the feet (ankles) and hands (wrists and fingers). Increased oedema may be reflected by an increase in the patient’s body weight and can be more easily assessed if the patient routinely records his or her weight and reviews this on a daily basis. Questions about tolerance to exercise are also useful in identifying patients who may be experiencing difficulties with their condition or where the treatment plan is suboptimal. Onset or deterioration of symptoms is often slow, and patients are more inclined to adapt their lifestyle gradually by moderating daily activities to compensate. This should be borne in mind whenever a patient assessment is undertaken.

Identifying the symptoms of poor heart failure control can be complicated by many factors, such as the presence of conditions like arthritis and parkinsonism, which can also affect a patient’s mobility. Poor control of respiratory disease, presenting as an increased shortness of breath or exacerbation of other respiratory symptoms, can also be mistaken for loss of control of heart failure. Therefore, consideration of these and other factors is necessary in the interpretation of presenting symptoms because a deterioration in symptoms may not be solely due to worsening heart failure or ineffective heart failure medication.

Dietary factors can lead to loss of symptom control, where failure to restrict sodium intake may contribute to an ongoing problem of fluid retention. Simple dietary advice to avoid

Table 21.9 Patient education and self-monitoring in the treatment of heart failure

Topic	Advice	Comment
Diuretics	<ul style="list-style-type: none"> • Will cause diuresis • Timing of dose • Flexible dosing (where indicated) 	Monitor for incontinence, muscle weakness, confusion, dizziness, gout, unusual gain in weight within very short time period (few days). Use of diary to record and monitor daily weight can help identify when to take an agreed extra dose of diuretic. Patient also able to adjust time of dose to suit lifestyle where necessary.
Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers	<ul style="list-style-type: none"> • Improve symptoms • Avoid standing rapidly 	Monitor for hypotension, dizziness, cough, taste disturbance, sore throat, rashes, tingling in hands, joint pain, signs of swelling under the skin (if the throat/tongue are involved and breathing is affected, urgent medical attention is required).
β -Blockers	<ul style="list-style-type: none"> • Symptoms worsen initially • Gradual increase in dose 	Monitor for hypotension, dizziness, headache, fatigue, gastrointestinal disturbances, bradycardia.
Sacubitril/valsartan	<ul style="list-style-type: none"> • Improve symptoms • Gradual increase in dose required 	Monitor for dizziness, light-headedness, cough, diarrhoea, tiredness, signs of swelling under the skin (if the throat/tongue are involved and breathing is affected, urgent medical attention is required).
Cardiac glycosides	<ul style="list-style-type: none"> • Report toxic symptoms 	Monitor for signs or symptoms of toxicity, such as anorexia, nausea, visual disturbances, diarrhoea, confusion, social withdrawal.
Nitrates	<ul style="list-style-type: none"> • Timing of dose • Postural hypotension • Avoid standing rapidly 	Monitor for headache, hypotension, dizziness, flushing (face or neck), gastro-intestinal upset. Ensure asymmetrical dosing pattern for nitrates to provide nitrate-free period and reduce risk of tolerance developing.
Potassium salts	<ul style="list-style-type: none"> • Administration of dose (soluble + non-soluble) 	Monitor for gastro-intestinal disturbances, swallowing difficulty, diarrhoea, tiredness, limb weakness. Ensure patient knows how to take the medication safely, e.g. swallow whole immediately after food, or soluble forms to be taken with appropriate amount of water/fruit juice after allowing fizzing to stop.
Purchased medicines	<ul style="list-style-type: none"> • Choice of medicines 	Ensure patient is aware of need to seek advice when purchasing medicines for minor ailments. Ask pharmacist to confirm suitability when selecting.
Understanding the condition	<ul style="list-style-type: none"> • What heart failure is • Impact on lifestyle • Treatment goals 	Ensure patient understands the condition, treatment goals and complications that may affect quality of life. Important to motivate the patient with respect to lifestyle modification and achievement of agreed treatment goals relative to the degree of heart failure present (asymptomatic, mild, moderate or severe symptoms).
Health issues	<ul style="list-style-type: none"> • Diet; sodium intake • Alcohol intake • Smoking • Exercise • Other risk factors 	Issues related to diet, alcohol consumption, smoking habit, regular gentle exercise (walking). Other associated risk factors (e.g. hypertension, ischaemic heart disease) need to be addressed where appropriate.

processed foods and not to add salt to food should be reinforced. According to some manufacturers, the absorption of ACE inhibitors, for example, captopril and perindopril, may be slowed by food or antacids, and therefore patients should be advised to take the dose before food in the morning to ensure maximum effect.

Patients with heart failure may often receive suboptimal drug treatment, due to the fact that they are not prescribed first-line therapy, such as ACE inhibitors, β -blockers and mineralocorticoid receptor antagonists, and the dosage is less than the recommended target dose. All patients at risk of suboptimal treatment need to be routinely identified, and this will

Box 21.1 Criteria for the assessment of drug treatment in a patient with chronic heart failure (Scottish Intercollegiate Guidelines Network, 2016)

Need for drug therapy (all patients)

1. Is an ACE inhibitor prescribed?

If symptomatic (NYHA II or above)

2. Is a β -blocker prescribed?
3. Is a MRA prescribed?
4. If intolerant to ACE inhibitor or MRA, is an ARB prescribed?
5. Has patient received pneumococcal vaccination?
6. Has patient received influenza vaccination?

Need for drug therapy (as appropriate)

7. If symptomatic on optimised doses of ACE inhibitor, β -blocker and MRA, has specialist advice on use of sacubitril/valsartan been considered?
8. If symptomatic on optimised therapy with a β -blocker, has specialist advice on use of ivabradine been considered?
9. If symptomatic on optimised therapy including 7 and/or 8 above, has specialist advice on use of digoxin or H-ISDN been considered?
10. If post-MI, is an antiplatelet and statin prescribed?
11. In AF is thromboembolic prophylaxis prescribed?

Need for dose titration

12. If an ACE inhibitor is prescribed, is target dose achieved?
13. If an ARB is prescribed, is target dose achieved?

14. If a β -blocker is prescribed, is target dose achieved?

15. If an MRA is prescribed, is target dose achieved?

16. If warfarin is prescribed, is dose titrated to INR?

Medication safety

17. Aggravating drugs avoided (if possible):
 - a. NSAIDs
 - b. Tricyclic antidepressants
 - c. Some antihistamines (e.g. diphenhydramine)
 - d. Dihydropyridine calcium channel blockers (except amlodipine or felodipine)
 - e. Diltiazem, verapamil
 - f. Anti-diabetics (e.g. glitazones, gliptins)
 - g. Minoxidil
 - h. Itraconazole and other azole antifungals
 - i. Macrolide antibiotics
 - j. Corticosteroids
 - k. Tadalafil
 - l. Lithium

ACE, Angiotensin-converting enzyme; AF, atrial fibrillation; ARB, angiotensin receptor blocker; H-ISDN, hydralazine-isosorbide dinitrate; INR, international normalised ratio; MI, myocardial infarction; MRA, mineralocorticoid receptor antagonist; NSAID, non-steroidal anti-inflammatory drug.

require the involvement of healthcare professionals in the monitoring of symptoms and the individualisation of each patient's therapeutic plan.

In an effort to systematically identify whether a patient's therapeutic plan adheres to the current evidence base for treatment and whether any changes might be required to optimise therapy, the audit tool shown in **Box 21.1** could be used in routine practice. The tool has been derived from published consensus-based clinical guidelines and could underpin a more comprehensive medication review.

Monitoring safety of drug treatment

A number of issues around the safe use of medication must be considered, especially in those patients with comorbidity and/or a high number of prescribed medicines. In these patients there is an increased risk of drug–drug and drug–disease interactions (**Tables 21.10–21.12**). It is important to be aware of clinically important interactions and to investigate potentially problematic combinations, as well as to regularly assess the patient for any signs or symptoms of drug therapy problems. Monitoring for problems such as negative inotropic effects, excessive blood pressure reduction and salt and fluid retention should be undertaken, and where appropriate, laboratory measurement of serum drug concentration (digoxin) or physiological markers (potassium, creatinine) should be performed to confirm or exclude adverse effects. Patients started on an ACE inhibitor should have renal function and serum electrolytes checked at 1 and 3 months after starting therapy, and every 6 months once a maintenance dose is reached.

Potential problems with diuretic therapy

The use of diuretic therapy for sodium and water retention is common in the treatment of heart failure, although there can be a number of problems for the patient to contend with. Elderly patients in particular are at risk from the unwanted effects of diuretics. The increase in urine volume can worsen incontinence or precipitate urinary retention in the presence of an enlarged prostate, whereas overuse can lead to a loss of control of heart failure and worsening of symptoms. Rapid diuresis with a loop diuretic leading to more than a 1 kg loss in body weight per day may exacerbate heart failure due to an acute reduction in blood volume, hypotension and diminished renal perfusion, with a consequent increase in renin release. Prolonged and excessive doses of diuretics can also contribute to symptoms of fatigue as a consequence of electrolyte disturbance and dehydration. The adverse biochemical effects of excessive diuresis include uraemia, hypokalaemia and alkalosis. Diuretic-induced glucose intolerance may affect diabetic control in type 2 diabetes, but more commonly diuretics reveal glucose intolerance in patients who are not diagnosed as being diabetic. Diuretics also increase serum urate, leading to hyperuricaemia, although this may not require a change in drug therapy if symptoms of gout are absent (estimated incidence of 2%).

Hyponatraemia may occur with diuretics and is usually due to water retention rather than sodium loss. Severe hyponatraemia (serum sodium concentration of less than 115 mmol/L) causes confusion and drowsiness. It commonly arises when potassium-sparing agents are used in diuretic combinations.

Table 21.10 Monitoring the effectiveness of drug treatment in patients with heart failure

Consider	Monitor for	Comment
Clinical markers	Poor symptom control Achievement of agreed treatment goals	Signs or symptoms of undertreatment or advancing disease need to be addressed (dyspnoea, breathlessness and/or fatigue). The aim is for good symptom control and either maintenance or improvement in quality of life. Persisting symptoms or hospitalisation may indicate a revision of drug therapy or the addition of other agents where appropriate.
Interactions	Drug–drug interactions	Some interactions may result in reduced effectiveness and require dosage adjustment or change in choice of drug.
Adherence	Formulation acceptability Dose timing and interval Unusual time interval between requests for prescription medication	Poor adherence can result from drug being ineffective (over- or underuse), experience of side effects, a complicated drug regimen or patient behaviour (intentional nonadherence or forgetfulness). Reasons need to be identified and addressed where possible, e.g. adjusting frequency and timing of doses, review choice of formulation, education. Initiation of devices to improve compliance should be considered where appropriate.
Evidence-based prescribing	Implementation of evidence-based guidelines Audit of prescribed treatment for heart failure	The drug of choice for a particular patient may not reflect the evidence base for treatment for patients with heart failure. It is important to ensure evidence-based treatments are considered for every patient, and choices of medication confirmed or changed where appropriate. Audit of guideline recommendations to help confirm that treatment plans are optimal can be systematically applied to help assess appropriateness of treatment (see Box 21.1).
Multidisciplinary working	Input from other healthcare professionals	It is important to be aware of what care has already been provided to minimise the risk of giving conflicting advice to the patient or duplicating work already done. It may also allow reinforcement of key information. There is an increasing evidence base for the benefits of multidisciplinary models of care for chronic heart failure patients.

Table 21.11 Common drug–drug interactions with prescribed heart failure medication

Drug	Interacts with	Result of interaction
Diuretic	NSAIDs Carbamazepine Lithium	Decreased effect of diuretic and increased risk of renal impairment Increased risk of hyponatraemia Excretion of lithium impaired (thiazides worse than loop diuretics)
ACE inhibitor or ARB	NSAIDs Ciclosporin Lithium Diuretics Sacubitril/valsartan	Antagonism of hypotensive effect; increased risk of renal impairment Increased risk of hyperkalaemia Excretion of lithium impaired Enhanced hypotensive effect; increased risk of hyperkalaemia with potassium-sparing drugs Increased risk of angioedema, hypotension, hyperkalaemia, renal impairment
Sacubitril/valsartan	ACE inhibitor or ARB Aliskiren Statins, e.g. atorvastatin Ciclosporin or rifampicin Cidofovir or tenofovir	Increased risk of angioedema, hypotension, hyperkalaemia, renal impairment Increased risk of hypotension, hyperkalaemia, renal impairment Increased risk of statin adverse effects Increased risk of hypotension Increased risk of hypotension
β-Blocker	Amiodarone Diltiazem Verapamil	Increased risk of bradycardia Increased risk of AV block and bradycardia Increased risk of hypotension, heart failure and asystole
Mineralocorticoid receptor antagonists	ACE inhibitor or ARB Digoxin Carbamazepine Antibacterials, e.g. clarithromycin Anticonvulsants, e.g. phenytoin Antifungals, e.g. ketoconazole St John's Wort	Increased risk of hyperkalaemia Increased plasma concentration of digoxin Decreased plasma concentration of eplerenone Increased plasma concentration of eplerenone Decreased plasma concentration of eplerenone Increased plasma concentration of eplerenone Decreased plasma concentration of eplerenone

Table 21.11 Common drug–drug interactions with prescribed heart failure medication—cont'd

Drug	Interacts with	Result of interaction
Digoxin	Amiodarone	Increased digoxin level (need to halve maintenance dose of digoxin)
	Propafenone	Increased digoxin level (need to halve maintenance dose of digoxin)
	Quinidine	Increased digoxin level (need to halve maintenance dose of digoxin)
	Verapamil	Increased risk of AV block
	Diuretics	Increased risk of hyperkalaemia and therefore toxicity
	Amphotericin	Increased cardiac toxicity if hypokalaemia present
Nitrates	Sildenafil	Increased hypotensive effect
	Heparin	Increased excretion of heparin

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AV, atrioventricular; NSAIDs, non-steroidal anti-inflammatory drugs.

Table 21.12 Common drug–disease interactions with prescribed heart failure medication

Drug	Concurrent disease	Potential outcome
Diuretic	Prostatism Hyperuricaemia Liver cirrhosis	Urinary retention/incontinence Exacerbation of gout Encephalopathy
ACE inhibitor or ARB	Renal artery stenosis Severe aortic stenosis Renal impairment Hypotension	Renal failure Exacerbation of heart failure Renal failure Further hypotension and cardiogenic shock
Sacubitril/valsartan	Renal artery stenosis Renal impairment Hepatic impairment Hypotension	Renal failure Renal failure Hepatic failure Further hypotension and cardiogenic shock
β-Blocker	Asthma Bradyarrhythmias Hypotension	Bronchoconstriction/respiratory arrest Exacerbation of heart failure Further hypotension and cardiogenic shock
Mineralocorticoid receptor antagonists	Renal impairment	Hyperkalaemia
Digoxin	Bradyarrhythmias Renal impairment	Exacerbation of heart failure Exacerbation of heart failure and digoxin toxicity leading to cardiac arrhythmias

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

Diuretics may also lead to hypokalaemia as a result of urinary sodium increasing the rate of K^+/Na^+ exchange in the distal tubule. The occurrence of hypokalaemia is hazardous for patients receiving digoxin and also for those with ischaemic heart disease or conduction disorders. It is more commonly found with thiazide diuretics than loop agents and is more likely to occur when diuretics are used for heart failure than for hypertension. This is probably due to the fact that higher doses are used, and there is an associated activation of the renin–angiotensin system. Patients with a serum potassium level of less than 3.5 mmol/L require treatment with potassium supplements or the addition of a potassium-sparing diuretic. The use of a potassium-sparing diuretic is considered to be more effective at preventing hypokalaemia than using potassium supplements. Prevention of hypokalaemia requires at least 25 mmol of

potassium, whereas treatment requires 60–120 mmol of potassium daily. Because proprietary diuretic-potassium combination products usually contain less than 12 mmol in each dose, their use is often inappropriate.

Potassium supplements are poorly tolerated at the high doses often needed to treat hypokalaemia, and a liquid formulation is more preferable to a solid form. This is mainly due to the fact that solid forms can produce local high concentrations of potassium salts in the gastro-intestinal tract, with the risk of damage to the tract in patients with swallowing difficulties or delayed gastro-intestinal transit. In patients with deteriorating renal function or renal failure, the use of potassium supplements or potassium-sparing diuretics might cause hyperkalaemia, and therefore careful monitoring of these agents is essential.

Potential problems with angiotensin-converting enzyme inhibitor, angiotensin II receptor blocker and mineralocorticoid receptor antagonist therapy

ACE inhibitors are the cornerstone of the treatment of heart failure, but there are also risks associated with their use. ARBs, which also act on the renin–angiotensin–aldosterone system, pose similar risks to those recognised for ACE inhibitors. Both agents can predispose patients to hyperkalaemia through a reduction in circulating aldosterone; therefore, potassium supplements or potassium-retaining agents should be used with care when co-prescribed, and careful monitoring of serum potassium should be mandatory. Although potassium retention can be a problem with ACE inhibitors and ARBs, it can also be an advantage by helping counteract the potassium loss that can result from the use of diuretic therapy. However, because this effect on potassium cannot be predicted, laboratory monitoring is still necessary to confirm that serum potassium concentration remains within safe limits.

The use of a mineralocorticoid receptor antagonist with an ACE inhibitor (or ARB if the patient is ACE inhibitor intolerant) can be safely undertaken with minimal effects on the serum potassium concentration, provided that recommended target doses for the mineralocorticoid receptor antagonist are not exceeded (see Table 21.6). Although this is usually the case, laboratory monitoring of potassium is mandatory to ensure patient safety. Heparin therapy has also been shown to increase the risk of hyperkalaemia when used alongside ACE inhibitor or ARB therapy, and therefore a similar approach to monitoring should be taken when co-prescribed.

When initiating ACE inhibitor or ARB therapy, volume depletion due to prior use of a diuretic increases the risk of a large drop in blood pressure occurring after the first dose. As a consequence, diuretic treatment is usually withheld during the initiation phase of therapy in an effort to minimise this effect.

A dry cough, which may be accompanied by a voice change, occurs in about 10% of patients receiving an ACE inhibitor. It is more common in women and is associated with a raised level of kinins. Rashes, loss or disturbances of taste, mouth ulcers and proteinuria may also occur with ACE inhibitor therapy, particularly with captopril. These unwanted effects tend to be more common in patients with connective tissue disorders.

A number of ACE inhibitors are administered as pro-drugs, so close monitoring is advised in patients with liver dysfunction, as this could reduce the benefits associated with their use. Most ACE inhibitors are dependent on the kidney for excretion and require careful dosage titration in patients with existing renal dysfunction. Differences in the pharmacokinetic characteristics do not fully explain the differences in duration of action seen with the ACE inhibitors because this is also related to ACE binding affinity. Throughout treatment, the dose must be individualised to obtain maximum benefit in relation to symptom relief and survival, with minimum side effects. When the experience of adverse effects requires a review of therapeutic alternatives, ARBs can be considered as an alternative treatment option. Although the side-effect

profile of ARB therapy is very similar to that of ACE inhibitors, it is not identical.

Potential problems with β -blocker therapy

Previously, the use of β -blockers was contraindicated in patients with heart failure due to negative inotropic and chronotropic effects. However, β -blockers have clearly been shown to be safe and effective in patients with symptoms of heart failure and should be used in patients in the absence of contraindications or intolerance. Initiation of treatment and titration of dose must be done under close supervision, with very small dose increments used to minimise transient worsening of heart failure symptoms. Titration of the dose to target is normally performed over a number of weeks or months, and close patient monitoring is required to ensure safety is not compromised. The maximum tolerable dose for a patient may be less than the target dose and may limit further dose titration. Monitoring for excessive bradycardia or rapid deterioration of symptoms is necessary to ensure patient safety while also monitoring the patient's prescribed dose to ensure that dosage increments are gradual and that the patient is not subjected to an overall worsening of symptoms.

Potential problems with sacubitril/valsartan therapy

The sacubitril/valsartan combination is the most recent addition to the range of medicines to treat heart failure, and given that one of the agents is an ARB, there will be a need for a similar approach to monitoring patient safety as outlined previously. There is also a need to be alert to the possible development of angioedema, particularly where there is a family history. Any swelling of the face, lips, tongue and/or throat, which may cause difficulties in breathing or swallowing, require immediate medical attention. Careful monitoring should be undertaken when switching from an ACE inhibitor to this combination, and it is important to ensure an interval of at least 36 hours between stopping the ACE inhibitor and starting the new therapy.

Potential problems with digoxin therapy

Although digoxin has been shown to reduce hospitalisation rates for patients with heart failure, its use is associated with a range of adverse effects, including nonspecific signs and symptoms of toxicity such as nausea, anorexia, tiredness, weakness, diarrhoea, confusion and visual disturbances. Digoxin also has the potential to cause fatal arrhythmias. It slows atrioventricular conduction and produces bradycardia, but it may also cause various ventricular and supraventricular arrhythmias. Digoxin toxicity typically causes conduction disturbances, with enhanced automaticity leading to premature ventricular contractions. Patients at particular risk are those with myocardial ischaemia, hypoxia, acidosis or renal failure.

The appropriateness of digoxin dosage should be guided by assessment of the patient's renal function (from serum creatinine and creatinine clearance determinations) and from the patient's

Table 21.13 Monitoring the safety of drug treatment in patients with heart failure

Consider	Monitor	Comment
Clinical markers	Side effects Toxicity Adverse drug reactions	There is a need to monitor for signs/symptoms of overtreatment with prescribed medication, such as diuretics (dehydration) and digoxin (nausea and vomiting). Look for signs of patient intolerance, allergy, serious adverse effects or troublesome side effects. Document unexpected adverse drug reactions if reported.
Laboratory markers	Changes in organ function Biochemical changes Haematological changes Suspected digoxin toxicity	Renal function assessment and implications for drug choice and dosage individualisation required, especially in the elderly and for initiation or titration of ACE inhibitor therapy (creatinine, potassium, urea). Hypokalaemia can lead to digoxin toxicity, and serum drug concentration measurement may be performed to confirm or exclude toxicity. Haematological side effects with some drugs have been reported, e.g. ACE inhibitors; therefore, laboratory checks may be required in response to clinical signs/symptoms presented.
Interactions	Drug–drug interactions Drug–disease interactions	Some interactions may result in harm to the patient.
Comorbidity	Drug selection for concomitant conditions	The presence of heart failure may influence treatment choice for co-existing diseases or conditions, e.g. coronary artery disease, thyroid disease, respiratory disease. Where possible, ensure drugs known to worsen heart failure are avoided or used with caution, e.g. non-steroidal anti-inflammatory agents or corticosteroids in rheumatoid arthritis.

ACE, Angiotensin-converting enzyme.

pulse rate. Renal function may also be affected by drug therapy or loss of control of heart failure; therefore, any medicine that affects in digoxin clearance will have an impact on the serum digoxin concentration. The possibility of a high serum digoxin concentration should also be considered in any patient whose health deteriorates or who shows signs and symptoms of potential digoxin toxicity.

Potential problems with other cardiovascular drugs

There are a number of other cardiovascular drugs that may be prescribed for patients with diseases or conditions other than heart failure, with some agents capable of worsening or aggravating symptoms. Patients with coronary artery disease may be candidates for calcium-blocking antianginal vasodilators. However, some of these agents, for example, diltiazem and verapamil, can exacerbate co-existing heart failure because their negative inotropic effects offset the potentially beneficial arterial vasodilation. Second-generation dihydropyridines such as amlodipine and felodipine have a preferential action on the vasculature. They have less pronounced effects on cardiac contractility than other calcium antagonists, and this makes them the agents of choice where a limitation of the heart rate is not required.

Symptoms of fainting or dizziness on standing may indicate a need to review diuretic or vasodilator therapy. Patients should be reassured about mild postural effects and given advice to avoid standing from a chair too quickly. The patient and the healthcare team need to confirm the safety of the patient's treatment plan regularly and be vigilant for any signs or symptoms suggesting otherwise.

A summary of the monitoring activity required to ensure the safety of drug use is outlined in [Table 21.13](#).

Potential problems with non-cardiovascular agents

A number of agents should be avoided or used with caution in patients with heart failure because of their known negative inotropic or pro-arrhythmic effects that may aggravate symptoms of heart failure (see [Box 21.1](#)). In particular, the use of non-steroidal anti-inflammatory drugs (NSAIDs) should be actively discouraged where possible. Not only do NSAIDs cause fluid retention and put patients at increased risk of bleeding, especially if they are already taking antiplatelets or anticoagulants, but there is also an increased risk of acute renal failure, particularly in those on long-term use and in the elderly, particularly when they experience intercurrent illness (diarrhoea, vomiting, severe infections) with dehydration. Recent articles have described the synergistic/cumulative adverse renal effects of combinations of ACE inhibitors or ARBs with diuretics and NSAIDs, which are particularly common in patients with heart failure.

Case studies

Case 21.1

Mr GF, a 57-year-old, suffered an MI 12 months ago and at that time was also found to have left ventricular systolic dysfunction on echocardiography. His functional status is currently classed as NYHA II. At your request, he has agreed to see you for a medication review regarding his drug therapy. He has a history of type 2 diabetes mellitus (8 years), and his current prescription includes

enalapril 10 mg twice daily, gliclazide 80 mg twice daily, bisoprolol 5 mg daily, aspirin 75 mg daily, and a glyceryl trinitrate spray to use when required.

Question

Is the current treatment plan for heart failure optimal?

Answer

Mr GF has echocardiographic evidence of left ventricular systolic dysfunction, and some signs and symptoms of heart failure are present. The absence of diuretic therapy should be explored as part of the review, and monitoring for signs/symptoms of fluid retention would be included as part of ongoing patient monitoring activity. He is prescribed an ACE inhibitor at the recommended target dose (enalapril 10–20 mg twice daily). Treatment with this agent could be increased if required. The current dose of bisoprolol (5 mg daily) is less than the recommended target and could, therefore, be titrated to a dose of 10 mg daily or the maximum tolerable dose. Any titration should be implemented gradually over a period of weeks or months, with close monitoring of blood pressure and heart rate. Regular assessment of the patient for side effects or signs and symptoms of heart failure should also be undertaken because each incremental rise in β -blocker dose may be accompanied by a worsening of heart failure symptoms. When considering other potential changes to the treatment plan for heart failure, there may be an opportunity for the introduction of a mineralocorticoid receptor antagonist.

With Mr GF's history of MI and type 2 diabetes mellitus, his cardiovascular risk is high, and he should therefore also be prescribed lipid-lowering therapy (regardless of his serum cholesterol measurement), for example, a statin.

Case 21.2

Mrs JM, 66-year-old, presents with a new prescription for candesartan 4 mg daily. On checking her medication record, she has been prescribed lisinopril 20 mg daily, bisoprolol 10 mg daily and furosemide 40 mg daily for the last 6 months to treat her heart failure (NYHA II–III). Her blood pressure was measured 2 weeks ago and was 128/78 mmHg.

Question

How do you respond to the new prescription?

Answer

It is unclear from the information given whether candesartan is prescribed as an adjunct to ACE inhibitor therapy (provided the dose has been optimised) or as an alternative to ACE inhibitor due to intolerance. If being used as an adjunct, it is also unclear whether the patient has an intolerance to an MRA, which would be the preferred choice according to the available evidence. Therefore, it is important to confirm the intended use of candesartan in this case through speaking to the patient and/or prescriber. If candesartan is being used as an alternative to either the ACE inhibitor or MRA, it is important to establish the reason for intolerance and ensure the therapeutic choice is appropriate for the patient. Patients are usually found to be intolerant of ACE inhibitors for three main reasons: dry cough, hypotension or compromised renal function. Because heart failure can produce

symptoms of a dry cough, it can sometimes be difficult to ascertain whether the ACE inhibitor or the heart failure is responsible. Dry cough occurs secondary to the inhibition of bradykinin metabolism and is generally identified shortly after initiation of an ACE inhibitor or after a dose increase; therefore, inquiry into the timing of symptoms attributed to ACE inhibitor intolerance is important. If the reason is due to persistent dry cough, an ARB would be a suitable alternative. However, if the ACE inhibitor intolerance is related to hypotension or renal dysfunction, it is likely an ARB would induce similar adverse effects, and therefore other alternatives may need to be discussed with a heart failure specialist. In patients intolerant of an MRA, the main reasons tend to be related to hyperkalaemia or unacceptable side effects such as gynaecomastia in men, gastro-intestinal intolerance and renal dysfunction.

If candesartan is being used as adjunctive therapy, careful introduction and titration of dose must be undertaken due to the increased risk of hypotension, renal dysfunction and hyperkalaemia. ACE inhibitors and ARBs are both potassium conserving. The addition of candesartan would normally be under the guidance of a heart failure specialist and should be initiated at a low dose and gradually titrated up to the target (32 mg daily) or maximum tolerable dose. It is important to note that dose increases during the titration period should be at least 2 weeks apart. Although Mrs JM has a normal blood pressure measurement at present, it is unclear whether renal function or blood biochemistry has previously been checked, and it is important that this is confirmed before starting candesartan. The monitoring plan for Mrs JM should include regular checks of blood pressure, serum creatinine (and estimation of renal function) and serum potassium and clinical assessment for any signs/symptoms of adverse effects/intolerance. This should be done 7–14 days after initiation and final dose titration. Because the addition of candesartan should improve heart failure symptom control, regular patient monitoring will allow an assessment of the effectiveness of therapy.

Case 21.3

Mr HS, 72-year-old, is admitted to hospital with increasing shortness of breath at rest. He has a previous medical history of severe left ventricular systolic dysfunction, confirmed by echocardiography, and angina. Before admission he had been taking the following medication: lisinopril 10 mg daily, furosemide 80 mg each morning and 40 mg at 2 pm, digoxin 62.5 micrograms each morning, ISMN SR 60 mg daily, glyceryl trinitrate spray 1–2 doses as required, aspirin 75 mg dispersible each morning. His chest X-ray shows severe pulmonary oedema, his blood pressure is 110/70 mmHg and serum urea and electrolytes are within normal range. During the admission, carvedilol 3.125 mg twice daily is started.

Questions

1. What therapeutic options would you choose to treat the acute symptoms presented by Mr HS at the beginning of his admission?
2. Was the addition of carvedilol appropriate for this patient?
3. What other drug treatment options might be considered for this patient in the longer-term?

Answers

1. The administration of furosemide by the intravenous route is necessary because there is decreased absorption of oral furosemide secondary to gastro-intestinal oedema in acute heart failure. The administration of i.v. furosemide allows rapid serum levels to be

achieved, which has the benefit of producing venodilation (reducing the preload), which helps improve symptoms long before there is diuresis. Only after the oedema has resolved should the patient revert back to oral administration of diuretics. At this time, the dosage can be adjusted to maintain an appropriate fluid balance. Where diuresis is inadequate with an oral loop diuretic alone, the addition of a thiazide diuretic such as bendroflumethiazide or metolazone should be considered. Metolazone should be given initially at a low dose of 2.5 mg daily, or less often if required, to avoid rapid diuresis leading to hypotension and/or renal failure.

- Although there is good evidence to show that β -blocker therapy is safe and effective for patients with NYHA stage IV heart failure, it is not currently recommended that it should be initiated in patients with acute symptoms of heart failure. Where β -blocker therapy is indicated, initiation should occur when the patient's heart failure has been stable for at least 2 weeks and started at a very low dose on specialist advice (i.e. carvedilol 3.125 mg twice daily). The dose should be titrated gradually over a period of months towards the recommended target dose where appropriate, provided the patient tolerates each increment. In Mr HS's case, however, there is evidence to suggest that β -blocker use at discharge can be done safely in patients with heart failure, with positive effects on survival for both heart failure and coronary heart disease.
- There is also scope to increase the dose of lisinopril to 20–35 mg daily, provided the patient can tolerate the higher dose, because this is associated with greater benefits on morbidity and mortality. Based on his systolic blood pressure and assuming satisfactory renal function, there is no reason why this option cannot be explored, and it would be reasonable to delay any titration of dosage until the symptoms become more stable. This is important because the use of large doses of loop diuretics in acutely ill patients may predispose to ACE inhibitor-induced renal impairment. A mineralocorticoid receptor antagonist could be added to Mr HS's existing drug therapy if the patient is poorly controlled on optimised doses of ACE inhibitor and β -blocker. This would provide benefits to morbidity and mortality if added to the existing treatment plan. The decision to initiate further treatment options would usually lie with a heart failure specialist based on the individual patient, which may include replacing digoxin therapy with a more effective agent. As Mr HS approaches end-stage heart failure, there may be a need to focus solely on symptom relief.

Case 21.4

Mrs FM, a 70-year-old with chronic asthma and mild heart failure, has been prescribed naproxen 250 mg three times daily. On inspection of her medication record, it is discovered that she is also receiving:

- furosemide 40 mg each morning,
- ramipril 5 mg in the morning,
- prednisolone 5 mg daily,
- salbutamol inhaler two puffs four times daily when required,
- salmeterol 50 micrograms inhaler one puff twice daily,
- beclometasone 250 micrograms inhaler two puffs twice daily,
- omeprazole 10 mg daily.

When asked her about symptom control, she said she is still breathless at night, which, in addition to her painful knee, is keeping her awake.

Questions

- Do you think Mrs FM should be taking naproxen?
- What other aspects of this patient's medication regimen could be improved?

- What is the likely effect of the prescribed therapy on serum potassium concentrations?

Answers

- NSAIDs such as naproxen can exacerbate asthma and heart failure by inducing bronchospasm and by causing fluid retention, respectively. They can also lead to upper gastro-intestinal problems, particularly when co-prescribed with oral steroids. It would be worth checking what has been tried already. If the painful knee is responsive to a simple analgesic such as paracetamol, this would be the preferred option. Alternatively, if an NSAID is necessary and tolerated, the use of ibuprofen in low dosage would be slightly less likely to have an effect on respiratory and renal function, although it may still aggravate symptoms of heart failure. Further investigation into the persistence of respiratory symptoms is required because it is unclear whether the patient's breathlessness is due to an exacerbation of her asthma or a worsening of her heart failure, and therefore the interpretation of this symptom is difficult.
- The clinical nature of the breathlessness is not easy to determine and therefore makes the solution to this case uncertain at this stage. A number of issues, which also include confirming both diagnoses, should be considered. It is important to establish whether the patient is receiving maximum benefit from the inhaled treatment. Inhaler technique must be checked and improved if necessary and the dose of beclometasone optimised. A regular regimen of salbutamol is not advisable because it may impair control of asthma by masking the onset of exacerbations. A review of the need for an oral steroid should be undertaken, and any reduction in the use of an oral steroid must be done gradually to avoid exacerbation of the asthma and ensure that the patient does not experience adrenal insufficiency. Reduction of the oral steroid dose may benefit the heart failure. Although the prednisolone dose is low, its impact on treated heart failure is probably low but nevertheless should be taken into account in the review of its use.

When considering the treatment of heart failure, application of the criteria set identified the following issues in Mrs FM's treatment:

- Target dose of ACE inhibitor not achieved
- Not prescribed any mineralocorticoid receptor antagonist
- Potentially aggravating drug prescribed (NSAID, naproxen)
- Has specialist advice on use of sacubitril/valsartan been sought?
- Has specialist advice on use of ivabradine been sought?

There is scope to increase the dose of ramipril to 5 mg twice daily if tolerated, which is the target dose in heart failure patients. However, because a β -blocker is contraindicated in this patient due to her asthma, consideration may be given to adjunctive therapy such as an MRA, for example, spironolactone. If the patient was known to be intolerant of an MRA, an ARB, for example, candesartan, could be added instead. The decision about which agent to select first may come down to personal choice if symptoms are moderate. An increase in the dose of furosemide could also be considered, provided the breathlessness is due to heart failure.

- Mrs FM is receiving a number of medications with the potential to affect serum potassium. Diuretics, oral and inhaled steroids (high dose) and β -agonists can reduce potassium, whereas ACE inhibitors can increase potassium. It is impossible to predict the extent to which each agent will affect potassium, especially with inhaled treatments, because the dose normally needs to be high before there is any significant systemic absorption. Determination of serum potassium is necessary, and if it remains low under the current treatment plan or is at risk of being altered due to changes in drug dosage such as an increase in ramipril to 5 mg twice daily, then close observation will be required.

Case 21.5

Mr CH, a 78-year-old, regularly visits your pharmacy for his medication and has moderately symptomatic heart failure (NYHA III). During a recent review with his primary care doctor, Mr CH described worsening of his heart failure symptoms. His doctor has said he could take an extra dose of furosemide 40 mg if required, but Mr CH would need to be referred back to the hospital cardiologist consultant before changing any other medication. He is currently prescribed ramipril 5 mg daily, nebivolol 2.5 mg daily and furosemide 40 mg daily. His blood pressure has been measured as 103/62 mmHg (heart rate 54 bpm), and he has an eGFR of 30 ml/min/1.73 m².

Questions

1. What is the rationale behind the decision to refer Mr CH to the cardiology consultant?
2. What other drug treatment options might be considered?

Answers

1. Mr CH is prescribed both ACE inhibitor and β -blocker therapy in accordance with the evidence base for treatment. As Mr CH has symptomatic heart failure (NYHA III), he is also prescribed furosemide in response to signs and symptoms of fluid retention. When Mr CH reports deterioration in the control of his heart failure symptoms, the prescriber must consider what treatment options are available for Mr CH and make any necessary changes. Neither

the ACE inhibitor nor β -blocker is prescribed at the recommended target dose (see Table 21.7); therefore, there is scope to titrate the dose of either agent to the target dose, which should result in improvement of symptoms and a reduced need for diuretic therapy. However, there may be reluctance to increase the dose of ACE inhibitor, possibly due to the fact that Mr CH has a relatively low blood pressure and compromised renal function (eGFR of 30 ml/min/1.73 m²). However, it is unclear whether Mr CH is receiving maximally tolerated doses and whether his apparent hypotension is indeed symptomatic. Similarly, there may be reluctance to increase the dose of β -blocker due to a low blood pressure and heart rate (54 beats/min). Because both options may adversely affect the patient, the doctor has decided to treat the symptoms with additional diuretic when required as a short-term solution before Mr CH's appointment with the cardiologist consultant for advice. In Mr CH's case, it is likely that specialist supervision is required in considering the addition of further agents and for the optimisation of therapy.

2. It is unlikely that there will be much scope to add further medication, and optimising either ACE inhibitor or β -blocker therapy will be limited due to their effects on blood pressure and/or renal function. There are some agents that could be added, although Mr CH may be a likely candidate for cardiac resynchronisation therapy (CRT) and should probably be assessed for this. An ECG would confirm his eligibility for therapy if his QRS duration was greater than 120 ms, and this would be likely to improve his symptoms and survival. It may also help increase his blood pressure and renal function to a point where further optimisation of ACE inhibitor and β -blocker dose or addition of other therapeutic options might become possible.

22 Arrhythmias

Simon Sporton and Sotiris Antoniou

Key points

- The heart functions most efficiently in sinus rhythm. Any arrhythmia compromises cardiac function.
- Although drugs have been the mainstay of arrhythmia treatment, they are often of limited efficacy and may be associated with significant toxicity.
- An understanding of the ionic basis of the cardiac action potential is important because antiarrhythmic drugs act predominantly by altering the function of transmembrane ion channels.
- Antiarrhythmic drugs are grouped by the Vaughan–Williams classification, based on their action upon specific transmembrane ion channels.
- Antiarrhythmic drugs may be proarrhythmic in certain circumstances.
- The use of non-pharmacological treatments for arrhythmias (catheter ablation and device therapy) is increasing.
- Atrial fibrillation is the most common arrhythmia and is associated with an increased risk of thromboembolic stroke. All patients with atrial fibrillation should undergo assessment of their stroke risk.

Normal cardiac electrophysiology

The normal cardiac rhythm, sinus rhythm, is characterised by contraction of first the atria and then the ventricles (systole) followed by relaxation (diastole), during which the heart refills with blood before the next cardiac cycle begins. This orderly sequence of contraction and relaxation is regulated by the heart's electrical activity. Heart muscle cells (myocytes) are electrically active and capable of generating action potentials, which initiate contraction of the myocyte through a process known as excitation–contraction coupling. Adjacent myocytes form electrical connections through protein channels called gap junctions. An action potential in one myocyte causes current flow between itself and adjacent myocytes, which in turn generate their own action potentials, and in this way an 'activation wavefront' spreads through the myocardium, resulting in a wave of contraction.

Cardiac action potential

An understanding of the ionic basis of the cardiac action potential is important because drugs used in the treatment of

cardiac arrhythmias act by altering the function of transmembrane ion channels. Inherited abnormalities of ion channel function ('channelopathies') are an important cause of sudden cardiac death due to arrhythmia and are increasingly implicated in the pathogenesis of other arrhythmias including atrial fibrillation (AF).

The phospholipid membrane of cardiac myocytes is spanned by numerous proteins known as ion channels, whose permeability to specific ions varies during the cardiac cycle, resulting in a resting (diastolic) membrane potential, diastolic depolarisation in cells with pacemaker activity, and action potentials.

Resting membrane potential

The resting membrane potential of -60 to -90 mV occurs because the intracellular potassium (K^+) concentration is much higher than the extracellular K^+ concentration as a result of a transmembrane pump known as $Na^+K^+ATPase$, which pumps K^+ ions into the cell in exchange for sodium (Na^+) ions. K^+ ions diffuse out of the cell through selective K^+ channels (the inward rectifier current or I_{K1}) unaccompanied by anions, resulting in a net loss of charge and thus a negative resting, diastolic or phase 4, transmembrane potential (Fig. 22.1A).

Pacemaker activity

Certain specialised myocytes form the cardiac conduction system and these cells have pacemaker activity; that is, they are capable of generating their own action potentials because of gradual depolarisation of the transmembrane potential during diastole (phase 4), referred to as the pacemaker potential (see Fig. 22.1B). The pacemaker potential occurs as a result of: (1) a gradual reduction in an outward K^+ current called the delayed rectifier (I_{K1}) current, (2) a gradual reduction in an acetylcholine-activated outward K^+ current I_{KAch} , and (3) increasing dominance of an inward current of Na^+ and some K^+ ions known as I_f (f stands for 'funny').

As a result of the pacemaker potential, the transmembrane potential gradually becomes less negative until a threshold potential is reached at which an action potential is triggered. The rate of depolarisation of the pacemaker potential, and hence

Fig. 22.1 Cardiac action potential. (A) An action potential from ventricular myocardium. During diastole (phase 4), the resting transmembrane potential is constant at -90 mV. The upstroke (phase 0) of the action potential is due to the rapid influx of Na^+ ions. The early phase of repolarisation (phase 1) is due to efflux of K^+ ions, followed by a plateau phase (phase 2) at about 0 mV during which influx of Ca^{2+} ions is balanced by efflux of K^+ ions. Towards the end of diastole, influx of Ca^{2+} ions diminishes and efflux of K^+ ions increases, resulting in repolarisation (phase 3) back to the negative resting membrane potential. (B) An action potential from the sinus node. During diastole (phase 4), there is progressive depolarisation towards a threshold potential at which an action potential is triggered. The upstroke (phase 0) of the action potential is less steep than in ventricular myocardial cells because the sinus node cells lack ‘fast’ Na^+ channels, and so depolarisation is dependent upon influx of Ca^{2+} ions.

the heart rate, is influenced by the autonomic nervous system. Sympathetic nervous system activation and circulating catecholamines increase the heart rate by binding to β_1 -adrenoreceptors, leading to an increase in intracellular cyclic adenosine monophosphate (cAMP), which increases the pacemaker current I_f , leading to more rapid depolarisation of the sinus node and hence a faster heart rate. Parasympathetic nervous system activation, mediated by muscarinic cholinergic receptors, has the opposite effect: reduction of cAMP with inhibition of the pacemaker current I_f and an increase in the outward K^+ current I_{KAch} , reducing the rate of depolarisation of the sinus node and hence a slower heart rate.

Depolarisation

The rapid depolarisation of the cardiac action potential (see Fig. 22.1A, phase 0) occurs because of a rapid increase in the permeability of the cell membrane to Na^+ ions, which enter rapidly through ‘fast’ Na^+ channels in a current known as I_{Na} . The I_{Na} current is brief because the ‘fast’ Na^+ channels inactivate rapidly.

Repolarisation

The early phase of repolarisation (phase 1) is due to closure of the fast Na^+ channels, an outward K^+ current known as I_{to} (to – transient outward), and in atrial myocytes, a further K^+ current known as the ultra-rapid component of the delayed rectifier current, or I_{Kur} . The plateau phase (phase 2) of the cardiac action potential occurs because the inward movement of Ca^{2+} ions (I_{Ca}) is balanced by the outward movement of K^+ ions. Repolarisation (phase 3) is completed as I_{Ca} diminishes, and two further components of the delayed rectifier (I_{K}) current known as the rapid (I_{Kr}) and slow (I_{Ks}) components predominate, with an important contribution from I_{K1} and also I_{KAch} .

There is considerable variation in the expression of transmembrane ion channels in different parts of the heart, with corresponding variation in the morphology of the action potential. The most marked example is that myocytes in the sinus and AV nodes contain few Na^+ channels. The upstroke of the action potential in these cells is due, predominantly, to the influx of Ca^{2+} ions and, therefore, is considerably slower than the upstroke in other myocytes (see Fig. 22.1B). This results in slow propagation of the cardiac impulse in nodal tissue. The variation in ion channel expression throughout the heart is essential for normal cardiac function, helps explain the pathophysiology of many inherited and acquired diseases complicated by cardiac arrhythmia, and accounts for the relative selectivity of antiarrhythmic and other drugs for certain parts of the heart.

Refractoriness

The action potential of cardiac myocytes differs from that seen in nerve cells by the presence of a plateau phase during which the myocyte is electrically inexcitable (refractory), that is, incapable of generating another action potential. It is only towards the end of repolarisation (phase 3) that the myocyte regains excitability. The time interval between the onset of the action potential and the regaining of electrical excitability is known as the refractory period. Under most circumstances the refractory period of a cardiac myocyte corresponds closely to the duration of the cardiac action potential; therefore, drugs that prolong action potential duration (APD) prolong the refractory period.

Normal cardiac conduction

During sinus rhythm (Fig. 22.2), an activation wavefront begins in the sinus node, a group of cells with pacemaker activity on the upper free wall of the right atrium. The rate of diastolic depolarisation, and hence the rate of discharge of the sinus node, is increased

Fig. 22.2 Normal cardiac conduction system. During sinus rhythm, an activation wavefront spreads from the sinus (sinoatrial [SA]) node across the atrial myocardium before entering the atrioventricular (AV) node. The activation wavefront then enters the bundle of His, which penetrates the annulus fibrosus and forms the only electrical connection between the atria and ventricles. The bundle of His divides into right and left bundle branches, which ramify into a subendocardial network of Purkinje fibres that transmit the activation wavefront rapidly across the ventricles. Activation of the ventricles proceeds from endocardium to epicardium. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

by sympathetic nerve stimulation, circulating catecholamines or sympathomimetic drugs mediated by β_1 -adrenoreceptors on the cell membranes of the sinus node myocytes. Parasympathetic (vagus) nerve stimulation exerts the opposite effect, mediated by muscarinic cholinergic receptors.

An activation wavefront spreads across the atrial myocardium, leading to atrial contraction and generating the P wave on the surface electrocardiogram (ECG; Fig. 22.3). The last part of the atria to be activated is the atrioventricular (AV) node, the electrical and structural properties of which result in a slow conduction velocity, allowing atrial emptying to be completed before ventricular contraction begins and reflected by the PR interval on the ECG. Conduction velocity in the AV node is increased by sympathetic nerve stimulation, circulating catecholamines or sympathomimetic drugs, mediated by β_1 -adrenoreceptors, whereas parasympathetic (vagus) nerve stimulation exerts the opposite effect via muscarinic cholinergic receptors.

The atria and ventricles are electrically isolated from each other by the annulus fibrosus, the electrically non-conductive fibrous tissue forming the valve rings. In the normal heart, there is just one electrical connection between the atria and ventricles, the bundle of His, which conveys the activation wavefront from the AV node and penetrates the annulus fibrosus before dividing into the right and left bundle branches. The bundle branches ramify

Fig. 22.3 Normal electrocardiogram (ECG). The P wave results from activation (depolarisation of the atria). The PR interval is isoelectric as the activation wavefront proceeds slowly through the atrioventricular node. The QRS complex reflects activation of the ventricles and is large compared with the P wave because of the much greater mass of the ventricular myocardium and brief, reflecting extremely rapid conduction in the His–Purkinje system. The T wave represents ventricular repolarisation.

into a sub-endocardial network of Purkinje fibres, which convey the activation wavefront rapidly across the ventricles ensuring near-simultaneous contraction of the ventricular myocardium, reflected by the narrow QRS complex of the ECG. Finally, the activation wavefront spreads from endocardium to epicardium. A wave of repolarisation then spreads across the ventricles resulting in the T wave. The QT interval on the ECG therefore represents the duration of ventricular depolarisation and repolarisation. There is an inverse relationship between the time to activation of different areas of the ventricular myocardium and APD such that the latest areas to be activated have the shortest APD. The purpose of this relationship is that repolarisation is rapid and uniform throughout the ventricular myocardium, which serves to maintain electrical stability.

Arrhythmia mechanisms

Cardiac arrhythmias occur because of abnormalities of impulse formation or propagation.

Abnormal impulse formation

Abnormal automaticity

Automaticity is another term for pacemaker activity, a characteristic possessed by all cells of the specialised cardiac conduction system during health and, potentially, by other cardiac

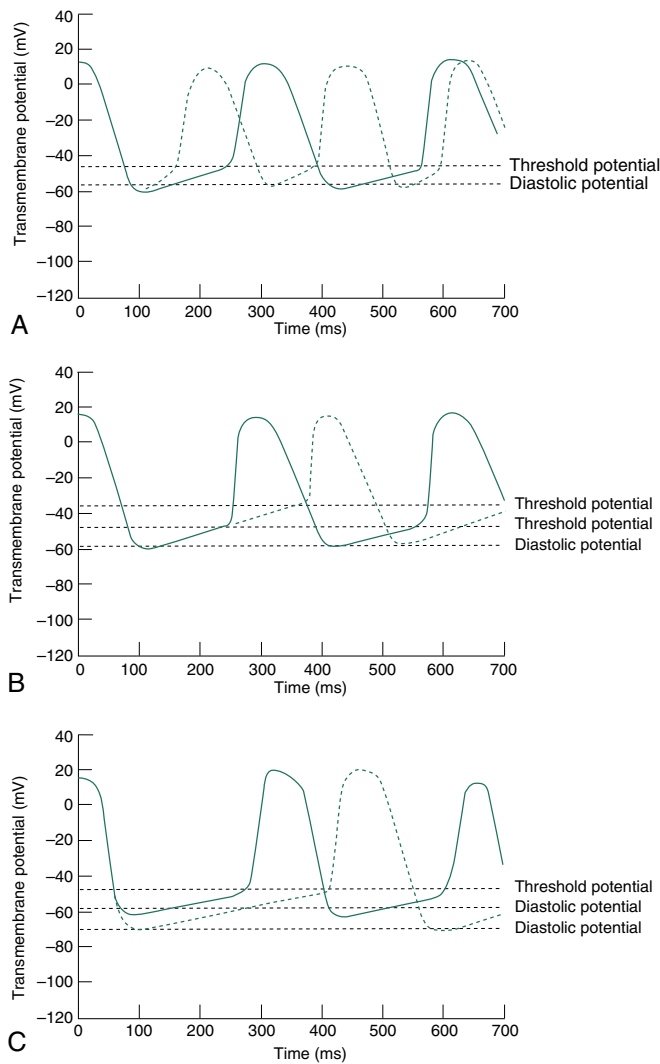

Fig. 22.4 Abnormal automaticity. A sinus node action potential is shown (in bold) with a characteristic slow upstroke. After repolarisation, gradual diastolic depolarisation occurs as a result of pacemaker currents. When the threshold potential is reached, a further action potential is generated. The rate of firing of the pacemaker cell is governed largely by the duration of the diastolic interval, which is in turn determined by (A) the slope of diastolic depolarisation, (B) the threshold potential, and (C) the maximum diastolic potential. Each of these (shown by dotted lines) may be altered by disease states leading to abnormal automaticity.

myocytes during certain disease states. The rate of firing of a pacemaker cell is largely determined by the duration of the phase 4 diastolic interval (Fig. 22.4). This in turn is determined by: (1) the maximum diastolic potential following repolarisation of the preceding action potential, (2) the slope of diastolic depolarisation due to pacemaker currents, and (3) the threshold potential for generation of a new action potential. In the healthy state, there is a hierarchy of firing rates within the specialised conduction system, with the highest rate in the sinus node followed by the AV node and then the His–Purkinje system. The sinus node is, therefore, the dominant pacemaker and determines the heart rate, whereas the pacemaker activity in the distal conduction

Fig. 22.5 Triggered activity. (A) An early afterdepolarisation (EAD) occurring at the start of phase 3 of the cardiac action potential. (B) A delayed afterdepolarisation (DAD) occurring after repolarisation, during phase 4. Either EADs or DADs may reach the threshold potential for generation of a further action potential.

system is ‘overdriven’ by the sinus node. Abnormal automaticity describes either accelerated pacemaker activity in cells of the distal cardiac conduction system such that they escape from overdrive suppression by the sinus node, or the development of pacemaker activity in cells that do not form part of the cardiac conduction system.

Triggered activity

Triggered activity describes impulse formation dependent upon afterdepolarisations. Early afterdepolarisations (EADs) occur during phase 2 or 3 of the cardiac action potential, whereas delayed afterdepolarisations (DADs) occur during phase 4 (Fig. 22.5). In both cases, afterdepolarisation may reach the threshold potential required for generation of a new action potential.

EADs are characteristic of the congenital and acquired long QT syndromes. The prolonged APD promotes reactivation of the inward calcium current I_{Ca} , which may directly cause EADs during phase 2. Furthermore, action potential

prolongation and β -adrenoreceptor stimulation promote calcium overload in the sarcoplasmic reticulum. This, in turn, leads to the spontaneous release of calcium in bursts by the sarcoplasmic reticulum. The resultant increase in intracellular calcium concentration activates the transmembrane $\text{Na}^+/\text{Ca}^{2+}$ exchanger, which moves one calcium ion out of the myocyte in exchange for three sodium ions and, therefore, results in an EAD during phase 3. In the long QT syndromes, an EAD may initiate a form of polymorphic ventricular tachycardia (VT) known as Torsade de pointes. EADs are more prominent at slow heart rates.

DADs are seen during reperfusion following ischaemia, heart failure, digitalis toxicity, and in catecholaminergic polymorphic VT. They occur because of spontaneous release of calcium in bursts by the sarcoplasmic reticulum, activating the $\text{Na}^+/\text{Ca}^{2+}$ exchanger as described for EADs and resulting in a DAD during phase 4. A DAD may result in a single extrastimulus ('ectopic beat') or in repetitive firing, that is, tachycardia. DADs are more prominent at rapid heart rates and during sympathetic nervous stimulation of β -adrenoreceptors.

Abnormal impulse propagation

Re-entry

Many clinically important arrhythmias are due to re-entry, in which an activation wavefront rotates continuously around a circuit. Re-entry depends upon a trigger in the form of a premature beat and a substrate, that is, the re-entry circuit itself. A precise set of electrophysiological conditions must be met for re-entry to occur (Fig. 22.6): (1) there must be a central non-conducting obstacle around which the re-entry circuit develops; (2) a premature beat must encounter unidirectional conduction block in one limb (a) of the re-entry circuit; (3) conduction must proceed slowly enough down the other limb (b) of the re-entry circuit that electrical excitability has returned in the original limb (a), allowing the activation wavefront to propagate in a retrograde direction along that limb; and (4) the circulating activation wavefront must continue to encounter electrically excitable

Fig. 22.6 Re-entry. During sinus rhythm, (A) an activation wavefront encounters a zone of fixed conduction block but can propagate anterogradely on either side of this zone, down limbs (a) and (b) of a potential re-entry circuit. A premature beat (B) encounters unidirectional conduction block in limb (a), but propagates anterogradely down limb (b) and re-enters limb (a) retrogradely. If limb (a) is now capable of retrograde conduction, the re-entry circuit is completed and re-entry continues (C) as long as the activation wavefront continually meets electrically excitable tissue.

tissue. This is a function of the length of the re-entry circuit, the conduction velocity of the activation wavefront, and the effective refractory period of the myocardium throughout the circuit. Class I antiarrhythmic drugs block sodium channels and, therefore, reduce the amplitude and rate of rise of the cardiac action potential and, in so doing, reduce the conduction velocity of an activation wavefront. Class I antiarrhythmic drugs may exert their major antiarrhythmic effect by abolishing conduction altogether in areas of diseased myocardium forming part of a re-entry circuit in which conduction is already critically depressed. Class III antiarrhythmic drugs prolong cardiac APD, and hence the refractory period. If previously activated cells in a re-entry circuit (the 'tail') remain refractory when the re-entrant wavefront (the 'head') returns to that area, conduction will fail and re-entry will be abolished. Drug-induced prolongation of the refractory period may, therefore, terminate and/or prevent re-entrant arrhythmias.

Clinical problems

Patients with a cardiac arrhythmia may present with a number of symptoms:

- The most common symptom is palpitation, an awareness of an abnormal heartbeat, although some patients with clearly documented arrhythmia have no palpitation. Arrhythmias start suddenly; therefore, if the patient clearly describes palpitation of sudden onset ('like flicking a switch'), this is a useful pointer to an arrhythmia rather than heightened awareness of sinus tachycardia, which has a less sudden onset.
- The heart is designed to work most efficiently in sinus rhythm. Any arrhythmia compromises cardiac function. Symptoms that arise due to reduced cardiac output and/or pulmonary venous congestion include reduced exercise capacity, breathlessness and fatigue.
- Angina may accompany tachycardia, even in the absence of coronary artery disease. Tachycardia increases the metabolic rate of cardiac muscle and hence its demand for blood flow. Myocardial perfusion occurs predominantly during diastole, and during tachycardia proportionately less time is spent in diastole and so myocardial demand for blood can exceed supply, resulting in angina.
- A sudden drop in cardiac output may accompany either bradycardia or tachycardia, causing episodes of dizziness (presyncope), loss of consciousness (syncope) or, in extreme cases, sudden death from cardiac arrest.
- Atrial tachyarrhythmias such as atrial flutter and AF may be complicated by the development of intracardiac thrombus, usually within the left atrial appendage (LAA). This thrombus may embolise to any part of the body, but the most common clinical presentation is with a transient ischaemic attack or stroke.
- Arrhythmias may aggravate heart failure in two ways: (1) the haemodynamic effect of the arrhythmia may precipitate heart failure or aggravate existing heart failure, and (2) prolonged tachycardia of any type may lead to tachycardia-induced cardiomyopathy.

Diagnosis

A detailed history should be obtained, covering all of the symptoms listed above. A characteristic of cardiac arrhythmias is their random onset. Symptoms that occur under specific circumstances are less likely to be due to arrhythmia, but there are exceptions including certain uncommon types of VT, some cases of supraventricular tachycardia (SVT) due to an accessory pathway, and vasovagal syncope (faints). Other key features of the history include:

- a history of cardiac disease;
- a family history of heart disease and of sudden unexpected death;
- other diagnosed medical conditions;
- a full drug history, including over-the-counter medicines and recreational drugs including alcohol.

Physical examination is essential but often normal between episodes of arrhythmia. Mandatory investigation includes a 12-lead ECG and an echocardiogram to detect structural heart disease. Other investigations for structural and ischaemic heart disease may be indicated at this stage with the aim of detecting any underlying structural heart disease. If the history does not include sinister features such as syncope or a family history of sudden unexpected death at a young age, and the resting 12-lead ECG and echocardiogram are normal, then the patient can be reassured that they are extremely unlikely to have a serious heart rhythm disturbance. The extent of further investigation will be dictated by how troublesome the symptoms are.

The most certain way of reaching a firm diagnosis is a 12-lead ECG recorded during the patient's symptoms demonstrating arrhythmia. Because many arrhythmias occur intermittently, some form of ECG monitoring is often necessary. This may include a continuous ambulatory ECG (Holter) recording for up to 7 days at a time if the symptoms occur frequently, or for less frequent symptoms an event recorder, which may store ECG strips automatically if it detects an arrhythmia or if activated by the patient during their symptoms. An insertable loop recorder may be implanted subcutaneously and is an ECG event recorder with a battery life of about 3 years, making it a useful tool for the diagnosis of infrequent arrhythmias. There are now attachments for mobile phones that turn them into single-lead ECG recorders, enabling patients with suspected or actual arrhythmia to make high-quality recordings of their heart rhythm at any time, although the onset of the arrhythmia is unlikely to be captured, which may limit their usefulness.

Management

Tachycardia

Tachycardia is conventionally defined as a resting heart rate greater than 100 beats/min and can be classified according to whether it arises in or involves the atria (supraventricular tachycardias [SVTs]) or the ventricle (ventricular tachyarrhythmias). Management of tachycardia may involve the use of drugs, direct current (DC) cardioversion, catheter ablation or implantable devices. DC cardioversion is performed under either anaesthesia or sedation and may be either 'external', where a shock is delivered across the chest

wall via either handheld paddles or adhesive patches, or 'internal', where a shock is delivered using a catheter inserted into the heart via a vein. DC cardioversion converts most tachycardias promptly to sinus rhythm, but the recurrence rate is high. Catheter ablation may cure many types of tachycardia and involves the delivery of either radiofrequency or cryothermal energy via a catheter, resulting in the destruction of arrhythmogenic tissue by highly localised heating or freezing, respectively.

Supraventricular tachycardias

Supraventricular tachycardias are tachycardias that arise from or involve the atria.

Inappropriate sinus tachycardia

Although uncommon, inappropriate sinus tachycardia, that is, sinus tachycardia with no identifiable underlying cause, is one of the more difficult arrhythmias to treat. The presenting symptom is usually palpitation, and the typical patient is a young, predominantly female, adult with no history of heart disease or other physical illness. The 12-lead ECG shows sinus tachycardia and ambulatory ECG monitoring demonstrates sinus tachycardia, but with diurnal variation in heart rate. Echocardiography is required to exclude structural heart disease, and thyroid function and urinary catecholamine excretion should be measured to detect thyrotoxicosis and phaeochromocytoma, respectively, as rare underlying causes of sinus tachycardia. If treatment is required on symptomatic grounds, β -blockers or verapamil are first-line therapy. Ivabradine, a selective 'funny channel' blocker, has been used in resistant cases but is not currently licensed for this indication. These drugs are typically taken regularly in an attempt to control the heart rate and hence the symptoms. Catheter ablation of the sinus node has been performed in highly symptomatic, drug-resistant, inappropriate sinus tachycardia, but with limited success and risks including symptomatic sinus bradycardia and phrenic nerve palsy.

Atrial flutter

Atrial flutter is a right atrial tachycardia with a re-entry circuit around the tricuspid valve annulus. The atrial rate is typically 300 per minute. The long refractory period of the AV node protects the ventricles from 1:1 conduction. In the presence of a healthy AV node and the absence of AV node-modifying drugs, there is usually 2:1 AV conduction resulting in a regular narrow-complex tachycardia with a ventricular rate of 150 per minute.

Atrial flutter confers a risk of thromboembolism similar to that of AF, and this risk should be managed in the same way as for AF (see later). Emergency management of atrial flutter is dictated by the clinical presentation but may include DC cardioversion or ventricular rate control with drugs that increase the refractory period of the AV node such as β -blockers, verapamil, diltiazem, or digoxin. DC cardioversion would be appropriate in the case of significant haemodynamic compromise and might be considered in a chronically anticoagulated patient or where the onset of the arrhythmia is certain and is less than 48 hours. In other situations, ventricular rate control with drugs would be appropriate.

Fig. 22.7 A 12-lead electrocardiogram (ECG) recorded during the administration of intravenous adenosine. The initial rhythm is atrial flutter with 2:1 conduction from atria to ventricles. The QRS complexes obscure the atrial activity on the ECG. Adenosine does not terminate the atrial flutter but causes temporary atrioventricular block, revealing the characteristic 'sawtooth' ECG morphology of typical atrial flutter.

β -Blockers, verapamil, and digoxin may be given intravenously. β -Blockers or calcium channel blockers (CCBs) would usually be used as first-line treatment, whereas the delayed onset of action of digoxin makes it less useful for rapid heart rate control in an acute setting. Because the re-entry circuit is confined to the right atrium and does not involve the AV node, adenosine will not terminate atrial flutter but will produce transient AV block, allowing the characteristic flutter waves to be seen on the ECG (Fig. 22.7).

There is a limited role for antiarrhythmic drugs, whether used acutely to achieve chemical cardioversion or in the longer-term to maintain sinus rhythm. Class Ic antiarrhythmic drugs such as flecainide or propafenone should be used only in conjunction with AV node-modifying drugs such as β -blockers, verapamil, diltiazem, or digoxin because they may otherwise cause slowing of the atrial flutter circuit and 1:1 conduction through the AV node, which may be life-threatening. Sotalol and amiodarone have been used to restore and maintain sinus rhythm and have the advantage of helping to control the ventricular rate where rhythm control is incomplete. Catheter ablation of atrial flutter is highly effective, safe, and is increasingly used in preference to long-term drug treatment.

Focal atrial tachycardia

As its name implies, this relatively uncommon arrhythmia results from the repetitive discharge of a focal source within the atria or surrounding venous structures. The tachycardia

mechanism may be caused by abnormal automaticity, triggered activity or microreentry. Management is as described for atrial flutter with three exceptions: (1) some focal atrial tachycardias terminate with adenosine; (2) the potential for class Ic antiarrhythmic drugs to slow tachycardia and result in 1:1 AV conduction is lower than for atrial flutter; and (3) catheter ablation of focal atrial tachycardia may be more challenging than that of atrial flutter, but it is curative in a majority of cases.

Junctional re-entry tachycardia

The term supraventricular tachycardias is widely used to describe junctional re-entry tachycardias, but it is a misnomer because it implies any tachycardia arising from the atria. Junctional re-entry tachycardia is a more specific term and may be preferable.

Two mechanisms account for most junctional re-entry tachycardias, and both involve a macroreentry circuit (Fig. 22.8). AV nodal re-entry tachycardia (AVNRT) rotates around a circuit including the AV node itself and the so-called AV nodal fast and slow pathways, which feed into the AV node. AV re-entry tachycardia (AVRT) comprises a re-entry circuit involving the atrial myocardium, the AV node, the ventricular myocardium and an accessory pathway, a congenital abnormality providing a second electrical connection between the atria and ventricles in addition to the His bundle, thus forming a potential re-entry circuit.

Many accessory pathways conduct only retrogradely from the ventricles to the atrium. In these cases, the ECG during sinus

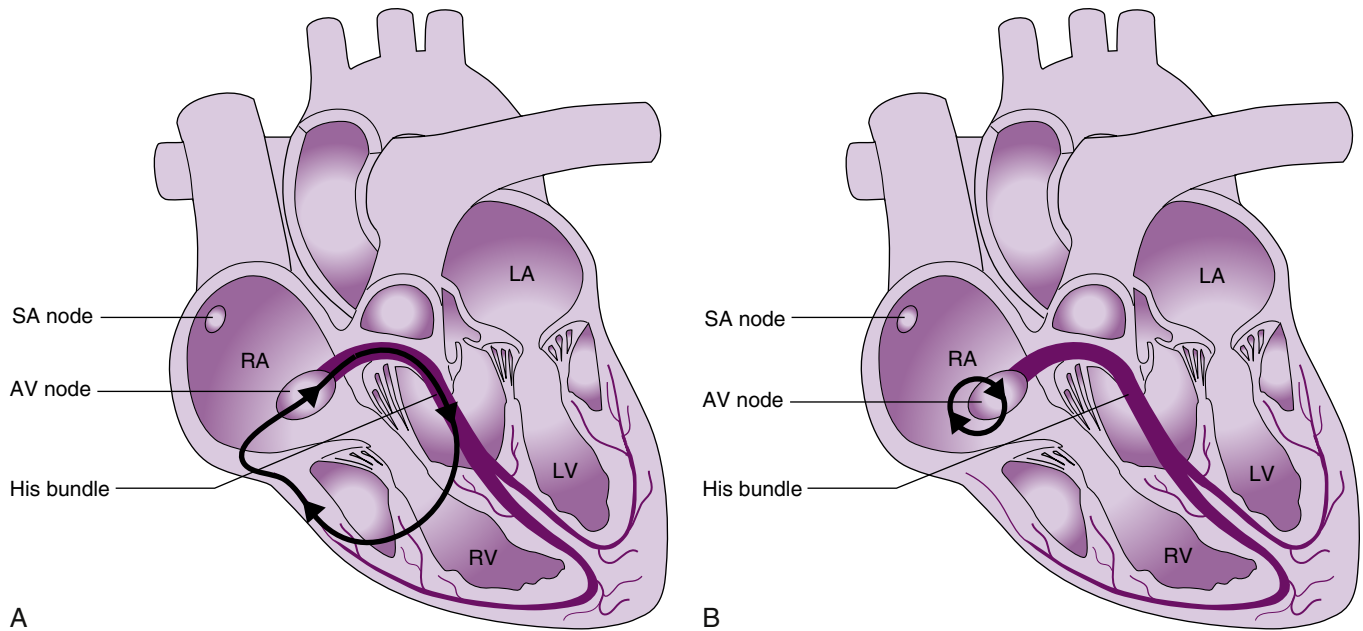

Fig. 22.8 The re-entry circuits of (A) atrioventricular (AV) re-entry tachycardia (AVRT) and (B) AV nodal re-entry tachycardia (AVNRT). (A) The AVRT circuit comprises atrial myocardium, the AV node and His bundle, ventricular myocardium and an accessory pathway, a small strand of muscle providing a second, abnormal, connection between atrium and ventricle, thus forming a potential re-entry circuit. The accessory pathway itself is the target of catheter ablation. (B) The AVNRT circuit comprises 'fast' and 'slow' pathways feeding into the AV node itself. The slow pathway is the target of catheter ablation. AV, Atrioventricular; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SA, sinoatrial.

Fig. 22.9 Electrocardiogram showing a Wolff-Parkinson-White pattern. The PR interval is short and the QRS complex is abnormally broad, with a slurred upstroke or delta wave.

rhythm appears normal and the accessory pathway is described as 'concealed'. Other accessory pathways conduct anterogradely and retrogradely. In these cases, the ECG during sinus rhythm is abnormal and is described as having a Wolff-Parkinson-White pattern (Fig. 22.9). This abnormality is characterised by a short

PR interval, because the conduction velocity of an accessory pathway is usually faster than that of the AV node, and a delta wave, a slurred onset to the QRS complex that occurs because an accessory pathway inserts into the ventricular myocardium which conducts more slowly than the His-Purkinje system.

Junctional re-entry tachycardias are characterised by a history of discrete episodes of rapid regular palpitation that start and stop suddenly and occur without warning and apparently at random. The peak age range at which symptoms begin is from the mid-teens to the mid-thirties, and the condition is more common in women. There are no symptoms between episodes, and cardiac examination and investigation at these times are usually normal. The diagnosis is usually made on the basis of the history, ideally confirmed by an ECG recorded during an episode showing a regular narrow-complex tachycardia with no discernible P waves or P waves occurring in a 1:1 relationship with the QRS complexes.

Acute treatment of junctional re-entry tachycardia aims to terminate the tachycardia by causing transient conduction block in the AV node, an obligatory part of the re-entry circuit. Vagotonic manoeuvres such as carotid sinus massage, a Valsalva manoeuvre or eliciting the diving reflex by immersion of the face in ice-cold water may all result in a brief vagal discharge sufficient to block conduction in the AV node, terminating tachycardia. The same effect may be achieved with intravenous adenosine given as a rapid bolus injection in doses up to 12 mg. Intravenous verapamil 5 mg as a rapid bolus injection is also a good alternative where adenosine is contraindicated, for example, in patients with asthma. However, verapamil should not be used if the patient has been recently treated with β -blockers.

Junctional re-entry tachycardia is often recurrent. There is a limited role for prophylactic drug treatment because this is generally not a dangerous condition affecting young and otherwise healthy people. Among other factors, the efficacy, toxicity, and acceptability of what may be long-term drug treatment requires careful consideration. Options for prophylactic drug treatment include β -blockers, verapamil, diltiazem, flecainide, and sotalol. Particular importance should be given to discussion about the management of junctional re-entry tachycardia during pregnancy. Catheter ablation is curative in one sitting in a majority of cases and is widely regarded as preferable to long-term drug therapy in this typically young and otherwise healthy group of patients.

Atrial fibrillation

AF is the most common sustained arrhythmia, affecting about 1% of the population. AF is rare before the age of 50 years, but its prevalence approximately doubles with each decade thereafter such that about 10% of those older than 80 years are affected. AF is characterised by extremely rapid and uncoordinated electrical activity in the atria and variable conduction through the AV node, resulting in irregular and usually rapid ventricular contraction.

The clinical importance of AF results from:

1. symptoms including palpitation, reduced exercise capacity, breathlessness and fatigue;
2. increased risk of thromboembolic stroke;
3. exacerbation of heart failure through its direct haemodynamic effect and by causing tachycardia-induced cardiomyopathy;
4. increased all-cause mortality (odds ratio 1.5 for men and 1.9 for women).

AF may be classified as:

Paroxysmal: self-limiting episodes of AF lasting no more than 7 days;

Persistent: AF lasting more than 7 days or requiring cardioversion;
Longstanding persistent: continuous AF for more than 1 year; or
Permanent: where a decision has been made not to attempt cure of persistent AF.

AF may also be classified as 'valvular' or 'nonvalvular'. The term valvular AF is used for AF in the context of rheumatic valvular disease (predominantly mitral stenosis) or prosthetic heart valves.

Stroke risk. Non-valvular AF is associated with a fivefold increase in the risk of stroke. Most strokes complicating AF are ischaemic, as a result of embolism of thrombus that forms predominantly within the left atrial appendage due, at least in part, to sluggish blood flow within the fibrillating atria. Oral anticoagulants reduce stroke risk in AF by between 60% and 70% (Hart et al., 2007), whereas antiplatelet drugs prescribed as monotherapy provide little or no protection against stroke in this population and confer a risk of intracranial bleeding similar to that seen with oral anticoagulants, especially in elderly patients.

Guidelines for stroke risk management. Stroke risk management in patients with atrial flutter and AF is the subject of national and international guidelines (Camm et al., 2012; National Institute for Health and Care Excellence [NICE], 2014). All patients presenting with AF (or atrial flutter) should undergo assessment of their stroke risk. The type of AF (paroxysmal, persistent, or permanent) does not appear substantially to influence stroke risk, but there is strong evidence that stroke risk in AF is determined by the entire stroke risk factor profile.

Patients with valvular AF (i.e. rheumatic mitral valve disease or a prosthetic heart valve) should be treated with a vitamin K antagonist (VKA) such as warfarin.

For patients with non-valvular AF, stroke risk is currently assessed by the CHA₂DS₂-VASc score (Table 22.1), which ranges from 0 to 9. The risk of thromboembolism is directly

Table 22.1 The CHA₂DS₂-VASc score for the assessment of stroke risk in non-valvular atrial fibrillation

Stroke risk factor	CHA ₂ DS ₂ -VASc score
Congestive cardiac failure and/or moderate-to-severely impaired left ventricular systolic function	1
Hypertension	1
Age \geq 75 years (2 points)	2
Diabetes mellitus	1
History of stroke, transient ischaemic attack or other thromboembolism	2
Arterial vascular disease (history of myocardial infarction, aortic atheroma or peripheral vascular disease)	1
Age between 65 and 74 years	1
Sex category (female)	1

proportional to the CHA₂DS₂-VASc score (Fig. 22.10) (Olesen et al., 2011). Patients younger than 65 years with non-valvular AF and no other stroke risk factors (including female patients) are considered to have a low enough stroke risk that no stroke-preventative therapy is indicated. For all other patients, the CHA₂DS₂-VASc score should be calculated, and those with a CHA₂DS₂-VASc score ≥ 1 should be considered for treatment with either a VKA or a non-VKA oral anticoagulant (NOAC; also referred to as a direct oral anticoagulant [DOAC]): a direct thrombin inhibitor such as dabigatran or one of the factor Xa inhibitors apixaban, rivaroxaban and edoxaban.

Antiplatelet agents are no longer recommended for stroke prevention in patients with AF. Dual antiplatelet therapy with aspirin and clopidogrel has been shown to reduce stroke risk by comparison with aspirin alone in patients with AF with moderately high stroke risk considered unsuitable for treatment with an oral anticoagulant (ACTIVE Investigators et al., 2009), but is associated with a significantly increased risk of internal bleeding, and this combination is not recommended by current guidance.

Assessment of bleeding risk. The benefit of oral anticoagulants in terms of stroke risk reduction in patients with AF is partially offset by an increased risk of bleeding. Several bleeding risk scores have been proposed, among them the HAS-BLED score (Table 22.2), which has been validated in the AF population (Pisters et al., 2010) (Fig. 22.11).

The use of bleeding risk scores is not sufficiently refined to allow accurate assessment of the anticipated net clinical benefit of anticoagulation in individuals with AF according to their CHA₂DS₂-VASc score. However, it prompts consideration of the risk of bleeding, modification where possible of bleeding risk factors and perhaps intensified monitoring.

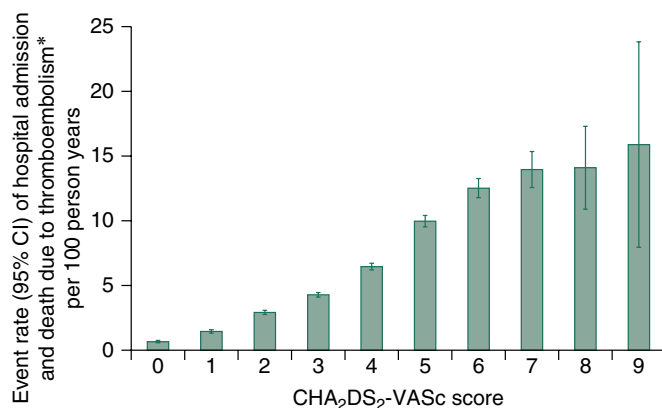

Choice of oral anticoagulant. VKAs, such as warfarin, which inhibit the synthesis of clotting factors II, VII, IX and X, have been the mainstay of oral anticoagulant treatment for AF. The beneficial effect of VKAs is seen with an

international normalised ratio (INR) in the range 2.0–3.0. A sub-therapeutic INR increases substantially the risk of stroke or arterial thromboembolism. Conversely, a high INR increases the risk of bleeding (Fig. 22.12). The approximate annual frequency of major and minor bleeding with VKAs is 3% and 10%, respectively. It may be difficult to maintain an INR within the therapeutic range of 2.0–3.0, and indeed there is evidence from real-world studies that the INR may be outside of this range for much of the time. Patients' and doctors' concerns about the use of VKAs have resulted in their under-utilisation, particularly among elderly people, who are at the greatest risk of stroke. This concern has led to the development of the NOACs (also referred to as DOACs). The perceived advantages of the DOACs over VKAs include:

1. a predictable effect of the drugs upon coagulation such that a standard dose is taken without the need for blood tests to assess its effect,

Table 22.2 The HAS-BLED score for calculation of the risk of bleeding (Pisters et al., 2010)

2. lower potential for interaction with other drugs,
3. no dietary restrictions.

The following are potential disadvantages of DOACs by comparison with VKAs:

1. Assessing adherence may be problematic.
2. The DOACs are all to some extent renally excreted: Dose reduction is necessary in patients with impaired renal function, and the drugs are contraindicated in those with severely impaired renal function.
3. The ability to achieve rapid reversal of the anticoagulant effect of DOACs is a concern, although there is evidence that the intravenous administration of dried prothrombin complex (factors II, VII, IX and X) may reverse the anticoagulant of factor Xa inhibitors. Specific reversal agents are becoming available: idarucizumab, a reversal agent for dabigatran, received European Medicines Agency/U.S. Food and Drug Administration approval in the fourth quarter of 2015, and reversal agents for factor Xa inhibitors are in development.
4. Some DOACs require twice-daily dosing, which may reduce adherence.

Characteristics of the DOACs are summarised in [Table 22.3](#).

Fig. 22.12 The risk of stroke or intracranial bleeding according to the international normalised ratio (INR) in patients who are taking vitamin K antagonists. ¹Hylek et al. (1996); ²Fang et al. (2004).

Each of the DOACs has been compared with warfarin in a prospective, randomised, multicentre clinical trial examining both efficacy for stroke risk reduction and safety in patients with AF and moderately increased stroke risk (Connolly et al., 2009; Giugliano et al., 2013; Granger et al., 2011; Patel et al., 2011). The results are summarised in [Table 22.4](#).

Current European Society of Cardiology guidance (Kirchhof et al., 2016) is that where an oral anticoagulant is indicated for stroke risk reduction in AF:

- DOACs are recommended where there are difficulties in maintaining the INR within the therapeutic range with a VKA, where side effects are experienced with a VKA or where a patient is unable or unwilling to undertake INR monitoring.
- DOACs should be considered rather than VKAs for most patients with non-valvular AF based on their net clinical benefit.

Non-pharmacologic means of stroke risk reduction in atrial fibrillation. A majority of intracardiac thrombi occurring in the context of AF develop in the left atrial appendage. It is common practice to excise the left atrial appendage during surgical operations on the mitral valve, because patients with mitral valve disease requiring surgery are at high risk of development of AF. Left atrial appendage closure devices implanted percutaneously obviate the need for long-term treatment with an oral anticoagulant and have been shown to provide protection against stroke equivalent to that of warfarin in moderate-risk patients with AF. The medium- to long-term benefit of these devices is partially offset by a short-term risk of procedure-related complications.

Catheter ablation of AF may be curative. An important question is whether successful catheter ablation reduces stroke risk to the extent that it may no longer be necessary to take an oral anticoagulant. The results of several retrospective/observational studies suggest that this may indeed be the case (Bunch et al., 2013). The methodological limitations of this type of study are such that, pending the results of ongoing prospective trials addressing this question, current guidelines recommend

the continuation of oral anticoagulants following catheter ablation of AF according to the CHA₂DS₂-VASc score (Camm et al., 2012).

Duration of treatment with oral anticoagulants. In trials comparing different drug-based treatment strategies for AF, a majority of strokes occurred in patients who had been considered to have good heart rhythm control and whose oral anticoagulants had therefore been stopped (Sherman et al., 2005). It is known that asymptomatic AF is commonplace, even in patients who also have symptomatic episodes of AF. Furthermore, the presence and prevalence of AF may be underestimated by many detection strategies. For these and other reasons it is rarely appropriate to discontinue oral anticoagulant treatment in those patients with a CHA₂DS₂-VASc score ≥ 1 .

Emergency management of atrial fibrillation. AF associated with unstable angina, heart failure or hypotension requires emergency treatment. In most cases, the treatment of choice is DC cardioversion. Concerns about thromboembolism as the heart returns to sinus rhythm are valid but should not delay emergency treatment. Immediate DC cardioversion is appropriate when the onset of AF is clearly identified as within 48 hours of presentation or when the patient is already taking an oral anticoagulant with, in the case of warfarin, a therapeutic INR for at least 4 weeks. If facilities permit, a transoesophageal echocardiogram may be performed in patients not already receiving an oral anticoagulant to exclude intracardiac thrombus. Heparin should then be given immediately and continued until the patient is established on an oral anticoagulant. A DOAC would be an attractive choice in this situation because of the rapid onset of action of this class of drugs. Anticoagulant therapy should be continued for at least 3 months following cardioversion because the complete return of effective contraction of the atrial musculature may take several weeks following the restoration of sinus rhythm. The need for long-term stroke prophylaxis is guided thereafter by the CHA₂DS₂-VASc score.

If DC cardioversion is deemed inappropriate, rapid ventricular rate control may be achieved with intravenous β -blockers, verapamil or digoxin.

Long-term management of atrial fibrillation. There has been considerable debate about the pros and cons of a rate-control strategy focusing on achieving adequate control of the ventricular rate with drugs modifying the AV node versus a rhythm-control strategy, in which an attempt is made to restore and maintain sinus rhythm with antiarrhythmic drugs with or without DC cardioversion. These strategies have been compared in several large-scale prospective randomised trials, which have failed to demonstrate an advantage to a rhythm-control strategy. Sinus rhythm has been associated with a 47% reduction in all-cause mortality, although this benefit was offset by a 49% increase in mortality associated with the use of antiarrhythmic drugs (AFFIRM Investigators, 2004). In that study, a wide variety of antiarrhythmic drugs was used at the discretion of the investigator. These included several class I antiarrhythmic drugs, sotalol and amiodarone. A rhythm-control strategy may be more appropriate in (1) younger patients, (2) those with paroxysmal AF, (3) those with AF associated with heart failure, and (4) patients who remain symptomatic despite adequate ventricular rate control.

Ventricular rate control. The mainstay of a ventricular rate-control strategy is the use of drugs that prolong the AV nodal refractory period, thus reducing the ventricular rate. β -Blockers or CCBs (verapamil or diltiazem) are generally effective both at rest and on exertion, although a combination of these drugs is occasionally necessary. Digoxin may control the ventricular rate at rest but is less successful at controlling the rate during exertion, and therefore should only be considered in patients with non-paroxysmal AF who do no or little physical exercise. Where ventricular rate control cannot be achieved with drugs, catheter ablation of the AV node in combination with permanent pacemaker implantation can provide excellent symptom relief. The adverse effects of right ventricular apical pacing may

offset some of the benefit of a slower ventricular rate and regular rhythm; therefore, biventricular pacing may be more appropriate in this situation.

Rhythm control. Rhythm control can be considered in terms of either restoration or maintenance of sinus rhythm. The most rapid and effective means of restoring sinus rhythm is DC cardioversion. Where AF is of short duration, well-tolerated and not associated with structural heart disease, class IC antiarrhythmic drugs such as flecainide and class III drugs such as amiodarone may be used intravenously to achieve chemical cardioversion. Stroke risk should be managed in the same way as described for the emergency management of AF.

Although sinus rhythm can be restored in most patients with DC cardioversion and/or antiarrhythmic drugs, most patients will revert to AF without further treatment. The SAFE-T trial examined 665 patients with AF of at least 72 hours' duration. Sinus rhythm was restored with antiarrhythmic drugs (sotalol or amiodarone) or placebo, supplemented where necessary by DC cardioversion (Singh et al., 2005). Patients were then maintained on placebo, sotalol or amiodarone. By 2 years, that probability of remaining in sinus rhythm was 10% (placebo), 30% (sotalol) and 50% (amiodarone). Another similar study (Roy et al., 2000) demonstrated equivalent efficacy of sotalol and the class Ic antiarrhythmic drug propafenone in the maintenance of sinus rhythm (40% at 2 years) and confirmed the superiority of amiodarone (60%). Most heart rhythm specialists consider that the toxicity of amiodarone precludes its long-term use for the management of AF. It was hoped that dronedarone would provide efficacy similar to amiodarone, but it has been shown to be less effective, although it has far fewer side effects and is not used widely. In practice, for long-term treatment, flecainide tends to be used in younger patients with structurally normal hearts and with no evidence of cardiac conduction system disease. Sotalol is preferred in patients with hypertensive or ischaemic heart disease, and amiodarone is generally reserved for elderly patients in whom there may be fewer concerns about the side effects of long-term amiodarone (Kirchhof et al., 2016).

Modern strategies for curative catheter ablation of AF followed the discovery in 1998 that paroxysmal AF is due, in most cases, to rapid firing by the musculature surrounding the pulmonary veins close to their junctions with the left atrium. The cornerstone of most current ablation strategies for paroxysmal AF is complete electrical isolation of all four pulmonary veins from the left atrium, using either radiofrequency ablation (cautery) or cryoablation to ablate in rings around the pairs of ipsilateral veins. Catheter ablation can cure a majority of paroxysmal AF but needs to be repeated in 20–25% of patients and carries risk, including stroke (2–3/1000) and pericardial effusion (1–2/100). Catheter ablation has been shown to be superior to antiarrhythmic drug therapy in maintaining sinus rhythm and improving symptoms and quality of life. Catheter ablation has also been shown in non-randomised studies to improve left ventricular ejection fraction and heart failure symptoms. The CASTLE-AF study (Marrouche et al., 2018) was the first to demonstrate that catheter ablation is associated with a reduction in mortality by comparison with standard medical therapy, in patients with severely impaired left ventricular systolic function and heart failure symptoms. No benefit has been convincingly demonstrated in terms of reduced stroke risk. The natural history of AF is for episodes of AF to increase

in frequency and duration until persistent AF supervenes. This progression appears to occur as a result of atrial remodelling, a complex and incompletely understood process involving electrical and structural changes in the whole atrial myocardium predisposing to the development of AF independent of the pulmonary veins. Catheter ablation strategies for persistent AF are more complex than those for paroxysmal AF with a correspondingly higher rate of repeat procedures and a lower overall success rate. For all of these reasons, drug therapy remains the first-line treatment of AF, with catheter ablation reserved for patients with symptomatic AF that cannot be managed satisfactorily with drugs and whose symptoms trouble them enough to undergo ablation.

Ventricular tachyarrhythmias

Ventricular tachycardia

VT is a rapid, abnormal heart rhythm that originates in the ventricles. VT may present with palpitation, chest pain, breathlessness, presyncope, syncope or sudden cardiac death (death occurring suddenly and unexpectedly within 1 hour of the onset of symptoms from a presumed cardiac cause). It is clinically useful to subdivide VT in the following ways: VT complicating structural heart disease and 'normal heart' VT.

Ventricular tachycardia complicating structural heart disease. Most VT occurs in patients with significant structural heart disease. The predominant cause is healed myocardial infarction, but other important causes include hypertensive and valvular heart disease and a variety of cardiomyopathies including dilated cardiomyopathy, hypertrophic cardiomyopathy, or arrhythmogenic right ventricular cardiomyopathy. VT of this type is usually due to re-entry. Scarring of ventricular myocardium creates the central obstacle around which potential re-entry circuits develop forming the VT 'substrate'. In this setting, a single ventricular premature beat, the VT 'trigger', may induce VT. The importance of VT complicating structural heart disease is that there is a high chance of the VT recurring, and patients are at substantially increased risk of sudden cardiac death.

'Normal heart' ventricular tachycardia. These uncommon VTs occur in the context of a structurally normal heart and a normal ECG in sinus rhythm and are exemplified by right ventricular outflow tract (RVOT) tachycardia and fascicular tachycardia. The importance of recognising these VTs is that unlike VT associated with structural heart disease, they are associated with a normal prognosis, may be managed successfully with drugs (β -blockers, verapamil or flecainide for RVOT tachycardia, verapamil for fascicular tachycardia) and are curable by catheter ablation.

Ventricular fibrillation

Ventricular fibrillation (VF) comprises rapid and totally disorganised electrical activity in the ventricles such that effective contraction ceases and results in sudden death unless sinus rhythm is restored either spontaneously or by defibrillation. Acute myocardial ischaemia and infarction are probably responsible for most VF, although virtually any structural heart disease may also be complicated by VF. Other cases occur in the context of a group of conditions known as channelopathies.

Channelopathies. Channelopathies are a group of inherited conditions characterised by abnormal function of the protein channels present in the cardiac myocyte cell membrane that regulate the flow of ions responsible for generating the resting transmembrane potential and the action potential. These include the long QT syndromes, short QT syndrome, early repolarisation syndrome, Brugada syndrome and catecholaminergic polymorphic VT. A detailed description of these conditions is beyond the scope of this chapter, but there are certain key points:

- With the exception of catecholaminergic polymorphic VT, each is associated with characteristic abnormalities of the resting ECG in sinus rhythm.
- Each may be complicated by ventricular tachyarrhythmias and sudden cardiac death.
- β -Blockers reduce the likelihood of arrhythmia in long QT syndromes and catecholaminergic polymorphic VT.
- Many drugs lengthen the QT interval (Box 22.1) and are contraindicated in patients with long QT syndromes. A list of drugs known to prolong the QT interval can be found at <http://www.crediblemeds.org>.
- Class I antiarrhythmic drugs and a variety of other drugs are contraindicated in Brugada syndrome. A list of drugs to avoid in the Brugada syndrome can be found at <http://www.brugadadrugs.org>.
- Most patients with these conditions who experience syncope or cardiac arrest or who develop spontaneous ventricular arrhythmias will be considered for an implantable cardioverter-defibrillator (ICD).

Emergency management of ventricular arrhythmias

VF and pulseless VT should be managed according to Resuscitation Council (UK) guidelines for advanced life support, which are updated periodically and can be found at <http://www.resus.org.uk>.

VT associated with a pulse is also the subject of guidelines by the Resuscitation Council (UK) (<http://www.resus.org.uk>). If the patient is hypotensive in a low cardiac output state or has heart failure, the correct treatment is prompt DC cardioversion. If none of these features are present, chemical cardioversion may be attempted with intravenous amiodarone

Box 22.1 Drugs associated with prolonged QT intervals

Inhalational agents: halothane, isoflurane
 Macrolide antibiotics: erythromycin, clarithromycin
 Halofantrine
 Lithium
 Fosphenytoin
 Mizolastine
 Phenothiazines
 Pentamidine
 Sertindole
 Antihistamines: terfenadine, astemizole, mizolastine
 Antipsychotics: haloperidol, droperidol, pimozide
 Tricyclic antidepressants: amitriptyline, imipramine
 Class IA or III antiarrhythmics

300 mg over 20–60 minutes followed by 900 mg over the next 24 hours. Amiodarone must be given via a central vein because it can cause thrombophlebitis when given peripherally and limb-threatening soft tissue damage if extravasation occurs.

Ongoing management of ventricular arrhythmias

Once stabilised, patients presenting with VT or VF should remain in hospital and their management should be discussed at an early stage with a specialist cardiac electrophysiology service. Investigations should be performed to establish the nature and extent of underlying heart disease, with emphasis on detecting structural heart disease, coronary artery disease, inducible myocardial ischaemia and consideration of channelopathies in those with structurally normal hearts.

Most patients with ischaemic heart disease should be treated with aspirin, statins, angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists and β -blockers. β -Blockers and ACE inhibitors reduce somewhat the risk of sudden cardiac death. Although these patients remain at high risk of sudden cardiac death because of recurrent ventricular tachyarrhythmias, there is no role for the routine use of antiarrhythmic drugs. In patients with complex ventricular ectopy and impaired left ventricular systolic function following acute myocardial infarction, class Ic antiarrhythmic drugs including flecainide were shown in the Cardiac Arrhythmia Suppression Trial (CAST) (Echt et al., 1991) to increase mortality, whereas in other high-risk groups amiodarone has been shown to have no effect on all-cause mortality (Cairns et al., 1997; Julian et al., 1997). All patients should be considered for an ICD. These devices have been shown to improve prognosis following:

- cardiac arrest due to VT or VF in the absence of a reversible underlying cause,
- VT associated with syncope or significant haemodynamic compromise,
- VT with a left ventricular ejection fraction of less than 35%.

Although ICDs treat further episodes of VT and VF, they do not prevent these arrhythmias from recurring and resulting in device therapies including shocks that are psychologically traumatic and lead to premature battery depletion. In the case of frequently recurring ventricular arrhythmias, patients should be on the maximum tolerated dose of a β -blocker, and there is a role in this situation for antiarrhythmic drugs including amiodarone and mexiletine (mexiletine has a European license and is available by special order in the UK). Catheter ablation of VT is an important adjunctive treatment.

Bradycardia

Bradycardia is conventionally defined as a resting heart rate of less than 60 per minute when awake or 50 per minute when asleep. Bradycardia can be classified as sinus bradycardia, where the sinus node discharges too slowly, or AV block ('heart block'), where conduction between the atria and ventricles is impaired. AV block may be subdivided into three classes:

First degree. Every P wave conducts to the ventricles but takes longer than normal to do so. The PR interval on the ECG is

prolonged to greater than 200 ms (one large square on a standard ECG recorded at 25 mm/s).

Second degree. Some, but not all, P waves conduct to the ventricles. Progressive PR interval prolongation followed by a non-conducted P wave is referred to as Mobitz type I or Wenckebach heart block and implies block occurring in the AV node. Mobitz type II heart block is the term used when a non-conducted P wave is not preceded by progressive PR interval prolongation and implies block occurring in the conducting system below the level of the AV node.

Third degree ('complete heart block'). No P waves conduct to the ventricles.

Bradycardia may be due to intrinsic cardiac disease or secondary to non-cardiac disease or drugs. In many cases, bradycardia due to intrinsic cardiac disease is idiopathic, that is, occurs without other identifiable heart disease. Bradycardia may also complicate acute myocardial infarction or virtually any form of structural heart disease and is also common following cardiac surgery. Non-cardiac causes of bradycardia include neurocardiogenic ('vasovagal') syncope (faints), hypothyroidism, hyperkalaemia, hypothermia and raised intracranial pressure. Complete heart block may occur as a complication of Lyme disease (tick-borne borreliosis). Drugs commonly associated with bradycardia include β -blockers, verapamil, diltiazem, digoxin and antiarrhythmic drugs of any class.

The management of bradycardia is as follows:

- Treat underlying medical conditions.
- Consider stopping or reducing the dose of causative drugs.
- Consider temporary or permanent pacemaker implantation. Permanent pacemaker implantation is indicated for symptomatic bradycardia as a result of sinus bradycardia or AV block, or on prognostic grounds for Mobitz type 2 second-degree or third-degree AV block.

In an emergency situation, drugs may be used in an attempt to support the heart rate until transvenous pacing can be established. The most useful drugs in this situation are atropine in 500-microgram boluses up to a total of 3 mg, adrenaline infused at a rate of 2–10 micrograms/min or isoprenaline 1–10 micrograms/min, titrated against heart rate. External pacing is another useful measure until transvenous pacing can be established. More detailed guidance on the emergency management of bradycardia may be viewed at <http://www.resus.org.uk>.

Drug therapy

Antiarrhythmic drug therapy is used to control the frequency and severity of arrhythmias, with the aim of maintaining sinus rhythm where possible. Although antiarrhythmic drug treatment has been the mainstay of arrhythmia treatment, many of these drugs have limited efficacy and important toxicity. Many arrhythmias are now curable by catheter ablation. Implantable devices such as permanent pacemakers and ICDs have assumed an increasingly important role in the treatment of arrhythmias, and in many cases, antiarrhythmic drugs have an adjunctive role. Antiarrhythmic drugs can be grouped according to their electrophysiological

effects at a cellular level, using the Vaughan–Williams classification (Vaughan-Williams, 1970). Alternatively, antiarrhythmic drugs may be classified according to their main sites of action within the heart.

Vaughan–Williams classification

All antiarrhythmic drugs act by altering the movement of electrolytes across the myocardial cell membrane. The Vaughan–Williams classification groups drugs according to their ability to block the movement of one or more of these ions across the myocardial cell membrane (Vaughan-Williams, 1970). Most drugs have several modes of action, and their effectiveness as antiarrhythmic agents depends upon the summation of these effects. The effect of the different drug classes on the various phases of the action potential are shown in Table 22.5. The choice of which drug to use is based upon the origin of the arrhythmia, regardless of its pattern. However, the preference of one class over another may vary, depending on a clinician's experience with particular drugs, on the presentation of the arrhythmia and on patient characteristics. Such factors also govern the choice of drug within a class. The drug chosen should have the dosing schedule and adverse effect profile that best suit the patient or inconvenience them least (see Tables 22.6 and 22.7). Thus, for example, a patient with glaucoma or prostatism should not be given disopyramide, which possesses marked anticholinergic properties, and a patient with obstructive airways disease should preferably not be prescribed a β -blocker (class II), although if considered essential they could have a cardio-selective agent.

The pharmacokinetic profiles of selected antiarrhythmic drugs are presented in Table 22.8.

Class I antiarrhythmic drugs

Class I antiarrhythmic drugs block sodium channels and therefore inhibit the inward sodium current I_{Na} , responsible for the upstroke of the action potential in cells other than those of the sinoatrial and AV nodes. The result of I_{Na} inhibition is to slow conduction velocity, which should promote re-entry, and thus be proarrhythmic. The antiarrhythmic effect of class I

Table 22.5 Effect of different drug classes on phases of action potential

Phase	Dominant ion movement	Drug class	Effect
0	Sodium inward	IA IB IC	Block ++ Block + Block +++
2	Calcium inward	IV	Block
3	Potassium outward	III	Marked slowing
4	Sodium inward, potassium outward	I, II, IV	Slows

Table 22.6 Adverse effects of antiarrhythmic drugs (class I)

Drug	Cardiac	Non-cardiac	Caution or avoid in
Disopyramide	Torsade de pointes Myodepressant	Anticholinergic (urinary retention, constipation, dry mouth, blurred vision)	Glaucoma, prostatism, hypotension
Procainamide		Lupus, nausea, diarrhoea	Myasthenia gravis, slow acetylators (increased risk of lupus)
Quinidine	Torsade de pointes Vasodilation (i.v.)	Diarrhoea, nausea, tinnitus, headache, deafness, confusion, visual disturbances, blood dyscrasias	Myasthenia gravis
Lidocaine (lignocaine)		Convulsions in overdose, paraesthesiae	Liver failure (reduce dose)
Mexiletine		Nausea, paraesthesiae	Second- or third-degree heart block
Flecainide	Proarrhythmic	Paraesthesiae, tremor	Not recommended if any cardiac dysfunction
	Myodepressant		
Propafenone	Proarrhythmic Myodepressant	Gastro-intestinal disturbances	Not recommended if any cardiac dysfunction
