- Nocturnal hypoglycaemia, once confirmed, may be managed by either having a bedtime snack or by reducing the dose of night-time insulin. In the case of Mr RK, stopping his sulfonylurea may also help resolve the problem. The timing of the insulin dose may also be adjusted to ensure that the peak activity is not overnight. If this does not help or is not practical, then a long-acting insulin analogue may be appropriate,

Case 45.3

Mr JS is a 69-year-old man with longstanding type 2 diabetes. He has recently noticed that his left shoe has been rubbing his foot, which he finds confusing because he has been wearing these shoes for 6 months with no problems. His whole left foot now looks red and swollen. When Mr JS inspected it closely, he noticed that there was a weeping sore. However, his foot is not painful, so he does not feel too concerned.

Questions

- What is the most likely reason that Mr JS did not feel any pain associated with the sore?
- Why might Mr JS's shoe suddenly have started to rub his foot?
- Should Mr JS be more concerned?

Answers

- Mr JS has probably developed sensory neuropathy in his feet. This usually begins with the loss of the sensation of vibration, then inability to feel a monofilament, and then may progressively lead to complete loss of sensation.
- The shape of the feet of people with diabetes has been observed to change over time. This may be due to the development of neuropathy, which can weaken muscles, causing alterations to the shape of the arch of the foot and toes. In this case, Mr JS has sensory neuropathy because he is unable to feel the pain of the weeping sore. It is likely that Mr JS may also have motor neuropathy. Shoes should be checked by the patient daily because, quite often, patients walk around on foreign bodies (small stones, etc.) without even knowing.
- Mr JS should be concerned because his lack of sensation does not indicate that the foot injury is not serious. He is at risk of developing an infected ulcer and needs prompt treatment to prevent the problem from becoming severe. If Mr JS does not seek treatment, he may even risk losing his foot through amputation. Diabetes patients with neuropathy and a foot problem should always be seen urgently by a healthcare professional on the same day.

Case 45.4

Miss IL is a 17-year-old teenager with recently diagnosed type 1 diabetes. She has been admitted to hospital with DKA, which was precipitated by a diarrhoea and vomiting bug. Because she was vomiting, she was not eating, and hence she temporarily stopped injecting her insulin. Miss IL is normally well controlled on a basal-bolus insulin regimen comprising insulin glargine (Lantus) at night and insulin glulisine (Apidra) three times daily with meals.

Questions

- Why was it a mistake for Miss IL not to inject her insulin whilst she was not feeling well enough to eat?
- What advice should patients on insulin be given regarding glucose management when they are feeling unwell and not able to eat normally?
- What are the initial management priorities for patients admitted with diabetic ketoacidosis?
- What is the correct way for subcutaneous insulin to be re-introduced after a patient has been on a continuous intravenous insulin infusion?

Answers

- This is a common misunderstanding amongst patients and sometimes even healthcare professionals. When a person is unwell, his or her insulin requirements can often increase, despite not eating. This is because of the stress involved and the increase in the production of counter-regulatory hormones, which increase glucose levels.

- Patients should be counselled on what are commonly referred to as 'sick-day rules' and should be given contact numbers for advice if they are unclear or struggling with management. Generally, patients need to increase the frequency of glucose monitoring to every 2–4 hours and test blood ketones on a regular basis. Carbohydrate intake should be maintained as much as possible using sugary drinks or fruit juice, soups, jelly or snack foods if patients are having difficulty in eating. Fluid intake is important, and patients should be advised to have a glass of water every hour, aiming for 3 L in 24 hours. Depending on the glucose and ketone levels, boluses of quick-acting insulin equivalent to 10–20% of their total daily dose will need to be given every 2–4 hours until ketone levels resolve.
- Intravenous sodium chloride 0.9% should be started as soon as possible. A fixed-rate intravenous insulin infusion should then be started. Current recommendations are to begin at a rate of 0.1 units/kg. Regular hourly monitoring of blood glucose and ketones should be undertaken along with 2-hourly monitoring of serum potassium for the first 6 hours.
- When the patient is biochemically stable, the patient may be converted back to subcutaneous insulin. The current national guidelines from the [Joint British Societies Inpatient Care Group \(2010\)](#) recommend that long-acting subcutaneous insulin analogues are continued throughout treatment of diabetic ketoacidosis to prevent rebound hyperglycaemia when the intravenous infusion is stopped. Therefore, Miss IL's glargine should have been continued. Her rapid-acting insulin (Apidra) should be re-introduced at the next meal, and the intravenous insulin infusion should be stopped 30 minutes afterward.
- The additional information required includes details about Mr PG's current and baseline renal function because this may impact the choice of antidiabetic agents. Discussion about his job and whether he drives are also important. Mr PG's beliefs about medications and aims of treatment should also be considered, taking into account his comorbidities.
- The lifestyle factors that should be discussed with Mr PG are smoking cessation and weight management as part of a personal plan. Weight reduction should be part of an individualised plan that involves healthy eating based on the individual's nutritional needs, personal choices, cultural preferences and willingness to change. Because Mr PG is obese, medication options that could be considered are the use of orlistat to reduce the absorption of lipids. In addition, GLP-1 receptor agonists could be used to manage his diabetes; this class of medication has been associated with significant weight loss, leading to further improvements in diabetes control.

Case 45.5

Mr PG is a 55-year-old man. He smokes 10 cigarettes a day and has smoked for more than 30 years. He is prescribed metformin 1 g twice daily, gliclazide 160 mg twice daily and pioglitazone 30 mg once a day. His primary care doctor started the pioglitazone about 4 months ago because his blood glucose had not been well controlled. His BMI is 36 kg/m² and his recent HbA_{1c} was 82 mmol/mol. Mr PG has been admitted to hospital with shortness of breath; he is awaiting a cardiac echo to confirm the suspected diagnosis of heart failure.

Questions

- What would be your next therapeutic intervention?
- What medication options remain for managing Mr PG's diabetes?
- What additional information would you need to help you and Mr PG decide on which medication is appropriate?
- What lifestyle factors should you discuss with Mr PG?

Answers

- Due to the potential for worsening heart failure, pioglitazone should not be prescribed in people with heart failure and should therefore be stopped in Mr PG. In the UK, a yellow card (Medicines and Healthcare Products Regulatory Agency [MHRA] report of adverse drug reaction) should be completed because the pioglitazone may have contributed to the heart failure. Metformin should also be suspended if there is renal impairment.
- The remaining options for managing Mr PG's diabetes are DPP-4 inhibitors, SGLT-2 inhibitors, GLP-1 receptor agonists and insulin.

Case 45.6

Mrs FR is 77-year-old woman. She is usually very independent and has never taken any regular medication. She was recently prescribed two courses of antibiotics for urinary tract infections. Her daughter visited this morning and called the ambulance because her mother was very confused and looked very unwell. Review in the emergency department identified that Mrs FR is extremely dehydrated; her blood glucose level on the standard machine read 'HI' (>27.8 mmol/L), and the laboratory blood glucose was confirmed at 65 mmol/L. Her sodium is 168 mmol/L (normal range 135–145 mmol/L). Her eGFR is reduced to 13 mL/min from her usual baseline of 26 mL/min.

Questions

- What is the likely cause of Mrs FR's symptoms and elevated blood glucose?
- How should Mrs FR be managed?
- What advice should be given about the long-term management of her blood glucose?

Answers

- The likely cause of the symptoms is prolonged hyperglycaemia and undiagnosed type 2 diabetes. The glycosuria has caused urinary tract infections, and this acute illness has put further physiological strain on Mrs FR. This in turn has caused further increases in the blood glucose and increased dehydration, culminating in the acute emergency episode of HHS.
- Initial management is fluid resuscitation with sodium chloride 0.9%. This is required to reverse the extreme dehydration, stabilise the blood pressure, improve circulation and increase urine output. Fixed-rate insulin (0.05 units/kg/h) should be started if blood glucose fails to fall despite adequate fluid replacement. Prophylaxis of thromboembolism is also required.
- Because Mrs FR has renal impairment, metformin, SGLT-2s and some DPP-4s are not suitable. Pioglitazone is not appropriate due to bone fracture risk in post-menopausal women. The remaining agents should be considered on an individual basis. Sulfonylureas and insulin are clinically effective options and will have an immediate effect. Consideration should also be given to the risk of hypoglycaemia, treatment targets and Mrs FR's confidence in monitoring blood glucose results. A non-renal cleared DPP-4 such as linagliptin may also be appropriate.

Case 45.7

Mr PR is a 42-year-old university lecturer. He was diagnosed with type 2 diabetes when he was 27 years old. He is motivated to self-manage his diabetes. His BMI is 29 kg/m². His regular prescription is Levemir 20 units twice daily and NovoRapid variable dose adjusted to carbohydrate intake. Mr PR was recently prescribed a SGLT-2 inhibitor to improve his blood glucose control and possibly aid weight loss. Today Mr PR has come to hospital because he is feeling very unwell, experiencing abdominal pain and has vomited twice; his breathing is very fast and shallow. When he first started his new medicine, the pharmacist had advised that he should seek urgent medical attention if he had these symptoms, even if his blood glucose were normal. The hospital blood test results are as follows:

Blood glucose 8.2 mmol/L
Blood ketones 4.6 mmol/L
Bicarbonate 13 mmol/L

Questions

1. What is the likely cause of Mr PR's symptoms?
2. What changes should be made to Mr PR's medication?
3. What further action should be taken?

Acknowledgments

Answers

1. The most likely cause of Mr PR's symptoms is DKA. Ketones are present, and symptoms are typical of DKA. An SGLT-2 inhibitor has recently been started, and MHRA reports a link between DKA and SGLT-2 inhibitors. SGLT-2 inhibitors are licensed for use in type 2 diabetes. Blood glucose levels may be only moderately elevated, which is atypical for DKA. This atypical presentation could delay diagnosis and treatment. Reports indicate that half of the cases occurred during the first 2 months of treatment. Some cases occurred shortly after stopping the SGLT-2 inhibitor.
2. The SGLT medication should be stopped and not restarted because the underlying mechanism for SGLT-2 inhibitor-associated DKA has not been established. Counselling points with Mr PR should include that the medicine has been stopped due to his presenting symptoms being indicative of DKA (e.g. nausea, vomiting, anorexia, abdominal pain, excessive thirst, difficulty breathing, confusion, unusual fatigue or sleepiness), and the blood test for raised ketones confirmed this diagnosis. This is serious side effect, and the medicine should not be restarted.
3. A yellow card report for the potential adverse event to SGLT should be completed and submitted to the MHRA.

46 Menstrual Cycle Disorders

Kay Marshall and Emma Crosbie

Key points

- Girls can begin experiencing menstrual disorders soon after menarche.
- Up to 95% of women experience changes premenstrually, but severe premenstrual syndrome is more common in the 30- to 40-year age group.
- The aetiology of premenstrual syndrome is multifactorial, the symptomatology complex and treatment options diverse.
- It has been estimated that 50–80% of women of childbearing age will suffer from dysmenorrhoea at some time.
- Treatment options vary according to the type of dysmenorrhoea (primary or secondary) but include non-steroidal anti-inflammatory drugs, combined oral contraceptive pills and progestogen-only preparations.
- Heavy menstrual bleeding (previously known as menorrhagia) affects up to 30% of menstruating women. The management of the condition depends upon the cause and can be either medical or surgical.
- Endometriosis (the presence of extrauterine endometrial tissue) can give rise to an array of symptoms including subfertility. Treatment may be designed to improve fertility and/or manage symptoms. Medical and surgical treatments are available.

Once a girl reaches puberty, various physiological events occur, leading to the onset of menstruation, or the menarche. The average age of the menarche has decreased to around 12.5 years, and a halt in this trend towards earlier menarche is not evident. This decline has been attributed to an improvement in nutrition and overall health. Body weight is linked to menarchal age, and it is possible that as body fat increases so does serum leptin (hormone which influences calorie intake), which in turn may increase the pulsatile release of gonadotrophin-releasing hormone (GnRH). However, the data regarding non-genetic influences remain inconclusive. Early menarche is associated with health problems in later life, and these include predisposition to breast cancer, endometrial cancer, type 2 diabetes and psychological problems.

Menstruation is an event that occurs relatively late in puberty, and 95% of girls experience menarche between the ages of 11 and 15 years. One UK study has shown that one girl in eight begins to menstruate whilst still at primary school. Factors that influence menarcheal age are discussed by [Morris et al. \(2011\)](#). Even before the first ovulatory cycle has taken place, childhood ovarian activity will have gradually increased the production of

oestrogen, leading to the development of the secondary sexual characteristics. These events are probably initiated by the central nervous system (CNS), which ultimately triggers the necessary gonadal changes that will eventually lead to the establishment of the menstrual cycle. It may take up to 2 years for the hypothalamic–pituitary–gonadal axis to mature and for regular ovulation to take place. In girls who only start to menstruate when they are older, it may take even longer. This should be considered when taking a patient's medical history.

Menstruation itself occurs as a result of cyclic hormonal variations ([Fig. 46.1](#)). During the first half or follicular phase of the menstrual cycle, the endometrium thickens under the influence of increasing levels of oestrogen (most notably estradiol, which at the peak of its preovulatory surge reaches around 2000 pmol/L) secreted from the developing ovarian follicles. Once the serum oestrogen level has surpassed a critical point it triggers, by positive feedback, the anterior pituitary to release, about 24 hours later, a surge of luteinising hormone (up to 50 IU/L) and after 30–36 hours, ovulation follows.

After ovulation, which occurs around day 14 of a 28-day menstrual cycle, and as the luteal phase progresses, the endometrium begins to respond to increasing levels of progesterone. Both progesterone and oestrogen are secreted from the corpus luteum, which is formed from the remains of the ovarian follicle after ovulation. The lifespan of the corpus luteum is remarkably constant and lasts between 12 and 14 days; hence the length of the second half or the luteal phase of the menstrual cycle is between 12 and 14 days. Between days 18 and 22 of a 28-day cycle, both sex steroids peak, with levels of progesterone reaching around 30 nmol/L. Because progesterone has a thermogenic effect upon the hypothalamus, basal body temperature increases by about 1 °C in the second half of an ovulatory cycle ([Fig. 46.2](#)). Most ovulatory cycles range from 21 to 34 days.

These synchronised changes mean that about a week after ovulation, the endometrium is prepared for implantation, providing fertilisation has taken place. If conception does not occur, then luteolysis begins and steroid levels fall. This means that the endometrium cannot be maintained, there is a loss of stromal fluid, leucocyte infiltration begins and there is intraglandular extravasation of blood. Finally, endometrial blood flow is reduced, and this leads to necrosis and sloughing, that is, menstruation. Initially, the blood vessels that remain intact after sloughing are sealed by fibrin and platelet plugs; subsequent haemostasis is probably achieved as a result of vasoconstriction of the remaining basal arteries. Nitric oxide may be involved in the initiation and maintenance of

Fig. 46.1 The hormonal events that occur during the menstrual cycle in women.

Fig. 46.2 Typical temperature chart from a 28-day ovulatory menstrual cycle.

menstrual bleeding by promoting vasodilation and inhibiting platelet aggregation. The myometrium is the muscular layer of the uterus that contracts spontaneously throughout the menstrual cycle, the frequency of these contractions being influenced by the hormonal milieu. The myometrium is also more active during menstruation. The average blood loss per period is between 30 and 40 mL.

There is evidence to suggest a physiological and pathological role for the local hormones, known as prostaglandins, in the process of menstruation. Prostaglandins are 20-carbon oxygenated, polyunsaturated bioactive lipids, which are cyclo-oxygenase (COX)-derived products of arachidonic acid. Indeed, both the myometrium and the endometrium are capable of synthesising and responding to prostaglandins. A potential role for another family of autocooids, the leukotrienes, in the regulation of uterine function remains uncertain, although it is known that leukotrienes can also be synthesised from arachidonic acid by lipoxygenase enzymes (Fig. 46.3).

Disorders associated with menstruation are a major medical and social problem for women which also impact upon their families.

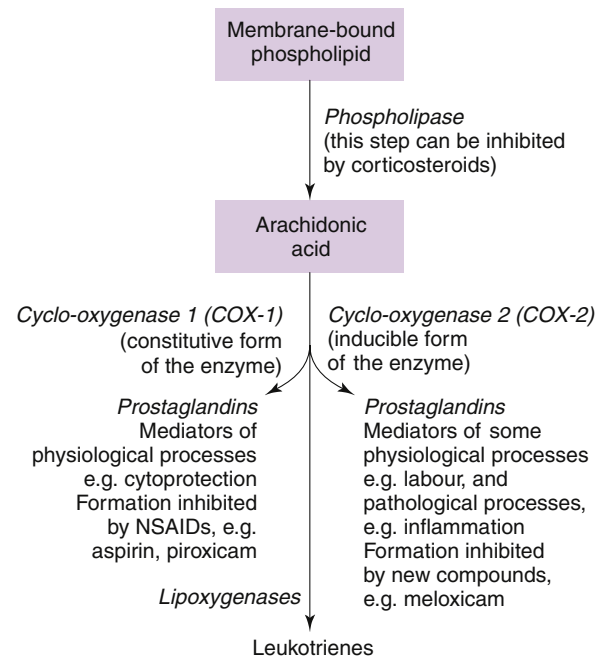

Fig. 46.3 Eicosanoid biosynthesis and inhibition.

Premenstrual syndrome

Premenstrual syndrome (PMS) encompasses both mood changes and physical symptoms. Symptoms may start up to 14 days before menstruation, although more usually they begin just a few days before and disappear at the onset of, or shortly after, menstruation. However, for some women, the beginning of menstruation may not signal the complete resolution of symptoms. Numerous studies have demonstrated that this condition can cause substantial impairment of normal daily activity, including reduced occupational activity and significant levels of work absenteeism. Severity varies from cycle to cycle and may be influenced by other life factors such as stress and tiredness. The most severe form of PMS may be referred to as premenstrual dysphoric disorder (PMDD) as defined by *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, or DSM-V (American Psychiatric Association, 2013). In this edition it is noteworthy that PMDD has been placed in the main text of the manual, thus gaining full diagnostic status. The main criteria are set out in Box 46.1. Other bodies (American College of Obstetricians and Gynecologists, 2000) have published diagnostic criteria for PMS (Box 46.2). There is considerable overlap between PMS and PMDD. The Royal College of Obstetricians & Gynaecologists (2016) ‘Green top’ guidance for diagnosis and management of PMS was published in 2016. This guidance does include a useful menstrual diary/symptom table.

Epidemiology

Up to 95% of menstruating women experience some changes premenstrually. Clinically relevant PMS occurs in about 15–20% of these women, and PMDD has an estimated incidence rate of 3–8%. It has been estimated that PMS may account for more than 17 million disability-adjusted life years in the European Union. PMS affects young and older women alike and does not appear to be influenced

Box 46.1 Summary of DSM-V diagnostic criteria for premenstrual dysphoric disorder (American Psychiatric Association, 2013)

One-year duration of symptoms which are present for the majority of cycles (occur luteal/remit follicular) as evidenced by prospective daily ratings during at least two consecutive cycles

Five of the following Criteria A symptoms (with at least one of those marked with an asterisk [*]) must occur during the week before menses and subside within days of menses.

1. Marked lability (e.g. mood swings)*
2. Marked irritability or anger*
3. Markedly depressed mood*
4. Marked anxiety and tension*
5. Decreased interest in usual activities
6. Difficulty in concentration
7. Lethargy and marked lack of energy
8. Marked change in appetite (e.g. overeating or specific food cravings)
9. Hypersomnia or insomnia
10. Feeling overwhelmed or out of control
11. Physical symptoms (e.g. breast tenderness or swelling, joint or muscle pain, a sensation of bloating and weight gain)

Box 46.2 Diagnostic criteria for premenstrual syndrome (American College of Obstetricians and Gynecologists, 2000)

Patient reports one or more of the following affective and somatic symptoms during the 5 days before menses in each of three prior menstrual cycles.

Affective	Somatic
Depression	Breast tenderness
Angry outbursts	Abdominal bloating
Irritability	Headache
Anxiety	Swelling of extremities
Confusion	
Social withdrawal	

Symptoms relieved within 4 days of menses onset without recurrence until at least cycle day 13

Symptoms present in absence of any pharmacological therapy, hormone ingestion, or drug or alcohol abuse

Symptoms occur reproducibly during two cycles of prospective recording

Patient suffers from identifiable dysfunction in social or economic performance

by parity. Severe PMS is more common in the 30- to 40-year age range, and married women with young children commonly seek help. Certain events may be linked with the onset of PMS, including childbirth, cessation of oral contraceptive use (incidence of reported PMS is lower in pill users), sterilisation, hysterectomy or even increasing age. PMS may be exacerbated by other stresses, typically those associated with family life. Women with a body mass index greater than 30 are more likely to suffer from PMS. There is also some evidence that crimes, accidents, examination failure, absenteeism and marital disturbances may be more common premenstrually.

Aetiology

PMS is not seen before puberty, during pregnancy or in postmenopausal women; therefore, the ovarian hormones have been implicated. The mineralocorticoids, prolactin, androgens, prostaglandins, endorphins, nutritional factors (e.g. pyridoxine, calcium and essential fatty acids) and hypoglycaemia may be involved. In addition, changes in CNS function have been implicated because cerebral blood flow in the temporal lobes is decreased premenstrually in PMS sufferers, and noradrenergic cyclicity is disrupted. Because symptoms vary so much from cycle to cycle, and from individual to individual, it is likely that different aetiological factors apply to different women, all of which may be affected by extenuating emotional circumstances. There is some evidence that predisposition to PMDD may be familial.

Hormones

The cyclicity of PMS suggests an ovarian involvement. This is substantiated by the fact that it is still experienced after hysterectomy if the ovaries are left intact and that it disappears during pregnancy and after menopause. One theory attributes PMS to luteal phase progesterone deficiency leading to a progesterone/estradiol imbalance, but there is no direct clinical evidence to support this in terms of serum progesterone levels. However, the problem could lie at the cellular level, that is, a paucity of functional steroid receptors leading to differential sensitivity to hormones. One such explanation could include genetic variations in the oestrogen receptor alpha gene. Alternatively, it could be a central control defect, because ovarian suppression by GnRH analogues can alleviate symptoms in some women; however, the use of these drugs is generally not recommended because of their unwanted effects associated with production of a hypo-oestrogenic state.

The central actions of the sex steroids or their neuroactive metabolites are important. Research into the complex relationship between the steroids and the CNS is ongoing, but is progressing with the advent of new tools such as the progesterone receptor modulators. Estradiol increases neuronal excitability possibly via increasing the activity of glutamate (an important excitatory neurotransmitter). Progesterone, and its metabolites, can bind to the γ -aminobutyric acid A (GABA_A) receptor, and this interaction would induce an effect similar to that evoked by benzodiazepines. The mineralocorticoid, aldosterone, may be associated with the increase in fluid retention because serum levels of this hormone are elevated in the luteal phase. However, no significant difference in blood levels of this mineralocorticoid has been found between PMS sufferers and non-sufferers. In contrast, one study has found that baseline levels of cortisol were elevated during the luteal phase in PMS sufferers.

Prolactin is secreted from the decidual cells at the end of the luteal phase of the menstrual cycle, as well as from the anterior pituitary. This hormone has a direct effect upon breast tissue, and hence may be associated with breast tenderness. Prolactin is also associated with stress and has an indirect relationship with dopamine metabolism and release in the CNS. It promotes sodium, potassium and water retention. However, there are no consistent differences in hormone blood levels of prolactin between PMS sufferers and non-sufferers. Again, the differences could lie at the

receptor level. Local hormones such as the prostaglandins may also be implicated in the aetiology of PMS because synthesis of these autocoids can be affected by the sex hormones, as well as substrate availability. Prostaglandin imbalance is implicated in PMS because increased synthesis of certain prostaglandins, for example, prostaglandin E_2 (PGE_2), has antidiuretic and central sedative effects, as well as promotes capillary permeability and vasodilation. Deficiencies of others, for example, PGE_1 , which can attenuate some of the actions of prolactin, may also contribute to the syndrome.

Vitamins and minerals

Pyridoxine phosphate is a cofactor in a number of enzyme reactions, particularly those leading to production of dopamine and serotonin (5-hydroxytryptamine). It has been suggested that disturbances of the oestrogen–progesterone balance could cause a relative deficiency of pyridoxine, and supplementation with this vitamin appears to ease the depression sometimes associated with the oral contraceptive pill. Decreased dopamine levels would tend to increase serum prolactin, and decreased serotonin levels could be a factor in emotional disturbances, particularly depression. There is some evidence that premenstrual mood changes are linked to cycle-related alterations in serotonergic activity within the CNS; therefore, serotonin may be important in the pathogenesis of PMS. There are also data to suggest that a variety of nutrients may play a role in the aetiology of PMS, specifically calcium and vitamin D. Further hydroxylation of 25-hydroxyvitamin D_3 [$25(OH)D_3$] takes place in target tissues which include the breast and the endometrium. In the Nurses' Health Study II, high total vitamin D intake reduced risk of PMS by almost a third (Bertone-Johnson et al., 2005). Oestrogen influences calcium metabolism by affecting intestinal absorption, as well as parathyroid gene expression and secretion, thus triggering fluctuations throughout the menstrual cycle. Disruption of calcium homeostasis has been associated with affective disorders.

Essential fatty acids

Essential fatty acids, such as γ -linolenic (or gamolenic acid), provide a substrate for prostaglandin synthesis. γ -Linolenic is converted into dihomono- γ -linolenic acid, which forms the starting point for the synthesis of prostaglandins of the 1 series (e.g. PGE_1). It has been suggested that women with PMS are abnormally sensitive to normal levels of prolactin, and that PGE_1 is able to attenuate the biological effects of this hormone. Hence, if there is a γ -linolenic deficiency, then there is less substrate for PGE_1 synthesis. Therefore, the effect of prolactin with respect to breast tenderness, fluid retention and mood disturbances may be exaggerated. Numerous other dietary factors may also be involved, including excess saturated fats and cholesterol, moderate-to-high alcohol consumption, zinc and magnesium deficiencies, diabetes, ageing and viral infections, all of which hinder the conversion of cis-linolenic acid to γ -linolenic. Pyridoxine, ascorbic acid and niacin also increase conversion of γ -linolenic to PGE_1 , although there is some evidence to suggest that linolenic acid metabolite levels are reduced in women with PMS.

Psychological factors

PMS may not be wholly explicable in pathophysiological terms, but it should not be regarded as a psychosomatic disorder because there is no simple relationship between its existence, severity and personality. It is not strictly confined to particular types of women, although there is no doubt that PMS interacts with many aspects of life, especially difficult or stressful times. The latter has been termed the 'vulnerability factor' which, although not a function of the menstrual cycle, can affect the way a woman reacts.

Symptoms

Symptoms occur 1–14 days before menstruation begins and disappear at the onset or shortly after menstruation begins. For the rest of the cycle, the woman feels well. Symptoms are cyclical, although they may not be experienced every cycle, and can be either physical and/or psychological (see Boxes 46.1 and 46.2 for symptomatology). The lives of the 5% or so of women who are severely affected may be completely disrupted in the second half of the menstrual cycle. The symptoms of PMS tend to decrease as a woman gets closer to menopause as her ovulatory cycles become less frequent.

Management

The first step in the management of PMS is recognition of the problem and realisation that many other women also suffer. Keeping a menstrual diary is useful and will establish any link between symptoms and menstruation; this also will provide a cornerstone for diagnosis. After a few months, it will allow the patient to make predictions and help her deal with changes when they arrive. The effectiveness of medical intervention depends upon which symptoms are being experienced, underlining the importance of a menstrual diary and experimentation. In terms of treatment, self-help and perseverance will be required in the management of PMS. The wide variety of symptoms may require exploring a number of treatment options before optimal relief can be achieved.

Non-pharmacological strategies

Maintenance of good general health is important, especially with respect to diet and possible deficiencies. Dietary modifications that may be helpful include restricting caffeine and alcohol intake. Smoking can also exacerbate symptoms. Exercise may help, as may learning simple relaxation techniques. If fluid retention is a problem, then reducing fluid and salt intake may be of value. Increasing the intake of natural diuretics such as prunes, figs, celery, cucumber, parsley and foods high in potassium such as bananas, oranges, dried fruits, nuts, soya beans and tomatoes may all be useful. Hypoglycaemia may also be involved in premenstrual tiredness, so eating small, protein-rich meals more frequently may help.

Results from clinical trials involving pyridoxine (vitamin B_6) have shown conflicting results. However, some women do respond to pyridoxine and show improvement, particularly with

respect to mood change, breast discomfort and headache. A typical dosage regimen would be 50 mg twice daily after meals or 100 mg after breakfast. The dose should not exceed 100 mg/day. Gastric upset and headaches have been reported at doses greater than 200 mg. High doses over long periods have also been associated with peripheral neuropathies. Pyridoxine should be commenced 3 days before symptom onset and continued for 2 days after menstruation has started.

Calcium supplementation has shown some activity in reducing emotional, behavioural and physical symptoms. In addition, vitamin D and magnesium nutritional status have been found to be compromised in women with PMS. There is limited evidence that supplementation with γ -linolenic acid, found in evening primrose oil, gives relief from physical symptoms, especially breast tenderness.

Pharmacological management

Progestogens. Synthetic progestogens, in preparations such as Cyclogest, have been used in the past. However, because of the lack of convincing trial evidence and the risk of side effects, the use of progestogens is no longer recommended. Possible side effects include weight gain, nausea, breast discomfort, breakthrough bleeding and changes in cycle length. Problems arise because some synthetic progestogens, especially 19-nortestosterone (19-nor) compounds such as norethisterone and levonorgestrel, also display some affinity for glucocorticoid, mineralocorticoid and androgen receptors. The specificity of these synthetic agents is influenced by the substituents present on the steroid nucleus, particularly at C13. For example, the third-generation progestogens that have an ethyl group at C13 (gestodene, desogestrel and norgestimate) have the least androgenic activity of all the 19-nor compounds but are still orally active.

Combined oral contraceptives. Some women are helped by the combined oral contraceptives (COCs) pill because it prevents ovulation from taking place. However, the use of exogenous oestrogen may be contraindicated because it can increase the risk of venous thromboembolism. This occurs because oestrogen decreases blood levels of the potent natural anticoagulant anti-thrombin III and at the same time increases serum levels of some clotting factors. Women with other risk factors for thromboembolic disease should also avoid this form of therapy. In the March 2016 British National Formulary ([Joint Formulary Committee, 2016](#)) the incidence of venous thromboembolism in healthy, non-pregnant women who are not taking an oral contraceptive is cited as 2 cases per 10,000 women per year. For those using COCs that contain second-generation progestogens (e.g. levonorgestrel), this incidence is about 5–7 per 10,000 women per year of use. Some studies have reported a greater risk of venous thromboembolism in women using preparations containing the third-generation progestogens desogestrel and gestodene. The incidence in these women is about 9–12 per 10,000 women per year of use. However, it should be noted that the absolute risk of venous thromboembolism in women using COCs that contain these third-generation progestogens remains very small and well below the venous thromboembolism risk associated with pregnancy.

It is thought that use of third-generation progestogens is associated with increased resistance to the anticoagulant action of activated protein C. Oral contraceptive treatment diminishes the efficacy with which activated protein C downregulates *in vitro* thrombin formation. This is known as activated protein C resistance and is more pronounced in women using the COC pills that contain desogestrel than in women using those that contain levonorgestrel. However, it has also been recognised that women who do react to third-generation progestogens with venous thromboembolism may be revealing a latent thrombophilia. Several conditions, congenital or acquired, can cause thrombophilic alterations. A genetic factor known as factor V Leiden mutation is the most common inherited cause of thrombophilia, and this mutation results in resistance to the effects of activated protein C. Carriers of this mutation have more than a 30-fold increase in risk of thrombotic complications during oral contraceptive use, although this has been disputed ([Farmer et al., 2000](#)) because no increase in risk of venous thromboembolism was found with the third-generation progestogens. In conclusion, if there is a history of thromboembolic disease at a young age in the immediate family, then disturbances of the coagulation system must be ruled out.

The combination of ethinylestradiol with drospirenone is also available as an oral contraceptive and appears to be useful in the management of PMS. Drospirenone is a derivative of spironolactone, with affinity for progesterone receptors, but it also acts as a mineralocorticoid antagonist. This progestogen, therefore, alleviates some of the salt-retaining effects of the ethinylestradiol.

Further comprehensive information on UK Medical Eligibility Criteria for the hormonal contraceptives is available on the [Faculty of Sexual and Reproductive Healthcare \(2016\)](#) website (<https://www.fsrh.org>).

Antidepressants. The selective serotonin reuptake inhibitors (SSRIs) are becoming more popular in the treatment of PMS-related depression because they are effective and well tolerated ([Brown et al., 2009](#)). Several randomised controlled trials using fluoxetine, sertraline, citalopram, fluvoxamine or paroxetine concluded that SSRIs are an effective first-line therapy for severe PMS, and the side effects at low doses are generally acceptable. It is possible that SSRIs increase allopregnanolone levels which enhances GABA-A function. Studies have also found that not only do SSRIs improve behavioural symptoms, but some improvement in physical symptoms has also been noted, and this is being reflected in the increased prescribing of SSRIs ([Sammon et al., 2016](#)). Common side effects experienced include headache, nervousness, drowsiness and fatigue, sexual dysfunction and gastro-intestinal disturbances. Other agents such as tricyclic antidepressants and anxiolytics such as buspirone have been used. However, they appear to improve fewer PMS symptoms than the SSRIs. A Cochrane review ([Marjoribanks et al., 2013](#)) acknowledged that the overall quality of evidence was low to moderate. However, SSRIs, which could be taken continuously across the cycle or restricted to only the luteal phase, can reduce the symptoms of PMS. Dose-dependent adverse effects are common (e.g. nausea and asthenia). St John's wort has been used to reduce the severity of PMS, but the available evidence is limited.

Other treatments. Bromocriptine stimulates central dopamine receptors, and thus inhibits the release of prolactin. It may

be useful for breast tenderness and occasionally has beneficial effects upon fluid retention and mood changes. However, side effects would now be seen as far outweighing the benefits for this particular indication.

Improvements in tension, irritability, depression, headache and general aches and pains can be seen in some women who take prostaglandin synthesis inhibitors. Most of the available information centres upon the use of mefenamic acid at dosages of 250 mg three times a day 12 days before a period is due, increasing to 500 mg three times a day 9 days before the period and continuing until the third day of menstruation. Other inhibitors of prostaglandin synthesis are likely to be just as effective and may be associated with fewer side effects. Some experimental evidence, however, suggests that, in addition to being a COX inhibitor, mefenamic acid also has activity as an antagonist at PGE receptors; therefore, this may be useful if heavy menstrual bleeding is also a problem. For optimum effectiveness, this form of therapy should be started 24 hours before the onset of symptoms. However, this starting point may be difficult to predict for women with irregular cycles.

GnRH analogues, sometimes referred to as gonadorelin analogues, are useful for managing the physical symptoms, but are less effective with respect to emotional symptoms. These agents inhibit the hypothalamic–pituitary–gonadal axis. However, they can be used for only short periods, no more than 6 months, because they induce a hypo-oestrogenic state; therefore, bone loss becomes significant after 6 months of treatment. Should a patient respond well to GnRH analogues for PMS following hysterectomy, because of underlying pelvic pathology, bilateral oophorectomy may also be of benefit.

Dysmenorrhoea

Dysmenorrhoea is usually subdivided into primary and secondary dysmenorrhoea. The former may also be referred to as spasmodic dysmenorrhoea, which is a uterine problem and is predominantly an issue of young women. Secondary dysmenorrhoea is so-called because it occurs secondary to some underlying pelvic pathology such as endometriosis or pelvic inflammatory disease (PID).

Epidemiology

The estimates vary, but epidemiological studies suggest that between 45% and 95% of women will suffer from dysmenorrhoea at some time during their reproductive life, and up to 15% of these women will be seriously debilitated by the condition. However, dysmenorrhoea is still frequently under-diagnosed and under-treated because few women seek medical advice and treatment. This carries social and economic consequences. In the USA, it has been estimated that dysmenorrhoea accounts for the loss of 600 million working hours which equates to more than \$2 billion. Such estimates frequently only take into account absenteeism and do not include loss in productivity. Women in Western countries now have fewer pregnancies, and this may be a contributory factor in the increasing prevalence of dysmenorrhoea.

Primary dysmenorrhoea

Aetiology and symptoms

The incidence of primary dysmenorrhoea peaks in women in their late teens and early 20s; the pain coincides with establishment of ovulatory cycles. A typical sufferer will usually describe lower abdominal pain (cramping), which may radiate down into the thighs, and backache. Some women also suffer gastro-intestinal symptoms (nausea, vomiting, diarrhoea), headaches and faintness. Symptoms are intense on the first day of menses but rarely continue beyond day 1 or 2 of the cycle. Factors that appear to increase the severity include young age at menarche, extended duration of menstrual flow (pain can be most severe when the flow is lighter), smoking and parity (the prevalence and severity of dysmenorrhoea is decreased in parous women). Other factors such as weight, length of menstrual cycle or frequency of physical exercise do not influence the condition. However, recurrent menstrual pain as experienced by women with dysmenorrhoea negatively impacts upon quality of life, sleep quality, physical activity and mood, and it may also increase sensitivity to pain (Iacovides et al., 2015).

In terms of aetiology, studies carried out in the 1950s and 1960s first drew attention to the possible role of the prostaglandins. This was followed by many *in vivo* studies which showed that women suffering from primary dysmenorrhoea do have greater concentrations of prostaglandins, predominantly PGF_{2α}, and to some extent PGE₂, in their menstrual fluid compared with matched control subjects. Such a prostaglandin imbalance would favour increased myometrial contractility. The effects of the prostaglandins on human myometrium are now well documented, and increased biosynthesis of prostaglandins may also account for the gastro-intestinal problems encountered by some sufferers. A role for the prostaglandins is substantiated by the fact that women whose diet contains more omega-3 fatty acids tend to suffer less. When eicosapentaenoic acid is the substrate for prostaglandin biosynthesis, prostaglandins of the three series are produced (e.g. PGE₃ and thromboxane A₃). Such local hormones are less potent stimulators of the myometrium and less effective vasoconstrictors. Other potential mediators are the endothelins, vasoactive peptides produced in the endometrium that may play a role in the local regulation of prostaglandin synthesis, and vasopressin, a posterior pituitary hormone that stimulates uterine activity and decreases uterine blood flow. The smaller branches of the uterine arteries are very sensitive to the vasoconstrictor actions of these mediators, and it is these resistance vessels that are important in the control of uterine blood flow. The interrelationship between blood flow and myometrial activity is summarised in Fig. 46.4.

Measurements of intrauterine pressure and myometrial activity have been made for research purposes, but there are no simple objective measurements for dysmenorrhoea.

Secondary dysmenorrhoea

Aetiology and symptoms

Secondary dysmenorrhoea tends to afflict women in their 30s and 40s, and usually occurs as a consequence of some other pelvic pathology such as endometriosis or pelvic inflammation. In

Fig. 46.4 The interactive role of myometrial stimulants and vasoconstrictive agents in the pathway leading to pain in dysmenorrhoea.

terms of symptoms, it differs from primary dysmenorrhoea in that the pain may actually start before menstruation begins, continue for the duration of menses and be associated with abdominal bloating, backache and a general feeling of ‘heaviness’ in the pelvic area. Women with inflammatory bowel disease also have symptom exacerbation during menses, and it is possible that the prostaglandins are involved in this aspect of pathoetiology. The intrauterine contraceptive device may also exacerbate menstrual pain, because it causes localised inflammation that triggers the release of prostaglandins. The prostaglandins may also be implicated in the chain of events that lead to pain associated with secondary dysmenorrhoea. For example, if the cause is endometriosis, in which endometrial tissue is found outside the uterine cavity, then this extrauterine tissue can also synthesise prostaglandins, which may in turn disrupt normal uterine function.

Treatment

In terms of analgesia, the most rational choice would be a non-steroidal anti-inflammatory drug (NSAID) (Zahradnik et al., 2010), because these compounds decrease prostaglandin biosynthesis by inhibiting COX. There is substantive evidence (Marjoribanks et al., 2010) that NSAIDs are effective in the treatment of dysmenorrhoea and are more effective than paracetamol. Differences in anti-inflammatory activity between different NSAIDs are small. There is considerable variation in individual patient tolerance and response, and a lack of response to one particular agent does not mean that a patient would not respond to a different NSAID. However, there is insufficient evidence regarding the comparative efficacy of individual agents in terms of superiority of analgesia or side-effect profile. Further information on when to use a NSAID and more importantly when not to is available in Clinical Knowledge Summaries (National Institute for Health and Care Excellence [NICE], 2015).

Mefenamic acid is frequently used to manage pain caused by dysmenorrhoea. As previously stated, this compound not only inhibits prostaglandin production but also appears to possess some PGE receptor blocking activity which may serve to augment its effect. However, these preparations are not suitable for all women, and some (about 30% of women) will not respond.

The lack of an effect with an NSAID may be explained by pathway diversion, because the arachidonic acid that was to be converted to a prostaglandin via the action of COX can be utilised by an alternative biosynthetic route, leading to increased formation of leukotrienes. Alternatively, the second COX enzyme (COX-2), which is generally induced under pathological conditions, may be involved. Many of the currently available NSAIDs

are relatively poor inhibitors of COX-2, and if some of the prostaglandins in these uterine disorders are produced via the action of this form of COX, then it is not surprising that the NSAIDs are not 100% effective. Celecoxib and etoricoxib have been shown to be effective, although neither is currently licensed for use in dysmenorrhoea.

A small study has investigated the use of the leukotriene receptor antagonist montelukast (Singulair) in the treatment of dysmenorrhoea (Fujiwara et al., 2010). The results suggest blockade of leukotriene receptors alleviate pain and reduce NSAID usage, and this appears to be most effective in women without endometriosis.

It has been estimated that approximately 50% of primary dysmenorrhoea sufferers will gain relief from taking the oral contraceptive pill, although, because this is a condition that afflicts young girls, there may be attitudinal problems to the use of these products either in the patient or her parents. The oral contraceptive pill inhibits ovulation and thereby prevents increased luteal-phase prostaglandin synthesis, thus decreasing uterine contractility. However, not all women are suitable candidates for COC use because of the potential problems associated with exogenous oestrogen. Contraindications include high blood pressure, obesity and a significant personal or family history of venous thromboembolism. Progestogenic preparations (e.g. norethisterone 5 mg three times daily from day 5 to 24 of the cycle) or progestogen-only pills may be useful if they inhibit ovulation. For pain relief, there appears to be no significant difference between the various formulations. Antispasmodics such as hyoscine butylbromide and propantheline bromide have a very limited role in the treatment of dysmenorrhoea, not least because of their poor oral bioavailability. Related compounds such as atropine also have negligible effects upon the human uterus. A summary of the treatment options for dysmenorrhoea is presented in Table 46.1. Future therapy may involve use of vasopressin antagonists. Clinical trials have shown these compounds to be effective and well tolerated, and they do not affect bleeding patterns.

For secondary dysmenorrhoea, the best treatment lies in finding the underlying cause and then taking an appropriate therapeutic route. For example, if some form of PID is diagnosed that can be attributed to a causative organism, then antimicrobial therapy is appropriate. PID is most commonly caused by the presence of a sexually transmitted infection. The most frequent causative organisms are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In addition, any procedure that may compromise the mucous barrier of the cervix, for example, insertion of an intrauterine device, may also increase the risk of contracting PID. Treatment of endometriosis will often reduce symptoms of dysmenorrhoea. Surgical treatment for secondary dysmenorrhoea such as hysterectomy is also possible for those women who do not want to become pregnant.

Non-pharmacological management options have been reviewed and include high-frequency transcutaneous nerve stimulation and acupuncture. Both of these therapies showed some potential benefit for acute pain compared with placebo. There is limited evidence to support the use of uterine nerve ablation and presacral neurectomy, to interrupt the sensory nerve fibres near the cervix blocking the pain pathway. Dietary therapies such as vitamin (e.g. vitamin B₁ 100 mg daily) and mineral supplementation have also been investigated. One study identified that vitamin B₁

Table 46.1 Summary of treatment options for dysmenorrhoea

Drug	Side effects
NSAIDs	Gastric irritation can be minimised by taking with or after food or selecting an agent with less gastrototoxicity (e.g. ibuprofen). Hypersensitivity reactions, particularly bronchospasm, may occur. Headache, dizziness, vertigo, hearing problems (e.g. tinnitus) and haematuria also may occur. NSAIDs may adversely affect renal function and provoke acute renal failure.
Combined oral contraceptives	Many side effects are dose related and thus the development of the ultra-low-dose preparations (i.e. those containing 20 micrograms ethinylestradiol) is beneficial. An alternative to the oral preparations is the low-dose transdermal combined contraceptive which releases 20 micrograms of ethinylestradiol and 150 micrograms of norelgestromin (active metabolite of the third-generation progestogen, norgestimate). The most serious potential adverse effect is the increased risk of thromboembolism due to a decrease in circulating levels of antithrombin III while increasing serum levels of some clotting factors. This risk increases with age and smoking. Analysis of current data suggests that the risk of breast cancer is not increased for most women who use the combined oral contraceptive for the major portion of their reproductive years. Use of the combined oral contraceptive also conveys several health benefits besides being an effective contraceptive. For progestogenic side effects, see below.
Progestogen-only preparations	Use of these agents may cause menstrual disturbances (e.g. breakthrough bleeding). Other adverse effects relate to the selectivity of the synthetic hormone; e.g. norethisterone is a first-generation progestogen and has some affinity for steroid receptors other than progesterone and so possesses androgenic, oestrogenic and anti-oestrogenic activity. The third-generation progestogens (gestodene, norgestimate and desogestrel) have the least androgenic activity. This should be advantageous because it is the androgenicity of the compounds that correlates with the decrease in high-density lipoproteins.

NSAID, Non-steroidal anti-inflammatory drug.

100 mg daily may be effective in relieving pain. Magnesium supplementation also shows promising results. Unfortunately, evidence is still lacking to support use of other herbal and dietary therapies, for example, omega-3 fatty acids. Some Chinese herbal medicines (e.g. Danggui Shaoyao San) have shown interesting results, but trial quality is poor because of high risk of bias.

Heavy menstrual bleeding

Blood loss is considered to be excessive if it exceeds 80 mL per period, although both women themselves and clinicians find it difficult to objectively quantify blood loss. In practice, it is defined by the woman's subjective assessment of blood loss. Any change in menstruation, whether real or perceived, may be disturbing with respect to social, occupational or sexual activities and can lead to other problems including depression and concern about an undiagnosed problem such as cancer. Physically, excessive blood loss will precipitate iron deficiency anaemia (haemoglobin <12 g/dL) which, if left undiagnosed and untreated, will compound the problems outlined earlier.

If a patient has any intermenstrual or postcoital bleeding, then referral to a gynaecologist for endometrial biopsy is essential in women older than 40 years to exclude intrauterine pathology. Up-to-date cervical cytology is also required. It should also be noted that hormonal contraceptives may cause some irregular spotting or breakthrough bleeding, but this is generally a tolerance effect. Non-oral methods, particularly implants, depots and intrauterine systems, decrease bleeding with continued use. The World Health Organisation recommends a 90-day reference period for reporting vaginal bleeding.

Epidemiology

In the UK about 30% of women report heavy menstrual bleeding, and about 1 in 20 women aged 25–44 years consult their primary care doctor about this problem. In the UK in excess of 800,000 women a year seek help for abnormal menstrual bleeding (Whitaker and Critchley, 2015). Historically, once referred to a gynaecologist, 60% of women could expect to have a hysterectomy within 5 years. Recent changes in the management of women with heavy menstrual bleeding and new treatment options, particularly endometrial ablations and the levonorgestrel intrauterine contraceptive devices (LNG-IUS), have significantly reduced hysterectomy rates to a third of the number in the late 2000s. However, it is estimated that one in three women in the USA, where more than 400,000 hysterectomies are performed each year, will have had a hysterectomy by the age of 60 years. Data suggest that alternatives to hysterectomy are being underused including hormonal and other forms of medical management, operative hysteroscopy, endometrial ablation and use of the LNG-IUS for primary management.

Aetiology and investigation

The aetiology of heavy menstrual bleeding can be divided into three categories: underlying pelvic pathology, systemic disease and dysfunctional uterine bleeding (Box 46.3). The typical symptoms suggestive of underlying pelvic pathology are presented in Box 46.4. Pelvic pathologies associated with heavy menstruation include myomas (fibroids, common benign tumours of the myometrium), endometriosis, adenomyosis (penetration of endometrial tissue into the myometrium), endometrial polyps, polycystic ovary syndrome and endometrial carcinoma. Although endometrial cancer is more typically

Box 46.3 Causes of heavy menstrual bleeding (percentage frequency)

- Dysfunctional uterine bleeding (60%); i.e. cause is unknown
 Other gynaecological causes (30%):
- Uterine or ovarian tumours
 - Endometriosis
 - Pelvic inflammatory disease
 - Intrauterine contraceptive devices
 - Early pregnancy complications

Box 46.4 Symptoms suggestive of underlying pelvic pathology

- Irregular bleeding
- Sudden change in blood loss
- Intermenstrual bleeding
- Postcoital bleeding
- Dyspareunia
- Pelvic pain
- Premenstrual pain

seen in postmenopausal women, approximately 50% of those patients diagnosed with it premenopausally will have associated heavy menstrual bleeding. Systemic diseases from which heavy menstrual bleeding may stem include hypothyroidism, disorders involving the coagulation system such as elevated endometrial levels of plasminogen activator, and systemic lupus erythematosus. Very few women fall into this group. About 60% of sufferers have no underlying systemic or pelvic pathology and have ovulatory cycles. These patients are said to have dysfunctional uterine bleeding, and local uterine mechanisms appear to be important in the control of menstrual blood loss. Occasionally cycles may be anovulatory, with heavy blood loss because the endometrium has become hyperplastic under the influence of oestrogen. In addition, use of an intrauterine contraceptive device may also increase menstrual blood loss.

Prostaglandins appear to play a role in the aforementioned local mechanisms and have been implicated in heavy menstrual bleeding. Studies have suggested an association between the type and quantity of endometrial prostaglandin synthesis and the degree of menstrual blood loss. In the mid-1970s, it was discovered that women with heavy periods had raised endometrial levels of $\text{PGF}_{2\alpha}$ and PGE_2 , and that blood loss could be reduced by the use of drugs inhibiting prostaglandin formation. More studies suggested that, in women with heavy menstrual loss, there is a shift towards increased biosynthesis of PGE_2 , which is known to dilate uterine vasculature and/or increase the number of membrane receptors for this prostanoid. The availability of arachidonic acid, a substrate for prostaglandin synthesis, is also greater in women with heavy periods. Levels of the vasodilators or their metabolites, PGI_2 and nitric oxide, are also increased in the menstrual blood collected from women with excessive blood loss. It has been suggested that heavy menstrual bleeding is an angiogenesis-related disease associated with changes in the pattern of

vascular fragility involving the upregulation of various vascular endothelial growth factors.

Excessive menstrual blood loss is the most common cause of iron deficiency anaemia in women of reproductive age. In an otherwise healthy, well-nourished woman, it has been estimated that menstrual blood loss would have to exceed 120 mL to precipitate iron deficiency anaemia. Objective measurement of menstrual blood loss is difficult, so measurement of full blood count (including red blood cell indices and serum ferritin levels) and, in particular, haemoglobin concentration gives some indication of blood loss. Thyroid function should also be assessed. If fibroids are suspected, then pelvic ultrasound may be required. Endometrial biopsy is needed in women older than 40 years if there is an associated irregularity of menstruation or if intermenstrual or postcoital bleeding is present. In the case of regular menses, however, investigation of the uterine cavity would usually be required only in women older than 40 years or if medical treatment fails to alleviate symptoms. Young women presenting with dysfunctional uterine bleeding may have underlying coagulopathies such as von Willebrand's disease or Christmas disease, which should be excluded.

The increasing use of inhibitors of activated factor X (factor Xa) has led to reports of heavy menstrual bleeding, particularly with rivaroxaban, compared with the use of vitamin K antagonists or low molecular weight heparins. It remains to be seen whether this is a class effect.

Going forward it is likely that a more structured diagnostic classification framework will be more widely adopted (e.g. FIGO PALM-COEIN) (Munro et al., 2011) which will support the use of treatment modalities optimised for the individual.

Treatment

The management of heavy menstrual bleeding depends upon the cause of the condition and a woman's desire to conceive. Treatment can be either surgical or medical (Table 46.2). The effectiveness of drug therapy is obviously influenced by the accuracy of the diagnosis. Drug treatment is also influenced by a woman's contraceptive needs; for example, COCs can reduce menstrual blood loss by up to 50%, but in women older than 35 years who smoke, this form of therapy would need careful consideration. Low-dose luteal-phase progestogens are no longer recommended for treatment of heavy but regular periods because they increase menstrual blood loss in this situation. However, they may be of value in women with an irregular cycle. Long-term, long-acting progestogens, however, may render a woman amenorrhoeic. Other hormonally based therapies include the GnRH analogues, although their propensity to induce a hypo-oestrogenic state with long-term use may be problematic (a 6-month course would reduce trabecular bone density by 5–6%). Trials of ormeloxifene, a selective oestrogen receptor modulator (similar to raloxifene), 60 mg twice weekly has been used successfully to reduce blood loss and increase haemoglobin levels with relatively few side effects (Dhananjay and Nanda, 2013). The development of selective progesterone receptor modulators such as ulipristal may also increase pharmacological choice because such compounds may decrease uterine blood flow as well as alter endometrial architecture, resulting in reduced blood loss.

Table 46.2 Summary of drug treatment options for heavy menstrual bleeding

Drug	Comments
Combined oral contraceptive	See Table 46.1 . These preparations are taken for 21 days with a 7-day pill-free (or placebo) period to allow for a withdrawal bleed
Progestogen-only preparations	See Table 46.1 . Compounds such as norethisterone can be used, e.g. 5 mg three times daily or 10 mg twice daily for the latter half of the cycle. Ten days of therapy should be sufficient from day 15 of the cycle in ovulatory cycles. However, if the cycles are anovulatory, then a minimum of 12 days of therapy is more appropriate. Progestogens for 12 days are also required to prevent endometrial hyperplasia in perimenopausal and postmenopausal women who are taking oestrogen. When progestogens such as norethisterone are used, the dosage required is higher than that used in the combined oral contraceptive pill, and the adverse effects associated with the synthetic progestogens, particularly the 19-nortestosterone derivatives, may be more pronounced.
Intrauterine progestogen-only contraceptive	The levonorgestrel-releasing intrauterine device typically releases 20 micrograms of levonorgestrel/24 h. Unlike non-medicated IUCDs, which may increase menstrual blood loss, this device appears to reduce it, as a result of the local endometrial actions of the progestogen. The device also offers contraceptive cover without many of the side effects associated with the non-medicated IUCDs. Progestogen-related side effects should be minimised because of the low dose of levonorgestrel employed. Initially, bleeding patterns may be disrupted, but menstrual blood loss should become lighter within three menstrual cycles
Danazol	Danazol suppress the pituitary–ovarian axis. Side effects include amenorrhoea, hot flushes, sweating, changes in libido, vaginitis and emotional lability. Danazol also causes androgenic side effects such as acne, oily skin and hair, hirsutism, oedema, weight gain, voice deepening and decreasing breast size. Danazol has to be taken daily.
Gonadotrophin-releasing hormone analogues (gonadorelin)	After an initial period of stimulation, these agents suppress the pituitary–ovarian axis. As result of inducing a hypo-oestrogenic state, these compounds should only be used for 6 months because they may decrease trabecular bone density.
Non-steroidal anti-inflammatory drugs	These agents only need to be taken for the first 3–4 days of menses.
Tranexamic acid	This drug appears well tolerated but can produce dose-related gastro-intestinal disturbances. Patients who may be predisposed to thrombosis are at risk if given antifibrinolytic therapy. This compound is usually only taken for the first 3 days of menses.

IUCD, Intrauterine contraceptive device.

Prostaglandins have been implicated in the aetiology of several forms of menorrhagia. Therefore, NSAIDs may be of use in some patients, especially if there is pain associated with menstruation. The NSAIDs can be used with antifibrinolytics.

Women with heavy menstrual bleeding have greater endometrial fibrinolytic activity, hence the use of antifibrinolytic drugs, which are plasminogen activator inhibitors. Tranexamic acid became available for purchase over the counter in UK pharmacies in 2010 as Cyklo-F. This can be sold to women aged 18–45 years old with a history of regular heavy menstrual bleeding over several consecutive menstrual cycles. Tranexamic acid reduces menstrual blood loss by up to 50% ([Lethaby et al., 2000](#)), the recommended dose being 1 g three times daily starting on the first day of menses for up to 4 days. Agents such as tranexamic acid carry a risk of unwanted thrombogenesis, but this does not appear to be translated into practice as increased numbers of deep vein thromboses. This class of drugs decreases menstrual blood loss better than NSAIDs and oral luteal phase progestogen ([Lethaby et al., 2005](#)). However, tranexamic acid, like NSAIDs, should be stopped if it has produced no benefit after three cycles.

The levonorgestrel intrauterine contraceptive devices (also known as intrauterine systems [LNG-IUSs]) can be left in place

for up to 5 years following insertion. They reduce menstrual blood loss by up to 90% after 12 months of use. The LNG-IUS provides relief from dysmenorrhoea, effective contraception and long-term control of heavy menstrual bleeding. In a Cochrane review ([Lethaby et al., 2015](#)) of trials, the LNG-IUS was compared with oral medications (norethisterone acetate, medroxyprogesterone acetate, oral contraceptives and mefenamic acid). The authors concluded that the LNG-IUS was more effective in reducing blood loss than the oral treatments but use was associated with more minor side effects. It was less effective than hysterectomy but more cost-effective.

Hysterectomy has been the traditional surgical treatment for heavy periods, with either a laparoscopic or open abdominal or vaginal approach used ([Marjoribanks et al., 2016](#)). Newer alternatives to hysterectomy include endometrial ablation, which can be done by electrosurgical, laser, microwave or thermal techniques. Endometrial ablation is less invasive than hysterectomy, but recurrence of heavy bleeding can occur and amenorrhoea cannot be guaranteed. There is evidence that pretreatment with a single dose of a GnRH agonist before the ablation procedure gives a better result. These preparations cause an initial stimulation of gonadotrophin release which then suppresses

the hypothalamic–pituitary axis, producing a hypo-oestrogenic state. If circulating levels of oestrogen are low, then endometrial growth will not be stimulated; thus, it will be thinner, making the surgical endometrial destruction more effective.

Endometriosis

Endometriosis is a condition in which endometrial tissue is found outside the uterus. These so-called ectopic endometrial foci have been found outside the reproductive tract in the gastro-intestinal tract, the urinary tract and even the lungs.

Aetiology

Aetiology remains unclear, although retrograde menstruation, when shed endometrial cells migrate up through the fallopian tubes, would appear to be involved. This may occur because abnormalities in uterine innervation cause disruption in the usual patterns of myometrial contractility with consequent loss of the usual fundocervical polarity. Endometriosis is found in women in whom the normal route for the menstrual flow is disrupted, such as when there is some genital tract abnormality. Women who have more frequent and heavier periods also seem to be more likely to suffer from endometriosis. Familial predisposition may also be a factor, and several gene polymorphisms have been identified.

Studies suggest that endometrium from endometriosis sufferers tends to be more invasive. This may reflect either biological or genetic differences in the peritoneal milieu and may be explained by the upregulation of certain types of metalloproteinase responsible for the degradation of basement membrane. Endometrial tissue from women with endometriosis may have aromatase activity which can be stimulated by PGE₂. Therefore, ostensibly the endometriotic lesions have their own oestrogen supply as aromatase converts androgenic precursors into oestrogen and oestrogen stimulates biosynthesis of PGE₂; thus, the cycle is self-perpetuating. In vitro studies have shown that eutopic and ectopic endometrial explants have different lipidomic profiles in terms of their prostaglandin release, and the myometrium from endometriosis sufferers is more contractile during menses. Recent work suggests that the growth factor hypoxia-inducible factor-1 α may play a critical role in the development of endometriosis, and thus provide another potential therapeutic target.

Epidemiology

Endometriosis was previously considered to be a disease affecting women in their 30s onwards, but increasing use of laparoscopy has revealed that it can occur at anytime throughout a woman's reproductive life. The condition is dependent upon oestrogen stimulation, and as such, it does not occur before the menarche or after menopause. The exact incidence of the disease is unknown, but it is believed to occur in about 10% in the general female population of reproductive age. One study has found a positive correlation between a menarche before 13 years and increased risk of development of endometriosis.

Symptoms

Although not all women with endometriosis are symptomatic, the pelvis is the most commonly affected site. Consequently, most of the symptoms of endometriosis relate to this region. Symptoms take the form of dysmenorrhoea and pelvic pain. However, the severity of the pain does not necessarily reflect the extent of the disease because women with severe pain may have few lesions, and vice versa. Dyspareunia often with postcoital discomfort is also common. There may also be menstrual irregularities.

The link between endometriosis and infertility is recognised, but the mechanisms involved have not been established. If the ovaries or fallopian tubes themselves are directly affected by the endometriotic lesions, then fertility may be compromised by purely mechanical means. However, the situation is less clear when the endometriosis does not cause any anatomical distortions. In this case, some of the postulated causes of infertility associated with endometriosis include ovulation disorders, such as luteinised unruptured follicle syndrome, anovulation and premature ovulation; hyperprolactinaemia; and changes in the peritoneal environment such as extrauterine endometrial material which, like normal endometrium, is subject to control by the ovarian steroids and, like its uterine counterpart, is also capable of producing prostaglandins. Prostaglandin levels, along with macrophage concentrations, are raised in the peritoneal fluid of women with endometriotic explants, and these may alter tubular and uterine motility within the abdomen.

Outside the reproductive tract, endometrial deposits can be found along the urinary and gastro-intestinal tracts. If the former is involved, then the patient may suffer from cyclical haematuria, dysuria or even ureteric obstruction. If there is gastro-intestinal tract involvement, then symptoms could include dyschezia, cyclical tenesmus and rectal bleeding or even obstruction. Very occasionally, the lesions are found at more distant sites such as the lungs, where they could cause cyclical haemoptysis. A reduction in bone mass in women with endometriosis has also been reported.

Treatment

The aims of treatment in endometriosis are to relieve symptoms and improve fertility if pregnancy is desired. Treatment can be either surgical or medical. Surgery is increasingly performed laparoscopically and can be used to restore normal pelvic anatomy, divide adhesions or ablate endometriotic tissue using either laser treatment or electrodiathermy. Medical treatment utilises the fact that endometriotic tissue is oestrogen dependent, and any drug therapy that will oppose the effects of oestrogen should, among other things, inhibit the growth of the endometriotic tissue. Hence, the choices of drug treatment are as follows.

- GnRH analogues include buserelin, goserelin, leuprorelin and nafarelin. These initially stimulate the hypothalamic–pituitary–ovarian axis but thereafter induce a hypo-oestrogenic state by paradoxically inhibiting follicle-stimulating hormone and luteinising hormone release. GnRH antagonists are currently being evaluated for management of endometriosis. These agents avoid the initial stimulation or ‘flare’ of the hypothalamic-pituitary-ovarian (HPO) axis. It may be possible to develop a dosing regimen that can be used for long-term

pain management that is sufficiently low to avoid bone loss and that does not need an 'add-back' adjuvant.

- Low-dose COC (20–30 micrograms of ethinylestradiol) monophasic preparations have been found to be as effective as GnRH analogues, and they may slow down disease progression in young women and preserve future fertility. Flexible dosing regimens are being trialed where withdrawal bleeds are being eliminated for longer periods. Research shows that half of pill users would prefer not have bleeds at all. However, they remain underused (Nappi et al., 2015), and many women still focus on the side effects rather than the benefits of the hormonal contraceptives.
- Compounds with androgenic activity such as danazol also inhibit pituitary gonadotrophin release by interfering with the negative feedback and cause atrophy of endometrial tissue. Danazol interacts with androgen receptors, but it also has some affinity for the progesterone receptor. It inhibits the pulsatile release of gonadotrophins from the anterior pituitary, and thus abolishes cyclical ovarian activity, leading to amenorrhoea in the majority of women and a subsequent fall in serum oestrogen levels. Side effects relate to the androgenicity of the compound and include nausea, giddiness, muscular pain, weight gain, acne and virilisation. These can be minimised by using locally administered low doses of 200 mg/day.
- Progestogens such as medroxyprogesterone acetate and norethisterone initially cause decidualisation (cellular and vascular changes) of the endometrial tissue followed by glandular atrophy.
- Aromatase inhibitors are still under investigation for use in endometriosis. However, early results suggest that their adverse effect profile, which includes flushes, myalgia, arthralgia, insomnia and decreased libido, is poorer than for the progestogens and oral contraceptives.

None of the aforementioned drug therapies are free from side effects. Use of the GnRH analogues may evoke menopausal symptoms such as hot flushes, decreased libido, vaginal dryness (topical vaginal lubricants may be helpful), mood changes and headache. The problems associated with the hypo-oestrogenic state limit the long-term use of GnRH analogues. Although lipoprotein levels are not affected adversely, bone mass is, and this loss of bone density may not be entirely reversible after cessation of therapy. Various add-back hormone replacement therapies have been successfully used to minimise bone demineralisation, for example, low-dose oestrogen/progestogen combinations used continuously. Such regimens protect against osteoporosis and other hypo-oestrogenic side effects without apparently affecting clinical efficacy. Pain associated with endometriosis was relieved similarly by goserelin and a low-dose oral contraceptive (Prentice et al., 1999). However, side-effect profiles differed, for example, hot flushes and vaginal dryness with the former agent, and headache and weight gain with the latter.

The androgenic compounds, because of their very nature, are associated with hirsutism, weight gain and acne. Side effects associated with synthetic progestogens relate again to androgenicity, although dydrogesterone, like natural progesterone, does not cause virilisation. However, using a levonorgestrel-releasing intrauterine device ensures the low dose of levonorgestrel is delivered locally, and the more direct pelvic distribution may be useful in the management of endometriosis. Recent results

suggest this device causes the downregulation of endometrial cell proliferation and increased apoptotic activity. Longer-term studies, over 5 years, need to be undertaken to determine how long this effect is maintained and also the effectiveness on symptoms such as dyspareunia and dyschezia.

Researchers have also found that certain dietary changes may be beneficial and reduce symptoms. A decreased intake of glycaemic carbohydrates such as sugar, rice and potatoes in addition to reducing/eliminating caffeine and increasing the intake of omega-3 oils such as flax seed oil may also be helpful. In addition, one study found that women with endometriosis tended to have a lower body mass index than those without the condition.

Total pelvic clearance, including the removal of the ovaries, is practical in women who have completed their family. This tends to be a last resort treatment, but it is usually effective. However, surgery may be difficult if multiple lesions are present. There is no evidence that hormonal suppression improves surgical outcome.

Neither surgical nor medical management is effective in all cases. Studies suggest that pain associated with endometriosis responds well to both surgical and medical treatment, but symptoms of recurrence occur in about 50% of patients within 5 years of stopping treatment. Fertility may be increased by the use of surgery to remove endometriotic foci causing anatomical distortion. The same benefit is not associated with medical treatment.

Case studies

Case 46.1

A 13-year-old girl, Miss FL, is brought to her primary care doctor by her mother. She has been struggling with long, heavy periods for 6 months and as a result is missing time at school.

Questions

1. What non-hormonal treatment options would be considered?
2. What other treatments might be an option?

Answers

1. In young girls, it is worthwhile to try non-hormonal treatment options first because they will tend to have a lower side-effect profile than hormonal treatment. Tranexamic acid at a dosage of 1 g three times a day for up to 4 days (maximum 4 g/day) should be taken while bleeding. This is a very simple and effective option with few side effects and a reported 50% reduction in menstrual blood loss. Another option would be to try a non-steroidal preparation such as mefenamic acid (500 mg three times daily from first day of bleeding until period ends), especially if associated dysmenorrhoea is a significant problem. Tranexamic acid and an NSAID can be taken together if required.
2. Cyclical norethisterone (5 mg three times daily for 10 days) can be helpful if the periods are irregular, but it is not recommended for heavy regular periods. Progestogenic side effects such as nausea and bloating can limit use. The COC pill can be very effective at relieving heavy bleeding and dysmenorrhoea, provided that there are no contraindications. Sometimes parents can raise concerns about the use of a contraceptive agent, some parents perhaps believing that it may promote promiscuity.

Case 46.2

A 33-year-old woman, Ms JP, has been diagnosed with endometriosis having presented with severe dysmenorrhoea. She has visited the gynaecology clinic to discuss treatment options but is very concerned about her fertility. Ms JP does not wish to conceive at the present time but would certainly plan to try for a baby in the next couple of years.

Questions

1. What effect does endometriosis and its treatment have on fertility?
2. What treatment options could be considered?

Answers

1. Severe endometriosis with significant distortion of the pelvic anatomy can cause tubal blockage and hence cause tubal factor infertility. Most patients will have much less severe endometriosis which, although not causing any anatomical abnormality, is associated with a reduction in fertility. Such couples tend to take longer to conceive perhaps because the endometrial deposits create an unfavourable milieu for the egg and sperm. Laparoscopic ablation or excision of endometriotic deposits improves conception rates, albeit for a short period. In women who wish to conceive, endometriomas larger than 4 cm in diameter are removed because this improves pregnancy rates. Medical treatments do not improve fertility rates as many treatment options are contraceptive in themselves and should not be used if women wish to try to conceive. In this situation, symptom control with analgesia may be the best option.
2. As this patient is not wishing to conceive, a trial of medical therapy should be considered. Surgery for endometriosis is a highly skilled procedure which has a significant risk of complications. Medical treatment options include the COC pill, a prolonged course of progestogens such as medroxyprogesterone acetate or GnRH analogues. All have different side effects and contraindications but are all equally effective at reducing symptoms of endometriosis. The COC pill can be taken in a conventional way, but anecdotal experience supports tricycling, that is, taking three packets back to back and only having a withdrawal bleed after the third packet. Clearly, the usual contraindications to taking a COC pill apply. Progestogens are often poorly tolerated with

side effects such as bloating and nausea. A 6-month course of a GnRH analogue is generally effective at reducing symptoms and well tolerated. Vasomotor symptoms can be treated with add-back hormone replacement therapy with a continuous combined preparation or tibolone. Treatment is limited to a 6-month course because of the bone loss associated with the GnRH-induced hypo-oestrogenism.

Case 46.3

A 33-year-old, Ms AR, with very heavy and prolonged periods presents to her primary care doctor requesting a hysterectomy. Her mother had a hysterectomy at age 38 and this patient feels that it is her only option.

Questions

1. What treatment options would you offer Ms AR before considering a hysterectomy?
2. What investigations are necessary?

Answers

1. Before considering treatment, Miss AR should have a pelvic examination, primarily to exclude large fibroids which are unlikely to respond to medical therapy. Current advice is to recommend a levonorgestrel-releasing intrauterine device as first line for heavy menstrual bleeding (NICE, 2007). If the patient declines or is not suitable for this, other options would include tranexamic acid and/or an NSAID such as mefenamic acid taken at the onset of the period. The COC pill could be considered if not contraindicated. Cyclical norethisterone may be of benefit if the menstrual cycle is irregular. Endometrial ablative techniques are effective in 80% of women but are recommended only for women who have completed their families. Hysterectomy should be reserved as the last option and if medical therapy fails.
2. If pelvic examination is normal, the only investigation recommended for Miss AR is a full blood count to exclude anaemia. If examination suggests the possibility of a pelvic mass, an ultrasound scan should be organised. Further endometrium investigation, by hysteroscopy or endometrial biopsy, in women younger than 40 years with heavy menstrual bleeding and no intermenstrual bleeding, is not indicated unless medical treatment options fail.

47 Menopause

Kay Marshall and Emma Crosbie

Key points

- Menopause is signalled by the last menstrual period; this cessation of menstruation results from a loss of ovarian follicular activity.
- The problems associated with menopause result from the ensuing loss of the female sex steroid oestrogen.
- On average, 35% of a woman's life is spent in a peri-menopausal or post-menopausal state.
- Declining oestrogen levels can give rise to vasomotor symptoms, localised atrophy of the genitalia, psychological problems, osteoporosis and coronary heart disease.
- In the UK, only about 50% of women seek help for their symptoms.
- The hormonal content of a particular hormone replacement therapy (HRT) regimen is important, as is the route of delivery, in determining the side effects observed.
- Contraindications to HRT include active arterial thromboembolic disease and thrombophilic disorders, undiagnosed vaginal bleeding in post-menopausal women or the presence of an oestrogen-dependent tumour.
- For women with an intact uterus, hormone replacement regimens must include a progestogenic component to prevent overstimulation of the endometrium.
- Alternative options to traditional HRT regimens include the use of tibolone, raloxifene and the bisphosphonates.

Menopause

The UK, like many countries in the developed world, has an ageing population; life expectancy is increasing, and women continue to live longer than men, whilst birth rates are declining. Currently, a woman can expect to live about 35% of her life in a post-menopausal state.

Menopause is signalled by a woman's last menstrual period and is defined as the permanent cessation of menstruation resulting from loss of ovarian follicular activity. The occurrence of the last menstruation can only be diagnosed retrospectively and is usually taken as being final if it is followed by a 12-month bleed-free interval; such women are defined as being post-menopausal. The mean age of menopause in the UK is 51 years, and by the age of 54 years, around 80% of women will be post-menopausal. If menopause occurs before 40 years, which happens in approximately 1% of women, it would be classed as a premature menopause. Many women will experience erratic periods before the

final cessation due to inadequate ovarian oestrogen secretion; these women are described as being peri-menopausal. This transitional phase usually lasts around 4–5 years. The problems associated with menopause result from oestrogen deprivation, and women should be given information about menopause and concomitant health implications, as well as benefits and risks of treatment.

Menopause is a natural event in the anatomical, physiological and psychological changes that form the female climacteric. Some women will go from the transition of being pre-menopausal to post-menopausal with no symptoms at all. Many will experience the symptoms associated with a lack of oestrogen, whether in the peri-menopausal or post-menopausal phase, which include:

- vasomotor symptoms,
- localised atrophy of urogenital tissues,
- osteoporosis,
- psychological and neurological problems,
- musculoskeletal problems,
- coronary heart disease.

Initially, the symptoms are more likely to include vasomotor symptoms such as hot flushes, night sweats and palpitations, and psychological problems, including mood changes, irritability, sleep disturbance, depression and decreased libido. Many women suffer from vaginal dryness and dyspareunia (painful sexual intercourse), which serve to enhance the loss of libido, and this in turn can adversely affect psychological well-being. The urethral mucosa may become atrophied, leading to an increased incidence of urinary tract infections or urinary incontinence. In some women, the urethra may eventually become fibrosed, leading to dysuria, frequency and urgency (urethral syndrome). The long-term consequences of oestrogen deprivation are often symptomless. There is a significant loss of calcium from the bones, which may give rise to frequent fractures, and there is a change in the blood lipid profile, which is associated with a rise in coronary heart disease.

Physiological changes

Ovarian

The approaching menopause is associated with loss of ovarian follicular activity. Human ovaries contain approximately 700,000 follicles at birth, but these cells have a high mortality rate, and fewer than 500 of them will be ovulated. This number falls progressively with increasing age so that by the

time the woman approaches 50 years of age, the number of follicles has fallen to zero or very few. The rate of follicle loss is highest during the decade between 40 and 50 years of age, possibly due to an increase in the rate of degeneration (atresia) of the earliest follicles. Women older than 45 years who are menstruating regularly have been shown to have 10 times as many follicles as those with irregular cycles; those who have not had a period for 12 months have few follicles remaining. Thus, the size of the follicular pool is an important determinant of ovarian function.

Ovarian function includes two major roles: the production of eggs (gametogenesis) and the synthesis and secretion of hormones (hormonogenesis). Both of these functions undergo subtle changes with ageing so that fewer ova are produced and they are less readily fertilised, and the hormone levels become irregular. It is the granulosa cells in the developing follicle that normally secrete estradiol, and a lack of this follicular activity results in diminishing oestrogen secretion. The diminution in the number of active follicles is followed by an increase in follicle-stimulating hormone (FSH) secretion from the anterior pituitary gland as the normal feedback mechanisms between ovarian estradiol secretion and the hypothalamus–pituitary axis become disrupted. It may be that there is an age-related decrease in sensitivity to feedback inhibition that exacerbates this increase in FSH levels. In women who are still bleeding, an FSH level exceeding 10–12 IU/L on day 2 or 3 of the bleed is indicative of a diminished ovarian response. A high FSH level (>30 IU/L) and a low estradiol level (<100 pmol/L) in the plasma characterise menopause. The National Institute of Health and Care Excellence (NICE) Clinical Guideline (NICE, 2015) on menopause includes a chapter on diagnostic testing and concludes that biochemical measurements and ovarian ultrasound are not useful in routine practice and that age and amenorrhoea remain sufficient for routine diagnosis. The low oestrogen level fails to stimulate growth of the uterine endometrium. Because endometrial growth has not occurred, there can be no menstruation (shedding of the endometrium), and this signifies that menopause has arrived. Because ova are not being released, the production of progesterone from the ovary also ceases, and the levels of luteinising hormone (LH) eventually rise. Thus, peri-menopausal and menopausal women are subjected to an increasing ovarian hormone deficiency, as shown in Table 47.1.

When the ovaries are conserved after hysterectomy, they will usually continue to produce some estradiol, but the levels of this hormone will decline up to the age of the natural menopause.

Table 47.1 Ovarian hormone secretion after the onset of the normal menstrual cycle

	Pre-menopausal (normal cyclic)	Peri-menopausal (irregular cycles)	Post-menopausal (cessation of cycle)
Oestrogens	+++	++	+→-
Progesterone	+++	+	-
Androgens	+	+	+→-

Post-menopausally, in all women, androstenedione (secreted from the adrenal cortex) is converted in adipose tissue and muscle (peripheral conversion) to estrone, which becomes the major circulating oestrogen (but estrone is about 10 times less potent than estradiol). The levels of FSH and LH remain elevated for many years if no HRT is given, but these elevated levels have no effect on the ovary because the follicles are atretic.

The cessation of reproductive function in the woman and the declining oestrogen production from the ovary are not the only physiological events associated with menopause. For many years, oestrogen was considered to be associated only with the genitourinary system, but its effects are more wide ranging, and the major tissues affected include blood vessels, bones and the brain.

Urogenital system

With the failure in ovarian oestrogen production, the number of uterine endometrial oestrogen receptors occupied falls, and endometrial growth is not sustained. Thus, in the post-menopausal woman, the endometrium becomes thin and atrophic. Likewise, in the other target tissues containing oestrogen receptors, the basal layers of the vaginal epithelium are no longer stimulated to maintain the vaginal epithelium and produce natural lubricants from the vaginal glands. The result is vaginal atrophy, and a thin, dry vagina may result in dyspareunia. It is estimated that 50% of post-menopausal women suffer symptoms attributable to vulvo-vaginal atrophy. Because the lower urinary tract and the lower genital tract share a common embryological origin, deprivation of oestrogen can also result in urethral and bladder problems. Often, peri-menopausal and post-menopausal women report an increase in urinary frequency, nocturia and urge incontinence. For some women, these changes may manifest as long as 10 years after menopause.

Bone

Osteoporosis is a systemic skeletal disease characterised by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture risk. Although the exact magnitude of the problem of osteoporosis is unknown, it has been estimated that it affects 200 million people worldwide. In addition, approximately 30% of women older than 50 years have one or more vertebral fractures compared with 20% of men older than 50 years who will have an osteoporosis-related fracture in their remaining lifetime. The total number of hip fractures in 1950 was 1.66 million, and by 2050, this figure could reach 6.26 million. Twenty percent of people die within 1 year of a hip fracture (Cooper, 1997). Typical morbidities after a vertebral fracture include:

- back pain,
- loss of height,
- deformity (kyphosis, protuberant abdomen),
- reduced pulmonary function,
- diminished quality of life: loss of self-esteem, distorted body image, dependence on narcotic analgesics, sleep disorder, depression or loss of independence.

To contextualise risk, the remaining lifetime probability in women at menopause of a fracture at any one of these sites exceeds that of breast cancer (~12%). Also, the likelihood of a fracture at any of these sites is 40% or more in developed countries (Kanis et al., 2000), a figure close to the probability of coronary heart disease. Risk factors for osteoporosis include low body mass index (<19 kg/m²), smoking, early menopause, family history of maternal hip fracture, long-term systemic corticosteroid use and conditions affecting bone metabolism, especially those causing prolonged immobility. Osteoporosis is most common in white women. People with osteoporosis are at risk of fragility fractures, occurring as a result of mechanical forces that would not ordinarily cause fracture. The clinically relevant outcome in evaluating treatments for osteoporosis is the incidence of fragility fracture because otherwise, this condition is asymptomatic and therefore undiagnosed. The most common sites for these fractures are the hip, vertebrae and wrist. In the UK, the cost of hospital care alone for patients with a hip fracture amounts to more than £2 billion per year.

Musculoskeletal system

Musculoskeletal problems are frequently reported by women as they reach menopause. These symptoms could also be attributed to ovarian quiescence and oestrogen deprivation. Muscle mass is inversely correlated with plasma oestrogen levels in women. The mechanism of action by which a decrease in oestrogen level may have a negative effect on muscle mass is not yet understood, but it has been suggested that the decrease in oestrogen concentrations may be associated with an increase in pro-inflammatory cytokines, such as tumor necrosis factor alpha and interleukin-6. It should be noted that skeletal muscle cells do contain oestrogen receptors, ER β , and hormone replacement improves muscle mass and strength.

Cardiovascular system

Young adult women are protected against the development of hypertension and its deleterious consequences in the cardiovascular system. Levels of low-density lipoprotein cholesterol (LDL-C) and very-low-density lipoprotein cholesterol (VLDL-C) are decreased by oestrogen, and the levels of high-density lipoprotein cholesterol (HDL-C) are increased, thereby giving some protection against atherosclerosis. HDL-C is known to promote cholesterol efflux from macrophages in the arterial wall, thereby reducing atheromatous plaque and conferring a protective effect against heart disease. However, after menopause, this protection is lost, and the incidence of high blood pressure and associated cardiovascular disease increases to levels similar to those found in age-matched men.

Oestrogen has direct beneficial effects in the control of blood pressure, possibly via regulating endothelium-mediated control of arteriolar tone. In women deprived of oestrogen, endothelium-dependent vasodilation is impaired. This dysfunction is largely associated with a reduction in nitric oxide availability. Oestrogen increases nitric oxide availability by stimulating endothelial nitric oxide synthase (eNOS). Oestrogen also stimulates the production of other endothelium-derived

relaxing factors, such as prostacyclin (prostaglandin I₂). The role of membrane G-protein-coupled estrogen receptors (GPERs), as opposed to ER α and ER β , which mediate classical genomic responses, are likely to be involved because they can mediate more rapid responses, which would explain the ability of oestrogen to modulate vascular tone (Prossnitz and Barton, 2014).

Miscellaneous changes

Thinning of the skin, brittle nails, hair loss and generalised aches and pains are also associated with reduced oestrogen levels (Hall and Phillips, 2005). The skin is the largest nonreproductive target on which oestrogen acts. Oestrogen receptors, predominantly of the ER β type, are widely distributed within the skin. Both types of oestrogen receptor (ER α and ER β) are expressed within the hair follicle and associated structures. Thus, epidermal thinning, declining terminal collagen content, diminished skin moisture, decreased laxity and impaired wound healing (selective ER α ligands are being investigated for their wound-healing properties) have been reported in postmenopausal women.

In addition, women also show increasing body weight associated with ageing. This weight gain tends to increase or begin near menopause. Body fat redistribution to the abdomen also occurs independent of weight gain. This type of centralised abdominal fat distribution is widely recognised as an independent risk factor for cardiovascular disease in women.

Psychological and neurological changes

Older age at menarche and younger age at menopause are associated with poorer cognitive functioning during ageing. Recent studies have demonstrated that sex steroids have a multifarious and complex relationship with the central nervous system (Hogervorst et al., 2009). For example, there may be a positive correlation between increasing parity and improved executive functioning in response to oestrogen. This temporal relationship between oestrogen deprivation and response to exogenous oestrogen was clearly exemplified in the memory study arm of the Women's Health Initiative (WHI; Coker et al., 2010) and Million Women Study (MWS) studies (Hogervorst and Bandelow., 2010) at the turn of the 21st century.

Depression is twice as common in women as in men and may increase during times of changing hormonal levels such as at menopause. Some aspects of decreased central nervous system function have been related to falling oestrogen levels. Preclinical studies have shown oestrogen to have several positive effects on central nervous system function. Perhaps the most important is the promotion of acetylcholine synthesis and increased synaptogenesis in the hippocampus. ER β is expressed in this area of the brain, as well as the entorhinal cortex and thalamus, areas crucially involved in explicit memory. Human neuroimaging studies have also indicated that oestrogen influences regional cerebral blood flow in women. In addition, oestrogens may exert neuroprotective actions against excitotoxic neuronal injury by enhancing glutamate transporter levels and their function.

Management

Hormone replacement therapy

Hormone replacement therapy (HRT) is a complicated clinical issue requiring an in-depth risk/benefit assessment. The vast amount of study data is often conflicting, and careful analysis is required. Many factors need to be reviewed before HRT is prescribed. One important factor is age; data have shown that if a woman aged less than 35 has a hysterectomy and a bilateral oophorectomy, her risk of non-fatal myocardial infarction is nearly eight times that of her age-matched counterpart who has retained her ovaries. Age at time of HRT prescription in relation to menopausal age, that is, number of years of oestrogen deprivation before replacement, is also of importance when considering outcomes, and this 'window' for replacing oestrogen is currently subject to close scientific scrutiny. Individual differences in hormone metabolism (both endogenous and exogenous) are also likely to be important because several different cytochrome enzymes metabolise oestrogen and may be affected by inherited polymorphisms. Therefore, some women may produce oestrogenic metabolites possessing considerable oestrogenic activity, whereas others produce metabolites that are relatively non-oestrogenic. Body mass index (BMI) also influences response to HRT, with increased plasma estradiol levels observed in women with higher BMIs.

HRT is effective for symptomatic relief of menopausal symptoms, and its use is justified when symptoms adversely affect quality of life. The publication of major trials, such as the Women's Health Initiative in the USA ([Women's Health Initiative, 2002](#)) and the Million Women Study in the UK ([Million Women Study Collaborators, 2003](#)) and the interpretation of their findings had a dramatic impact on HRT prescribing. However, the publication of the NICE guidelines in November 2015 may have begun to reverse this. The information in the [Box 47.1](#) is taken from these guidelines.

Contraindications to the use of HRT include undiagnosed vaginal bleeding in post-menopausal women, the presence of an oestrogen-dependent tumour, liver disease (where liver function tests have failed to return to normal), active thrombophlebitis and active or recent arterial thromboembolic disease, for example, angina or myocardial infarction. A history of deep vein thrombosis and pulmonary embolism requires careful evaluation before the use of oestrogen therapy. Use in patients with Dubin–Johnson and Rotor syndromes may also be contraindicated.

Oestrogen therapy

Because the symptoms and long-term effects of menopause are due to oestrogen deprivation, the mainstay of HRT is oestrogen. This may be administered orally or parenterally, but in either case, the oestrogens used are naturally occurring and include the following:

- estradiol,
- estriol,
- estrone,
- estropipate (piperazine estrone sulphate),
- conjugated equine oestrogen (estrone sulphate 40%, equilin sulphate 60%),
- estradiol valerate.

Box 47.1 The importance of patient information

- It is important for healthcare professionals to provide up-to-date, objective and accurate information on the benefits and risks for HRT to help women make an informed choice about which treatment to use for menopausal symptoms. Media reports about HRT have not always been accurate, so providing healthcare professionals and women with a robust source of information is vital.
- Although the Women's Health Initiative found that HRT prevented osteoporotic fractures and colon cancer, it initially reported that HRT increased the risk of having a cardiovascular event as well as the incidence of breast cancer. However, the association between HRT and cardiovascular disease has since been disputed, and the results show that the risk varies in accordance with individual factors.
- HRT dosage, regimen and duration of use should be individualised with yearly appraisals. The [NICE \(2015\)](#) guidelines and consensus statements published by the [British Menopause Society \(2016\)](#) and the International Menopause Society ([de Villier et al., 2016](#)) should be used by primary care doctors and other healthcare professionals to enable them to be more confident in prescribing HRT and women more confident in taking it.
- A knowledge gap among some primary care and other healthcare professionals could mean that they are reluctant to prescribe HRT because they overestimate the risks and contraindications and underestimate the impact of menopausal symptoms on a woman's quality of life.

HRT, Hormone replacement therapy.

The use of 'natural' oestrogens reduces the risk of the potentially dangerous oestrogenic effects such as raised blood pressure, alteration in coagulation factors and an undesirable lipid profile, which sometimes occur with the more potent synthetic oestrogens used in the oral contraceptive agents. A 'natural' oestrogen is defined as one that is normally found in the human female and has a physiological effect. Natural oestrogens are less potent (up to 200 times) than synthetic oestrogens. Because they are naturally occurring compounds, the plasma half-life of these oestrogens is similar to that of the ovarian-secreted oestrogens, and the duration of action is shorter than that of the synthetic oestrogens, such as ethinylestradiol, used in many formulations of the contraceptive pill. The plasma ratio of estradiol to estrone is normally about 1:1 to 2:1, and the aim of HRT should be to preserve this ratio.

There are four main routes of administration for oestrogens in HRT:

- oral,
- transdermal (patches/gels/cream),
- subcutaneous (implants),
- vaginal (creams and medicated rings).

The use of oral oestrogen therapy, although convenient for the patient, does mean that the oestrogen will be subjected to conversion to estrone by the liver and the gut, thereby altering the estradiol/estrone ratio in favour of the less active oestrogen, estrone. The oral preparations have different metabolic effects due to first-pass hepatic metabolism. Smoking stimulates metabolism of oestrogens by cytochrome P450 and decreases plasma oestrogen levels by 40–70% in oral oestrogen users. Smoking has no significant effect on plasma oestrogen levels in users of

Table 47.2 Effect of hormone replacement therapy administration route on lipid profile

Oral	Transdermal
↓ Low-density lipoprotein	↓ Low-density lipoprotein
↓ Total cholesterol	↓ Total cholesterol
↑ High-density lipoprotein	↔ High-density lipoprotein
↑ Triglycerides	↓ Triglycerides
↑ Bile cholesterol	↔ Bile cholesterol

transdermal preparations. Oral delivery compared with transdermal delivery (Table 47.2) also has different effects on lipid levels (Vrablik et al., 2008). In addition, orally administered oestrogens undergo first-pass hepatic metabolism, which may result in some reduction in anti-thrombin III, a potent inhibitor of coagulation. Implants and patches show smaller changes in coagulation, platelet function or fibrinolysis.

More constant levels of oestrogen result from the use of transdermal patches containing estradiol, and these have the added advantage of a more physiological estradiol/estrone ratio (Delmas et al., 1999). However, the adhesive used in these transdermal patches and the alcohol base can cause skin irritation. The patch is applied to the non-hairy skin of the lower body, and care should be taken to ensure that it is placed away from breast tissue. The patch is changed either once or twice a week, thus providing a constant reservoir of estradiol to provide a controlled release into the circulation. Estradiol is also available in a gel formulation, applied daily to the skin over the area of a template (to ensure correct dosage), but this formulation may give erratic absorption. The intranasal preparation, administered as a nasal spray, also avoids hepatic first-pass metabolism.

The oestrogen implant gives a constant level of oestrogen from a few days after insertion for up to 6 months. This formulation maintains the best estradiol/estrone ratio and is a convenient method of administration, requiring repeat implants only every 6 months. However, because the levels of oestrogen are constantly raised, there will be some increase in oestrogen receptor numbers, and this can lead to a recurrence of symptoms of oestrogen deficiency due to the presence of unoccupied oestrogen receptors, even in the presence of normal or even high oestrogen levels. This phenomenon, called tachyphylaxis, results in patients becoming symptomatic and requesting repeat implants earlier and earlier. In such cases, it is unwise to treat with additional oestrogen; the patient should receive counseling and perhaps a change of preparation. The disadvantage of the implant is that, once inserted, it cannot be removed readily, and even if it is removed, the oestrogen level will take at least a month to fall. There is also evidence that the uterine endometrium, if present, remains stimulated for some time after removal of the implant.

Both the transdermal and implant preparations avoid the first-pass hepatic effects of oral oestrogens and are less likely to affect liver enzyme systems and clotting factors. Some studies show an

increase in the incidence of venous thromboembolism (VTE) in women taking HRT. Therefore, patients who have a history of deep vein thrombosis (DVT) or pulmonary embolism will need careful guidance, with each woman being considered individually, and the relative risks evaluated. Other risk factors include severe varicose veins, obesity or a family history of DVT. If HRT is justified in such patients, transdermal preparations are a better alternative than oral preparations.

Vaginal creams containing oestrogen are available but generally fail to produce the reliable plasma levels required to protect against the long-term effects of oestrogen deprivation. They can be used to provide relief from atrophic vaginitis. An alternative formulation is the vaginal ring, which releases estradiol at a controlled rate in physiological levels for up to 3 months.

The dose of oestrogen used in HRT sufficient to preserve bone density is usually higher than that necessary to alleviate vasomotor symptoms. The doses suggested to protect bone density are estradiol 2 mg/day orally, 50 micrograms/day transdermally and 50 mg every 6 months by implant. If the conjugated equine oestrogens are used, the oral dose should be 0.625 mg/day. The lower doses found in vaginal creams may alleviate the vasomotor symptoms but will not protect against osteoporosis. Current guidelines advise the use of the lowest possible dose of HRT to relieve vasomotor symptoms and recommend alternative treatment to prevent and treat osteoporosis (NICE, 2015).

Oestrogens should be used alone only in women who have undergone a hysterectomy; if the uterus is present, the endometrium will be stimulated, and this increase in endometrial growth may be a precursor to the development of a malignant condition. Current practice is to administer progestogens with oestrogen. In the early 1970s, when oestrogen was used alone, HRT received bad press because in women who had not undergone hysterectomy, there was an increased incidence of endometrial carcinoma. In women who have undergone hysterectomy, oestrogens are usually administered continuously.

Progestogen therapy

The only proven reason for adding a progestogen to oestrogen therapy for HRT in women with an intact uterus is to protect the endometrium from hyperplasia and possible neoplasia. There are many preparations that contain progestogens added to oestrogen for a number of days per month. However, to effectively prevent endometrial hyperplasia, the progestogen must be taken for a minimum of 12 days. The minimum dose of progestogen required to protect against hyperplasia depends on the potency of the compound used.

The progestogens commonly available in HRT preparations are either derivatives of progesterone, such as medroxyprogesterone and dydrogesterone, or 19-nortestosterone substitutes such as norethisterone or levonorgestrel. All these synthetic progestogens are active after oral administration and provide adequate protection of the endometrium against oestrogen stimulation. Some transdermal preparations also incorporate a progestogenic compound in the regimen. As with all semi-synthetic or synthetic hormones, these compounds may act on receptors other than the progesterone receptor, and the long-term consequence of this is not predictable.

Box 47.2 Regimens of combined oestrogen and progestogen therapy for use in hormone replacement therapy

- Oestrogen 28 days + progestogen 12 or 14 days, then repeat without interval (bleed every 4 weeks)
- Oestrogen 70 days + progestogen 14 days followed by 7 days placebo tablets (bleed every 3 months)
- Oestrogen + progesterone continuously (no bleed)
- Oestrogen continuously + Mirena IUS (bleed variable, but levonorgestrel likely to reduce bleed and can provoke amenorrhoea)

Progesterone is the only progestogen to act solely on the progesterone receptor, but it has poor oral bioavailability, and so it is difficult to achieve satisfactory plasma concentrations. However, the micronised preparations are better absorbed. Progesterone may also be administered at night in the form of a pessary or suppository, or by injection in the form of a long-lasting subdermal implant. The progestogen in HRT is most commonly administered orally or transdermally, and usually, one of the synthetic progestogens is used.

Oestrogen and progestogen regimens

The monthly withdrawal bleed is perceived by some post-menopausal patients to be an unacceptable side effect of HRT, and this has resulted in the development of a number of regimens in an effort to minimise this effect (Box 47.2). Formulations have been produced with which bleeding only occurs every 3 months instead of every 4 weeks, or it does not occur at all.

The use of the 70-day oestrogen preparation, although being more popular with women because bleeding only occurs every 3 months, needs further evaluation regarding endometrial protection. Bleeding can be avoided altogether if a combination of oestrogen and progestogen is given continuously throughout the treatment (continuous combined HRT). Such a preparation should only be given to women who are at least 12 months post-menopausal and have an atrophied endometrium; otherwise, breakthrough bleeding may occur. Bleeding in the first 6 months (usually just spotting) is not uncommon, but bleeding after this time should be investigated, although the incidence of endometrial hyperplasia is low with this continuous regimen. Others recommend a 28-day interval between courses of treatment to allow the endometrium to become atrophic in patients who are changing from the cyclical therapy to the continuous combined therapy. Patients who commence cyclical HRT before ceasing menstruation should change to a continuous combined preparation only after the age of 54 (when there is an 80% chance that they will be post- rather than perimenopausal) to reduce the risk of breakthrough bleeding. An alternative option is to use the levonorgestrel-loaded intra-uterine system (IUS; e.g. Mirena) in conjunction with oral oestrogen. This option can be particularly useful for women intolerant of the progestogenic side effects associated with systemic dosing.

Not all progestogens have the same pharmacological profile, and these differences have implications for their usage. Two

of the most widely used synthetic progestogens are medroxyprogesterone acetate and norethisterone. These are used as the progestogenic component of an HRT regimen in combination with oestrogen but have been shown to increase the risk of breast cancer in long-term HRT users (Women's Health Initiative, 2002; Million Women Study Collaborators, 2003). Structurally, medroxyprogesterone acetate is more similar to natural progesterone than norethisterone. The metabolism of these two compounds is also different; medroxyprogesterone acetate is the major progestogenic compound rather than one of its metabolites. In contrast, the metabolites of norethisterone exhibit significant activity in addition to a wide range of non-progestogenic actions. Norethisterone also binds to sex hormone-binding globulin, whereas medroxyprogesterone acetate does not.

The most notable difference in steroid receptor-binding affinity between the two synthetic progestogens and endogenous progesterone is that although all the compounds have an affinity for the mineralocorticoid receptor, only the natural compound has antagonist activity. As a consequence, the synthetic compounds may be unable to counteract the sodium-retaining and blood pressure-raising effects of the oestrogens used in HRT. Endogenous progesterone affinity for the glucocorticoid receptor is also different, with medroxyprogesterone acetate a more potent antagonist than norethisterone. This may influence their side-effect profiles and impact on inflammation, immune response, adrenal function and bone metabolism.

Tibolone

Tibolone is a synthetic steroid that has oestrogenic, progestogenic and androgenic effects that alleviate menopausal symptoms without a monthly bleed. The oestrogenic effects are weak and should not promote endometrial hyperplasia, but 10–15% of women on this treatment experience breakthrough bleeding. The drug is given continuously but is not suitable for women within 1 year of menopause or immediately after oestrogen therapy because in such cases, breakthrough bleeding is most likely to occur. The evidence suggests that this drug is protective against osteoporosis, but the long-term cardioprotective effects have been debated because there is some evidence of a lowering of HDL-C and thickening of the intima-media in the carotid arteries; however, an epidemiological study (Savolainen-Peltonen et al., 2016) showed reductions in coronary heart disease (CHD) mortality risk if therapy was initiated before 60 years of age. It should also be withdrawn if signs of thromboembolic disease occur. The androgenic action of tibolone tends to increase libido. It has been reported that tibolone does have fewer breast-related adverse effects than oestrogenic or oestrogenic-progestogenic HRT regimens.

Raloxifene

Raloxifene is a non-steroidal benzothiophene that binds to some oestrogen receptors and belongs to a class of drugs referred to as selective oestrogen receptor modulators (SERMs). These compounds act selectively on some oestrogen receptors to increase bone mineral density and antagonise oestrogen-dependent effects

on breast and endometrial tissues in post-menopausal women. However, there is a reported increased risk of thromboembolism, particularly in the first 4 months of use. Raloxifene cannot be used to treat vasomotor symptoms in peri-menopausal women. In fact, it is reported to induce hot flushes. It has little or no stimulatory effect on the uterine endometrium and is not associated with uterine bleeding.

In summary, raloxifene is a compound that selectively stimulates one group of oestrogen receptors and may be considered a curative treatment for osteoporosis and a preventive agent in the development of oestrogen-dependent breast tumours.

Clinical monitoring

Before initiating HRT, a detailed patient history and physical examination are essential to eliminate medical disorders and genital malignancy. Bone mineral densitometry can also be helpful to establish a baseline for subsequent measurements. Blood tests should include serum electrolytes and creatinine, liver function tests, haemoglobin, lipids and a full blood count. Urine analysis should also be performed. The history and findings from the physical examination may indicate other tests. The patient should have undergone routine cervical smear examination and, preferably, mammography. In women with an intact uterus, any irregular vaginal bleeding should be investigated to exclude endometrial pathology.

After starting therapy, the woman should be seen within 3 months in the first instance and then at intervals between 6 and 12 months so that symptoms may be assessed and any side effects of therapy can be reported. Blood pressure measurements are undertaken on these routine visits; HRT is usually associated with a fall in blood pressure due to a vasodilator action of oestrogen. Hypertension is not a contraindication to treatment with HRT but does need treatment before starting on oestrogen therapy. Some women may have an elevated blood pressure on oral oestrogen but show no such effect with the non-oral route. Weight gain may occur some months after treatment has been initiated, and the patient should be advised to reduce calorie intake accordingly.

Stopping HRT

Guidelines in the British National Formulary ([Joint Formulary Committee, 2016](#)) indicate that there are a number of signs and symptoms suggesting that women should be advised to immediately stop taking HRT, and these include:

- sudden severe chest pain;
- sudden breathlessness or cough with blood-stained sputum;
- unexplained severe pain in calf of one leg;
- severe stomach pain;
- serious neurological effects;
- hepatitis, jaundice, liver enlargement;
- blood pressure above systolic 160 mmHg and diastolic 100 mmHg;
- detection of a risk factor, for example, prolonged immobility after surgery or leg injury.

Once HRT has been stopped, investigation and treatment should be undertaken as appropriate.

Examples of serious neurological effects include unusual severe, prolonged headache. This is especially important if the headache occurs for the first time or it becomes progressively worse. Marked numbness, especially if it suddenly affects one side or part of the body, is important to note. Other neurological effects are sudden partial or complete loss of vision or disturbance of hearing or other perceptual disorders. HRT should also be stopped if the following occur: dysphasia, bad fainting attack or collapse, a first unexplained epileptic seizure/weakness and motor disturbances.

For women who have elected to stop HRT, gradually reducing the dosage may limit recurrence of symptoms in the short-term.

Treatment with hormone replacement therapy

Vasomotor symptoms

Vasomotor symptoms include hot flushes, headaches, insomnia, giddiness and faintness. They occur in about 70–80% of women and result in physical distress in about 50%, lasting for up to 5 years in around one-quarter of the affected women. Flushes and sweats, particularly night sweats, indicate vasomotor instability and probably result from unoccupied oestrogen receptors on blood vessels. Oestrogens cause a rapid rise in blood flow through the blood vessels, and lack of oestrogen will render the oestrogen receptors in these vessels supersensitive to any subsequent rise in oestrogen level. During the peri-menopause and menopause, oestrogen levels tend to fluctuate, and it is suggested that it is these fluctuations that result in vasomotor symptoms. The extreme sensitivity of blood vessel oestrogen receptors tends to mean that a clinical response to vasomotor symptoms is achieved with low doses of oestrogen. There is also likely to be central control via a supra-pituitary mechanism incorporating several chemical pathways involving serotonin, noradrenaline and dopamine. General advice regarding diet, for example, avoiding certain foods and drinks that cause vasodilation, such as hot and spicy foods and alcohol, may be helpful to some women. There is some evidence that regular exercise, which stimulates the production of hypothalamic β -endorphins, may reduce the risk of hot flushes.

Urogenital tract

In the urogenital tract, symptoms include:

- vaginal dryness and dyspareunia;
- vaginal discharge and bleeding;
- urinary incontinence, urgency of micturition and/or recurrent symptoms of cystitis.

Symptoms result from oestrogen deficiency in menopausal women and may be treated either with systemic HRT preparations or with topical applications of oestrogen incorporated into vaginal creams, pessaries and silicone vaginal rings. Such topical routes of administration do result in some systemic absorption of oestrogen through the vaginal mucosa, and because this may be erratic, vasomotor symptoms could ensue. Exogenous oestrogen stimulates blood flow and epithelial thickening and decreases vaginal pH. These changes result in patients reporting

less dyspareunia, as well as less irritation and itching. The dose of oestrogen required to stimulate the oestrogen receptors in the vagina and the lower urethra is about 10 micrograms/day, and the efficiency of such low doses has been demonstrated in a number of clinical trials. Local administration is effective in relieving both short- and long-term problems associated with vaginal atrophy, but symptoms will return on cessation of treatment, and women should be told to report any unexpected vaginal bleeding. However, low-dose local administration is safe and has now been assessed as carrying no increased risk of endometrial hyperplasia, so there is no need to add in a progestogenic agent or perform routine endometrial surveillance. The effect of oestrogen on vaginal symptoms is more marked than its effect on urinary symptoms, but the incidence of urinary sensory dysfunction may be improved.

Ospemifene is a selective oestrogen receptor modulator that appears to have oestrogen agonist or antagonist (a partial agonist) effects depending on tissue type. It is used in the treatment of dyspareunia, a symptom of vulvar and vaginal atrophy, due to menopause. The usual oral dose is 60 mg daily with food (approved by the U.S. Food and Drug Administration [FDA], and now licensed in the UK and EU but not yet launched). It is also under investigation in the management of postmenopausal osteoporosis.

Bone

In a woman not treated with HRT, approximately 15% of bone mass is lost within 10 years of menopause, resulting in an increased incidence of fracture, typically of the hip. Such fractures take up at least 10% of orthopaedic beds, and the total cost in terms of morbidity and mortality is high. The effect of oestrogen lack is to increase osteoclastic bone resorption. There is an overall increase in bone turnover, more bone is resorbed than replaced and there is an associated increase in the rate of bone loss, which may continue for 5–10 years. Oestrogens may exert effects on bone through the calcium-regulating hormones such as calcitonin and parathyroid-regulating hormones. Evidence also exists for the effect of oestrogens on the local production of bone growth factors, cytokines, in particular osteoprotegerin, which blocks osteoclastogenesis, and prostaglandin E₂.

The greatest effect of oestrogen on bone is seen with implants, where an approximately 8% increase in vertebral bone density is seen within 1 year of treatment. Estradiol patches are the next most effective route of administration (Fig. 47.1), whereas oral therapy only achieves an increase in bone density of about 2% per annum. However, 5 years of oral oestrogen therapy will still achieve a lifetime reduction in femoral neck fracture of as much as 50%.

Oestrogen improves the quality and quantity of bone in the post-menopausal woman. It may be started at any time after menopause, and the benefit will continue for the duration of treatment. Therefore, HRT does significantly decrease the risk of fragility fracture, and although protection does decrease when treatment is stopped, it may persist for longer if HRT was used for longer. Raloxifene is licensed for the prevention and treatment of osteoporosis as an alternative to HRT. Raloxifene reduces bone loss and increases bone density at the spine and hip

Fig. 47.1 Percentage of change from baseline (mean \pm SEM) in lumbar spine bone mineral density in patients receiving placebo (open circles) or transdermal 17 β -estradiol 50 micrograms/day (filled circles), 75 micrograms/day (squares) or 100 micrograms/day (filled triangles). (From Delmas et al., 1999.)

in post-menopausal women. With its oestrogen antagonist effect on the breast and endometrium, raloxifene may prove to be an advance over oestrogen treatment in osteoporosis prevention and treatment in post-menopausal women. It does, however, cause hot flushes, which may be unacceptable for some.

Musculoskeletal system

A good body of evidence supports that the decline in muscle mass may be in line with the decrease in oestrogen that characterises the menopausal years. A decrease in muscle strength can play a detrimental role in physical function impairments, such as recovery after imbalance (which in turn could contribute to falls and so fractures). Oestrogen has an anabolic effect on muscle by the stimulation of IGF-1 receptors. The mechanism of this interaction is likely to be complex and could involve gene expression, which is controlled by epigenetic factors, such as DNA methylation, and it is plausible that at least part of the HRT effect is due to changes in the DNA methylation profile. More studies and trials are required to establish a formal relationship, but clinical experience suggests that musculoskeletal symptoms may be improved by HRT.

Cardiovascular system

Coronary heart disease

Women at 45 years are significantly less likely than men to die of coronary heart disease, but by the age of 60 years, the death rate from the disease is similar in both sexes. Oestrogen is probably central to this gender difference because women who experience early loss of endogenous estradiol have an accelerated risk of developing coronary heart disease. Intuitively, it would appear logical that post-menopausal women would gain benefit from receiving exogenous oestrogen. However, there are conflicting views as to whether this is, or is not, the case. Numerous trials have yielded conflicting results and debate around the routes of administration and actual hormone regimens used (particularly

Table 47.3 Estimated impact of hormone replacement therapy formulations and difference in number of breast cancers (per 1000 menopausal women older than 7.5 years, where baseline risk is 22.48 per 1000) using estimations based on randomised control trials or observation

	Current HRT users	Used for more than 5 years	Used for 5 to 10 years	More than 5 years since cessation of HRT
Oestrogen only (RCT)	4 less	No data	No data	5 fewer
Oestrogen only (O)	6 more	4 more	5 more	5 fewer
Combined HRT (RCT)	5 more	No data	No data	8 more
Combined HRT (O)	17 more	12 more	21 more	9 fewer

HRT, Hormone replacement therapy; O, observation; RCT, randomised control trials.
Adapted from [NICE \(2015\)](#).

with respect to the progestogenic component and the androgenicity of this component). The 2015 NICE guidance stressed that all healthcare professionals involved in the care of menopausal women should understand the following:

- HRT does not increase cardiovascular disease risk when started in women aged younger than 60 years.
- HRT does not affect the risk of dying from cardiovascular disease.
- The baseline risk of coronary heart disease and stroke for women around menopausal age varies from one woman to another according to the presence of cardiovascular risk factors.
- HRT with oestrogen alone is associated with no, or reduced, risk of coronary heart disease.
- HRT with oestrogen and progestogen is associated with little or no increase in the risk of coronary heart disease.

Since the [NICE \(2015\)](#) guidance, a large scale (498,105 women with 3.7 million exposure years) epidemiological study focused on the currently popular ‘window of opportunity hypothesis’ and found that the earlier (<60 years) estradiol-based replacement therapies were started, then the larger the risk reduction of CHD mortality risk; interestingly, the type of progestin (synthetic progestogen) used did not modify the timing effect ([Savolainen-Peltonen et al., 2016](#)). It was concluded that timing was important, but the results could not support the window of when or when not to initiate HRT because an increased cardiac mortality risk was not detected when therapy was started in women older than 60 years. Routes of HRT administration are also likely to influence risk factors because transdermal preparations avoid first-pass metabolism. Linked to cardiovascular health, one study found that transdermal but not oral oestrogen replacement therapy significantly reduced the atherogenic index of plasma ([Vrablik et al., 2008](#)). This occurred by increasing HDL particle size and therefore improving the antiatherogenic properties.

Venous thromboembolism

It is known that the oestrogen in the combined oral contraceptive pill contributes to thromboembolic disorders, but the dose of oestrogen found in HRT is much lower and more physiological than that in the oral contraceptive pill. All the trials and studies

that took into account route of administration of HRT agreed that any increase in risk is attenuated or even obviated with transdermal therapy. Oral oestrogen, in contrast to the transdermal route, undergoes extensive first-pass metabolism. This increases the production of prothrombotic factors in the liver and is associated with a reduction in fibrinogen and factor VII activation, such as von Willebrand’s factor and anti-thrombin, and enhanced fibrinolysis. HRT is also associated with increased resistance to activated protein C. Risk disappears after cessation of HRT use. If a woman has had a VTE or has a known thrombophilia such as factor V Leiden mutation, she may still be suitable for HRT but should be referred to a haematologist before commencing therapy.

The SERMs, such as raloxifene, are considered to carry the same risk of thrombosis as oestrogen-containing HRT.

Overall, minimising cardiovascular risk whilst obtaining the benefits of HRT is influenced by the age, body mass index, cardiovascular health and menopausal history of the woman being treated; the timing of initiation of HRT; the formulation of the product used; and polymorphism. Going forward, a better understanding of the non-genomic actions of oestrogen should facilitate the optimisation of therapy by, for example, selectively modulating cardiac non-genomic oestrogen receptor signalling ([Knowlton and Korzick, 2014](#)).

Cancer

Details of the estimated influence of HRT on the incidence of cancer are presented in [Table 47.3](#).

Colorectal cancer

Colorectal cancers tend to occur in women older than 50 years, and several studies have indicated that HRT transdermal oestrogen-only therapy may offer more protection than oral, and the benefit appears to be more pronounced with long-term use. The exact mechanism for this protective effect on the colon is unclear, although it has been suggested that oestrogen may decrease the formation of potentially carcinogenic bile acids.

Ovarian cancer

The risk of ovarian cancer is known to be influenced by hormonal events such as the age at menarche and menopause and parity use of exogenous hormones (oral contraceptives and HRT), with a reduced incidence consistently reported in users of oral contraceptives.

A meta-analysis found that risk of ovarian cancer, particularly of the two most common forms, serous and endometrioid tumours, was increased by HRT ([Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2015](#)). For example, in women aged 50 who took HRT for 5 years, there was one extra case per 1000 users. This analysis did not take into account formulations or delivery methods. However, a survival benefit relating to epithelial ovarian cancer, particularly in long-term users, has recently been reported in the European Prospective Investigation into Cancer and Nutrition (EPIC) study ([Besevic et al., 2015](#)).

Endometrial cancer

Unopposed oestrogen therapy at least doubles the risk of endometrial cancer, but the addition of a progestogen, either in continuous combined or sequential regimens, reduces this risk. Of the two regimens, continuous combined administration is more effective than sequential therapy in reducing the risk of endometrial hyperplasia.

Breast cancer

Breast cancer is the most common cancer in women worldwide, and globally, it is the principal cause of cancer death among women. Over the past 20 years, there has been a growing body of evidence to suggest that progesterone contributes to the development of breast cancer. Evidence to support this came from trials in which the use of combined regimens increased breast cancer risk more than oestrogen alone. This is thought to have occurred because the synthetic progestogens possessed some non-progesterone-like effects that potentiated the proliferating action of oestrogen. In the USA, the most commonly used progestogen in HRT is medroxyprogesterone acetate combined with conjugated equine oestrogen and administered orally. In contrast, in Central and Southern Europe, a wider range of progestogens is used, particularly the 19-nortestosterone derivatives. Studies investigating the use of natural micronised progesterone to improve bioavailability in HRT regimens have demonstrated no increased risk of breast cancer. In vitro studies with medroxyprogesterone have found that it promotes the reproductive transformation of estrone into estradiol by influencing the activity of 17 β -hydroxysteroid dehydrogenase. The properties of the synthetic progestogens are outlined in [Table 47.4](#).

The relationship between different HRT regimens and breast cancer is complex ([Table 47.4](#)). There are many potential confounders to be considered when interpreting trial data, for example, time of initiation of therapy in relation to menopausal status, body mass index and prior hormone use, among others. [Chlebowski et al. \(2009\)](#) reported on the decline in breast cancer in the USA after a reduction in HRT usage following publication of the 2002 WHI trial. This prompted a response from the president of the International Menopause Society ([Sturdee, 2009](#)), summarised as follows: Decline in breast cancer rates started at

Table 47.4 Properties of progestogens and their link to breast cancer

Progestogen	Action
19-Nortestosterone derivatives, medroxyprogesterone acetate	Oestrogenic activity Influence on 17 β -hydroxysteroid dehydrogenase
19-Nortestosterone derivatives, medroxyprogesterone acetate	Metabolic effects, opposing those of oestrogen, on insulin sensitivity Hepatic effects, opposing those of oestrogen, i.e. increasing insulin-like growth factor-1; decrease in sex hormone-binding globulin
19-Nortestosterone derivatives	Binding to sex hormone-binding globulin with consequent reduction in capacity to bind oestrogen

Adapted from [Campagnoli et al. \(2005\)](#).

least 3 years before the WHI study was halted (which led to a dramatic drop in HRT use). This implies that decline in breast cancer rates must be independent of the reduction in HRT use.

Breast cancer takes years to develop and at least a decade to reach the detectable stage. If HRT use causes breast cancer, then the drop in breast cancer rates would not be seen for some time. The drop in breast cancer rates could be due to other factors, for example, changes in screening.

Notwithstanding these arguments, the problem on what to advise women contemplating HRT can be problematic, and the [NICE \(2015\)](#) guidance states the following:

- The baseline risk of breast cancer for women around menopausal age varies from one woman to another according to the presence of underlying risk factors.
- HRT with oestrogen alone is associated with little or no change in the risk of breast cancer.
- HRT with oestrogen and progestogen can be associated with an increase in the risk of breast cancer.
- Any increase in the risk of breast cancer is related to treatment duration and reduces after stopping HRT.

Psychological symptoms

Psychological symptoms include:

- depression;
- mood changes and irritability, which may also be associated with other life changes occurring at this time;
- exhaustion;
- poor concentration and memory;
- panic attacks;
- lowered libido, which may be exacerbated by the other symptoms together with dyspareunia linked to lack of oestrogen and falling androgen levels.

The role of HRT in this area has not been clearly defined, although in several studies, surgical menopause has been associated with depression, indicating a correlation with oestrogen lack. Many women experience psychological symptoms around menopause,

and although these may be associated with oestrogen deficiency, they may also result from the changes in family life that often occur around this time. The disturbance of sleep pattern and sleep deprivation associated with menopause are likely to contribute to the psychological symptoms. Many women find that treatment with estradiol restores normal sleep, and psychological problems are then reduced. Some of the mood changes will respond to counselling and psychotropic drugs. Treatment with oestrogens at high doses (patches of 100 micrograms or implants of 50 mg) has also been shown to improve depression scores. If a progestogen is added to the regimen, then the results are less predictable because progestogen use is related to mood changes, particularly in women who have previously suffered from the pre-menstrual syndrome. Age negatively influences almost all sexual function domains in a significant manner.

HRT improves some aspects of sexual function during menopause, but it does not appear to improve the domains of desire and arousal. The lowered libido experienced during menopause is associated with reduced levels of circulating androgen resulting from ovarian failure. It has been demonstrated that subcutaneous implants of testosterone, 100 mg every 6 months, will increase the libido in a high proportion of patients, but implants are no longer available in the UK (withdrawn on the grounds of a lack of global profitability). Topical testosterone could be used, but it would be an off-label usage.

Central nervous system

The relationship between oestrogen and neurodegenerative conditions, in particular, Alzheimer's disease (Mulnard et al., 2000), has received attention in the light of an observation that there is an increased incidence of the disease in older women. The development of plaques of amyloid- β , a protein that disrupts nerve cell connections in the brain, occurs more rapidly in the absence of oestrogen. This effect of amyloid- β production results in the symptoms of short-term memory loss and disorientation that occur in Alzheimer's disease (AD). Further studies are essential to clarify the relationship between HRT and Alzheimer's disease. There is some evidence that heavier women, who have higher free estradiol levels, exhibit better cognitive function in several domains. Such women may also have a greater clinical response when using exogenous oestrogen. It should also be noted that conjugated equine oestrogen is composed primarily of oestrone sulphate, and this oestrogen has a much lower affinity for oestrogen receptors than oestradiol. Hence, the findings with respect to exogenous oestrogen and neurological function remain equivocal. The length of oestrogen deprivation before supplementation is also important because early administration of oestrogen for a period of several years may yet be found to be beneficial. Evidence is emerging that the progestogenic component in combined HRT is important, and medroxyprogesterone acetate usage has been associated with negative cognitive outcomes. The potential of SERMs as neuroprotectants has been evaluated in a breast cancer prevention trial which compared tamoxifen with raloxifene (Yaffe et al., 2001). Both agents were found to have similar effects on cognition. Work is also ongoing to develop the so-called neuro-SERMs, designed to provide the neurological benefits of estradiol. It is possible that HRT may

have a neuroprotective effect under certain circumstances in some women, and neuroimaging, for example, using Pittsburgh compound B (PiB; a fluorescent agent) positron emission tomography (PET) scanning, may reveal effects not detectable using cognitive testing. A recent trial using this technique has shown that transdermal 17 β -estradiol (used for 4 years) resulted in lower amyloid- β deposition, and this was not seen in women using oral conjugated equine oestrogens. Interpreting trial data has been difficult in this area because it is difficult to control for situational effects such as pre-existing pathologies and genetic polymorphisms (Kantarci et al., 2016).

Alternatives to hormone replacement therapy

HRT (particularly transdermal) remains the most effective treatment for vasomotor symptoms, resulting in 80–90% reduction in hot flushes. Of the non-hormonal agents, serotonin–norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine and its active metabolite desvenlafaxine appear to be useful treatments; clonidine is modestly effective in reducing hot flushes, but these agents are not considered as first-line therapies. In addition, there is limited evidence to support the use of selective serotonin reuptake inhibitors (SSRIs) for anxiety, and they do not appear to improve mood in women who are not clinically depressed. Cognitive behavioral therapy (CBT) may improve mood. CBT, isoflavones and black cohosh may help decrease anxiety. Generally, there is a lack of safety information and high-quality trial data regarding alternative therapies. The same is also true of Chinese medicines. Trials with black cohosh, red clover and soy foods, all of which contain phytoestrogens, have yielded conflicting results and have raised concerns about hepatotoxicity (black cohosh) and interactions with anticoagulants (red clover). An umbrella review by Goldstein et al. (2016) is under way to consider nonpharmacologic management of vasomotor symptoms.

Bisphosphonates such as alendronate, etidronate and risedronate are inhibitors of bone resorption and increase bone mineral density by altering osteoclast activation and function. Bisphosphonates are used with care in women with upper gastro-intestinal problems, and their posology is complex. They are contraindicated in patients with hypocalcaemia. Etidronate is also contraindicated in patients with severe renal impairment. For further information, see NICE technology appraisal guidance TA160, which was updated in 2011 (NICE, 2011). This guidance also includes strontium ranelate, which should only be used for severe osteoporosis because it carries a risk of serious cardiovascular side effects.

Teriparatide, a recombinant human parathyroid hormone, is licensed to treat osteoporosis in post-menopausal women. It stimulates formation of new bone and may increase resistance to fracture. However, it has several contraindications, including hypercalcaemia, severe renal impairment, metabolic bone diseases and unexplained elevations of alkaline phosphatase.

Advances in bone biology may lead to the design of more elegant therapies to deal with osteoporosis. An example would be denosumab, a human monoclonal antibody that binds to the receptor activator of nuclear factor- κ B ligand (RANKL), which is

responsible for osteoclast differentiation, activation and survival. Denosumab therefore mimics the function of osteoprotegerin, limiting bone resorption, and is currently used to treat osteoporosis and in the prevention of skeletal-related events in patients suffering from bone metastases due to solid tumours. However, preclinical experiments suggest that the RANKL/RANK pathway plays an important role in primary breast cancer development. Therefore, manipulation of the RANK/RANKL system could serve as a potential target for prevention and treatment of breast cancer.

Some small studies have shown that aerobic exercise can improve cardiovascular parameters and reduce menopausal symptoms in addition to reducing BMI.

Case studies

Case 47.1

A 50-year-old patient, Mrs GY, has been on cyclical combined hormone replacement therapy for 6 months for troublesome hot flushes. Her periods were irregular before starting HRT. The hot flushes have resolved with this treatment, and the withdrawal bleeds are acceptable, but Mrs GY is struggling with the progestogenic side effects. A friend has told her to ask for the 'no-bleed' HRT because she thought this might suit her better.

Questions

1. What is the problem with considering a no-bleed preparation?
2. What other options could you suggest?

Answers

1. No-bleed preparations include continuous combined HRT and tibolone. If these are used in women before they become truly menopausal (rather than just peri-menopausal), they are associated with significant problems of unscheduled bleeding because the dose of hormone in the preparation is insufficient to override any residual ovarian activity. In women who start on HRT while still peri-menopausal, it can be difficult to know when they are truly menopausal. The recommendation therefore is that women should not take continuous combined HRT or tibolone until they are at least 12 months from their last menstrual period or are 54 years of age (when it is estimated that 80% of women will be post-menopausal).
2. Two options could be considered. Tridestra could be used. This is a preparation in which a 14-day course of combined estradiol valerate and medroxyprogesterone acetate is taken after a 70-day course of estradiol valerate. Seven days of inactive tablets follow during which Mrs GY would be expected to have a withdrawal bleed. This means that Mrs GY would only experience a bleed every 3 months rather than monthly. The other option would be to consider using the levonorgestrel IUS as the progestogen component of HRT together with either an oral or transdermal oestrogen preparation. This has the advantage of very few progestogenic side effects and the possibility that Mrs GY will be rendered amenorrhoeic. If the levonorgestrel IUS is used, it should be replaced after 4 years rather than the usual 5 years when used for contraception or as a treatment for menorrhagia.

Case 47.2

A 53-year-old woman, Ms DR, who had a hysterectomy and a bilateral salpingo-oophorectomy for menstrual problems about 6 months ago, has now requested advice about HRT. She had previously refused HRT because she was particularly concerned about the associated cardiovascular risks, but Ms DR has recently found an article that said HRT may actually be safe.

Questions

1. What are the current recommendations relating to HRT and cardiovascular disease?
2. What would be a good HRT regimen for Ms DR?

Answers

1. Reassure Ms DR that the data show that HRT does not increase cardiovascular risk when it is initiated in those younger than 60 years. There is some evidence that there may be an increased risk of stroke (but not haemorrhagic) in menopause, but this is influenced by the preparation, with transdermal regimens carrying less risk than oral dosage forms. It is worth pointing out that recent studies have looked at the administration of HRT in younger women who have started HRT at or around menopause. More recent analyses show that HRT does not affect the risk of dying from cardiovascular disease. The opportunity should be taken to counsel the patient about general risk factors and cardiovascular health. Ms DR should be reassured that her blood pressure will be monitored regularly whilst she is using HRT and be advised of when HRT should be stopped pending further investigations (e.g. unexplained severe pain in the calf of one leg).
2. A suitable regimen for this patient need not contain a progestogen because Ms DR had a hysterectomy and therefore has no endometrium to protect from unopposed oestrogen therapy. Recent data suggest that oestrogen-only treatments are associated with no risk, or reduced risk, of coronary heart disease. She should also be advised that transdermal preparations such as Evorel have less impact on the risk of stroke than oral preparations.

Case 47.3

Ms EC, a 43-year-old woman, was started on cyclical HRT at the age of 37 when she was diagnosed with an early menopause after a 15-month period of amenorrhoea. She has no significant menopausal symptoms and regular light withdrawal bleeds. However, Ms EC has read that HRT should only be continued for 5 years and thinks she might stop HRT now.

Questions

1. Why should Ms EC be advised to continue HRT until the age of 50?
2. What advice would you give Ms EC regarding the dose and type of HRT?

Answers

1. Once a woman enters menopause, the fall in oestrogen levels increases the risk of cardiovascular disease and also increases bone loss, causing a greater risk of osteoporotic fractures. The earlier the menopause, the greater the risk. Concern about breast cancer rates rising with increased HRT was derived from data in women older

than the average age of the natural menopause, that is, in their 50s, 60s and 70s. Therefore, it should not be extrapolated to women who have undergone early menopause. Women with an early menopause should be advised that any increase in the breast cancer risk only becomes important once HRT use continues beyond age 50 years. In addition, the benefits of continuing HRT up to the age of 50 years in terms of cardiovascular and bone health are significant.

- The current advice is that the lowest dose of HRT to control menopausal symptoms should be used. This can result in the dose of HRT falling below the bone-protective dose, and therefore a risk assessment for osteoporosis should be undertaken. This should

include assessing lifestyle (dietary calcium, weight, weight-bearing exercise, etc.) in addition to a bone densitometry scan. Ms EC may wish to consider treatment with levonorgestrel IUS and oral or transdermal oestrogen because there may be a reduction in breast cancer risk associated with this combination when compared with standard cyclical HRT. This is because of limited systemic progestogen absorption. Ms EC's cardiovascular well-being should be assessed, for example, family history, body mass index, blood pressure, lipids and aerobic exercise, and improved where possible. This would be especially important if, following discussion of the risks and benefits, she still decided to stop HRT.

48 Drugs in Pregnancy and Lactation

Paula Russell, Laura Yates, Peter Golightly and Sarah Fenner

Key points

Drugs in pregnancy

- Assess risk/benefit ratio for the mother–fetus pair.
- Avoid non-essential drugs.
- Where drug treatment is clinically indicated, select an effective agent with the best safety profile.
- Use the lowest effective dose for the shortest possible time.
- Provide timely and accurate counselling to help avoid unfounded maternal fears about drug safety that may otherwise result in non-adherence with drug therapy or unnecessary pregnancy termination.
- Teratogenic risks of a drug may vary with each trimester of exposure.
- Drug exposure in the second and third trimesters may also result in fetal harm.

Drugs in lactation

- Avoid unnecessary use of drugs.
- Maternal therapy only rarely constitutes a reason to avoid breastfeeding.
- Assess the risk/benefit ratio for both mother and infant.
- Monitor the infant for unusual signs or symptoms.
- Avoid use of new drugs if there is a therapeutic equivalent for which data on use in lactation are available.

Drugs in pregnancy

The use of both prescription and over-the-counter drugs in pregnancy presents a number of challenges to those asked to provide advice to women either pre-conceptually or during pregnancy. This is in part due to the fact that no two cases are the same, and that each enquiry ideally requires an individual risk assessment that takes into account what is known about the drug and its effects on the developing fetus, as well as the woman's personal medical and family history. It is now well recognised that most medicines and/or their metabolites readily cross the placenta, and that some are teratogenic, resulting in harm to the fetus. Robust scientific human data on the effects of many drugs, particularly newer preparations, are, however, frequently lacking.

It is therefore generally accepted that maternal pharmacotherapy should be avoided if not necessary, or minimised where the maternal condition allows. Nevertheless, it has been estimated that more than 80% of expectant mothers take three or four drugs

at some stage of pregnancy (Headley et al., 2004), with a significant number of women taking medication at the time their pregnancy is detected. Indications for drug use range from chronic illnesses, such as epilepsy and depression, to those commonly associated with pregnancy, such as nausea and vomiting and urinary tract infections.

Approximately 2–3% of all live births are associated with a congenital anomaly. Although exogenous factors such as drugs may account for only 1–5% of these (affecting <0.2% of all live births), given that drug-associated malformations are largely preventable, they remain an important consideration.

Drugs as teratogens

A teratogen is defined as any agent that results in structural or functional abnormalities in the fetus, or in the child after birth, as a consequence of maternal exposure during pregnancy. Examples of drugs that are known to be human teratogens are listed in Box 48.1. The teratogenic mechanism for most drugs remains unclear but may be due to the direct effects of the drug on the fetus and/or as a consequence of indirect physiological changes in the mother or fetus. Perhaps the best known and most widely studied teratogen is thalidomide, a mild sedative that was widely marketed as a remedy for pregnancy-related nausea and vomiting. In 1961 thalidomide was withdrawn from the UK market after numerous reports of severe anatomical birth defects in infants of mothers who took the drug in early pregnancy. Whereas external congenital anomalies such as limb abnormalities, spina bifida and hydrocephalus may be obvious at birth, some defects may take many years to manifest clinically or be identified. Examples of delayed effects of teratogens are the behavioural and neurodevelopmental disorders associated with in utero sodium valproate exposure and the development of clear-cell vaginal cancer in young women after maternal intake of diethylstilboestrol, used first in the 1930s for the prevention of miscarriage and preterm delivery (Herbst et al., 1971).

Critical periods in human fetal development

The human gestation period is approximately 40 weeks from the first day of the last menstrual period (38 weeks post-conception) and is conventionally divided into the first, second and third trimesters, each lasting 3 calendar months. Another method

Box 48.1 Examples of drugs considered to be human teratogens

Angiotensin-converting enzyme inhibitors
 Androgens
 Carbamazepine
 Carbimazole
 Cytotoxics (some)
 Danazol
 Diethylstilboestrol
 Ethanol
 Lithium
 Methotrexate
 Misoprostol
 Mycophenolate mofetil
 Tetracyclines
 Thalidomide
 Valproic acid
 Vitamin A and derivatives, e.g. isotretinoin
 Warfarin

for classifying the stage of pregnancy is according to the stage of embryo-fetal development. This is a more useful approach when assessing the potential risks associated with drug use in pregnancy.

Pre-embryonic stage: weeks 0–2 post-conception

The first 2 weeks post-conception are regarded as the pre-embryonic stage and describe the period up to implantation of the fertilised ovum. Teratogenic exposure during the pre-embryonic stage, sometimes referred to as the ‘all-or-nothing’ period, is thought to carry a low risk of fetal harm, with most exposures leading either to death of the embryo or complete recovery and normal development of the fetus. Fetal malformations after drug exposure during this period are therefore thought to be unlikely, but robust scientific data to support a low risk of adverse fetal outcome are lacking. Risk to the fetus may also be increased where the half-life of the drug is sufficient to extend exposure into the embryonic stage. A good example of the latter is isotretinoin and related vitamin A derivatives that have half-lives up to a week, and which when used systemically, for example, for the treatment of acne and psoriasis, are recognised teratogens (Nulman et al., 1998).

Embryonic stage: weeks 3–8 post-conception

Organogenesis occurs predominantly during the embryonic stage and, with the exception of the central nervous system (CNS), eyes, teeth, external genitalia and ears, is complete by the end of the 10th week of pregnancy. Exposure to drugs during this critical period therefore represents the greatest risk of major birth defects. For this reason, women are often advised to avoid or minimise all drug use in the first trimester whenever possible. It is important to bear in mind, however, that very few drugs are in fact proven teratogens, and that exposure in the second and third trimesters may still result in fetal harm.

Fetal stage: weeks 9–38 post-conception

During the fetal stage, the fetus continues to develop, grow and mature and, importantly, remains susceptible to some drug effects. This is especially true for the CNS, which can be damaged by exposure to certain drugs, for example, ethanol, at any stage of pregnancy. The external genitalia also continue to form from the seventh week until term; consequently, danazol, which has weak androgenic properties, can cause virilisation of a female fetus if given in any trimester after the eighth week of pregnancy when the androgen receptors begin to form (Rosa, 1984).

Further examples include the angiotensin-converting enzyme inhibitors, which if given in the second and third trimesters can result in fetal renal dysfunction and subsequent oligohydramnios, that is, reduced amniotic fluid volume (Sedman et al., 1995). The non-steroidal anti-inflammatory drugs (NSAIDs) are another important group of drugs that may cause problems, specifically in the third trimester. These drugs inhibit prostaglandin synthesis in a dose-related fashion and, when given late in pregnancy, may result in premature closure of the fetal ductus arteriosus and fetal renal impairment (Koren et al., 2006). NSAIDs should therefore be avoided during the third trimester.

Principles of teratogenesis

In 1959 James Wilson, co-founder of The Teratology Society, proposed several principles of teratogenesis that have since been expanded and modified but remain fundamental in assessing whether a drug or chemical exposure during pregnancy is likely to be associated with reproductive or developmental toxicity. A basic understanding of these factors is essential to both the interpretation of preclinical (animal) reproductive toxicity studies and to enable accurate risk assessment in clinical practice. A subset of Wilson’s principles is discussed as follows.

Timing of exposure

The stage of pregnancy at which a drug exposure occurs is key to determining the likelihood, severity or nature of any adverse effect on the fetus. Risk both between and within trimesters may be variable. For example, folic acid antagonists such as trimethoprim have been associated with an increased risk of neural tube defects if exposure occurs before neural tube closure (third to fourth week post-conception), but not after this period (Hernandez-Diaz et al., 2001). It has also been suggested that trimethoprim should be avoided after 32 weeks’ gestation in view of the theoretical risk of severe jaundice in the neonate as a result of bilirubin displacement from protein binding, although clinical evidence to support this is lacking (Dunn, 1964). Unfortunately, the precise period of teratogenic risk is known for very few substances. One drug for which this period has been established is thalidomide, where exposure between days 20 and 36 post-conception is associated with a high risk of congenital malformation (Lenz, 1988; Newman, 1986).

Drug dose

A threshold dose above which drug-induced malformations or other adverse effects are more likely to occur has now been demonstrated for certain teratogenic compounds, although for most a 'safe dose' has not been conclusively determined. The likelihood of a dose relationship underlies the recommendation to use the lowest effective dose in pregnancy. For this reason more frequent monitoring of drug levels may be recommended for certain drugs during pregnancy.

Species

Teratogenicity of a drug may be species dependent. Interestingly, preclinical thalidomide studies in mice and rats did not result in congenital malformation in the offspring (Breitkreutz and Anderson, 2008; Müller et al., 2009; Vorhees et al., 2001). Birth defects or other adverse reproductive outcomes observed in animal studies cannot therefore be simply extrapolated to the human situation. Further, the drug dose and route of administration used in early animal studies may not be comparable with clinical use in humans.

Genotype and environmental interaction

Not all fetuses exposed to known teratogenic drugs show evidence of having been affected in utero. It remains undetermined whether this variable susceptibility to teratogenic drugs is a result of genetic differences in the exposed mothers, the fetal genotype, modifying environmental factors or a combination of all three. Malformations are reported to occur in only 20–50% of infants born to mothers exposed to thalidomide during the period of greatest risk of embryopathy, that is, days 20–36 post-fertilisation (Lenz, 1966; Newman, 1985). Similarly, maternal treatment with systemic isotretinoin during the first trimester results in fetal malformation in only 18–35% of the live born infants, with a further 30% of children exhibiting developmental delay in the absence of physical deformity (Benke, 1984; Braun et al., 1984; Hill, 1984).

Pharmacological effect

Pharmacological effects on the fetus are by far the most common drug effects during pregnancy, and the consequences are often minor and reversible compared with the idiosyncratic effects that can lead to major irreversible anomalies. Pharmacological effects are usually dose related and to some extent predictable. Drugs may adversely affect the fetus via effects on the maternal circulation, or they may cross the placenta and exert a direct pharmacological effect on the fetus. Equally, drugs are sometimes administered to pregnant women to treat fetal disorders; for example, flecainide has been used to resolve fetal tachycardia.

The neonate can also be adversely affected by maternal drug therapy (Table 48.1). It is generally only at birth that signs of fetal distress are observed due to in utero drug exposure or the effects of abrupt discontinuation of the maternal drug supply.

Table 48.1 Examples of drugs with pharmacological effects on the fetus or neonate

Drug	Possible adverse pharmacological effect	Notes
Angiotensin-converting enzyme inhibitors	Fetal and neonatal hypoxia, hypotension, renal dysfunction, oligohydramnios and intra-uterine growth retardation	Monitor fetus if long-term therapy in the second or third trimester
β-Blockers, e.g. atenolol	Neonatal bradycardia, hypotension and hyperglycaemia	Neonatal symptoms are usually mild and improve within 48 h; no long-term effects
Benzodiazepines	'Floppy infant syndrome' Withdrawal reactions	Risk if regular use in third trimester Neonatal observation recommended
Corticosteroid (high dose)	Fetal adrenal suppression	Dependent on dose and treatment interval
Non-steroidal anti-inflammatory drugs	Premature closure of the ductus arteriosus (affecting fetal circulation) and fetal renal impairment (decreased urine output)	Avoid repeated use after week 28; if unavoidable, fetal circulation monitored regularly
Opioids	Neonatal withdrawal symptoms Respiratory depression	Risk if used long-term Risk if used near term
Phenothiazines	Neonatal withdrawal and transient extrapyramidal symptoms	Observation for at least 48 h; symptoms may last for several weeks
Tricyclic and selective serotonin reuptake inhibitor anti-depressants	Neonatal withdrawal symptoms	Risk if used long-term and/or near term; observation for at least 48 h

Adapted from Schaefer et al. (2014).

The capacity of the neonate to eliminate drugs is reduced, and this can result in significant accumulation of some drugs, leading to toxicity. Neonatal withdrawal effects may require treatment.

Idiosyncratic drug effects in the fetus and neonate are possible but occur rarely compared with pharmacological effects.

Maternal pharmacokinetic changes

Physiological changes in pregnancy induce profound changes to the pharmacokinetic properties of many drugs. These changes,

Table 48.2 Summary of pharmacokinetic changes during pregnancy

	Change during pregnancy
Absorption	
Gastro-intestinal motility	↓
Lung function	↑
Skin blood circulation	↑
Distribution	
Plasma volume	↑
Body water	↑
Plasma protein	↓
Fat deposition	↑
Metabolism	
Liver activity	↑ ↓
Excretion	
Glomerular filtration	↑
Renal tubule secretion	↑

Adapted from Schaefer et al. (2014).

summarised in Table 48.2, affect absorption, distribution, metabolism, and excretion of drugs, and may also affect their pharmacodynamic properties. Some of the changes that occur in maternal organ systems are secondary to pregnancy-induced hormonal changes, whereas others occur to support the pregnant woman and the developing fetus.

Absorption

Gastric and intestinal emptying time increases by 30–40% in the second and third trimesters (Pavek et al., 2009) and could be important in delaying absorption and time to onset of action for some drugs (Loebstein et al., 1997). There is also a reduction in gastric acid secretion in the first and second trimesters, and an increase in mucous secretion. As a consequence of the increase in gastric pH, the ionisation, and hence absorption, of weak acids and bases can be affected.

Cardiac output and respiratory volume increase during pregnancy, leading to hyperventilation and increased pulmonary blood perfusion. These changes cause higher pulmonary absorption of anaesthetics, bronchodilators, pollutants, cigarette smoke and other volatile drugs.

Distribution

The volume of distribution of drugs may be altered because of an increase of up to 50% in blood (plasma) volume and a 30% increase in cardiac output. Renal blood flow increases by up to 50% at the end of the first trimester, and uterine blood flow increases and

peaks at term (36–42 L/h). There is also a mean increase of 8 L in body water (60% to placenta, fetus and amniotic fluid and 40% to maternal tissues). As a consequence, there may be increased dosage requirements for some drugs to achieve the same therapeutic effect, provided these effects are not offset by other pharmacokinetic changes. Both the total plasma and the free-drug concentrations of phenytoin, carbamazepine and valproic acid decrease during pregnancy, but the free-drug fraction (ratio of free to total plasma concentration) may increase (Pavek et al., 2009).

Protein binding. Albumin is the main plasma protein responsible for binding acidic drugs such as phenytoin and salicylates, whereas α_1 -acid glycoprotein predominantly binds basic drugs, including β -blockers and opioid analgesics. As pregnancy progresses the plasma volume increases at a greater rate than the increase in albumin which results in hypoalbuminaemia. In addition, steroid and placental hormones occupy the protein-binding sites. This leads to an increase in the fraction of unbound drug. Clinical effect is related to the concentration of unbound drug, which usually remains unchanged even though the total (bound plus unbound) plasma concentration is decreased. Thus, a decline in the total plasma concentration does not usually require an increase in dose. The α_1 -acid glycoprotein concentrations remain the same as those in non-pregnancy.

Phenytoin is bound to albumin and exhibits the effects described earlier, but the situation is further complicated by increased hepatic metabolism that may necessitate a dose increase. Consequently, therapy can only be reliably guided by clinical assessment or measurement of unbound rather than total plasma concentration.

Metabolism

The metabolic activity of cytochrome P450 isoenzymes CYP3A4, CYP2D6, CYP2A6 and CYP2C9 and uridine 5'-diphosphate glucuronosyltransferase (UGT) isoenzymes (UGT1a1, UGT1A4 and UGT2B7) is increased during pregnancy. Drugs metabolised by these isoenzymes may therefore require dose adjustment. This may decrease the amount of the drug available for transfer across the placenta, and thereby influence fetal exposure. In contrast, the metabolic activity of CYP1A2 and CYP2C19 is decreased during pregnancy, and drugs metabolised by these isoenzymes may need dose reduction to minimise toxicity. These changes and their extent depend on the stage of pregnancy, so there may be clinically significant changes in drug concentrations between trimesters (Table 48.3) (Anderson, 2005; Deligiannidis et al., 2014). In general the effects on individual drugs are inconsistent and difficult to predict, but knowledge of the effect of pregnancy on isoenzymes may inform decisions about possible monitoring and/or dose alterations.

Excretion

Within the first few weeks of pregnancy the glomerular filtration rate (GFR) increases by approximately 50%. Consequently, those drugs which are excreted primarily unchanged by the kidneys, for example, lithium, digoxin and penicillin, show enhanced elimination and lower steady-state concentrations. The following

Table 48.3 Summary of pregnancy-induced effects on hepatic metabolism of some drugs

Isoenzyme	Drugs/ probes	Effect on clearance		
		First trimester	Second trimester	Third trimester
CYP1A2	Caffeine	↓ 33%	↓ 50%	↓ 65%
CYP2A6	Nicotine	ND	↑ 54% (combined data)	
CYP2C9	Phenytoin	No effect	No effect	↑ 20%
CYP2C19	Proguanil	ND	↓ 50%	↓ 50%
CYP2D6	Dextromethorphan ^a Metoprolol	ND	ND	↑ 50%
CYP3A4	Cortisol ^a Nifedipine	ND	ND	↑ Variable ^b
UGT1A4	Lamotrigine monotherapy	↑ 200%	↑ 200%	↑ 300%
	Polytherapy	↑ 65%	↑ 65%	↑ 90%
UGT2B7 (limited data)	Morphine	ND	ND	↑ Variable ^b

^aDextromethorphan and cortisol used as probes of CYP2D6 and CYP3A4 activity.
^bExtent variable depending on the drug studied.
 ND, Not detectable.
 Adapted from Anderson (2005).

drugs have shown pregnancy-induced increases of 20–65% on their renal elimination (Anderson, 2005):

- ampicillin,
- cefuroxime,
- ceftazidime,
- cefazolin,
- piperacillin,
- atenolol,
- sotalol,
- digoxin,
- lithium,
- dalteparin sodium,
- enoxaparin sodium.

Fetal–placental transfer

Most drugs have a molecular weight less than 600 and diffuse easily across the placenta to enter the fetal circulation to some extent. In general, the fetal/maternal drug concentration ratio is less than 1. Drugs differ in the extent to which they bind to fetal

and maternal proteins. For example, fetal and newborn plasma proteins appear to bind ampicillin and benzylpenicillin with less affinity and salicylates with greater affinity than maternal proteins. Maternal albumin gradually decreases during pregnancy and fetal albumin concentrations increase, so different fetal/maternal albumin concentrations occur at different stages of pregnancy. The degree of protein binding of any drug is an important determinant of its movement across the placenta. Drugs that are highly protein bound tend to achieve higher maternal and lower fetal concentrations. Drugs with very large molecular weights such as insulin and heparin have negligible transfer. Lipophilic, un-ionised drugs cross the placenta more easily than polar drugs, and weakly basic drugs may become ‘trapped’ in the fetal circulation because of the slightly lower pH compared with maternal plasma.

Some other factors such as enzymes or drug efflux transporters in the placenta may facilitate or restrict the transfer of a drug to the fetus. The influence of transporter activity on placental transfer is increasingly recognised. For example, the accumulating evidence about transport mechanisms operating at the placental barrier is expected to be useful in developing techniques to control fetal and placental transfer of antiviral drugs, thus achieving maximum therapeutic benefit while minimising potential fetal toxicity (Tomi et al., 2011).

Maternal pharmacodynamic changes

Pharmacodynamic changes in pregnancy are less well studied than pharmacokinetic changes, but increases in blood pressure and blood glucose associated with corticosteroids may be more common in pregnancy. It is thought that impairment of cell-mediated immunity affects the efficacy of vaccination, particularly late in pregnancy. Sensitivity to the bradycardic effects of β -receptor blocking drugs such as propranolol may also be increased in pregnancy (Rubin et al., 1987). There is currently not a good understanding of pharmacodynamic changes and their clinical implications in pregnancy.

Drug dosing in pregnancy

As a general principle, the dose of a drug given at any stage of pregnancy should be as low as possible to minimise potential toxic effects to the fetus. Drug therapy that is considered essential can be tapered to the lowest effective dose either before conception (ideally) or at the time the pregnancy is diagnosed. Where drug exposure during the third trimester is predicted to have an adverse effect on the neonate postpartum, consideration may be given to slowly reducing the dose towards term to minimise the risks to the baby. Such decisions are, however, not always straightforward. Recommendations to wean an expectant mother off antidepressants and antipsychotics to reduce the likelihood of neonatal withdrawal syndrome (characterised by jitteriness, altered muscle tone, poor feeding and irritability) and, in the case of the selective serotonin reuptake inhibitors (SSRIs), avoid the possible increased risk of persistent pulmonary hypertension of the newborn are now being challenged. Not only are there insufficient data to conclusively demonstrate neonatal benefit or an optimal time of weaning, but also the increased risk of psychiatric

problems and relapse in the mother's immediate postpartum period needs to be taken into account.

Many physiological changes occur during pregnancy that may affect the way the body handles drugs. Knowledge of these changes can allow some prediction of the impact on pharmacotherapy while remaining aware that there is variability in the extent of these changes during the pregnancy and high inter-individual variability. The need for changes in dosages is influenced by whether the drug is excreted unchanged by the kidneys or which metabolic isoenzymes are involved in its elimination. Women who are taking drugs with enhanced clearance and for which a good correlation between plasma levels and therapeutic effect exists should have their plasma concentrations closely monitored and dose adjusted to reduce the risk of suboptimal therapy, for example, with phenytoin, carbamazepine, lithium and digoxin. Similarly, highly protein-bound drugs may require free-drug concentration monitoring. However, there is no clear guidance for adjusting doses during pregnancy, and for most drugs, the concentration of free drug, and therefore the effect of that drug, is unchanged.

Pregnancy itself can cause a temporary worsening or improvement of some diseases and in that way influence drug dosages.

Drug selection in pregnancy

Although there are few, if any, drugs for which safe use in pregnancy can be absolutely assured, only a handful of drugs in current clinical use have been conclusively shown to be teratogenic. In general, drugs that have been used extensively in pregnant women without apparent problems are recommended in preference to new drugs for which there is less experience of use. For example, methyldopa is used rarely to treat hypertension in the non-pregnant state but has historically been preferred in pregnancy because of a long history of safe use ([National Institute for Health and Care Excellence \[NICE\], 2011](#)). However, older drugs may be less effective in terms of controlling maternal illness and are often associated with an increased side-effect risk profile.

In most cases the decision whether to commence or continue with a medication in pregnancy will depend on the risk–benefit analysis for that specific mother–infant pair. A frequent error made by health professionals was to apply the recently discontinued US Food and Drug Administration (FDA) pregnancy risk categories (A [*no demonstrable risk*]; B, C, D and X [*teratogenic agents that are considered to be completely contraindicated in pregnancy*]) when considering whether to prescribe a drug in pregnancy. It is now widely accepted that these categories were oversimplified and of little practical help in a clinical setting. More detailed information sheets containing a summary of the fetal risks and the additional maternal factors that need to be taken into consideration are now being used. Consideration also needs to be given to the quality and quantity of both human and animal data, the study design, dose exposure and any reported congenital malformations and/or adverse events (see <http://www.fda.gov> for up-to-date information).

It is worth noting that standard literature sources often contain unhelpful information such as ‘do not use in pregnancy unless

the benefits outweigh the risks’. This is understandable from a medico-legal point of view but offers little in terms of risk assessment. The primary literature is frequently inadequate because ethical and legal restraints mean that randomised controlled trials are rarely undertaken in pregnant women. Often the only information that is available is confined to retrospective studies, voluntary reporting schemes and/or animal studies. The rate of anomalies in retrospective studies and voluntary reporting databases may be erroneously elevated due to preferential reporting of abnormal outcomes. Individual case reports are also difficult to interpret because the denominator of drug exposure is unknown, and an abnormal outcome may be coincidental to the drug exposure. More recently, prospective controlled trials have been utilised where the pregnancy outcomes of a defined cohort of women exposed to the drug are compared with outcomes of a matched control group. Complete follow-up of each pregnancy and postnatal monitoring is an essential feature of this type of investigation.

Pre-conception advice

Drug use during the first trimester, in particular, the embryonic stage, carries the greatest risk of malformation because this is when the fetal organs are being formed. Ideally all unnecessary drug therapy should be discontinued prior to conception. However, inadvertent drug exposure frequently occurs, because approximately half of all pregnancies are unplanned. It is thus critical to make careful drug choices when prescribing for women of reproductive potential.

Women with chronic illnesses who require drug treatment should be offered specialist counselling before conception, and the options explored to reduce or change drug therapy to a safer agent if necessary. It is also important to note that many pregnant women become less adherent to their drug therapy out of concern about possible harm to their infant. In many cases, such as asthma, inflammatory bowel disease and epilepsy, inadequate treatment of the underlying disease may be more detrimental to the mother–fetus pair than the drugs used to treat the condition. It is thus essential that women of reproductive potential are given clear and up-to-date information so that unrealistic fears about the risks to their baby do not result in unnecessary pregnancy termination or disease relapse.

All women who are planning a pregnancy should be offered general advice to minimise the risk of congenital anomalies. This includes avoidance of recreational drugs, ‘natural’ or herbal remedies, alcohol, smoking and vitamin A products; minimisation of caffeine consumption; and beginning daily supplementation with at least 400 micrograms of folic acid to reduce the risk of neural tube defects ([NICE, 2014](#)). It is recommended that the daily dose of folic acid be increased to around 5 mg daily in women who have epilepsy ([NICE, 2016](#)) or who have had a previous child with a neural tube defect ([NICE, 2014](#)). Some infectious diseases may carry important fetal consequences if contracted during pregnancy. For example, rubella infection in the first 20 weeks of pregnancy is associated with an increased risk of miscarriage and a syndrome comprising problems such as deafness, cardiac defects and mental retardation in more than 20% of pregnancies. Women who lack immunity to rubella should be immunised prior to conception.

Post-conception advice

It is important to draw distinction between advice given to women pre-conceptually and that provided to a pregnant woman who has already been exposed to a drug. In the former setting, it may be recommended that an alternative preparation be considered or that a drug treatment be stopped where clinically appropriate. This advice often hinges on the lack of definitive safety data and does not automatically translate to exposure to that drug in pregnancy being an indication for discontinuing the drug, additional fetal monitoring or termination of the pregnancy on the basis of the exposure. Any change to the woman's medication should be based on a careful and individual risk assessment, and include a discussion with the woman to provide her with accurate, up-to-date, evidence-based advice. In many such cases the woman can be reassured that a healthy baby is the most likely outcome, or where appropriate be offered additional prenatal investigation to screen for congenital malformation where the risk to the fetus is considered to be significant.

Teratology information services and pregnancy registries

It is difficult to keep up to date with the published literature. There is an increasing need for summary documents that include and critically appraise all available data, and which enable health-care providers to have a balanced and informed discussion with patients regarding the risks and benefits of a certain therapy in pregnancy. This is evidenced by the ongoing debate surrounding the teratogenic potential of various antidepressants with conflicting opinion even amongst experts in the field.

Teratology Information Services have been established in several countries across the world and provide evidence-based, up-to-date information and individual case-based risk assessments. In addition to reviewing published literature on drugs, teratology services also have access to specialist online databases and discussion forums. A number routinely collect pregnancy outcome data on the women about whom they receive an enquiry, to enable surveillance for potential teratogens.

For some new drugs, pregnancy registries have been initiated that record all reported drug exposures and follow up the outcome of the pregnancy. These registries are cumulative and work on the basis that specific anomalies would be identified relatively quickly, and that there will eventually be sufficient statistical power to detect the magnitude of any increased risk relative to the general population. These registries may be held by a Teratology Information Service or by independent groups with an interest in a defined area. The 2009 A/H1N1 influenza pandemic provided an example of teratology services across the globe responding to the urgent need for safety data by establishing registries on antiviral and pandemic vaccine exposure during the pandemic.

Drugs in lactation

Breast milk is the best form of nutrition for young infants. It provides all the energy and nutrients required for the first 6 months of life. The World Health Organization (WHO, 2001) and the United Nations Children's Fund recommend exclusive breastfeeding

for this period. Benefits of breastfeeding include protection of the infant against infectious diseases (gastro-intestinal, upper and lower respiratory tract, otitis media and urinary tract) and reduction in rates of obesity, types 1 and 2 diabetes, inflammatory bowel disease, childhood leukaemia, asthma, coeliac disease and atopic disease (Eidelman and Schanler, 2012; Kramer and Kakuma, 2012). There is evidence to show that adults who were breastfed as infants have a predisposition to lower blood pressure and cholesterol levels (Horta et al., 2007). Maternal benefits include reduced risk of development of postpartum depression, cardiovascular disease, diabetes (Eidelman and Schanler, 2012), premenopausal breast and ovarian cancer, and delayed resumption of menstrual cycle (Department of Health, 2003; Eidelman and Schanler, 2012). Breastfeeding strengthens the mother-infant bond.

There are few contraindications to breastfeeding; these include galactosaemia in an infant and active untreated tuberculosis and HIV infection in developed countries. However, in the developing world, where mortality is increased in non-breastfeeding infants from a combination of malnutrition and infectious diseases, breastfeeding may outweigh the risk of acquiring HIV infection from human milk.

Reasons for early discontinuation of breastfeeding include problems latching, sore/cracked nipples, engorgement, inconvenience (return to work, feeding in public, lifestyle choices), concerns about inadequate lactation and nutritional adequacy, personal illness and medication, and infant factors (Li et al., 2008).

Breastfeeding mothers frequently require treatment with prescription medicines or may self-medicate with over-the-counter preparations, nutritional supplements or herbal medicines. It is important for health professionals to understand the principles of safe use of medications during lactation to provide appropriate advice.

There are two main goals to consider when formulating advice for nursing mothers. These are to protect the infant from maternal drug-related adverse effects and to allow, whenever possible, necessary maternal medication (Berlin et al., 2009).

Transfer of drugs into breast milk

Most drugs pass into breast milk to some degree, although transfer is usually low. The drug 'dose' ingested by the infant via breast milk only rarely causes adverse effects. Examples of adverse effects observed in breastfed infants exposed to commonly used medicines via breast milk are given in Table 48.4. These examples are of reports that are considered to have a high probability of a direct association between infant exposure in breast milk and maternal ingestion, although not all of these are proven to be directly caused by the drug ingested via breast milk. There are a significant number of reports of possible adverse reactions in breastfed infants due to maternal medication in which the association is less clear, unsubstantiated or anecdotal (Anderson et al., 2003, 2016).

Almost all drugs enter milk by passive diffusion of unionised, unbound drug through the lipid membranes of the alveolar cells of the breast, according to the pH partitioning theory. Several factors influence the rate and extent of passive diffusion.

Table 48.4 Adverse reactions reported in breastfed infants (Anderson et al., 2003, 2016)

Drug	Adverse reaction
Acebutolol	Hypotension, bradycardia, tachypnoea
Aspirin	Metabolic acidosis, thrombocytopenic purpura
Atenolol	Bradycardia, cyanosis, hypotension
Ciprofloxacin	Pseudomembranous colitis
Codeine	Apnoea, bradycardia, death
Cyclophosphamide	Neutropenia, thrombocytopenia
Dapsone	Haemolytic anaemia
Diazepam	Lethargy, sedation, poor suckling
Doxepin	Sedation and respiratory arrest
Erythromycin	Pyloric stenosis
Fluoxetine	Colic, irritability, sedation
Indometacin	Seizures
Lamotrigine	Apnoea, cyanosis
Lithium	Cyanosis, lethargy, T-wave abnormalities, thyroid-stimulating hormone elevation
Mesalazine	Watery diarrhoea
Naproxen	Prolonged bleeding, haemorrhage, anaemia
Oxycodone	Sedation, hypothermia, poor feeding
Paroxetine	Agitation, feeding difficulty
Phenindione	Postoperative haemorrhage
Phenytoin	Methaemoglobinaemia
Sulfasalazine	Bloody diarrhoea
Theophylline	Irritability, poor sleep
Topiramate	Diarrhoea
Yellow fever vaccine	Fever, irritability, convulsions, meningo-encephalitis

These include maternal plasma level, physiological differences between plasma and milk, and the physicochemical properties of the drug. Differences in composition between blood and milk determine which physicochemical characteristics influence diffusion.

Milk differs from blood in that it has a lower pH (7.2 vs. 7.4), less buffering capacity and higher fat content. The following drug parameters affect the extent of transfer into milk:

- pK_a : This is a measure of the fraction of the drug that is ionised at a given pH, for example, physiological pH. Highly ionised drugs tend not to concentrate in milk. For basic drugs (e.g. erythromycin), a greater fraction will be ionised at an acidic pH, so the milk compartment will tend to ‘trap’ weak bases. In contrast, acidic drugs (e.g. penicillins) are more ionised at higher pH values and will be ‘trapped’ in the plasma compartment. Drugs with higher pK_a values generally have higher milk/plasma ratios.
- *Protein binding*: Drugs that are highly bound to plasma proteins (e.g. warfarin) are likely to be relatively retained in maternal plasma because there is a lower total protein content in the milk. High protein binding essentially restricts the drug to the plasma compartment because only the free fraction of the drug crosses the biological membrane. Milk concentrations of highly protein-bound drugs are usually low.
- *Lipophilicity*: The alveolar epithelium of the breast is a lipid barrier. Transfer of water-soluble drugs and ions is inhibited by this barrier. CNS active drugs usually have the characteristics required to pass into milk.
- *Molecular weight*: Drugs with low molecular weights (<200) readily pass into milk through small pores in the cell walls of alveolar cells. Drugs with higher molecular weights cross cell membranes by dissolving in the lipid layer which may substantially reduce milk concentrations. Proteins such as heparin or insulin with very large molecular weights greater than 6000 are virtually excluded from milk.

The profile of a drug that passes minimally into milk would therefore be an acidic drug that is highly protein bound and has low-to-moderate lipophilicity (e.g. most NSAIDs). In contrast, a weakly basic drug that has low plasma protein binding and is relatively lipophilic will achieve higher concentrations in the milk compartment (e.g. sotalol).

In the first few days of life, large gaps exist between the alveolar cells. These permit enhanced passage of drugs into milk. By the end of the first week these gaps close under the influence of prolactin (Lawrence and Lawrence, 2016). There is greater passage of drugs into colostrum (early milk) than in mature milk because the former contains more protein and less fat. There is also some variation in fat and protein content of milk between the beginning and end of a feed, but these changes have less influence on drug passage than the physicochemical properties of the drug.

Milk/plasma concentration ratio

Several methods have been proposed to determine the amount of drug transferred to breast milk. The milk/plasma (M/P) ratio is often used as a measure of the extent of drug transfer into breast milk. It is usually obtained from case reports or small clinical studies and may be based on paired concentrations or full area under the concentration–time curve (AUC) analysis. M/P ratios that are based on a pair of milk and plasma samples collected simultaneously may be inaccurate because they

Fig. 48.1 Diagrammatic representation of a drug concentration–time profile in the maternal plasma and milk phases after a single oral dose. The points a, b and c illustrate simultaneous sampling times from both phases. Sampling at (a) would yield an estimated milk/plasma (M/P) ratio of 0.2, at (b) a value of 1.0, and at (c) a value of 9.3. All can be misleading. The true M/P ratio calculated by the area under the concentration–time curve method is 1.2 when extrapolated to infinity.

assume that the concentrations of drug in milk and plasma are in parallel, which may not be the case. It is better to collect multiple samples of plasma and milk across a dosing interval, or until the drug is cleared from both phases after a single dose, for determination of a M/P ratio based on the respective AUCs (M/P_{AUC}). Fig. 48.1 demonstrates the markedly different estimates of M/P ratio that can be obtained via both sampling methods. The true M/P ratio may vary significantly during the same episode of breastfeeding.

If human-derived M/P ratios are lacking for a particular drug, it may be possible to predict the extent of transfer using known physicochemical properties, for example, pK_a , and a published predictive model (Atkinson and Begg, 1990; Begg et al., 1992; Zhao et al., 2006). M/P ratios obtained from animal studies should not be used for clinical decision making because they may not correlate well with human M/P ratios.

Studies in humans demonstrate that most drugs have an M/P ratio less than 1.0, with the range of reported ratios being from around 0.1–5.0. It is often thought that drugs with high M/P ratios (e.g. 5.0) are unsafe because the concentration in milk exceeds that in plasma, while those with low ratios (<1.0) are believed to be safe. This is not always the case because the M/P ratio often fails to correlate with the ‘dose’ of drug the infant ingests via milk. The amount of drug transferred into milk is principally determined by the maternal plasma level. Thus, even where the M/P ratio is high, if the maternal plasma level is low, drug transfer is still low. Therefore, the M/P ratio must never be used as the sole measure of drug safety in breastfeeding. However, it can be used to estimate the ‘dose’ ingested via milk, which is a better predictor of safety.

Calculating the infant ‘dose’ ingested via milk

Infant plasma drug levels are the most accurate indicator of drug exposure, but these are seldom available.

Fig. 48.2 The cumulative dose received by the infant is plotted against time. The arrows represent the maternal dose times. This type of study is undertaken by the mother expressing all the milk, from both breasts, at usual feeding times. An aliquot of milk is taken and assayed for the drug. The volume of milk is measured, and the total amount of drug at each time is calculated as the product of concentration and volume. This type of study must be undertaken at steady state.

When using quantitative data from milk analyses, the most accurate estimation of the infant ‘dose’ is from studies in which the milk is collected over a complete dose interval at steady state and the total dose is calculated (Fig. 48.2). Unfortunately, these studies are seldom performed. Therefore, information must be obtained from less than ideal conditions.

If the M/P ratio is known from published studies, the likely infant dose (D_{inf}) can be calculated as follows, with some assumptions:

$$D_{inf} = C_{p_{mat}} \times M/P \times V_{milk}$$

where $C_{p_{mat}}$ is the average maternal plasma concentration, and the M/P_{AUC} should be used in preference to a ratio based on paired concentrations when available. The volume of milk ingested (V_{milk}) is not known but is generally assumed to be around 150 mL of milk per kilogram of body weight per day. The above equation simplifies if the actual milk concentration data are available:

$$D_{inf} = C_{milk} \times V_{milk}$$

The likely infant plasma drug concentration ($C_{p_{inf}}$) can be calculated by:

$$C_{p_{inf}} = F \times D_{inf} / Cl_{inf}$$

where F is oral availability and Cl_{inf} is the infant clearance. Unfortunately, neither F nor Cl_{inf} is known accurately for infants, so estimation of the likely steady-state average plasma drug concentration will be very approximate. Weight-adjusted Cl_{inf} values (i.e. L/h/kg) are often significantly less than adult values in the early stages of life (Table 48.5).

Given the difficulty in estimating infant plasma drug concentrations, the relative infant dose (RID), for example, compared with a therapeutic infant dose, is often used as a surrogate of exposure. To give some basis for comparison, the likely infant dose from milk can be compared with an infant therapeutic dose. This is reasonable for drugs such as paracetamol that are usually administered to infants, but is unsuitable for drugs such as anti-depressants that are not. In the absence of a clearly defined range

Table 48.5 Approximate drug clearance by age as percentage of maternal value (Begg, 2000)

Post-conceptual age (weeks)	Approximate drug clearance (%)
24–28	5
28–34	10
34–40	33
40–44	50
44–68	66
>68	100

of infant doses, the weight-adjusted maternal dose expressed as a percentage (% dose) is widely used to indicate infant drug exposure.

$$\text{Relative infant dose (RID)} = \frac{D_{\text{inf}} (\text{mg/kg/day})}{D_{\text{mat}} (\text{mg/kg/day})} \times 100$$

D_{inf} represents dose in infant via milk, and D_{mat} represents dose in mother.

For the great majority of drugs, this calculation yields infant doses in the order of 0.1–5.0% of the weight-adjusted maternal dose expressed as a percentage (% dose). It is generally thought that RID values of less than 10% of the maternal dose are probably safe. However, the inherent toxicity of the drug should be taken into account when using this figure.

To calculate the daily infant drug intake via milk, the standard milk intake of 150 mL/kg/day is multiplied by the concentration of the medication in milk. Some authors use the peak concentration in milk to indicate the maximum infant intake.

$$\begin{aligned} \text{Estimated daily infant intake} &= \text{drug concentration in milk} \\ (\text{micrograms/day}) & \quad (\text{micrograms/L}) \times 0.15 \times \\ & \quad \text{infant weight (kg)} \end{aligned}$$

Variability

To further complicate matters, there will be significant variability between and within individuals in the values used to estimate infant exposure (i.e. D_{inf} , F , Cl_{inf} , where D_{inf} is itself a function of the estimated parameters $C_{\text{p,mat}}$, M/P and volume of milk). Some of this variability will change over time because of developing organ function in the maturing baby, and some will be unexplained variability. In addition to this pharmacokinetic variability, there will be variability in response of the infant to any given concentration of the drug. It is fortunate that most drugs seem to fall readily into a safe range (RID <10%) based on expected exposure. However, care should be taken when using these values to assess drug safety in lactation, when variability in the estimates of the parameters used may impact on the accuracy of prediction of their safety. This is especially true for those circumstances when initial estimates of these parameters are less precise, for example, in neonates.

Box 48.2 Factors that affect infant risk from maternal therapy

- Drug adverse reaction profile
- Relative infant dose
- Oral bioavailability
- Active metabolites
- Half-life
- Gestational age of the infant
- Full maternal drug regimen
- Pharmacogenetic factors

Assessing the risk to the infant

Many factors must be considered when assessing the risk of maternal drug therapy to the breastfeeding infant (Box 48.2).

Pharmacokinetic and pharmacodynamic factors

Inherent toxicity of the drug will be a main factor in determining infant safety. Thus, antineoplastic drugs, radionuclides and iodine-containing compounds would be of concern. Multiple maternal therapy with drugs with similar side-effect profiles, for example, psychotropic drugs or anticonvulsants, is likely to increase the risk to the infant. Oral bioavailability is an indicator of the drug's ability to reach the systemic circulation after oral administration. Drugs with a low oral bioavailability are either poorly absorbed from the gastro-intestinal tract, broken down in the gut or undergo extensive 'first-pass' metabolism in the liver before entering plasma.

The presence of active metabolites (e.g. desmethyldiazepam) may prolong infant drug exposure and lead to drug accumulation, especially where drug clearance is low, such as in the neonatal period. Similarly, drugs with long half-lives (e.g. fluoxetine) may be problematic at this time. Drug clearance by the infant does not reach adult values until 6–7 months (see Table 48.5). A premature infant of 30 weeks' gestational age has a drug clearance value of about 10% of the maternal value. It is important to distinguish between gestational age and time after delivery. A 2-week-old infant born at 28 weeks will have a gestational age of 30 weeks.

The maternal drug regimen can affect infant risk. Single doses or short courses seldom present problems, whereas chronic therapy can be problematic. Topical or inhalation therapy usually results in much lower plasma drug levels and, therefore, lower passage into milk. Multiple maternal medications increase the risk to the infant.

Pharmacogenetic factors

Recently, attention has been focused on the possible role of pharmacogenetic factors in affecting the safety of breastfed infants exposed to drugs via milk (Madadi et al., 2009). Sedation (and one death) occurred in infants of mothers with rare genotypes of cytochrome P450 CYP2D6, leading to ultrarapid metabolism of codeine to morphine. The incidence of these genotypes varies amongst different populations. The overall percentage of Western Europeans with the CYP2D6 ultrarapid metaboliser phenotype is 5.4% (Ingelman-Sundberg, 2005). Higher percentages have been reported in populations from northeast Africa and the Middle East.

Reducing risk to the breastfed infant

A number of strategies may be adopted to reduce the risk of drug-related side effects in the breastfed infant. One technique that has been recommended for reducing infant exposure is to give the maternal dose immediately after the infant has been fed with the aim of avoiding feeding at peak milk concentrations. However, this is often impractical, especially where young infants are feeding frequently up to 2 hourly. In addition, accurate data on times of peak levels in milk are often unavailable, and it cannot be assumed that times of peak milk levels mirror those in plasma. This technique should be used selectively, where the drug has a short half-life and where peak and trough levels are predictable (e.g. antibiotics, anaesthetics).

Where a single dose of a drug known to be hazardous is given to a breastfeeding mother, for example, a radiopharmaceutical, it will usually be possible to resume breastfeeding after a suitable washout period, calculated as five times the half-life. Where the half-life is very long, the washout period necessary to avoid hazardous exposure to the infant may exceed the period of sustainable lactation.

Breastfeeding mothers should be advised to avoid self-medication. Where drug use is clearly indicated, the lowest effective dose should be used for the shortest possible time. Use of topical therapy, such as eye/nasal drops for hay fever, would reduce drug exposure in comparison with oral antihistamines.

The maternal regimen should be simplified wherever possible. A review of therapy before delivery will help reduce risks to the neonate. New drugs are best avoided if a therapeutic equivalent is available for which data on safe use in lactation exists. All infants exposed to drugs via breast milk should be monitored for any untoward effects. Measures to ensure the safety of the breastfed infant are summarised in [Box 48.3](#).

Some commonly used drugs thought to be safe to use in mothers of full-term, healthy infants are listed in [Table 48.6](#).

Special situations

Neonates and premature infants

Neonates and premature infants are at greater risk of development of adverse effects after exposure to drugs via breast milk. Gastric emptying time is significantly prolonged and, in some cases, may alter absorption kinetics. Protein binding is decreased and values for total body water are higher than for adults. Renal function is limited because the kidney is anatomically and functionally immature ([van den Anket, 1996](#)). The neonate's capacity to conjugate drugs in the liver is often deficient.

Glucose-6-phosphate dehydrogenase deficiency

Infants with glucose-6-phosphate dehydrogenase (G6PD) deficiency are susceptible to adverse effects even when only small amounts of certain drugs are present in milk. G6PD is an enzyme present in erythrocytes that is responsible for maintaining the antioxidant compound glutathione in its active form. Deficiency of this enzyme makes the erythrocyte more susceptible to oxidative stress, resulting in haemolysis. Only small amounts of drug are needed to cause such a reaction.

Box 48.3 Measures to ensure the safety of the breastfed infant

- Avoid unnecessary maternal drug use.
- Seek professional advice on the suitability of over-the-counter products.
- Avoid herbal products because of lack of data to support safe use.
- Assess the risk/benefit ratio for both mother and infant.
- Use the minimum clinically effective dose for the shortest possible time.
- Review maternal therapy towards the end of pregnancy.
- Choose a drug regimen and route of administration which presents the minimum of drug to the infant via breast milk.
- Avoid drugs known to cause serious toxicity in adults or children.
- Monitor the infant for unusual signs or symptoms.
- Avoid new drugs if there is a therapeutic equivalent with data to support safe use in lactation.
- Recognise risk factors, e.g. prematurity, infant morbidity and multiple maternal medications.

Table 48.6 Examples of commonly used drugs thought to be safe for use in breastfeeding mothers of full-term, healthy infants

Drug groups	Individual drugs
Antacids	Cetirizine
Bulk laxatives	Chloroquine/proguanil
Cephalosporins	Clotrimazole
Contrast media	Cromoglycate
Inhaled medications (e.g. salbutamol, beclometasone)	Diclofenac
Insulins	Fluconazole
Penicillins	Heparin (including low molecular weight)
Progestogen-only contraceptives	Ibuprofen
Topical formulations (except when applied to breast)	Iron supplements
Vaccines (except yellow fever)	Loratadine
Vitamins (except high-dose A and D)	Lactulose
	Levothyroxine
	Nystatin
	Omeprazole
	Paracetamol
	Paroxetine/sertraline
	Warfarin

This table is to be used as a guide only. Expert advice is required when the maternal dose is high and if the infant is premature, has renal or hepatic disease, or has glucose-6-phosphate dehydrogenase deficiency.

Breastfeeding should be avoided or a safer alternative chosen if the infant has a known or suspected G6PD deficiency and the mother is taking drugs that have been reported to cause oxidative stress (e.g. nitrofurantoin, dapsone).

Allergy

The theoretical possibility exists for an allergic reaction in an infant exposed to a drug in breast milk. Even minimal exposure to the drug could cause an allergic response. However, in practice, such reactions are rare, and only if the infant has already

experienced an allergic reaction to a particular drug should maternal use be discouraged or breastfeeding avoided.

Recreational drug use

Accurate background data of maternal use of recreational drugs may be difficult to obtain. Usage may be chronic or sporadic. The role of the healthcare professional in ensuring the safety of the breastfed infant is important, and the advice should be that substances such as cannabis, LSD and cocaine should be avoided whilst breastfeeding.

Significant amounts of alcohol pass into milk, although it is not normally harmful to the infant if the quantity and duration of intake are limited. The occasional consumption of a small alcoholic beverage is acceptable if breastfeeding is avoided for about 2 hours after the drink. Chronic or heavy consumers of alcohol should not breastfeed. High intakes of alcohol decrease milk let-down and disrupt nursing until maternal levels decrease. Heavy maternal use may cause infant sedation, fluid retention and hormone imbalances in breastfed infants.

Nicotine has been suggested to decrease basal prolactin production, although effects may be variable. Ideally mothers should be encouraged not to smoke whilst breastfeeding. Nicotine and its metabolite, cotinine, are both present in milk. Undertaking smoking cessation with a nicotine patch is a safer option than continued smoking. Whilst transdermal nicotine patches produce a sustained lower nicotine plasma level, nicotine gums produce large variations in peak levels. A 2- to 3-hour washout period is recommended before breastfeeding after maternal use of a nicotine gum.

Caffeine appears in breast milk rapidly after maternal intake. Fussiness, jitteriness and poor sleep patterns have been reported in infants of mothers with very high caffeine intakes equivalent to about 10 or more cups of coffee daily. Preterm and newborn infants metabolise caffeine very slowly and are at increased risk of adverse effects.

Drug effects on lactation

Drugs that affect dopamine activity are the main cause of effects on milk production, mainly mediated by effects on prolactin. Early postpartum use of oestrogens may reduce the volume of milk, but the effect is variable and depends on the dose and the individual response. Progestogen only contraceptives are preferred.

Drugs may occasionally be used therapeutically for their effect on lactation. Dopamine agonists such as cabergoline decrease milk production and this effect may be utilised, for example, after an infant death. Dopamine agonists should not be used routinely for relief of the symptoms of postpartum pain or engorgement that can be managed with simple analgesics or breast support. Dopamine antagonists such as domperidone may be used in cases of inadequate lactation that have not responded to first-line methods such as improved technique or milk expression by hand or pump. However, a European and UK regulatory review has recommended restricted use of domperidone because of the risk of cardiac adverse effects ([Medicines and Healthcare Products Regulatory Agency, 2014](#)). The use of domperidone to enhance lactation is not specifically covered by the review because it is

an unlicensed ('off-label') indication. However, it is appropriate for the recommendations from the review to apply to its use as a galactagogue. Because there are limited alternative options for the stimulation of lactation, the use of domperidone can be considered provided non-pharmacological options have been unsuccessful. A maternal dosage of 30 mg daily for 1 week should not usually be exceeded, and it should not be used if the mother or infant:

- has conditions where cardiac conduction is, or could be, impaired;
- has underlying cardiac diseases such as congestive heart failure;
- is receiving other medications known to prolong QT interval or are potent CYP3A4 inhibitors;
- has severe hepatic impairment.

If treatment is still required after 1 week, the risks of continuing domperidone must be considered carefully. Alternatively, metoclopramide can be used; however, only for up to 5 days because of the risk of neurological side effects ([European Medicines Agency, 2013](#)).

Other drugs may affect lactation as an unwanted side effect, for example, diuretics causing dehydration. When these are used on a long-term basis, infant weight gain should be monitored.

Case studies

Case 48.1

Ms LP is 6 weeks' pregnant and has been diagnosed with depression that warrants pharmacological intervention. She wishes to recommence venlafaxine, which has been helpful in the past. Ms LP is also anxious that the ethanol she consumed around the time of conception may have harmed her baby.

Questions

1. What are the safest antidepressants in the first trimester of pregnancy?
2. Is it reasonable for Ms LP to commence venlafaxine?
3. Is there any risk from the ethanol ingestion?

Answers

1. The concept of 'safe' needs to take into account the risks of inadequate treatment of the mother, as well as those to the fetus through in utero exposure to a particular antidepressant. Choice of antidepressant in pregnancy will therefore depend on the severity of the maternal depression, the presence of associated symptoms such as anxiety or obsessive-compulsive behaviors, availability and suitability of non-pharmaceutical interventions and, finally, any prior treatment regimens that have been successfully or unsuccessfully used. SSRIs are currently the most commonly prescribed antidepressant group and the most studied in pregnancy. However, human pregnancy data will vary for individual SSRIs. Although not without risk to the fetus, SSRIs are generally prescribed as first-line therapy in preference to tricyclic antidepressants which carry a higher risk of maternal toxicity, especially in overdose, and which are less well studied in human pregnancy.

- Experience with the use of venlafaxine and many other antidepressants (e.g. moclobemide) in pregnancy is limited. However, in some instances it may be necessary to use an agent such as venlafaxine. For example, if the mother had a history of severe depression that did not respond to multiple trials of other antidepressants, then venlafaxine may be considered the most appropriate choice of antidepressant for that woman. In this case any potential risks associated with venlafaxine are likely to be less than those associated with inadequately treated depression. Discussion of the available data and its limitations with Ms LP is, however, necessary to enable her to make an informed decision.
- Ethanol is a human teratogen. Fetal alcohol spectrum disorders are characterised by low birth weight, facial dysmorphogenesis and/or delayed development. A 'safe limit' for alcohol consumption in pregnancy has not been defined, and best practice is therefore to avoid all alcohol exposure in pregnancy. In this case Ms LP ingested ethanol at the time of conception. She should be reassured that this is regarded as a relatively low-risk period for fetal harm, but that further ethanol ingestion should be avoided.

Case 48.2

A 30-year-old woman with epilepsy, Ms AD, is currently taking valproic acid 1500 mg daily. She wishes to conceive but is concerned about the possibility of birth defects caused by valproate exposure in pregnancy. Ms AD's seizures have been difficult to control with alternative anticonvulsants.

Questions

- What are the risks associated with valproate treatment in pregnancy?
- What advice should Ms AD be given?

Answers

- Valproate is a human teratogen which has been associated with both structural and lasting neurodevelopmental effects. These may include neural tube defects, craniofacial anomalies such as cleft lip and palate, heart defects, autism, attention deficit hyperactivity disorder and learning difficulties. Recommendations from a European-wide review in 2014 ([European Medicines Agency, 2014](https://www.european-council.org/en/eu-council/2014/04/european-council-recommends-against-valproate-use-in-women-of-childbearing-potential)) advise against valproate use in female children, in female adolescents, in women of childbearing potential and in pregnant women unless other treatments are ineffective or not tolerated. Women of childbearing potential in whom valproate treatment is considered necessary for the treatment of epilepsy are advised to remain on effective contraception during treatment. The MHRA has produced a number of guidance documents for healthcare professionals in the UK, including an openly accessible toolkit for women (<https://www.gov.uk/government/publications/toolkit-on-the-risks-of-valproate-medicines-in-female-patients>).
- It is imperative that Ms AD be advised to request referral to, or review by, a neurologist, ideally with expertise in the treatment of women with epilepsy who become pregnant, and that she continues to use effective contraception until the risks and options available to her have been fully reviewed and discussed. New anticonvulsant therapies that do not appear to carry the same risks as valproate may have become available since Ms AD was last reviewed. Valproate teratogenicity appears to increase with increasing dose. Although no 'safe

dose' has been defined, if this patient needs to remain taking valproate, it may be possible to gradually reduce her daily dose under specialist review. General preconception advice could be given, that is, commence folic acid, optimise weight and general health, etc. It is important that Ms AD understands that folic acid 5 mg daily is advised for all women with epilepsy who are planning a pregnancy (NICE, 2016), but that at present there is no evidence that it prevents or reduces the risk of birth defects or neurodevelopmental impairment caused by valproate.

Case 48.3

A mother, Ms TF, with a history of depression has relapsed and requires treatment with an antidepressant. Ms TF is fully breastfeeding a 2-week old, full-term, fit and healthy baby. In the past she has taken fluoxetine, but stopped this when she found out she was pregnant.

Questions

- What is the antidepressant of choice during breastfeeding?
- Ms TF has responded well to fluoxetine previously, so can this be used during breastfeeding?
- What are the potential risks of using fluoxetine?

Answers

- Sertraline and paroxetine are the preferred SSRIs for use during breastfeeding because they have shorter half-lives, lower passage into milk and a larger evidence base compared with the other SSRIs. However, it is important that Ms TF has an antidepressant that works for her, so choice of agent should primarily be based on suitability for the patient rather than safety during breastfeeding.
- If a woman has been successfully treated with an SSRI during pregnancy and requires continued therapy in the postnatal period there is no need to change therapy, provided the infant is full term, fit and healthy, and can be adequately monitored. Although fluoxetine is not a preferred SSRI during lactation, due to its long half-life, because it has proved effective for Ms TF in the past, the balance of benefit to risk will favour use of fluoxetine in this mother.
- Because fluoxetine has a very long half-life there is a risk of accumulation and, therefore, adverse effects in the breastfed baby. The baby should be monitored for drowsiness, poor feeding, irritability and behavioural effects.

Case 48.4

A mother, Ms CG, is breastfeeding her 20-day-old, full-term, fit and healthy baby. She has postpartum hypertension and has been started on labetalol.

Labetalol does not control Ms CG's hypertension and she is started on nifedipine.

Questions

- Comment on the suitability of labetalol as a suitable β -blocker for use during breastfeeding.
- Are there any monitoring requirements?
- Can Ms CG still continue to breastfeed?

Answers

1. In general, β -blockers that are considered to pose less risk to a breastfeeding infant have, or are predicted to have, lower levels in breast milk, due to a high degree of plasma protein binding, low lipid solubility and a short half-life, and relatively low renal excretion. The risks of available β -blockers vary widely due to these features. Although propranolol is considered to be the β -blocker of choice in breastfeeding, because clinical properties of β -blockers vary widely, propranolol may not always be a suitable clinical choice. Metoprolol and labetalol are also considered to pose low risk. Labetalol would be suitable to use in this situation, with appropriate monitoring.
2. The breastfed infant should be monitored for signs of β -blockade, especially bradycardia. Also consider monitoring for hypotension and hypoglycaemia.
3. Because there will be low levels of nifedipine in breastmilk, amounts ingested by the baby will be small. Nifedipine, including modified-release preparations, is considered compatible with breastfeeding. Therefore, Ms CG can continue to breastfeed, but the risk of additive adverse effects in the baby must be remembered.

Case 48.5

A breastfeeding mother, Ms SV, returned to see her midwife 4 weeks after delivery of a full-term, healthy infant. She is complaining of bilateral nipple pain during and after breastfeeding, a problem that was constant for the past 4 days. Ms SV was advised to use miconazole cream 2% to the nipples after each feed. This provided initial relief, but symptoms returned after a few days.

She was given a course of fluconazole 200 mg daily for 10 days for a presumed candidal infection but expressed concern that the medication might affect the infant.

Questions

1. Is this regimen safe to use in lactation?
2. What other therapeutic measures should be taken?

Answers

1. Topical miconazole is effective in treating superficial candidal infections, but oral therapy with fluconazole is needed when the infection spreads to the milk ducts. Fluconazole, after a 200 mg oral dose, produces levels in breast milk similar to those found in maternal plasma. Fluconazole is recommended for use in the treatment of neonates with fungal infections at a dose starting at 3 mg/kg every 72 hours. The calculated dose of fluconazole ingested by an infant feeding at times of peak milk levels of fluconazole would be approximately 0.6 mg/kg/day, which is 60% of the neonatal dose and 20% of the dose for infants aged ≥ 1 month. Ms SV may be reassured that the amount of drug reaching the infant via milk is a fraction of the dose that would be used to treat an infection in the infant.
2. Candidal infections are easily passed between the mother and the infant, and both should receive treatment. Infants can be treated with nystatin suspension or oral miconazole gel. Miconazole gel is not licensed for use in children younger than 4 months because of the small risk of choking in young babies; this risk can be reduced by using smaller quantities of the gel, applying the gel with a clean finger rather than a spoon and being careful not to touch the back of the infant's throat when applying the gel.

49 Prostate Disease

Linda Ross, Ben Challocombe and Sophie Rintoul-Hoad

Key points

Benign prostatic hyperplasia

- Benign prostatic hyperplasia is a common condition that affects only males and increases in prevalence with age.
- A combination of increased adrenergic tone in the prostatic stroma and bladder neck, as well as the anatomical effects of an enlarging prostate, can lead to lower urinary tract symptoms and bladder outflow.
- α -Adrenoceptor blocking drugs are effective in reducing symptoms and increasing flow rates.
- 5α -Reductase inhibitors reduce prostate size, improve symptoms, increase urinary flow rates and reduce the risk of development of complications such as acute urinary retention or the need for prostate surgery.
- Surgical treatments such as transurethral resection of the prostate are effective and commonly used, but other less invasive procedures are also available.

Prostate cancer

- Prostate cancer typically progresses slowly but is influenced by factors such as tumour grade, stage of the disease, comorbidities and life expectancy.
- Aetiology is multifactorial and includes age, race, and family history, with some links to dietary habits.
- Early detection is difficult because no symptoms are specific to prostate cancer, and it starts on the peripheral parts of the prostate away from the urethra.
- A combination of digital rectal examination, serum prostate-specific antigen and magnetic resonance imaging followed by prostate biopsies are used to confirm diagnosis.
- Prostate biopsies can be performed transrectally or transperineally.
- Treatment depends on the grade, volume and stage of tumour, life expectancy and patient choice.
- Curative treatments include radical prostatectomy, brachytherapy and radiotherapy.
- Hormonal treatments arrest prostate and cancer growth, but they are not a cure.

Prostatitis

- Prostatitis is classified as acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/chronic pelvic pain syndrome and asymptomatic inflammatory prostatitis.
- There is no absolute diagnostic tool for prostatitis. Diagnosis is based on physical examination and clinical history.
- The pathophysiology of prostatitis is poorly understood, and the aetiology is unclear in the majority of patients.
- Prostatitis cases associated with infection or inflammation are treated with antibiotics.

- α -Adrenoceptor antagonists, analgesics and other pain-modulating agents are used for the treatment of chronic prostatitis/chronic pelvic pain syndrome.

Benign prostatic hyperplasia

Epidemiology

Benign prostatic hyperplasia (BPH) is the most common benign tumour in men and is responsible for urinary symptoms in the majority of males older than 50 years. Autopsy studies have revealed the histological presence of BPH in 50–60% of males in their 60s, increasing to 80–90% in those in their 70s and 80s (Roehrborn, 2005). By the age of 80 years, virtually all men exhibit one or more of the symptoms associated with BPH.

BPH is seen in all races, although the overall size of the prostate varies from race to race.

Pathophysiology

The prostate is a part glandular, part fibromuscular structure about the size of a walnut that surrounds the first part of the male urethra at the base of the bladder (Fig. 49.1). In simple terms, the prostate can be divided into a lobular inner zone encapsulated by an external layer. The inner transition zone is where benign hypertrophic changes are generally found, whereas most malignant changes originate in the peripheral zone.

Prostatic hypertrophy is directly related to the ageing process and to hormone activity. Within the prostate, testosterone is converted by 5α -reductase to dihydrotestosterone (DHT). DHT is five times more potent than testosterone and is responsible for stimulating growth factors that influence cell division, leading to prostatic hyperplasia and enlargement.

Histologically, depending on the predominance of the type of prostatic tissue present, prostatic hypertrophy can be stromal, fibromuscular, muscular, fibroadenomatous or fibromyoadenomatous.

As the prostate enlarges, it can compress the urethra (Fig. 49.2) and this, together with increased adrenergic tone, can lead to bladder outflow obstruction and lower urinary tract symptoms.

Fig. 49.1 Male urinary system demonstrating the location of the prostate.

However, not all large prostates will cause symptoms. Therefore, the term benign prostatic enlargement is used to describe the clinical features associated with urinary obstruction and lower urinary tract symptoms. BPH should be reserved for describing a histological diagnosis; but for the purpose of this chapter, we will use the term BPH.

Symptoms

Men with BPH can experience bothersome lower urinary tract symptoms that can impact negatively on their quality of life. It is important to emphasise that lower urinary tract symptoms can have different aetiologies, including bladder cancer, bladder stones, overactive bladder (OAB), urinary tract infection (UTI), urethral stricture, among others.

Lower urinary tract symptoms can be divided into symptoms of failure of urine storage (storage) and those caused by failure to empty the bladder (voiding).

Storage symptoms

- Frequency
- Nocturia
- Urgency and urge incontinence

Obstructive symptoms

- Weak urinary flow
- Intermittent stream
- Straining/need to bear down
- Hesitancy in initiating micturition
- Incomplete emptying
- Terminal dribbling
- Post-micturition dribbling

Fig. 49.2 Diagrammatic representation of the impact of prostate hyperplasia on the urethra demonstrating overgrowth of cells in the inner zone of the prostate. BPH, Benign prostatic hyperplasia.

Examination and investigations

A range of investigations and diagnostic tests are available for the evaluation of patients with suspected BPH. Some tests are

standard during the assessment of all men with lower urinary tract symptoms. Other investigations are optional and are only performed depending on the patient's presentation and the clinician's judgement.

History

A focused medical history of all men with lower urinary tract symptoms should be taken to elucidate the aetiology of their symptoms. As part of the process, lower urinary tract symptoms should be evaluated using a validated scoring tool such as the International Prostate Symptom Score (IPSS) (Barry et al., 1992) and a bladder voiding diary. This can be used to monitor the severity and progression of the disease, and assess the impact of therapy on lower urinary tract symptoms.

Physical examination

All patients who present with suspected BPH should undergo an abdominal and genital examination and a digital rectal examination (DRE) to evaluate for size, asymmetry and any change in texture, such as areas of generalised or localised firmness (nodules) which could indicate the presence of cancer. A DRE involves the examiner inserting a finger into the anal canal and palpating the prostate through the rectum wall; this assesses a small proportion of the prostate, but the area most likely to harbour cancer, the peripheral zone. It is important that patients give verbal consent for this intimate examination and should be offered the presence of a chaperone; both consent and the offer of a chaperone should be documented.

Investigations

Investigations may be carried out in the clinic to facilitate the diagnostic assessment of patients with lower urinary tract symptoms caused by BPH, and these include urinalysis, urine cultures if infection is suspected, and serum creatinine to assess renal function and establish possible upper urinary tract damage. The measurement of serum prostate-specific antigen (PSA) can be considered after counselling the patient, particularly if DRE reveals a nodular or hard prostate.

Urodynamic studies

Simple non-invasive urodynamic studies provide a surrogate, but objective, measure of bladder outflow obstruction. These include maximum flow rate and post-void residual (PVR). A flow-rate test involves patients passing urine into a specialised machine which measures the speed and volume of urine passed. Slower flow-rate curves than expected may indicate obstruction. After urination the PVR is measured on a simplified, bedside ultrasound scanning machine. Large PVRs of 500 mL, for example, are indicative of bladder dysfunction and predict a poor response to therapy.

Invasive urodynamic studies (used when there is diagnostic uncertainty) involve insertion of a fluid-filled transducer into the bladder and rectum to measure the vesical and abdominal pressures, which can be used to calculate detrusor pressure. These can then be recorded during filling and voiding

phases to assess the compliance and capacity of the bladder. This is especially helpful to ascertain whether bladder emptying is problematic due to obstruction or due to muscular failure.

Imaging

Imaging of the urinary tract via ultrasound scan is important in cases of haematuria or deterioration in renal function. The latter may be an indicator of bladder outflow obstruction causing pressure on the kidneys which results in the ultrasonographic finding of hydronephrosis and/or hydroureter.

Prostatic ultrasound scan

Prostatic ultrasound or transrectal ultrasound (TRUS) uses high-frequency scanners to produce images of the prostate. This imaging is used to obtain an accurate evaluation of the prostate volume and to detect malignant change. TRUS is also used to guide the placement of the needle when obtaining prostatic biopsies.

Flexible cystoscopy

Flexible cystoscopy provides an endoscopic image of the urethra and bladder, and can be used for the assessment of prostatic obstruction and excluding other causes of lower urinary tract symptoms such as bladder cancer. It can inform the urologist on the presence of urethral strictures, the height of the bladder neck, degree of obstruction in the prostatic urethra and the presence of a median lobe. This may inform possible management options.

Treatment

Most men older than 50 years exhibit some of the symptoms of BPH. The range of treatment options for the management of BPH includes watchful waiting/lifestyle advice, medical therapies and surgical interventions. The key issue, therefore, is deciding who should be treated and when.

The European Association of Urology has published guidelines for the management of BPH in primary care (Gravas et al., 2017) (Figs. 49.3 and 49.4).

Watchful waiting

Men with mild or moderate and not significantly bothersome lower urinary tract symptoms should be offered a trial of watchful waiting. This management strategy does not include any medical or surgical treatment but involves regular active monitoring. In some cases, symptoms remain unchanged for years and no further interventions are necessary because disease progression is minimal. Patients who adopt this modality should be offered education and lifestyle advice (Box 49.1) to manage their urological symptoms together with a review of their

medication, particularly diuretics or other medicines known to affect the urinary system.

Therapeutic management

The principal treatment options are α -adrenoceptor blocking drugs, 5 α -reductase inhibitors, antimuscarinic antagonists, β_3 agonists and combination therapies. Phytotherapy is also used in the management of BPH, although the benefits remain unproven.

α -Adrenoceptor blocking drugs

The prostate gland is very responsive to adrenergic stimulation. In fact, prostatic outlet obstruction in BPH is partly due to the hypertrophied bulk of the gland, but it also arises from an increase in adrenergic tone. In the prostate, α_1 receptors predominate and mediate the contraction of the gland's smooth muscle. At least three subtypes of this receptor exist (α_{1A} , α_{1B} and α_{1D}). α_{1A} is thought to be the dominant receptor in the prostate, although its role clinically has still to be confirmed. This increase in sympathetic tone is potentially reversible by α -adrenoceptor antagonists.

In general, all of the agents are considered to produce similar clinical improvements of lower urinary tract symptoms and urinary flow. Benefits can be seen usually within the first few days of therapy and can be maintained in the long-term. α -Adrenoceptor antagonists also have a comparable side-effect profile, which includes postural hypotension, dizziness, fatigue, headache, drowsiness, nasal congestion and ejaculatory dysfunction.

Patients with BPH frequently experience erectile and ejaculatory dysfunction. The treatment of BPH should also aim to improve sexual function. However, the effect of α_1 -adrenoceptor antagonists on male sexual function is variable and influenced by the choice of agent and patient characteristics (Van Dijk et al., 2006).

Prazosin, terazosin and indoramin were the first α_1 -blockers used to relieve the symptoms of BPH, but as they have been associated with adverse effects such as drowsiness, weakness, headache and postural hypotension, they are no longer used very often because of poor tolerability.

Doxazosin. Doxazosin has a long half-life of about 22 hours, which allows for once-daily dosing. When starting treatment, dose titration is recommended to limit postural hypotension. There would appear to be no significant difference in symptom score regardless of whether the standard or controlled-release preparation is used (Kirby et al., 2001).

Tamsulosin. Tamsulosin is a selective inhibitor of the α_{1A} - and α_{1B} -adrenoceptor. It has an elimination half-life of about 13 hours and is available as a prolonged-release formulation that allows once-daily dosing. There is no requirement to titrate the dose upwards when initiating treatment. Although the side-effect profile of tamsulosin is similar to other α_1 -adrenoceptor antagonists, it is normally well tolerated (O'Leary, 2001). Intraoperative floppy iris syndrome (IFIS) has been reported during cataract surgery in men treated with

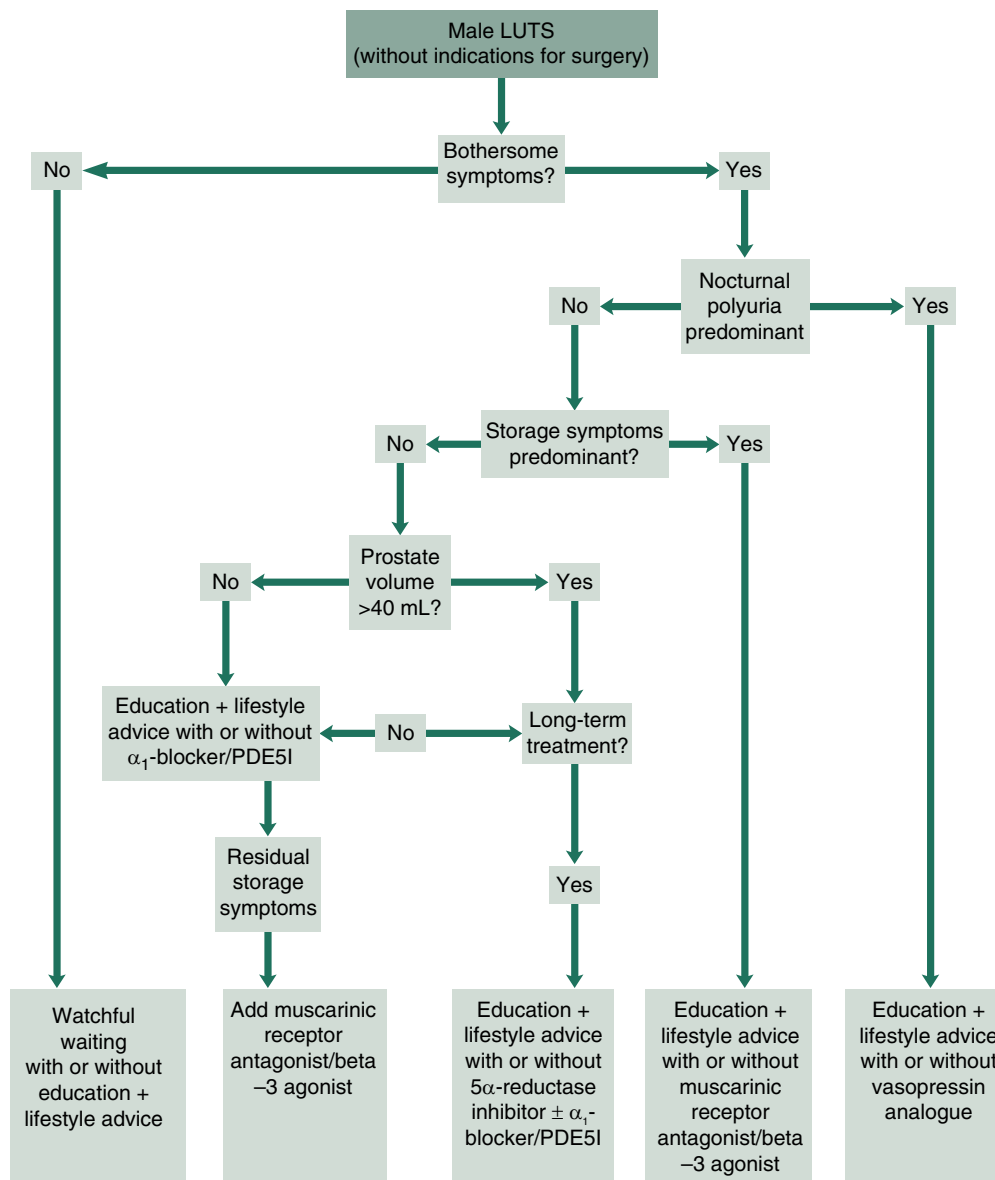

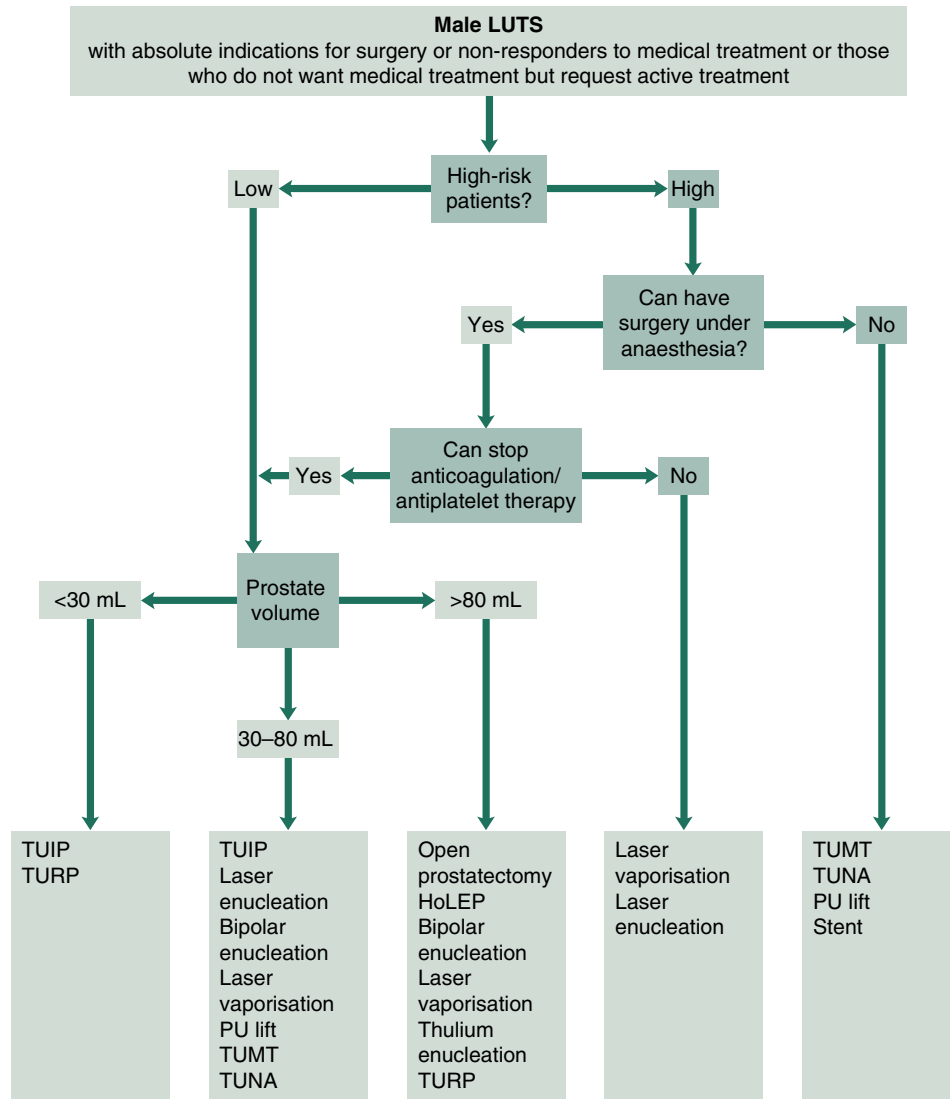

Fig. 49.3 Treatment algorithm of male lower urinary tract symptoms (LUTS) using medical and/or conservative treatment options (Gravas et al., 2017). Treatment decisions depend on results assessed during initial evaluation. Note that patients' preferences may result in different treatment decisions. LUTS, Lower urinary tract symptoms, PDE5I, phosphodiesterase type 5 inhibitors.

tamsulosin, because it is highly selective to iris dilator muscle (Chaim et al., 2009). IFIS can lead to complications and poor outcomes during cataract surgery. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk of all the α_1 -blockers (Chatziralli and Sergentanis, 2011). However, the odds ratio for IFIS was much higher for tamsulosin. As a result it is essential that patients inform their cataract surgeon that they are taking tamsulosin and all α_1 -blockers during the pre-operative assessment. It has been recommended to avoid starting treatment and to discontinue treatment with tamsulosin 1–2 weeks before cataract surgery.

Alfuzosin. Alfuzosin displays a higher selectivity for the prostate compared with tamsulosin or doxazosin. It has a half-life of 5 hours, but it is available as a once-daily formulation. It has a rapid onset of action and good tolerability (MacDonald and Wilt, 2005). It reduces the overall clinical progression of BPH, and it appears to have a sustained beneficial effect on quality of life (Roehrborn, 2006). Alfuzosin has the least effect on ejaculatory function. Alfuzosin should not be co-administered with potent inhibitors of cytochrome P450 (CYP) 3A4, such as itraconazole, ketoconazole and ritonavir, because this can lead to a several-fold increase in exposure to alfuzosin.

The alternative treatments are presented in alphabetical order.

Notice: Readers are strongly recommended to read the full text that highlights the current position of each treatment in detail.

5 α -Reductase inhibitors

The primary androgen responsible for the development and progression of BPH is DHT. There are two isoenzymes of 5 α -reductase: type 1 is found in most 5 α -reductase-producing tissues such as the liver, skin and hair; type 2 is predominant in genital tissue, including the prostate. 5 α -Reductase inhibitors downregulate prostate growth by blocking the conversion of testosterone to the more potent DHT.

The two agents currently available in this group are finasteride and dutasteride. Both have been shown to reduce prostate

volume, to improve symptom scores and flow rates, and to reduce the incidence of complications such as acute urinary retention and the need for surgical intervention to treat BPH (Roehrborn et al., 2000, 2002). Improvements in lower urinary tract symptoms are normally seen after the first 6 months of treatment and are sustained during continuous treatment (Lam et al., 2003).

Finasteride. Finasteride is a type 2, 5 α -reductase inhibitor that can reduce prostate size, improve symptom scores and increase urinary flow. Those most likely to benefit are men with a prostate larger than 40 mL (Gravas et al., 2017). Side effects

Box 49.1 Advice for the management of lower urinary tract symptoms

- Limit fluid consumption before going out and before going to bed (to reduce urinary frequency and nocturia).
- Reduce alcohol and caffeine intake.
- Schedule toilet visits.
- Manage constipation.
- Review medication (including diuretics and other medicines that can affect the urinary system).
- Attempt bladder training (encourage patient to go longer between voiding and increase the volume voided).
- Use distraction techniques (practice breathing exercises and penile squeezing to control symptoms of irritation).

include decreased libido, impotence, reduced ejaculatory volume and, less commonly, gynaecomastia and breast tenderness. Serum concentrations of PSA may be reduced by 50% in the first year of treatment with finasteride (Gravas et al., 2017), a fact which must be taken into account when attempting to interpret the PSA concentration in men with suspected prostate cancer (PC).

Dutasteride. Dutasteride inhibits both type 1 and type 2 isoenzymes of 5 α -reductase. Dutasteride decreases prostate volume and reduces the risk of progression to serious complications of BPH. Lower urinary tract symptoms also improve after 6 months of treatment. Dutasteride is well tolerated, although side effects which include erectile and ejaculatory dysfunction and breast enlargement occur with similar frequency to finasteride.

Antimuscarinic receptor antagonists

The detrusor muscle is stimulated by the parasympathetic nervous system, whose main neurotransmitter is acetylcholine, which stimulates muscarinic cholinergic receptors on the smooth muscle cells. There are five muscarinic receptor subtypes (M1–M5); M2 and M3 are the main ones in the detrusor muscle.

The following agents are currently available for treating storage symptoms: darifenacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine and trospium.

Originally it was believed that prostate-specific drugs should not be used to treat lower urinary tract symptoms in men, and antimuscarinics were therefore mainly tested in females. However, a subanalysis of patients in an open-label trial of tolterodine for OAB showed that age, but not gender, has an impact on urgency, frequency or urgency incontinence (Michel et al., 2002). Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency and urgency-related voiding, and improve patient perception of treatment benefit.

Side effects of these drugs include dry mouth, constipation, micturition difficulties, nasopharyngitis and dizziness.

Phosphodiesterase 5 inhibitors

Whilst phosphodiesterase (PDE) type 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus

reducing smooth muscle tone of the detrusor, prostate and urethra, they may also reduce chronic inflammation in the prostate and bladder.

Tadalafil, 5 mg once daily, is the only selective oral PDE5I that is currently licensed for the treatment of signs and symptoms of benign hyperplasia and lower urinary tract symptoms in men. Tadalafil is contraindicated in patients prescribed some medicines (e.g. nitrates, nicorandil, doxazosin or terazosin) and in some medical conditions (e.g. unstable angina). Side effects include back pain, dyspepsia, flushing, headache, myalgia, and nausea and vomiting.

β_3 -Adrenoceptor agonists

Mirabegron is a β_3 -adrenoceptor agonist which activates β_3 -adrenoceptors, causing the bladder to relax, which helps it to fill and also to store urine. It is licensed for the treatment of urinary frequency, urgency and urge incontinence associated with OAB syndrome. The usual starting dosage is 50 mg once daily, but this needs to be reduced to 25 mg once daily in patients with mild hepatic impairment and those receiving inhibitors of CYP3A4. The most common side effects are tachycardia and UTIs.

Vasopressin analogue

Desmopressin, an antidiuretic hormone arginine vasopressin, regulates water homeostasis. It can be used for the treatment of nocturia due to nocturnal polyuria. Desmopressin is taken once daily before sleeping. Patients can vary in the dose they require; therefore, it is usually initiated at a low dose and increased gradually. Patients should be informed to avoid drinking fluids at least 1 hour before and for 8 hours after dosing.

Combination therapy

It is well established that α -adrenoceptor antagonists are best for managing acute symptoms but have no impact on reducing the risk of complications such as acute urinary retention or progression to prostate surgery. In contrast, 5 α -reductase inhibitors have little impact on short-term acute symptoms but reduce prostate size and improve urinary flow and obstructive symptoms in the long-term. Furthermore, α -adrenoceptor antagonists are effective regardless of prostate volume, whereas the 5 α -reductase inhibitors are more suited for the management of lower urinary tract symptoms in men with large prostates. In terms of long-term benefits, continued treatment with 5 α -reductase inhibitors decreases the risk of acute urinary retention and BPH-related surgery. Therefore, it appears logical to use a combination of an α -adrenoceptor antagonist and a 5 α -reductase inhibitor to manage acute symptoms and reduce progression of BPH.

The benefits of using a combination of doxazosin and finasteride compared with monotherapy have been demonstrated in more than 3000 men (McConnell et al., 2003). Similarly, the CombAT trial (Roehrborn et al., 2010) involved nearly 5000

men with moderate-to-severe symptoms of BPH and prostate enlargement treated with a combination of dutasteride and tamsulosin. This study demonstrated a significant improvement in BPH symptoms over a 4-year period when compared with either agent used alone. The combination was also found to reduce acute urinary retention and progression to BPH-related surgery, and although superior to tamsulosin with respect to these complications, combination therapy was not better than dutasteride. Overall, the adverse events associated with combination therapy were few and treatment was well tolerated.

Combination therapy with an α -adrenoceptor antagonist and a 5α -reductase inhibitor has now been widely adopted into routine practice for the early management of lower urinary tract symptoms and to reduce progression of BPH. A combined preparation of tamsulosin 400 micrograms and dutasteride 500 mg exists in a single tablet.

Combination therapy with an α -adrenoceptor antagonist and muscarinic receptor antagonists has been explored in several randomised controlled trials and prospective studies. It is useful for lower urinary tract symptoms in men with OAB and presumed BPH or as a sequential treatment for storage symptoms persisting whilst on an α_1 -blocker alone. The risk of urinary retention does not increase whilst using antimuscarinics. The commonest side effect is xerostomia (dry mouth).

Phytotherapy

A number of plant extracts are reputed to be effective in the management of symptoms of BPH. They include saw palmetto berry (*Serenoa repens*), African plum tree (*Pygeum africanum*), stinging nettle (*Urtica dioica*) and rye grass pollen. Their mechanism of action remains unclear but may exert an anti-inflammatory effect by inhibition of prostanoid formation and perhaps produce some degree of inhibition of 5α -reductase. Most of the data available to support the use of plant extracts are derived from poorly designed studies. Because evidence to assess efficacy and safety is lacking, phytotherapy remedies are not currently recommended by international guidelines for the management of BPH.

Surgical treatments

Surgical intervention is offered to men with lower urinary tract symptoms caused by BPH that have not successfully responded to medical treatment and are affecting the individual's quality of life. Surgery is also indicated in patients who experience complications such as intractable or recurrent urinary retention, renal impairment, persistent haematuria, recurrent UTIs or bladder stones. BPH can affect men of any age but increasingly affects men of older age who may have serious comorbidities. Therefore, the choice of which surgical intervention to offer must be appropriate for that patient. Clear information should be given to patients who are undergoing surgery regarding the risks, benefits and expected post-operative recovery.

Transurethral resection of the prostate. Transurethral resection of the prostate (TURP) is a common and effective procedure which achieves a high level of improvement in symptoms and flow rate. It is the preferred surgical intervention in men with a prostate volume between 30 and 80 mL. Sections of prostate are

removed under vision using electrical wire loops attached to a tubelike telescope (resectoscope) inserted into the urethra. The tissue removed is collected for histological assessment.

There is a small incidence of perioperative mortality associated with TURP, along with complications such as bleeding, UTI and pain on urination. Importantly, there is a risk of electrolyte disturbance as a result of the irrigation solution glycine, resulting in 'TUR syndrome'. Reducing the risks of this includes 1-hour maximum resection time, height of irrigation fluid and education of health professionals to enable early recognition. Long-term complications include stress incontinence, urethral and bladder neck strictures, retrograde ejaculation and erectile dysfunction.

Conventionally, monopolar diathermy is used; however, newer bipolar resection equipment has the advantage of using saline as the irrigating fluid. This has a theoretical advantage of reducing risk of TUR syndrome and ability for longer resection times. Currently, there are no clear differences in outcomes and complications between the two techniques (Hueber et al., 2011).

Open prostatectomy. Open prostatectomy involves the surgical removal of an enlarged prostate. Typically, an incision is made through the lower abdomen, although sometimes the incision is between the rectum and the base of the penis. This procedure is now performed infrequently and is restricted to very enlarged prostate glands (larger than 100 mL) and those with large bladder stones or bladder diverticula (Stoevelaar and McDonnell, 2001). Open prostatectomy requires a longer hospital stay than transurethral resection and is associated with a higher incidence of bleeding and other complications.

Photoselective vaporisation of the prostate. Photoselective vaporisation of the prostate uses an Nd:YAG laser that passes through a specific crystal which doubles the laser's frequency, resulting in green light (Zorn and Liberman, 2011). This high energy vaporises the prostatic tissue and creates a channel. Its advantages include reduced post-operative bleeding leading to early removal of catheter; it can be offered to patients who cannot reduce or stop their anticoagulant medications.

Holmium laser enucleation of the prostate. Holmium laser enucleation of the prostate (HoLEP) technique has evolved to use Holmium:YAG laser to enucleate each lobe of the prostate, then use a morcellator to remove tissue (Aho, 2013). It has been shown to be the preferred method for treating large prostates (>80–100 g), with a very low incidence of recurrence and blood transfusion. It is the current gold standard treatment for men with symptomatic very large BPH.

These newer techniques such as bipolar TURP, photovaporisation of the prostate and HoLEP have shown efficacy outcomes comparable with conventional techniques, yet a reduced complication rate (Cornu et al., 2015). However, they are associated with a surgical learning curve and new equipment; therefore, the standard for many hospitals is monopolar TURP.

Prostate artery embolisation

Prostate artery embolisation (PAE) is a new, minimally invasive technique performed by interventional radiologists; prostatic arteries are selectively embolised (blocked) leading to reduced blood supply and subsequently reduced prostatic volume. PAE does not require a general anaesthetic, there is no

Table 49.1 Common therapeutic problems and proposed management strategies in benign prostatic hyperplasia

Problem	Solution
Patient taking α -blocker still symptomatic after 2 weeks	Patients should be advised that it may take 2–6 weeks before symptomatic treatment relief is seen
Patient taking an α -adrenoceptor blocker complains of cardiovascular adverse effects such as dizziness, syncope, palpitations, tachycardia or angina	These side effects are more likely in elderly patients. They are most common after the first dose and reflect the hypotensive effects of the drugs. They can be reduced by titrating the dose or using more uroselective drugs such as tamsulosin
Sexual dysfunction	Decreased libido or impotence can occur in patients taking finasteride and dutasteride. Abnormal ejaculation can be caused by α -blockers. Tamsulosin in particular can cause a dry climax (retrograde ejaculation). Patients should be forewarned when discussing treatment options
Patient taking finasteride notices breast enlargement	Unilateral or bilateral gynaecomastia is a frequently reported side effect with finasteride and patients need to be counselled accordingly when discussing treatment options
Patient taking finasteride or dutasteride has a sexual partner who is pregnant	Exposure to semen should be avoided as both drugs can cause abnormalities to genitalia in a male fetus. The patient should be advised to use a condom

upper limit of prostatic size that can be effectively treated by PAE and clinical success rates are in the order of 80% when bilateral embolisation is possible (Mirakhur and McWilliams, 2017). However, this is new technology with ongoing multicentre, randomised controlled trials that will hopefully provide the evidence needed to better understand its contraindications and longer-term outcomes.

UroLift

The UroLift system uses adjustable, permanent implants to pull excess prostatic tissue laterally so that it does not narrow or block the urethra (National Institute for Health and Care Excellence (NICE), 2015). In this way, the device is designed to relieve symptoms of urinary outflow obstruction without cutting or removing tissue and aims to avoid sexual dysfunction. It can be used in a day-case setting in men aged 50 years and older and who have a prostate of less than 100 mL without an obstructing middle lobe.

Patient care

Patients generally seek medical help for BPH because of the impact of symptoms on their quality of life. Most men tolerate a high degree of symptoms and impact on daily activities before they seek help. Table 49.1 lists some common therapeutic problems in the management of BPH. Patients should receive information about the management options available, the investigations that they need to undergo and possible treatment outcomes and adverse effects. Patients who are receiving drug therapy should receive specific information about their treatment, including potential benefits, timeline of expected outcomes and possible side effects.

There are two websites which produce particularly useful educational material on prostatic disease: the Men's Health Forum (<http://www.menshealthforum.org.uk/>) and Prostate Cancer UK section on BPH (<http://prostatecanceruk.org/>).

Prostate cancer

Epidemiology

PC is the second most common cancer in the world and the most common form of cancer in men. Incidence varies from country to country, with the highest rates in Australia/New Zealand and Northern America and in Western and Northern Europe; they remain low in Eastern and South Central Asia (Globocan, n.d.). In the UK, nearly a quarter of all new male cancer diagnoses are of the prostate. The lifetime risk of PC is 1 in 8 in males in the UK.

The aetiology of PC is multifactorial. Testosterone and DHT have an important role in the disease because PC does not develop in males who undergo castration before puberty. Other factors which can influence the risk of development of PC include age, family history, diet and other factors.

Age

PC is rare before 50 years of age in Caucasians and before 40 years in Africans, but after this age, the incidence and mortality increase exponentially with every passing decade. Most cases are detected around the age of 70 years.

Family history

Presence of PC in a first-degree relative or in multiple family members who need not be first-degree relatives increases the risk. Inheritance of a susceptible gene or polymorphism of gene may be responsible for this.

Diet

Although there is no compelling evidence to prove the direct influence of diet, high intake of fat, red meat and dairy produce, typically the main sources of dietary fatty acids in a Western diet,

have individually been linked with PC. The low incidence of PC in China and Japan may be because of their use of soya bean products which contain isoflavones and inhibit protein tyrosine kinases that are responsible for cell proliferation.

Other factors

Other factors include exposure to cadmium (found in cigarette smoke), pesticides, alkaline batteries, radionuclides and heavy metals.

Pathophysiology

The growth and differentiation of cells in the prostate is under androgen control. In the prostate, free testosterone diffuses into the epithelial cells, where it is converted to DHT. Various growth factors are present in stromal cells, and the interaction of these with epithelial cells can play a role in cell proliferation and growth. The development of PC is generally a slow, gradual process where cellular structure changes from normal through dysplastic to cancer. High-grade prostatic intra-epithelial neoplasia represents the precancerous stage of cellular proliferation in prostate cells and can be detected by biopsy. It can predate carcinoma by 10 years or more. There is no link between PC and BPH, but they can co-exist.

Screening

Population-based screening based on PSA levels is prevalent in the USA, and the annual incidence there has doubled due to this. In the UK, screening is not advocated because due to the nature of PC, most patients will not be symptomatic in their lifetime and screening hugely increases the rates of over-treatment with only limited effects on mortality. Targeted testing of at-risk men with a racial or family history is appropriate.

Symptoms

Clinical symptoms of PC are similar to those for BPH, and there are no symptoms which correlate specifically to early PC. As more than 50% of men older than 50 years have prostate-related symptoms, it is difficult to detect early PC. Advanced PC typically presents with symptoms of urethral and bladder outlet obstruction, anaemia, renal failure, weight loss, haematuria or bone pain.

Examination and investigation

Physical examination

A DRE is an important diagnostic tool for PC with an estimated sensitivity of more than 60%. A palpable tumour will have a distinctive texture, but the accuracy of detection may depend on the

Table 49.2 Age-specific levels of prostate-specific antigen

Age (years)	Prostate-specific antigen (ng/mL)
40–49	≤2.5
50–59	≤3.5
60–69	≤4.5
>70	≤6.5

experience of the clinician. False-positive results can occur in the presence of BPH or cysts.

Imaging

A prostate magnetic resonance imaging (MRI) scan is being increasingly used to detect PC. Estimates of the sensitivity of MRI for the detection of cancer vary widely depending on method of analysis used and the definition of significant disease. Estimates using T2-weighted sequences and endorectal coils vary from 60% to 96% (Kirkham et al., 2006). Specificity is not yet good enough to consider the use of MRI in screening but can be used to help target suspicious lesions and in patient follow-up.

Computed tomography (CT) images of the pelvis and isotope bone scan are useful to stage PC, but they are not effective as diagnostic tools.

Prostate-specific antigen

Measurement of PSA is an accurate and clinically useful biochemical marker because it is specific to prostate tissue and produced by the columnar epithelial cells in the prostate gland. Unfortunately, PSA is prostate but not PC specific, and damage to the internal architecture of the prostate can result in its release. As a consequence, it is not a useful tool for diagnosing cancer on its own, but it is useful in monitoring the effect of treatment or tumour progression in untreated patients. Generally, PSA is high in PC, but it can sometimes be low in high-grade malignancy. The standard assay for PSA measures total PSA and includes all molecular forms. The proportion of bound and unbound PSA can be calculated as a percentage; it is thought that a higher proportion of free PSA suggests a lower risk of PC.

Age-specific ranges are available (Table 49.2) and help make it a better predictor, but this is only a rough guide because variations occur due to racial difference. There is no threshold for PSA below which PC cannot be found.

Prostate biopsy

Prostate biopsy is a definitive method to diagnose PC; a sample, or 'core', of the prostate is sent to the laboratory for histological analysis. TRUS-guided biopsy will help obtain samples from the peripheral and transitional zones of the prostate and other suspicious areas. A traditional TRUS-guided biopsy involves random sampling of the prostate with 10–12 biopsies of the peripheral zone. More recently, areas suspicious for PC as seen on TRUS or MRI are the focus of biopsy.

Fig. 49.5 Gleason scale.

Transperineal biopsies, also known as ‘template biopsy’, is a new method for performing strategic biopsies of the prostate gland using a ‘mapping’ grid. This also increases the number of prostate biopsies taken; it is performed under general anaesthetic. It can be advantageous in relation to areas where TRUS biopsy commonly fails to reach. The peripheral zone of the prostate is the location where the majority of the PC occurs. It is difficult to identify PC from transurethral resection of the prostate specimens because not much of it occurs in the transitional zone.

Until 2016 the Gleason scale (Gleason and Mellinger, 1974) was the most widely accepted histological grading system used in the UK, USA and Europe. Histological examination of biopsy tissue is undertaken to identify cancer cells, and these are scored from 1 to 5 depending on the different pattern of glandular tissue (Fig. 49.5). A score of 1 corresponds to well-differentiated cells, whereas a score of 5 corresponds to poorly differentiated cells; the higher the score, the more aggressive the cancer. The number for the two most common types of cell in the sample are added together to get a Gleason score. The score ranges from 2 to 10. The score was used to help predict the future behaviour of the tumour and determine the treatment required.

In 2014 it was recognised that the Gleason scale needed modification. A consensus conference was held and a new scoring system was proposed (Box 49.2) (Epstein et al., 2016) that has also been accepted by the World Health Organization.

Cancer staging

Results from a DRE, biopsy and scan are used to identify the extent of the cancer. The tumour volume, whether there is invasion into or through the capsule, and spread to lymph nodes or bone are all taken into consideration for staging. Staging based on the tumour, node, metastasis system is a classification accepted worldwide (Epstein et al., 2005). Based on the tumour, node, metastasis classification, PC can be classified into: (1) localised disease, (2) locally advanced disease or (3) advanced/metastatic disease.

Box 49.2 Histological definition of new grading system (Epstein et al., 2016)

Grade group 1 (Gleason score ≥ 6) – only individual discrete, well-formed glands
 Grade group 2 (Gleason score $3 + 4 = 7$) – predominantly well-formed glands with lesser component of poorly formed/fused/cribriform glands
 Grade group 3 (Gleason score $4 + 3 = 7$) – predominantly poorly formed/fused/cribriform glands with lesser component of well-formed glands^a
 Grade group 4 (Gleason score $4 + 4 = 8$; $3 + 5 = 8$; $5 + 3 = 8$) – only poorly formed/fused/cribriform glands or predominantly well-formed glands and lesser component lacking glands^b or predominantly lacking glands and lesser component of well-formed glands^b
 Grade group 5 (Gleason score 9–10) – lacks gland formation (or with necrosis) with or without poorly formed/fused/cribriform glands^a

^aFor cases with >95% poorly formed/fused/cribriform glands or lack of glands on a core or at radical prostatectomy, the component of <5% well-formed glands is not factored into the grade.

^bPoorly formed/fused/cribriform glands can be a more minor component.

Treatment

The factors that must be considered to aid the treatment decision relate to the tumour and the patient.

Tumour: staging result, histology, scoring system result and the PSA concentration

Patient: age at diagnosis, life expectancy and the presence of comorbidities such as cardiovascular disease, chronic obstructive pulmonary disease and diabetes

Fig. 49.6 illustrates the site of action of some treatments used in PC.

Localised prostate cancer

Established treatments with curative intent

Active surveillance. It is difficult to distinguish PC which may not cause any problems from that which may grow and spread aggressively. Curative treatment can improve longevity but has side effects which include impotence and incontinence, and can affect the quality of life of the individual. Patients on active surveillance are monitored closely by repeated testing of PSA levels, DRE and biopsy with the intention to make a radical intervention to treat if there is disease progression. A 20-year outcome study following conservative management of localised PC found that the annual mortality rates did not support aggressive treatment (Albertsen et al., 2005). Although active surveillance can spare side effects of treatment without compromising survival, regular biopsies used to monitor the disease can also be uncomfortable and carry a risk of infection. The optimal schedule for measuring PSA and repeating biopsies is unclear.

Radical prostatectomy. Radical prostatectomy is the treatment of choice for localised PC, and the procedure involves

Fig. 49.6 Diagrammatic representation of the site of action of some treatments used in prostate cancer.

the total removal of a prostate, seminal vesicle, distal vasa, ejaculatory ducts and prostatic urethra. In the open procedure it is performed by the retro pubic or perineal approach based on the surgeon's choice. Laparoscopic prostatectomy, and more recently robotic-assisted laparoscopy, have been developed and are now the commonest treatment modalities. The most common complications of prostatectomy are blood loss, post-operative thromboembolism, urinary incontinence, impotence and rectal injury.

Radical external-beam radiotherapy. Radiotherapy is used for locally confined disease and more recently for locally advanced disease state as well. In this treatment high-energy photons produced by a linear accelerator are targeted at the prostate. Sometimes special particles such as protons and heavy ions are used and have advantages over photons in terms of dose distribution. The side effects of radiotherapy include impotence, genitourinary stricture, rectal bleeding, haematuria and incontinence.

Interstitial brachytherapy. With interstitial brachytherapy radioactive isotope seeds are placed in the prostate under ultrasound control. These implants can emit radiation of low energy over several weeks and can be temporary or permanent. This treatment has the potential advantage of less erectile dysfunction than other treatments.

Minimally invasive procedures

Several minimally invasive procedures are in the development stage, and although they may be used in some centres, there are no medium- or long-term follow-up data to prove efficacy. The various procedures are detailed in the following subsections.

Cryosurgical ablation of prostate. Cryosurgical ablation involves freezing the prostate which results in cell death by protein denaturation, direct rupture of cellular membranes and apoptosis. Freezing is achieved by placing 12–15 cryoneedles into the prostate guided by a transrectal ultrasonograph and using the cryoneedles to create freeze–thaw cycles using temperatures of -40°C .

High-intensity focused ultrasound. In high-intensity focused ultrasound, ultrasound waves from a transducer are focused on the prostate tissue to cause damage to the cells by mechanical and thermal effects. The malignant tissue is subjected to temperatures above 65°C , and hence is destroyed by coagulative necrosis.

Radiofrequency interstitial tumour ablation. Radiofrequency interstitial tumour ablation involves a needle electrode being placed inside the prostate and radiofrequency waves being delivered through it to heat the tissue up to 100°C , thereby causing necrosis.

Non-curative intent: 'Watchful waiting'

The 'watching waiting' approach implies that the patient is observed for symptomatic progression and will only receive palliative treatment when clinical symptoms develop. Because the disease often progresses slowly, watchful waiting is an option for patients with early disease because it maintains their quality of life and avoids complications related to surgery or radiation therapy. On the downside, it is not a curative option; the cancer can metastasise, be a source of pain and reduce life expectancy.

Locally advanced prostate cancer

Hormonal therapy/androgen deprivation therapy

In locally advanced disease involving areas outside the capsule, there is an increased risk of relapse and lymph node metastasis after prostatectomy. Testosterone (an androgen) is thought to drive PC; therefore, there are available treatments to reduce available androgens (see Fig. 49.6).

Androgens are produced both in the testes (95%) under the stimulation of luteinising hormone (LH) and luteinising hormone–releasing hormone (LHRH) from the pituitary gland, and in the adrenal glands (5%) under the stimulation of adrenocorticotropic hormone (ACTH). The androgens produced by the adrenal gland are hormone precursors that are enzymatically converted to testosterone and DHT in prostatic and peripheral tissue. Because testosterone is a well-known aetiological factor associated with PC, it follows that testosterone deprivation can be utilised as part of treatment strategies. In practice this can be achieved by either surgical or medical castration with the period of hormonal control varying from a few months to years.

Medical castration. A number of drugs can be used to reduce the levels of testosterone to those achieved by castration.

Luteinising hormone–releasing hormone agonists. LHRH is released in the hypothalamus and stimulates the secretion of LH by binding to the LHRH receptors in the pituitary. This LHRH receptor complex is normally broken down by enzymes which lead to the release of LH and frees the receptors for further binding with LHRH. LHRH agonists are synthetic analogues that bind to the LHRH receptor, and the complex

formed is resistant to enzymatic action. Thus, they maintain a continuous presence on the receptor and render the pituitary gland refractory to hypothalamic regulation compared with the pulsatile release in normal individuals. Continuous administration of LHRH agonists exhibits a biphasic response. There is an initial increase in LH and testosterone release which may cause a ‘tumour flare’ in metastatic disease followed by a fall over the following 1–2 weeks because of the negative feedback down-regulation and decrease in LHRH release as the receptors are continuously occupied. ‘Tumour flare-up’ is prevented by first initiating treatment with an anti-androgen before the use of LHRH agonist. The anti-androgen is then continued for a further 2 weeks. Currently available LHRH analogues include buserelin (nasal spray), goserelin, triptorelin and leuprorelin. Goserelin and leuprorelin are administered subcutaneously at monthly or 3 monthly intervals, whereas triptorelin is administered intramuscularly at monthly, 3 monthly or 6 monthly intervals.

Anti-androgens. Anti-androgens competitively inhibit the effect of androgens peripherally by competing with testosterone and DHT for binding sites in the prostate. This results in inhibition of cell growth and apoptosis. Based on their chemical structure, the anti-androgens can be further divided into steroidal agents, which include cyproterone acetate, megestrol acetate and medroxyprogesterone, and non-steroidal agents such as nilutamide, flutamide and bicalutamide.

The steroidal agents also possess progestational activity and inhibit LH secretion by acting centrally on the pituitary, thereby reducing serum testosterone levels. The non-steroidal agents do not possess this additional property. Cyproterone is the most widely used steroidal agent normally administered in two or three daily doses of 100 mg despite having a half-life of 30–40 hours. It can be used to treat the hot flushes associated with LHRH agonists or orchiectomy. Side effects include hepatotoxicity, loss of libido and potency, fatigue and depression. Use of medroxyprogesterone and megestrol is limited because of less favourable outcomes in clinical trials compared with cyproterone.

Non-steroidal anti-androgens are used in patients who wish to preserve their quality of life as they do not suppress testosterone and hence preserve libido, physical performance and bone mineral density. The disadvantage of bicalutamide, flutamide and nilutamide is a reduced survival when used as monotherapy because of a gradual rise in testosterone. All three agents have side effects of gynaecomastia, gastro-intestinal upset, idiopathic hepatocellular toxicity and haematuria. Bicalutamide has a better safety and tolerability profile compared with nilutamide and flutamide (Inversion, 2002) and is the commonest one seen in clinical practice. Some trials show that non-steroidal anti-androgens used in combination with surgical castration or LHRH agonists bring about complete or total androgen blockade by also reducing the production of androgens from the adrenal glands, which normally accounts for 5% of the body’s production, thereby conferring a small survival advantage.

LHRH agonists and the non-steroidal anti-androgens have been used as neoadjuvant treatment to reduce tumour size before further surgery or other treatment. They can also be used as adjuvant treatment given in addition to primary/initial treatment to reach a treatment goal, or with radiotherapy to improve disease-free and overall survival in patients with locally advanced disease.

Metastatic prostate cancer

Metastatic PC infers the spread of cancer to other areas of the body; it is commonly spread via blood to the bones (90%), lung, liver and adrenals plus via the lymphatic system. Bone metastases commonly appear in the vertebrae and ribs, as well as skull, thorax, pelvis, spine and proximal long bones. X-rays typically show PC metastases as sclerotic lesions, but they appear late. A bone scan or CT/positron emission tomography imaging can be used to detect areas of skeletal metastases, but can have false-positive results. In some patients with vertebral metastases, spinal cord compression can occur and is treated as an oncological emergency.

The following subsections discuss options to arrest PC spread by suppressing the testosterone axis, but these options are not curative and eventually castrate-resistant disease will develop in most patients.

Luteinising hormone-releasing hormone agonists

Patients with metastatic cancer of the prostate usually respond to treatment with LHRH agonists and use is as described earlier for locally advanced disease.

Surgical castration

Surgical castration by bilateral orchiectomy is the treatment of choice for metastatic disease. Advantages include its low cost and morbidity, with testosterone levels falling to castration levels within 5–12 hours of surgery. The disadvantages include psychological trauma, its irreversible nature and the fact that nearly half experience side effects including loss of libido and potency, hot flushes, and bone and muscle loss.

Other palliative treatments

Luteinising hormone-releasing hormone antagonists. LHRH antagonists, which include degarelix and abarelix, work by competitively binding to LHRH receptors in the pituitary, thereby suppressing LH release and creating a rapid and sustained decrease in testosterone levels. They do not cause an initial surge in testosterone levels, and hence there is no risk of ‘tumour flare’ or need for short-term treatment with anti-androgens, unlike the LHRH agonists. Abarelix requires an induction regimen followed by monthly injections, and use is associated with anaphylactic reactions. Degarelix is given as a monthly depot injection; the most common side effect is a local reaction at the injection site such as swelling and erythema. Degarelix has a place in metastatic PC where the patient is acutely symptomatic with impending spinal cord compression, ureteric obstruction and urinary retention. Degarelix reduces testosterone, LH and PSA levels faster than LHRH agonists and reduces microsurgues of testosterone.

Bisphosphonates. Skeletal involvement in PC can be disease related or due to androgen depletion therapy. Bisphosphonates are pyrophosphates that inhibit osteoclast activity in bones, and hence prevent and treat bone lesions. They are administered by intravenous infusion. Pamidronate prevents bone loss, whereas zoledronate not only increases bone mass while on androgen depletion therapy, but also reduces skeletal complications in patients with bone metastasis secondary to PC (Saad and Schulman, 2004).

Bisphosphonates are also recommended for pain relief when analgesics and palliative radiotherapy to bone have failed. Dental examination needs to be carried out before commencing treatment with a bisphosphonate because of the risk of osteonecrosis of the jaw in those with a history of dental trauma, infection or surgery.

Ketoconazole. This anti-fungal can be used at a higher dose than is normal for its anti-fungal effect to inhibit the testicular and adrenal cytochrome P450 enzyme synthesis of sex steroids. It has a rapid onset of action, is usually prescribed at a dosage of 400 mg three times daily and is generally used at the time of acute presentation of metastatic PC. Because it causes adrenal suppression, hydrocortisone supplementation is necessary. Side effects of ketoconazole include drug-induced toxicity, adrenal suppression and hepatotoxicity.

Dexamethasone. Dexamethasone is used if spinal cord compression is suspected and in the palliative setting to improve symptoms and relieve pain.

Castrate-resistant prostate cancer

Androgen deprivation therapy will eventually fail to control disease progression. The reasons for this are unclear but include the clonal selection hypothesis or adaption hypothesis. In the clonal selection hypothesis, the premise is that the basal cells are the stem cells of the prostate and generate secretory epithelial cells. Whilst the secretory epithelial cells undergo apoptosis upon androgen withdrawal, this is not the case with basal or stromal cells. As a consequence, there is selective survival of these androgen-independent cells within the tumour. With the adaption hypothesis, there is the assumption that androgen independence may be an intrinsic, but dormant property of some prostate cells that is activated by androgen deprivation. Whatever the explanation, when there is failure of first-line therapy, quality of life can be improved by using single or combination therapy that includes maximal androgen blockade (by adding an anti-androgen), second-line hormone treatment (oestrogens), corticosteroids, ketoconazole, chemotherapy and bisphosphonates for short-term palliative response.

Oestrogen

Diethylstilboestrol is a synthetic oestrogen which acts by producing negative feedback on the hypothalamus and anterior pituitary, thereby down-regulating the secretion of LHRH, and hence the production of testosterone. Diethylstilboestrol is the least expensive of the synthetic oestrogens and causes fewer hot flushes and psychological trauma compared with the surgical option. Side effects include gynaecomastia, loss of libido and potency, oedema, nausea and vomiting, and significantly increased risk of thromboembolism. It is usually used in a dose of 1 mg once daily to reduce the risk of cardiovascular side effects because it is associated with increased cardiovascular mortality. It is now mainly avoided in practice for this reason.

Corticosteroids

Both prednisolone and hydrocortisone are anti-inflammatory, can alter the body's immune response to various stimuli and are used in combination with other treatments.

Chemotherapy

Chemotherapy inhibits cell growth and proliferation; it has a variable response rate and is used as a last resort.

In the UK, NICE (2006) recommended that docetaxel is used within its licensed indication to treat men with hormone refractory metastatic disease. Repeat courses of treatment are not recommended if the disease reoccurs when the planned course of 10 cycles is complete.

The UK-led STAMPEDE trial is a complex multi-centre randomised controlled trial for patients with locally advanced or metastatic PC who are about to commence androgen deprivation therapy (James et al., 2016). The addition of docetaxel to standard care was associated with increased survival. The trial is still ongoing, but increasing numbers of men are offered upfront chemotherapy as a result.

For the treatment of adult men with metastatic castration-resistant PC whose disease has progressed during, or after, docetaxel therapy, abiraterone (NICE, 2016a), cabazitaxel (NICE, 2016b) and enzalutamide (NICE, 2016c) are approved by NICE.

Abiraterone acetate. Abiraterone acetate is an androgen biosynthesis inhibitor that blocks biosynthesis of extragonadal androgens. Abiraterone leads to a rebound increase in LH and in ACTH, and so it is given with low-dose corticosteroids to normalise mineralocorticoid levels and reduce side effects. Abiraterone is taken orally in combination with prednisolone 5 mg twice daily, on a 28-day cycle. It must not be taken with food. Patients should be advised that taking the dose at night can often minimise the lethargy that is a potential side effect. If toxicity occurs, treatment should be suspended and restarted with the advice of the treating oncologist; there is no evidence to support reducing the dose. The most commonly observed side effects are hypokalaemia, hypertension, lower-limb oedema, diarrhoea and lethargy.

Enzalutamide. Enzalutamide acts on three steps in the androgen receptor signalling pathway: as an androgen receptor antagonist (no agonist activity); by inhibiting translocation of the androgen-receptor complex to the cell nucleus; and by inhibiting receptor binding to DNA in the nucleus and, therefore, preventing cell replication and instigating apoptosis. Enzalutamide is another oral agent and should be swallowed whole with water and can be taken with or without food. If a patient experiences serious toxicity or an intolerable adverse reaction, he will require interruption of enzalutamide therapy and dosing should be withheld for 1 week, or until symptoms improve, then resumed at the same or a reduced dose. The most common side effects are hypertension, hot flushes and headache.

Both abiraterone and enzalutamide can interact with other drugs. Abiraterone may increase exposure of other medicines metabolised by cytochrome P450 (CYP) 2D6, which include metoprolol, propranolol, desipramine, venlafaxine, haloperidol, risperidone, propafenone, flecainide, codeine, oxycodone and tramadol. Enzalutamide is a strong CYP3A4 enzyme inducer. Interactions with medicines that are eliminated via CYP3A4 metabolism are expected, including fentanyl, clarithromycin, cabazitaxel, warfarin, anti-epileptics and calcium channel blockers.

Table 49.3 Common problems associated with prostate cancer

Problem	Solution
Loss of erectile function after prostatectomy	Phosphodiesterase 5 inhibitors such as sildenafil have shown efficacy in prevention and help improve chance of spontaneous erection. If medication fails or is contraindicated a vacuum device, intraurethral inserts or penile prosthesis may be used
Advanced disease with impending spinal cord compression	Treat with oral dexamethasone and either cyproterone or ketoconazole with external-beam radiotherapy. LHRH agonist treatment is not advisable as the tumour flare up in the initial stage can stimulate tumour growth and exacerbate the condition
Bleeding and coagulation disorder	Prostate cancer can cause disseminated intravascular coagulation as a pathological response to the disease. This is a rare condition where small blood clots are formed in the body, disrupt the normal coagulation process and cause bleeding. This can be further complicated if the patient has comorbidities which require treatment with anticoagulants. Prompt treatment of the cancer with hormones and in some cases replacement of blood, platelets and clotting factors may be required
Hot flushes during androgen deprivation therapy	The hypothalamus is the centre for thermoregulation. Orchiectomy and LHRH agonists inhibit some of the peptides involved in thermoregulation. This increases central adrenergic activity and inappropriate stimulation of thermoregulatory centres, causing peripheral body vasodilatation and hot flushes. Low dose cyproterone acetate (100 mg a day) has been used to suppress hot flushes

LHRH, Luteinising hormone–releasing hormone.

Sipuleucel-T

The autologous cellular immunotherapy vaccine sipuleucel-T stimulates the patient's own immune cells to identify and attack PC cells. It is generated from a patient's own peripheral immune cells, obtained via leucopheresis, which are then exposed to a fusion peptide of granulocyte macrophage colony-stimulating factor (serving as immune adjuvant) and pulmonary alveolar proteinosis. It is extremely expensive and available only in a few specialist centres. However, there is renewed interest in immune therapy in oncology; therefore, further trials are expected.

Radium-223

Radium-223 is a radioactive isotope that emits low levels of alpha particle radiation, which causes double-strand breaks in DNA, killing cells. It acts as a 'calcium mimetic' that, like calcium, accumulates preferentially in areas of bone that are undergoing increased turnover, and therefore acts against bone metastases. Patients receiving radium-223 also reported a better quality of life than patients in the placebo group (Parker et al., 2013).

Chemoprevention

Chemoprevention is defined as the administration of micronutrients, dietary products or drugs to prevent or delay the progression of PC.

Diet

There has been interest in a variety of products, and numerous studies have been conducted. Currently in favour are soya-containing foods, green tea, pomegranates and omega-3 fatty

acids. Selenium and vitamin E are no longer considered favourable because large, randomised studies showed no benefit and some cardiovascular downsides. Similarly, vitamin D and lycopene found in tomatoes are also out of favour due to the lack of hard positive outcomes.

Drugs

5 α -Reductase inhibitors which are currently used in BPH to reduce prostate size due to their inhibitory effect on the production of DHT are thought to have potential for chemoprevention.

Patient care

Treatment options are decided after discussing the various options and side effects with the individual and as part of a multidisciplinary team meeting. Urinary- and sexual function-related problems are common side effects of most treatments in PC and need to be discussed in detail with the patient. Emotional factors like depression may also need to be addressed because they can adversely affect the quality of life of the individual. Clinical nurse specialists are an excellent source of support and information for patients. Some of the common problems associated with PC are listed in Table 49.3. Patients can also be referred to the NHS website (<http://www.nhs.uk/prostatecancer>) for facts, information and details of choices available in the diagnosis and treatment of PC. Information on how to cope with the disease and live with PC together with details of various support organisations are available online (such as <http://www.cancerresearchuk.org/about-cancer/>).

Prostatitis

Epidemiology

The term prostatitis comprises a range of disorders that have been defined and classified (Table 49.4) by the International Prostatitis Collaborative Network into four categories (Krieger et al., 1999).

Prostatitis has been estimated to affect up to 16% of adult men. Unlike BPH and PC, which are more prevalent in older men, prostatitis affects men of all ages.

In most instances (between 90% and 95%) the aetiology of prostatitis is unknown with bacteria isolated in only 5–10% of men presenting with prostatitis.

Pathophysiology

Acute bacterial prostatitis is caused by bacterial infection. The most common isolated uropathogen is *Escherichia coli*. Other causative agents include *Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp. and, less commonly, enterococci, *Bacteroides* and *Staphylococcus* spp. Chronic bacterial prostatitis usually involves recurrent bacterial urinary infections caused by the same organism involved in acute bacterial prostatitis. Both syndromes are of infective origin and represent the minority of cases of prostatitis.

In contrast, the aetiology of chronic prostatitis/chronic pelvic pain syndrome is poorly understood. Several possible mechanisms have been proposed including autoimmune disorders, infection, neurogenic inflammation and voiding dysfunction.

Symptoms

In prostatitis, the clinical presentation and symptoms are a strong diagnostic determinant. A validated questionnaire, the Chronic

Prostatitis Symptom Index, quantifies the severity, frequency and location of pain and discomfort. It is also used to assess urinary symptoms and to establish the impact of symptoms on the patient's quality of life.

Patients with acute bacterial prostatitis usually present with symptoms of an UTI which may include dysuria, urinary frequency or urgency, whilst some may present with pain of penile, lower back or perineal origin. Signs and symptoms of systemic infection can be present in some cases and include pyrexia, rigors, malaise and myalgia. Acute bacterial prostatitis can sometimes precipitate acute urinary retention due to prostatic inflammation. A recent history of transrectal biopsies, cystoscopy or catheterisation is common.

In chronic bacterial prostatitis, symptoms of UTI and pain can also be present. Typically, men with chronic bacterial prostatitis remain asymptomatic between infective episodes.

The main feature in chronic prostatitis/chronic pelvic pain syndrome is urological pain (perineum, lower abdomen and back, rectum, penis and testicles). These symptoms are usually present for at least 3 months before a diagnosis can be made. Lower urinary tract symptoms and ejaculatory dysfunction can also affect men with chronic prostatitis/chronic pelvic pain syndrome.

Patients with asymptomatic inflammatory prostatitis have no symptoms. The condition is usually diagnosed when patients undergo investigation to assess other genitourinary complaints. For example, prostatitis may be found in biopsies taken from patients investigated for elevated PSA or when leucocytes are found in semen samples from men being investigated for infertility.

Examination and investigations

If acute bacterial prostatitis is suspected, a urine dipstick and culture are performed to reveal the presence of pathogens and leucocytes. Depending on the clinical picture, a blood culture may be indicated to diagnose concomitant bacteraemia. An ultrasound scan of the bladder can be conducted to evaluate the residual volume of urine and problems with voiding and urinary retention. Rectal examination may reveal an exquisitely tender prostate.

Chronic bacterial prostatitis is diagnosed in men with a history of recurrent or relapsing UTIs. A positive urine dipstick and culture is a common finding during acute episodes. Microscopy and culture of lower tract urinary secretions (urine and prostatic) between symptomatic periods can be performed and will help identify the prostate as the main focus of infection. Imaging of the urinary tract via ultrasound or MRI can be conducted to rule out any structural abnormalities.

Chronic prostatitis/chronic pelvic pain syndrome is a diagnosis of exclusion. Typical disorders which must be excluded include the presence of active urethritis, urogenital cancer, urinary tract disease, functionally significant urethral stricture or neurological disease affecting the bladder (Krieger et al., 1999). The main component of this syndrome is the presence of genitourinary pain. After taking a detailed medical history, the evaluation of symptoms can be done using the Chronic

Table 49.4 International Prostatitis Collaborative Network classification of prostatitis

International Prostatitis Collaborative Network classification	Comment
I. Acute bacterial prostatitis	Acute infection of the prostate
II. Chronic bacterial prostatitis	Chronic infection of the prostate
III. Chronic prostatitis/chronic pelvic pain syndrome	No evidence of infection
A. Inflammatory	Leucocytes in prostatic secretions, post-prostate massage urine or semen
B. Non-inflammatory	No evidence of inflammation
IV. Asymptomatic inflammatory prostatitis	Lack of genitourinary symptoms

Prostatitis Symptom Index. Other investigations include a DRE, urinalysis, urine culture and cytology, screening for sexually transmitted diseases, urodynamic studies, prostatic TRUS and serum PSA.

Treatment

Acute bacterial prostatitis can present as a serious infection, and therapy normally includes empirical treatment with parenteral antibiotics. Commonly used agents include broad-spectrum penicillins, fluoroquinolones or third-generation cephalosporins usually in combination with aminoglycosides. Urine culture and sensitivities will inform the choice of future antibiotic treatment, which is recommended to be continued for 2–4 weeks. General supportive measures such as maintenance of appropriate hydration and pain relief are important. Suprapubic catheterisation may be required if acute urinary retention is present.

The treatment of chronic bacterial prostatitis involves long courses (at least 4 weeks) of antibiotics. Fluoroquinolones (e.g. ciprofloxacin, ofloxacin) are used as first-choice agents because of good prostatic penetration, their spectrum of antibacterial activity and favourable safety profile. If infective episodes are frequent, patients can be offered prophylactic antibiotics for several months with periodic follow-up to monitor progress (McNaughton-Collins et al., 2007).

Because the aetiology of most cases of chronic prostatitis/chronic pelvic pain syndrome is unknown, management often involves empirical treatment. Despite not being considered to have an infective nature, up to 50% of patients with chronic prostatitis/chronic pelvic pain syndrome respond to long courses of fluoroquinolones (Nickel et al., 2001), especially men with symptoms of relatively recent onset (a few weeks). Patients with longstanding symptoms refractory to treatment are less likely to benefit from fluoroquinolones. α -Adrenoceptor antagonists are also used alone or in combination with antibiotics in the management of chronic prostatitis/chronic pelvic pain syndrome. The evidence for efficacy is conflicting but remains an option for patients with persistent symptoms. Initially non-steroidal anti-inflammatory drugs (NSAIDs) have a role, as do the neurological pain agents such as gabapentin. There are also limited data describing the use of other therapies in chronic prostatitis/chronic pelvic pain syndrome such as fluoxetine, pollen extract, quercetin, finasteride, mepartricin and pelvic electromagnetic therapy.

No treatment is necessary for patients with asymptomatic inflammatory prostatitis because the condition is characterised by the lack of symptoms.

Patient care

Patients need to be made aware that prostatitis is common, affecting between 1 and 2 out of every 10 men, but very difficult to treat and eradicate. The cause is generally poorly understood,

and it is difficult to diagnose. In chronic cases of prostatitis, symptoms may persist for long periods, although the severity can vary over time. Treatment may involve several therapies. Patients treated with antibiotics must be informed of the importance of completing the prolonged courses necessary to eradicate infection.

The British Prostatitis Support Association's website (<http://www.bps-assoc.org.uk>) offers information and support to patients.

Case studies

Case 49.1

Mr AT, a 64-year-old man, presents with poor urinary flow and waking at least twice during the night to pass urine. There is no family history of prostate disease, and he is taking no medication.

Question

What investigations are appropriate, and how should Mr AT be managed?

Answer

This patient should be asked to complete a frequency volume chart of voided urine and International Prostate Symptom Score questionnaire, then undergo a full clinical examination, including DRE, abdominal and genital examination. The patient can be offered PSA testing. The PVR volume of urine within the bladder should be measured after micturition.

If the residual volume is low (0–100 mL), the flow rate adequate (>15 mL/s) and the patient's symptoms not bothersome, then he can be reassured and adopt a 'watch and wait' policy. If the PSA is high, then this should be investigated further with imaging as per local hospital policy. Evidence of urinary retention should be managed with catheterisation.

If, however, the patient has slow flow, PVR 100–300 mL and/or has bothersome symptoms, then he can be counselled on medical therapy and offered an α -adrenoceptor antagonist. If he is not hypertensive, a uroselective drug such as tamsulosin can be considered. This should have few systemic side effects and requires no initial titration of dose. If he is hypertensive, a less specific α -blocker may be more appropriate which will serve the dual purpose of an antihypertensive agent, as well as treating his urinary symptoms. Careful dose titration may be necessary initially to counter any potential postural hypotension. The combination of 5 α -reductase inhibitor may be considered in patients with larger prostates (>40 g) because this may reduce the risk of progression of BPH.

Case 49.2

Mr CH, a 50-year-old man, requests treatment from his primary care doctor for a 'bladder infection'. On questioning, he describes symptoms of urinary frequency, urgency and urge incontinence, but fever and dysuria are absent.

Question

How should Mr CH be treated?

Answer

The layperson may interpret the symptoms of frequency and urgency as representing an UTI, but in the absence of dysuria this is unlikely. Urinalysis should be performed to assess the presence of leucocytes, blood and nitrites in the urine, which would confirm an infection.

In the absence of infection the patient should be referred for a full clinical assessment which could include urodynamic studies, filling and voiding cystometry, an ultrasound scan of the upper urinary tract, measurement of PSA and assessment of renal function. It is likely the patient has an outflow obstruction which has given rise to secondary instability of the detrusor muscle in the bladder, causing involuntary contractions of the bladder and resulting in incontinence. The other differential is idiopathic detrusor instability or OAB. The obstruction may be caused by either prostate enlargement or a dysfunctional bladder neck. In either case, treatment with an α -adrenoceptor antagonist is appropriate to reduce the outflow resistance. Should the flow be adequate but symptoms of incontinence persist, then concurrent treatment with an antimuscarinic drug such as oxybutynin or tolterodine may be necessary to inhibit the cholinergic-mediated contractions of the detrusor. A combination preparation of tamsulosin and solifenacin (Vesomni) may be preferred.

Case 49.3

Mr IK, a 75-year-old man, presents with acute urinary retention and a history of nocturnal enuresis for the past 2–3 months. His medical history includes a heart valve replacement. He denies any haematuria or dysuria and felt he had a good flow while passing urine. On DRE, the prostate is found to be hard and nodular, and the PSA was 662 ng/mL. He has a palpable bladder to the level of the umbilicus.

The MRI pelvis revealed an enlarged and irregular prostate with intra-vesicle extension of the medial lobe into the bladder neck. Mr IK was confirmed to have adenocarcinoma of the prostate with a Gleason score of 8 and with bone metastasis.

Mr IK's PSA declined from 662 to 130 ng/mL in 5 months and continued to fall to 3.2 ng/mL after 9 months, indicating a good response to hormonal treatment. Although Mr IK wanted to be catheter free, he failed several trials without a catheter and was offered radical radiotherapy and a channel TURP to control local obstructive symptoms.

Questions

1. What investigations are recommended, and how should Mr IK be managed?
2. What treatment choice is available for Mr IK?
3. What are the most likely future complications expected for Mr IK?

Answers

1. Because acute urinary retention can cause renal damage, Mr IK needs to be catheterised to relieve his bladder outflow, and the residual volume and renal function measured. A hard and nodular prostate on DRE together with elevated PSA suggests PC. A high PSA in the context of acute urinary retention does not directly infer PC; if the DRE is normal, then the PSA should be repeated at a later date prior to further investigation. However, with a PSA greater than 100 ng/mL, PC is extremely likely. In view of the suspicious DRE the patient needs to have a range of baseline investigations including a TRUS biopsy and/or MRI of the pelvis

and/or isotope bone scan. Although the DRE is suggestive of PC, the TRUS biopsy helps to grade the cancer using the Gleason scale and helps in making the decision about treatment. The bone scan helps identify bone metastasis, which along with the results from MRI is used to stage the cancer based on the tumour, node, metastasis score.

2. Surgical castration can bring down the testosterone levels immediately and is relatively inexpensive but may have a psychological impact on the patient in addition to impotence and hot flushes. Medical castration with LHRH analogues would be effective treatment as well. LHRH agonists can be used to treat systemically, but the concern with this group of drugs is the flare of the disease due to the initial surge in testosterone levels, in addition to the other side effects of decreased libido, hot flush and impotence. Flare can precipitate life-threatening symptoms of the disease if the cancer is close to the spinal cord, where it may cause spinal cord compression and paralysis. If lymph nodes near the ureter are involved, the flare can increase the node size and compress the ureter causing renal impairment. It can also increase bone disease causing severe bone pain. Although initiation of anti-androgens can reduce symptoms of hot flushes associated with flare-up to some extent, the preferred option for patients with increased risk of spinal cord compression would be LHRH antagonist because it can reduce testosterone levels much more quickly with no flare-up. Hormonal treatment was commenced with an LHRH agonist injection together with a 1-month course of bicalutamide to protect against tumour flare.
3. As the disease progresses, Mr IK may develop hormone resistance, and non-hormonal treatment such as chemotherapy with docetaxel and abiraterone/enzalutamide may need to be considered. Osteoporosis is an important potential complication of long-term androgen deprivation therapy and metastatic bone disease, and consequently the patient may experience severe bone pain. Palliative radiotherapy to metastatic bone areas and NSAIDs are recommended to control the symptoms initially, but if pain persists, use of bisphosphonates may be necessary because they are known to inhibit osteoclast activity and relieve bone pain.

Case 49.4

Mr PH, a 35-year-old man, presents with a 3-month history of dysuria, frequency and hesitancy. He also reports pain in the perineum, radiating down the thighs, and discomfort while ejaculating. A DRE reveals the size and shape of his prostate seems to be normal, although it is tender on examination.

Question

What are the various conditions that need to be considered, and what medication will help confirm the diagnosis?

Answer

A urine dipstick and culture is recommended to rule out UTI. PSA can be measured but is raised in BPH, PC and prostatitis, and hence is not a definitive test, so this should be taken into consideration. The symptoms and physical examination are suggestive of chronic prostatitis. A swab should be taken to rule out chlamydia and other sexually transmitted diseases. Prostatitis needs to be confirmed after ruling out other possibilities such as epididymitis, epididymo-orchitis, urethral stricture, renal calculus, PC, bladder cancer and colorectal cancer.

The available evidence suggests a cure or an improvement in symptoms will occur if a quinolone antibiotic is prescribed for 4 weeks. NSAIDs and paracetamol can be used to relieve any associated pain, whilst faecal softeners may be required to reduce discomfort and pain when opening bowels.

Case 49.5

Mr AB, a 43-year-old man, seeks advice from a community pharmacist regarding his difficulty, over the past 3–4 months, when attempting to start urinating and then urinating for a long time. On questioning, he does not have any other significant medical history, and he has no symptoms of a UTI, pain or haematuria.

Questions

1. Is it appropriate to sell over-the-counter tamsulosin to Mr AB?
2. Does the pharmacist need to maintain a record of the sale?

Answers

1. Lower urinary tract symptoms, such as hesitancy and weak stream, indicate BPH which is prevalent in one in four men older than 40 years. Because it is a very sensitive topic for most males, the patient needs to be consulted in a private area to assess the severity of his symptoms by using the International Prostate Symptom Score (IPSS). This is a sum of seven urinary symptoms which include incomplete emptying, frequency, intermittency, urgency, weak stream, straining and nocturia. If these symptoms severely affect the quality of life and there are no contraindications, a supply of tamsulosin 400 micrograms to be taken once daily for 2 weeks initially and then for a further 4 weeks can be made while simultaneously referring the patient to his primary care doctor to confirm diagnosis and to assess his suitability for long-term treatment. If the symptoms do not improve within 14 days or the symptoms worsen, the patient should be asked to discontinue treatment and seek medical advice.
2. Record-keeping is necessary to confirm that the doctor has assessed the patient within 6 weeks of initiating treatment and thereby permits further supply. It is important that the patient's consent is obtained to keep this record.

50 Anaemia

Niamh McGarry and Anthony Cadogan

Key points

- Anaemia is a common condition. The World Health Organization estimates that the number of people worldwide with anaemia is 2 billion.
- Anaemia is a lack of haemoglobin and is proportional to the oxygen-carrying ability of the red blood cell.
- Anaemia can cause a myriad of symptoms, in part depending on the type of anaemia. The most consistent characteristic is tiredness-related symptoms.
- There are a number of causes, including iron deficiency (iron-deficient anaemia), defective haemoglobin synthesis (macrocytic anaemia and thalassaemia) or overactive destruction of red blood cells (haemolytic anaemia). It is useful to classify them based on the size of red blood cell: microcytic, normocytic or macrocytic anaemia.
- Treatment of anaemia begins with investigations to confirm the cause of the anaemia. There may be more than one cause of anaemia present.

Anaemia can be defined as a reduction from normal of the quantity of haemoglobin in the blood. The World Health Organization (WHO) defines anaemia in adults as haemoglobin levels less than 130 g/L for males and less than 120 g/L for females (WHO, 2011).

Epidemiology

Anaemia has a high prevalence worldwide. It has an impact on almost one-quarter of the population, based on WHO data from 1993–2005. In adults, the lowest prevalence is in men, at 12.7%. The threshold for anaemia in pregnancy is lower, and anaemia is more common in pregnancy. In the most recent WHO data from 2011, which did not include men, the prevalence of anaemia in non-pregnant women was 29% and was highest in pregnant women, at 38.2%. The average prevalence of anaemia in women of reproductive age was 29.4%. The elderly are susceptible to anaemia, with an average world prevalence of 23.9% (WHO, 2015).

There is a much higher occurrence of anaemia in South-East Asian, Eastern Mediterranean and African regions. This is due to a combination of factors, such as higher incidences of sickle cell anaemia and thalassaemias. It also reflects problems associated with sanitation, such as hookworm and schistosomiasis (WHO, 2015).

The haemoglobin level varies slightly in different altitudes and is higher in smokers. Haemoglobin is higher in males due to the influence of androgens, which increases haemoglobin production. In

the elderly, therefore, the haemoglobin values in men and women are less differentiated. Haemoglobin also has some dependence on the patient's fluid status. In dehydration, due to reduced circulating plasma volume, haemoglobin appears higher. In circumstances of higher plasma volume, such as pregnancy and splenomegaly, it will appear lower. The haemoglobin level does not always correlate with the degree of symptoms experienced by the patient.

Aetiology

The low haemoglobin level that defines anaemia results from two different mechanisms:

- increased haemoglobin loss due to either:
 - haemorrhage (red blood cell loss) or
 - haemolysis (red blood cell destruction).
- reduced haemoglobin synthesis due to either:
 - lack of nutrient or
 - bone marrow failure.

This chapter gives an explanation of the different types of anaemia. It focuses particularly on the types of anaemia that require drug treatment.

Haemopoiesis and erythropoiesis

Haemopoiesis

Haemopoiesis is the formation of blood cells, white blood cells, red blood cells and platelets. Haemopoiesis takes place predominantly in the bone marrow of the central skeleton and in the proximal ends of the long bones. It also takes place in the liver and the spleen, particularly at times of increased need.

All blood cells originate from the pluripotent haemopoietic stem cell. These stem cells have the potential to form any of the blood cells. The red blood cells (erythrocytes) are the most abundant of all the blood cells. Erythrocytes, once matured, do not contain a nucleus. This allows more capacity for the erythrocyte to carry oxygen.

Erythropoiesis

Erythropoiesis is the production line of red blood cells from the stem cells committed to red blood cell production (Fig. 50.1). The stem cell undergoes a complex series of cell divisions and differentiations. The first step is the stem cells proliferating into progenitor cells.

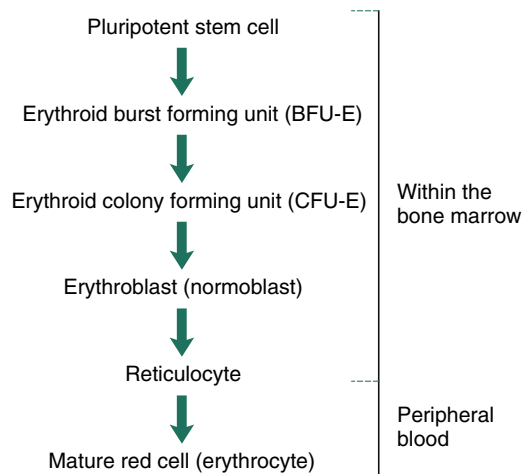

Fig. 50.1 Simplified diagram of some of the stages within erythropoiesis.

Haemoglobin, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) become synthesised along the way. Haemoglobin comprises four amino acid chains (globins), described as α_1 , α_2 , β_1 and β_2 , with each chain containing one haem molecule. A haem molecule is formed in mitochondria when a protoporphyrin (pigment) combines with iron in its ferrous state (Fe^{2+}), with pyridoxine acting as a co-factor. Each haem molecule can carry one molecule of oxygen.

The last stage of production in the bone marrow is the formation of the normoblast. A minority of these normoblasts die within the bone marrow without producing red blood cells (e.g. 10–15%). The majority of normoblasts, however, release a large number of reticulocytes into the circulation. Reticulocytes are immature red blood cells constituting a small proportion, 1–3% of all red blood cells. They mature into red blood cells within 48 hours. An increased percentage of reticulocytes is typical after acute blood loss.

Haemopoiesis and erythropoiesis are regulated by growth factors. The most important of these growth factors is erythropoietin. Erythropoietin is a hormone produced by the interstitial cells of the renal cortex. A small percentage, 10%, is produced in the liver and other organs. Erythropoietin production is influenced by the exposure to oxygen in the kidney and is increased in response to reduced oxygen tension. The kidney responds to hypoxia and anaemia by increasing the production of erythropoiesis. Hepcidin is also decreased; this is an inflammatory reactive protein that suppresses iron absorption.

Erythropoietin acts by increasing the number of progenitor cells committed to erythropoiesis. In renal failure, however, the kidney fails to produce sufficient erythropoietin and the patient becomes anaemic. As well as erythropoietin, bone marrow blood cell production requires a number of factors, such as iron, cobalt, vitamin B₁ (thiamine), B₆ (pyridoxine), B₁₂, vitamin C, vitamin E, riboflavin, androgens and thyroxine.

Erythropoietin production is suppressed in many inflammatory and/or chronic conditions, such as rheumatoid arthritis, cancer and sickle cell disease. It will also be sensitive to reduced oxygen tension changes due to impaired lung function and cardiovascular

Box 50.1 Non-specific signs and symptoms associated with anaemia

- Tiredness
- Pallor
- Fainting
- Exertional dyspnoea
- Tachycardia
- Palpitations
- Worsening angina
- Worsening cardiac failure
- Exacerbation of intermittent claudication

function. Each day, approximately 2×10^{11} erythrocytes enter the circulation (Hoffbrand and Moss, 2016).

Normal erythrocytes survive in the peripheral circulation for about 120 days. Abnormal erythrocytes have a shortened life-span. At the end of their life, the red blood cells are destroyed by the cells of the reticuloendothelial system found in the spleen and bone marrow. Iron is removed from the haem component of haemoglobin and transported back to the bone marrow for reuse. Part of the globin chains is excreted as conjugated bilirubin by the liver.

Clinical manifestations

Anaemia is a manifestation of a condition or more than one condition resulting in a decreased haemoglobin level. It varies widely in its presentation for different anaemia types. A reduction in haemoglobin means the red blood cells have less capacity for delivering oxygen to all the tissues and organs in the body. This results in related symptoms of tiredness, lethargy and exercise intolerance (Box 50.1). Cerebral symptoms such as reduced cognition, confusion, headaches and light-headedness may also be present. In severe or longstanding anaemia, it can progress to further symptoms of oxygen deprivation, such as shortness of breath, angina, tachycardia, palpitations and heart failure.

The speed of onset of anaemia is an important determinant of presentation. A rapid blood loss, for example, haemorrhage, produces shock, with collapse, dyspnoea and tachycardia. Anaemia that develops over a period of time allows the body to partially compensate. As the anaemia becomes worse, more and more signs and symptoms may develop.

Even though in anaemia the amount of haemoglobin is reduced, all the blood that passes through the lungs is fully oxygenated. Increasing the respiratory rate or increasing the FiO_2 (fraction of inspired oxygen) will not improve tissue oxygenation. When the haemoglobin falls to less than 70 or 80 g/L, there is almost always a compensatory increase in cardiac output. Hence, the impact of anaemia on a patient with existing cardiovascular or lung disease will be more profound. The elderly have a lower threshold for cerebral and cardiovascular symptoms than in a younger healthier adult.

Investigations

The diagnosis of anaemia requires a thorough medical history and holistic patient evaluation including noting any medicines the

Box 50.2 Anaemia classified by size and colour of red blood cells

Hypochromic–microcytic

- Folate deficiency
- Vitamin B₁₂ deficiency

Polychromatophilic macrocytic

- Haemolysis

patient is taking and any recent travel which could be linked with hookworm. It is important to be aware of any background of liver disease, chronic renal failure or other haematological history that could help explain laboratory test results and guide the diagnosis.

The investigation into the cause of anaemia begins with a full blood count. Haemoglobin, the mean corpuscular volume (MCV) and the mean cell haemoglobin (MCH) values are of particular interest. The MCV reflects the average size of the red blood cell. It is very useful and indicates microcytic (low MCV), normocytic (MCV in range) or macrocytic anaemia (high MCV). If there are two pathologies, where one causes large cells and other causes small cells, the MCV may appear normal or can be misleading.

The MCH is a similar indicator reflecting the density of the haemoglobin in the red blood cell and typically mirrors the MCV. It has been suggested that it is a more consistently reliable indicator due to the laboratory methods used to measure these indices (Goddard et al., 2011).

If in addition to haemoglobin, white blood cells (leukocytes) and platelet counts are also low this can be an indication of an overall bone marrow suppression (pancytopenia). In such cases, advice should be sought from haematology, and any drug-related causes of bone marrow suppression should be excluded.

Stained blood film allows examination of the morphology of the red blood cells. **Box 50.2** is a list of some of the most common anaemias categorised by size. This can give further evidence to the origin of the anaemia. It is particularly useful if there is more than one type of anaemia present.

Other haematinic tests needed for diagnosis are vitamin B₁₂, folate, ferritin, iron and iron-binding capacity/transferrin. Ferritin, iron and iron-binding capacity or variations of this may be referred to as an iron profile. In addition to the liver function tests and renal function tests mentioned, thyroid function tests should be checked because thyroxine is required for healthy bone marrow function. Ultimately, if the cause of the anaemia cannot be elucidated from peripheral blood, a bone marrow aspiration or biopsy will be required.

Iron-deficiency anaemia

Epidemiology

Iron deficiency is described as the most common deficiency state in the world and affects more than 2 billion people worldwide (Camascshella, 2015). A large proportion of this population will

Box 50.3 Major causes of iron-deficiency anaemia

- Inadequate iron absorption
 - Dietary deficiency
 - Malabsorption
- Increased physiological demand
- Loss through bleeding

have iron-deficiency anaemia (IDA). In developing countries, iron deficiency has a higher association with blood loss due to parasitic worms and insufficient dietary intake. In the developed world, it is attributed to dietary changes (such as veganism) and malabsorption or conditions leading to chronic blood loss. IDA occurs in 2–5% of adult men and postmenopausal women, in the developed world (Goddard et al., 2011). The incidence is always higher in women due to both menstrual blood loss and the high rate of IDA in pregnancy.

Aetiology

In Western societies, the commonest cause of iron deficiency is due to blood loss. In women of childbearing age, this is most commonly due to menstrual loss. Amongst adult males, the most likely cause is gastro-intestinal bleeding. Other causes of blood loss associated with iron-deficiency anaemia include haemorrhoids, nosebleeds or postpartum haemorrhage. The major causes of iron deficiency are listed in **Box 50.3**.

Pathophysiology

The elimination of iron is not controlled physiologically, so the homeostasis is maintained by controlling iron absorption. Iron is absorbed mainly from the duodenum and jejunum. Absorption itself is inefficient; iron bound to haem (found in red meat) is better absorbed than iron found in green vegetables. The presence of phosphates and phytates in some vegetables leads to the formation of unabsorbable iron complexes, whereas ascorbic acid increases the absorption of iron. In a healthy adult, approximately 10% of the dietary iron intake will be absorbed. Iron is transported around the body bound to a serum protein called transferrin. Normally, this protein is only one-third saturated with iron.

Anaemia may result from a mismatch between the body's iron requirements and iron absorption. The demand for iron varies with age (**Table 50.1**). Diets deficient in animal protein or ascorbic acid may not provide sufficient available iron to meet the demand.

Iron is an essential micronutrient needed for erythropoietic function. It has further roles in oxidative metabolism and in the cellular immune response. The human body contains around 50 mg/kg of iron. Most of this iron (65%) is stored in haemoglobin. A further 10% is stored in myoglobin in the muscles and other tissues. The remaining iron is stored in the liver, the reticuloendothelial system of the macrophages and in the bone marrow in the form of iron storage proteins, ferritin and haemosiderin.

Dietary intake is the source of iron. Typically, an adult might consume 15 mg iron daily, in haem (10%) and non-haem (90%) form, in the Western diet. Haem iron is found in meat and fish

Table 50.1 Typical daily requirements of iron

Infant (0–4 months)	0.5 mg
Adolescent male	1.8 mg
Adolescent female	2.4 mg
Adult male	0.9 mg
Menstruating female	2.0 mg
In pregnancy	3.0–5.0 mg
Postmenopausal female	0.9 mg

sources and is more easily absorbed than non-haem iron, which is found in non-meat sources such as whole grains, fruits and vegetables. Of our daily iron intake, 1–2 mg may be absorbed, mostly through the duodenum. Iron in its ferrous state, Fe²⁺, is more readily taken up than iron in its ferric form, Fe³⁺.

Intake of iron must be sufficient to replace daily iron loss. Each day, 0.5–1 mg iron is lost in faeces, sweat and urine. Over an average of a month, women lose an additional 0.5–1 mg/day in menstruation. In pregnancy, a further 1–2 mg iron is needed daily; therefore, IDA is common in these patient cohorts. The demand for iron also varies with age (see [Table 50.1](#)) ([Mason, 2008](#)).

The body has no active mechanism of excreting excess iron, so available iron in the body is regulated by the absorption of dietary iron from the duodenum. This must be tightly controlled to avoid IDA. Hepcidin, a regulatory protein, has a key role in inhibiting the uptake of iron from the duodenum.

IDA arises when there is an ongoing imbalance between the body's iron requirements and iron absorption.

The guidelines for the management of anaemia from the British Society of Gastroenterology ([Goddard et al., 2011](#)) categorise the causes of IDA into occult gastro-intestinal blood losses, malabsorption problems and non-gastro-intestinal blood losses. Causes of gastro-intestinal occult blood losses include gastric carcinoma, colonic carcinoma and benign gastric ulceration. Malabsorption includes coeliac disease and *Helicobacter pylori* colonisation, which causes iron deficiency ([Goddard et al., 2011](#)). Examples of non-gastro-intestinal blood losses most typically include menstruation and blood donation.

Medicines that can cause bleeding can indirectly cause IDA ([Table 50.2](#)), with aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) being the main causes. The use of antacid preparations may mask the symptoms of *H. pylori*, which can cause iron deficiency.

Clinical manifestations

In addition to the general symptoms of anaemia, various other features may be present ([Box 50.4](#)). The colour of the skin is very subjective and often unreliable. Patients at risk of heart failure may present with breathlessness when anaemic. Koilonychia,

Table 50.2 Pathological contributors to iron deficiency anaemia in the UK with prevalence as percentage of total ([Goddard et al., 2011](#))

Contributor	Prevalence
Occult GI blood loss	
Common	
Aspirin/NSAID use	10–15%
Colonic carcinoma	5–10%
Gastric carcinoma	5%
Benign gastric ulceration	5%
Angiodysplasia	5%
Uncommon	
Oesophagitis	2–4%
Oesophageal carcinoma	1–2%
Gastric antral vascular ectasia	1–2%
Small bowel tumours	1–2%
Cameron ulcer in large hiatus hernia	<1%
Ampullary carcinoma	<1%
Ancylostoma duodenale	<1%
Malabsorption	
Common	
Coeliac disease	4–6%
Gastrectomy	<5%
Helicobacter pylori colonisation	<5%
Uncommon	
Gut resection	<1%
Bacterial overgrowth	<1%
Non-GI blood loss	
Common	
Menstruation	20–30%
Blood donation	5%
Uncommon	
Haematuria	1%
Epistaxis	<1%
GI, Gastro-intestinal; NSAID, non-steroidal anti-inflammatory drug.	

Box 50.4 Features of iron-deficiency anaemia

- Pale skin and mucous membranes
- Painless glossitis
- Angular stomatitis
- Koilonychia (spoon-shaped nails)
- Dysphagia (due to pharyngeal web)
- Pica (unusual cravings)
- Atrophic gastritis

dysphagia and pica are found only after chronic iron deficiency and are relatively rare.

Investigations

As with all anaemias, a full blood count is essential. IDA will show a low MCV and MCH. A stained blood film will also reveal typical IDA red blood cells, which will look microcytic and hypochromic with poikilocytes (often pencil-shaped) and occasional target cells. These are abnormal thin erythrocytes which show a dark centre and peripheral ring when stained.

The most definitive marker of IDA is the level of ferritin. This may be part of an iron profile laboratory tests. A decreased transferrin saturation and a raised total iron-binding capacity reflect a lack of available iron. A low ferritin is expected in IDA, for example, less than 15 micrograms/L. Ferritin is a reactive protein and becomes slightly raised on exposure to inflammatory conditions, infection and cancer. The low ferritin level will therefore be slightly masked and may be as high as 50 micrograms/L and still be consistent with IDA, in the presence of these conditions. A normocytic or microcytic anaemia without a corresponding low level of ferritin is often anaemia of chronic disease in which iron replacement does not provide any benefit clinically or in terms of an increase in haemoglobin. Serum iron is not useful. It exhibits diurnal variation, being higher in the morning and represents a tiny fraction of the total body iron.

Other investigations undertaken are the exclusion of other types of anaemia, the response to iron replacement and a history of IDA.

Treatment

The cause of iron deficiency must be fully elucidated. The treatment for IDA is iron replacement sufficient to restore haemoglobin levels, replenish iron stores, prevent recurrence and matched with an improvement in the patient's overall well-being. Iron replacement is suitable for patients with known ongoing malabsorption problems, for example, inflammatory bowel disease, women with IDA from menstruation, pregnancy and in patients where further investigation of the IDA is not deemed appropriate, such as frail elderly patients.

Iron must be taken long enough to allow the haemoglobin to be normalised and to allow a full-body iron store to be replete. It must be monitored thereafter for early identification of any reoccurrence of IDA. The iron formulation is not critical, but it is generally recommended to use ferrous sulphate,

for example, 200 mg tablets twice or three times daily if tolerated. If this is not tolerated, then ferrous sulphate 200 mg once daily is advised because it has been suggested that the incremental iron absorption is only slightly less with lower doses of iron. Slow-release preparations confer no advantage over regular formulations and may even exacerbate gastro-intestinal effects. Therefore, such preparations should be avoided. Iron can cause gastro-intestinal disturbances such as nausea, abdominal pains and, most typically, constipation, due to the effect iron has on the gut flora.

Patient care

It is important to counsel patients on gastro-intestinal effects and that their stools may appear black. It is important to check that the patient is not taking any medications that interact with iron and, if so, to ensure that they are managed accordingly, for example, having a gap between doses if necessary. If applicable, it may be helpful to remind patients of dietary sources of iron.

Haemoglobin should be checked within 2–4 weeks to assess response to treatment. It should rise by 20 g/L in 4 weeks, and the patient should feel the benefit after 1 week. If haemoglobin has not risen by this amount, the patient's tolerance of and adherence to the medicine should be assessed. The diagnosis should also be re-evaluated because this may be an indication that it is not, in fact, iron-deficiency anaemia. Iron should be continued until the patient's iron stores are replenished, as identified by an adequate ferritin level.

Occasionally, if the patient is severely intolerant of oral iron, treatment with parenteral iron may be necessary. Oral iron should be withheld for at least 7 days after parenteral injection.

Anaemia of chronic disease

Epidemiology

This is the second most common form of anaemia (after iron deficiency). It is associated with a wide variety of inflammatory diseases, including arthritis, malignancies, inflammatory bowel disease, human immunodeficiency virus (HIV) and other infections. It is increasingly being referred to as 'anaemia of inflammation' or 'anaemia of chronic inflammation'.

Aetiology

In anaemia of chronic disease, renal production of erythropoietin is inhibited by inflammatory cytokines. Heparin increases in the presence of chronic disease and inflammation. It also has a key role here: it decreases the amount of iron absorption from the gut and reduces the release of iron from body stores. This means that despite the patient having sufficient overall body iron stores, the patient has the symptoms of anaemia because the iron is not being utilised (De Loughrey, 2014).

In malignancies, in addition to the anaemia of chronic disease, the cytotoxic treatments themselves decrease erythrocyte production through their anti-proliferative effects on the bone marrow. Certain cytotoxic agents, such as platinum-based therapies, are more likely to cause anaemia.

In chronic kidney disease and chronic heart failure, the reduced renal blood flow leads to a decreased production of erythropoietin.

Pathophysiology

During infections, inflammation and cancer, the inflammatory cytokines, in particular interleukin-6 released from macrophages, lead to an increased production of hepcidin. Hepcidin, a peptide produced by hepatocytes, plays a key role in iron availability. The hepcidin causes:

- increased uptake of iron by hepatocytes,
- reduced iron absorption,
- reduced release of iron from macrophages.

The reduction of circulating iron is thought to limit this essential nutrient's availability to invading microbes and tumour cells, blocking their proliferation.

In addition, the inflammatory cytokines increase the production of white blood cells, which potentially leads to fewer stem cells being available for red blood cell production.

Clinical manifestations

Patients have the general symptoms of anaemia in addition to their symptoms of the chronic inflammatory condition. Anaemia may lead to a reduced quality of life.

Investigations

The full blood count may reflect a normocytic or microcytic anaemia. It will not be as pronounced as in IDA. See [Table 50.3](#) for a comparison. The ferritin, even allowing for inflammation, will not be low. Other evidence that supports the diagnosis of anaemia of chronic disease is the medical history, for example, heart failure or rheumatoid arthritis. Inflammatory markers may be raised, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). It should be considered that anaemia of chronic disease that cannot be attributed to any background conditions may signal an underlying gastro-intestinal malignancy. If anaemia of chronic disease has been mistaken for IDA, the patient will not respond to iron replacement, and the haemoglobin will remain unchanged, thus providing further support for a diagnosis of anaemia of chronic disease.

Table 50.3 Differentiation between iron-deficiency anaemia and anaemia of chronic disease

Test	Iron-deficiency anaemia	Anaemia of chronic disease
Serum iron	Low	Low
Serum ferritin	Low	Normal or high
Serum transferrin	High	Normal or low
Total iron-binding capacity	High	Low

Treatment

Treating the underlying chronic condition is important, where this is possible. If a patient has untreated polymyalgia rheumatica (PMR) with accompanying anaemia of chronic disease, treatment of PMR will reduce the anaemia of chronic disease, although it will never be abolished. Therefore, such patients are likely to always have some degree of anaemia of chronic disease.

Blood transfusions are rarely needed in anaemia of chronic disease. Oral iron therapy is not indicated despite the apparent reduced iron availability because these patients have a functional iron deficiency rather than an actual iron deficiency; also, the raised hepcidin levels reduce the oral absorption of iron.

Patients with chronic renal failure should be referred to a renal specialist. These patients are assessed for erythropoietin deficiency. Intravenous iron in combination with erythropoietin analogues is widely used in chronic kidney disease. The patient's serum ferritin is monitored to check for iron overload.

Patients with inflammatory bowel disease are likely to have IDA and anaemia of chronic disease. They will need iron replacement, and inevitably, intolerance of oral iron will be common in this patient group and necessitate the use of intravenous iron.

There are specialised guidelines for the use of erythropoietins in patients with anaemia induced by cancer treatment ([National Institute for Health and Care Excellence \[NICE\], 2014](#)).

Patient care

It is important to explain to the patient that there are different types of anaemia and that the anaemia they have is not the type that responds to iron therapy. If they are either prescribed iron or buying iron supplements, the patient should be counselled that these will not help.

Sideroblastic anaemias

Epidemiology

In haematopoiesis, there are multiple different steps in the development of the red blood cell in the bone marrow. The erythroblasts are one of the first stages in this process. Sideroblastic anaemia describes a group of anaemias which are characterised by the presence of abnormal erythroblasts, called ring sideroblasts in the bone marrow aspirate. Normal erythroblasts contain some iron granules. Sideroblasts are defective erythroblasts which contain an excess of iron granules in the mitochondrion. ([Aclindor and Bridges, 2002](#)). These excess iron granules are arranged in a distinct ring arrangement around the nucleus, hence ring sideroblasts. They are also characterised by impaired haem synthesis, where the body may have sufficient iron stores but is unable to incorporate it into haemoglobin. There are both hereditary and acquired forms of sideroblastic anaemia; the hereditary form of anaemia is comparatively rare.

Aetiology

In the majority of hereditary forms, there is an X chromosome-linked pattern of inheritance. Both autosomal-dominant and

autosomal-recessive families have been described. The main defect is a reduced activity of the enzyme 5-aminolevulinic acid synthase (ALAS), which is involved in haem synthesis. ALAS uses a pyridoxal-6-phosphate co-enzyme to function. There are other rare causes, such as mitochondrial defects.

The more common acquired forms include idiopathic sideroblastic anaemias and those associated with myeloproliferative disorders, for example, a type of sideroblastic anaemia associated with myelodysplasia (bone marrow suppression) called refractory anaemia with ring sideroblasts (MDS-RS, formerly RARS), and forms secondary to the ingestion of drugs (Box 50.5). Its occurrence can be linked to drug toxicity, copper deficiency and, in particular, with alcoholism.

Pathophysiology

A microscopic examination of the bone marrow typically shows cells known as ring sideroblasts. In the hereditary forms, there are low levels of ALAS. This mitochondrial enzyme is involved in the first step in the synthesis of haem and requires pyridoxal phosphate as a cofactor. Pyridoxine is a precursor for pyridoxal. Impaired use of iron by the mitochondria in sideroblastic anaemia has been suggested (Aclindor and Bridges, 2002).

Drugs and toxins

Alcohol can lead to the formation of ring sideroblasts. Alcohol is metabolised to acetaldehyde, which lowers the levels of ALAS and pyridoxal. It is also proposed that folate deficiency may contribute to the sideroblastic anaemia seen in alcoholism.

Isoniazid is a known cause of sideroblastic anaemia. Pyridoxine (vitamin B₆) prophylaxis is therefore usually prescribed for all patients on isoniazid as a prophylactic measure. Chloramphenicol and linezolid are also known putative agents in causing sideroblastic anaemia. This is thought to be due to the inhibition of mitochondrial protein synthesis. Sideroblastic anaemia is associated with copper deficiency, which can be caused by an overdose of medicines used to chelate copper (e.g. penicillamine and trientine

used in the treatment of Wilson's disease) or from nutritional deficiency as a result of long-term parenteral nutrition. Hydralazine, theoretically at least, may have the potential for causing sideroblastic anaemia because it is known to reduce pyridoxine levels.

Clinical manifestations

The hereditary forms typically develop in infancy or childhood. The anaemia can be moderate or severe (haemoglobin typically 40–100 g/L). There may be splenomegaly, which can lead to mild thrombocytopenia. The idiopathic acquired forms tend to develop insidiously, usually in middle age or later. Many patients may be asymptomatic for long periods. In the forms associated with other disorders, the clinical picture tends to be dominated by the underlying disease(s). It presents with the typical hallmarks of anaemia, fatigue, reduced exercise tolerance and dizziness. MDS-RS specifically may also present with bleeding tendencies and an increased susceptibility to infection, in common with other myelodysplasias.

Investigations

The common finding in all forms is the presence of sideroblasts in the bone marrow. In the hereditary form, the red blood cells in the peripheral blood are hypochromic and microcytic. Despite this, there are frequently increased iron stores in the bone marrow. The serum iron and ferritin may also be elevated. In the acquired forms, the peripheral blood has hypochromic cells, which may be either normocytic or macrocytic.

Treatment

Treatment is mostly supportive. For acquired forms, it involves eliminating any reversible problems (such as medication) which usually causes the sideroblastic anaemia to resolve. The patient should be investigated for copper and folate deficiency and supplemented if required. In hereditary forms, management will depend on its severity and could include blood transfusions for the most severely affected patients. Some patients with acquired or hereditary sideroblastic anaemia will benefit from pyridoxine therapy (usually 200–600 mg orally daily). Those who respond to pyridoxine therapy have a very positive response and respond quickly (Aclindor and Bridges, 2002). Because pyridoxine is a medicine with comparatively few side effects, it is worth patients being prescribed a course.

Iron deficiency is not associated with sideroblastic anaemia. Ferritin levels are usually raised in sideroblastic anaemia, and it is important that iron overload is avoided because this can contribute to sideroblastic anaemia.

Some patients with severe (hereditary) sideroblastic anaemia may ultimately require frequent blood transfusions. This carries the risk of iron overload.

Patient care

Education about sideroblastic anaemia is important, and health-care professionals should explain to the patient that it is different from other anaemias, for example, iron-deficiency anaemia,

Box 50.5 Acquired sideroblastic anaemia

Associated with other disorders

- Myelodysplastic syndromes
- Myeloid leukaemia
- Myeloma
- Collagen diseases

Associated with drugs and toxins

- Alcohol

- Progesterone
- Copper deficiency (associated with penicillamine, triethylene tetramine and tetrathiomolybdate)
- Lead
- Zinc

which most people will know about. The patient will need to understand that iron is not helpful in this anaemia and in fact makes the condition worse. Genetic counselling may be appropriate for patients with hereditary sideroblastic anaemia. It is also important to explain to patients commenced on pyridoxine that this medication is not effective in everyone.

Megaloblastic anaemias

The red blood cells in macrocytic anaemia are abnormally large, with a MCV of greater than 95 fl (femtolitres). Macrocytic anaemia encompasses both megaloblastic anaemias and non-megaloblastic anaemias. These are differentiated by the cells having distinctive differences in shape and appearance under microscopic examination, and they also have different causes. This section focuses on the megaloblastic types of macrocytic anaemia and its two main causes, vitamin B₁₂ deficiency and folate deficiency.

Epidemiology

WHO has acknowledged that there are no readily available data on the occurrence of vitamin B₁₂ deficiency and folate deficiencies, and incidence will vary with the multiple causes of deficiency (WHO, 2008). It could be expected that poor nutrition will be closely correlated, particularly with folate deficiency. Folate levels fall more quickly, with folate body stores becoming depleted in 4 months, whereas it may take vitamin B₁₂ 2–3 years to present as a deficiency. Because the main source of vitamin B₁₂ in the diet comes from animal sources, vegans will be at higher risk of vitamin B₁₂ deficiency. Alcoholism is often accompanied by malnutrition, which can lead to a risk of folate deficiency. The risk of developing deficiency is reputed to increase once the consumption is greater than 80 g alcohol a day (Devalia et al., 2014).

In pregnancy, folate requirements increase in view of increased cell turnover. The risk of B₁₂ deficiency and folate deficiency increases with age. One large study estimated that the incidence of vitamin B₁₂ and folate deficiency was around 5% in people aged 65–74 years and more than 10% in people 75 or over (Clarke et al., 2004).

Aetiology

Folate is integral in DNA synthesis. There is an increased demand for folate in times of increased cell turnover, which can therefore be associated with folate deficiency (e.g. pregnancy, malignancies and haematological conditions such as haemolytic anaemia). Folate deficiency can also arise if there is increased urinary excretion, for example, in renal dialysis patients. As well as dietary insufficiency, malabsorption can occur, such as in coeliac disease. Some drugs, such as anticonvulsants, are linked with folate deficiency. Trimethoprim and methotrexate are known folate antagonists.

The most common cause of vitamin B₁₂ deficiency is pernicious anaemia. Pernicious anaemia is an autoimmune condition causing stomach atrophy, achlorhydria and, ultimately, a lack of intrinsic factor in the stomach. The intrinsic factor is an essential

protein, produced by the gastric parietal cells, and it is needed for the uptake of vitamin B₁₂ from the gut. The lack of intrinsic factor accounts for the resulting vitamin B₁₂ deficiency in pernicious anaemia. It can also occur after gastrectomy surgery where there is a loss of intrinsic factor.

Pathophysiology

Folate is readily absorbed in the gut from folate-containing foods. Main dietary sources are green vegetables, nuts and yeast-containing foods. The daily requirement is 0.1–0.2 mg. Adult folate stores are typically 10–12 mg; this represents enough folate to sustain the body for 3–4 months in the absence of further folate supply. It is present inside the cells in the form of tetrahydrofolate and is critical in the biochemical reactions needed for DNA synthesis. Vitamin B₁₂ is needed as a catalyst to convert folate into its active form inside the cell.

Vitamin B₁₂ is essential for the neurological system. It is found in animal products such as fish, eggs and dairy products. After ingestion, it binds to intrinsic factor produced in the stomach and is eventually absorbed in the terminal ileum section of the gut. For vitamin B₁₂, the body stores (2–3 mg) are sufficient for 2–4 years (Hoffbrand and Moss, 2016).

Clinical manifestations

Megaloblastic anaemia presents with tiredness-related symptom such as fatigue, lethargy and dyspnea on effort. As with other types of anaemia, these can progress to palpitations and angina, especially if the patient has pre-existing cardiac disease. Further features found specifically with these anaemias are listed in Box 50.6. The patient may not realise he or she has anaemia because the onset is insidious, and it may be picked up when a patient is getting blood tests for another reason.

More serious signs of vitamin B₁₂ deficiency are neurological involvement such as unexplained paraesthesia, visual disturbances and cognitive changes such as confusion. Elderly patients may have confusion symptoms with only a slight vitamin B₁₂ deficiency. The feature that separates vitamin B₁₂ deficiency from other megaloblastic anaemias is progressive neuropathy. It is symmetrical and affects the legs rather than the arms. Occasionally, patients have muscle weakness, have difficulty in walking or experience frequent falls. In folate deficiency, mild peripheral neuropathy and depression may manifest.

Box 50.6 Features of megaloblastic anaemia

- Glossitis (sore, pale, smooth tongue)
- Angular stomatitis
- Altered bowel habit (diarrhoea or constipation)
- Anorexia
- Mild jaundice
- Insidious onset
- Sterility
- Bilateral peripheral neuropathy (mainly vitamin B₁₂ deficiency)
- Melanin skin pigmentation (rare)
- Fever (mainly vitamin B₁₂ deficiency)

Investigations

A diagnosis of either folate deficiency or vitamin B₁₂ deficiency is made from a medical history and clinical examination in combination with a full blood count and a serum folate and vitamin B₁₂ level.

A raised mean cell volume is a sign of megaloblastic anaemia. If there are suspicions that the patient may have vitamin B₁₂ deficiency, a normal MCV should not exclude further investigation. One source highlighted that 25% of patients presenting with neurological symptoms did not have an elevated MCV (Devalia et al., 2014). If there is a co-existing microcytic anaemia (such as IDA), this may mask megaloblastic anaemia. Leukopenia and thrombocytopenia may also be present, especially in more severe deficiency.

Laboratory reference values vary; however it is generally agreed that a vitamin B₁₂ level less than 200 nanograms/L along with a clinical suspicion indicates vitamin B₁₂ deficiency (Devalia et al., 2014). This blood test is not costly and easy to perform; however, the specificity of this test is not absolute. A blood film may be required if there are difficulties with ascertaining a diagnosis, in consultation with haematology specialist advice.

A serum folate level less than 3 micrograms/L would be indicative of folate deficiency. Serum folate level is influenced by recent folic acid intake. The gold-standard diagnostic test would be red blood cell folate; however, this is rarely required.

Treatment

It is necessary to establish whether the patient with megaloblastic anaemia has vitamin B₁₂ deficiency or folic acid deficiency or both. Replacement therapy with vitamin B₁₂ or folate is the mainstay of treatment.

Folic acid is normally administered as 5 mg daily. Four months should be ample duration for the folate to become replete. It should be stopped and then rechecked on an ongoing basis. Some patients may be on folic acid long-term. Folic acid should not be started before a vitamin B₁₂ deficiency is excluded. Vitamin B₁₂ replacement should ideally be started first if both deficiencies co-exist. Folic acid given alone, without correction of the vitamin B₁₂ deficiency, may further the neuropathy symptoms or precipitate a subacute combined degeneration of the spinal cord.

Hydroxocobalamin replacement therapy should follow the schedule in the British National Formulary (BNF) or equivalent local formularies. This is currently five doses of hydroxocobalamin 1 mg given intramuscularly over a period of 2 weeks then 1 mg every 3 months as a maintenance dose (Joint Formulary Committee, 2017).

It is given every 2 months where there is already neurological involvement. Neurological damage may be irreversible. Peripheral neuropathy of recent onset often partially improves, but any spinal cord damage is irreversible even with optimum therapy.

Response to therapy can be seen by an increase in reticulocyte numbers within 3–5 days. More importantly, the patient will start to feel better within 24–48 hours of starting treatment. The haemoglobin will rise slowly at a rate of 20–30 g/L.

Oral cyanocobalamin is poorly absorbed. It is used occasionally in mild deficiency related to diet. Hypokalaemia develops in some patients during the initial haematological response because potassium is an intracellular ion used in the production of new cells.

Potassium supplements may be needed in the elderly and patients receiving diuretics or digoxin. The serum iron level also falls as it is incorporated into haemoglobin. The more severe the anaemia, the more likely it is to see a fall in the serum potassium or iron level.

Treatment of any reversible or ongoing causes such as previously undiagnosed coeliac disease or tapeworm is also required. Prophylactic folic acid is used in pregnancy, and prophylactic vitamin B₁₂ injections are administered in patients after gastrectomy because they will lose intrinsic factor produced by the parietal cells.

Patient care

Folic acid deficiency anaemia

In patients who have a dietary component to their deficiency, appropriate nutritional advice should go alongside their folic acid therapy. If the cause of the deficiency has been eliminated, patients can expect to receive folic acid for approximately 4–6 months. In patients with a continuing requirement, for example, haemolytic anaemia patients can expect lifelong treatment. Those commencing folic acid therapy can anticipate feeling better after a few days but should be informed that their blood count will take much longer to return to normal.

Vitamin B₁₂ deficiency anaemia

Patients feel subjectively better very shortly after their first hydroxocobalamin injection. If they have glossitis, it will start to improve within 2 days and return to normal after 2–4 weeks. Patients need to be informed that they need regular injections, usually every 3 months. Surprisingly, some patients say that they feel they are ready for this injection as they approach their appointment time and feel better after their injection.

Patients should be advised to highlight to healthcare staff at appointments and if admitted to hospital that they receive regular vitamin B₁₂ injections and when their next injection is due.

Haemolytic anaemias

Normally, there is a natural continuous turnover of erythrocytes. After being produced in the bone marrow, liver or spleen, the new erythrocytes are released into the plasma as immature erythrocytes, reticulocytes. After circulation in the plasma for around 120 days, the erythrocyte gradually degrades and releases haem and globins which are reutilised in the body.

In the haemolytic anaemias, there is a reduced lifespan of the erythrocytes. Anaemia occurs when the rate of destruction of the erythrocytes exceeds their rate of production. Haemolytic anaemias account for 5% of all anaemias. There is a wide range of haemolytic anaemias, with both genetic and acquired disorders (Table 50.4). This section will focus on the main types of autoimmune haemolytic anaemias.

General clinical manifestations

The bone marrow compensates for this overdrive in red blood cell production by an expansion of the bone marrow. In fact, the

Table 50.4 Some examples of haemolytic anaemias

Examples	
Genetic disorders of	
Haemoglobin	Sickle cell anaemias Thalassaemias
Energy pathways	Glucose-6-phosphate deficiency
Membrane	Hereditary spherocytosis Hereditary ovalocytosis
Acquired disorders	
Immune	Autoimmune Rh or ABO incompatibility
Non-immune	Infections (parasitic, bacterial) Drugs and chemicals Hypersplenism

enlarged bone marrow can increase the rate of red blood cell production by up to eight times. This compensatory response can mean that symptoms may not present until the erythrocyte production has decreased for 30 days (Hoffbrand and Moss, 2016).

Patients with acute haemolytic anaemia commonly complain of malaise, fever, abdominal pain, dark urine and jaundice. The urine is dark because of excess storage iron (haemosiderin) being excreted in the urine. Jaundice may result from the increased cell turnover causing an increased serum bilirubin. The increased erythrocyte turnover is also reflected in an increased number of reticulocytes. Patients with chronic haemolytic anaemia also usually have splenomegaly. Their anaemia is usually normochromic and normocytic.

General treatment

This increased demand for folate caused by bone marrow hyperplasia may necessitate folate administration. Patients who require frequent transfusions are at risk of iron overload. Any other co-existing types of anaemia should be treated and any offending agents or causes addressed.

Autoimmune haemolytic anaemia

Epidemiology

Autoimmune haemolytic anaemia as the name implies is caused by the body's own immune system. It acts against its own red blood cell antigens. The incidence is described as approximately 1 per 100,000/year (Hill et al., 2017). It can occur at any age; however, it does become more common as people get older. It is divided serologically into two types by the Coombs test, which tests whether the antibody reacts more strongly with red blood cells at a cold temperature or a warm temperature. The result of this test determines how it should be treated. The warm type, called warm autoimmune haemolytic anaemia (WAIHA),

Box 50.7 Drugs associated with autoimmune haemolytic anaemia

- Ciclosporin
- Fludarabine
- Interferon A
- Levodopa
- Mefenamic acid
- Methyl dopa
- Penicillin
- Quinine
- Quinidine

accounts for 65% of this type of anaemia. The cold types, called cold haemagglutinin disease (CHAD) and paroxysmal cold haemoglobinuria, account for 29% and 1%, respectively. The remaining 5% is accounted for by a mixed type (Hill et al., 2017).

Aetiology

In WAIHA, the coating of the red blood cell membrane is rendered defective, making the red blood cell more easily degraded. It is most closely associated with immunoglobulin G (IgG), which attaches to the membrane, mostly in the spleen. It is common for WAIHA to occur in association with other immune-related diseases, such as systemic lupus erythematosus, but it may also occur alone. It typically has a remitting and relapsing course.

In CHAD, it is the IgM antibody that attaches to the red blood cell membrane, in this case, mostly in the peripheral circulation. Primary CHAD can present in middle or older age. It is aggravated by cold temperatures and often associated with intravascular haemolysis. Patients could suffer from cold-induced acrocyanosis (blue discolouration of the peripheries) or Raynaud's disease.

Secondary CHAD can be precipitated by an infection. Certain drugs have also been implicated as leading to immune haemolysis (Box 50.7).

Pathophysiology

The anaemia results from the presence of autoantibodies which agglutinate (clump together) or lyse the patient's own erythrocytes. In WAIHA, the haemolysis is usually extravascular and mediated by IgG. These antibodies react best at body temperature. CHAD is usually mediated by IgM, which attaches to the erythrocytes and causes them to agglutinate at temperatures less than 37 °C. This results in impaired blood flow to the fingers, toes, nose and ears when exposed to cold.

Clinical manifestations

The clinical manifestations of autoimmune haemolytic anaemia have the common signs of anaemia of tiredness-related symptoms but they also vary depending on which subtype is present. The symptoms in WAIHA are related to the severity of the haemolysis and can present as acute or chronic anaemia. The spleen may be enlarged.

In chronic CHAD the patient may present with splenomegaly and mild jaundice. It will generally worsen or become acute

during the cold weather. As previously identified, Raynaud's disease or acrocyanosis may occur.

Investigations

A positive direct Coomb's test indicates the presence of antibodies to red blood cells and distinguishes warm and cold subtypes. Drug-induced haemolytic anaemia may be difficult to distinguish from other forms of autoimmune haemolytic anaemia, and a detailed medication history will help. The antibodies produced may react with the red blood cells only in the presence of the drug (or one of its metabolites) or may also react without the drug being present.

Treatment

In WAIHA, the treatment includes removing any underlying cause, such as a drug, if applicable. The British Society of Haematology has produced recommendations on the treatment of autoimmune haemolytic anaemia (Hill et al., 2017). First-line treatment is with steroids, such as prednisolone 1 mg/kg/day. This has a generally good response rate of 80% and can achieve complete remission in two-thirds of patients (Hill et al., 2017). It will usually respond within 3 weeks, and once a haemoglobin of greater than 100 g/L is achieved, the steroid dose can be gradually reduced. Gastroprotection should be prescribed. Rituximab is very effective and can be used alone or as second-line treatment in combination with steroids. Different dosage regimens are used. Ultimately, if necessary, splenectomy is also an effective treatment. Immunosuppressants such as azathioprine and ciclosporin provide further treatment options (Hill et al., 2017).

A different approach is taken in CHAD. Therapeutic intervention should be considered if the patient is symptomatic, especially if the patient has severe symptoms. It is imperative that the patient is proactive in avoiding cold exposure and dresses accordingly. Rituximab may also be used in CHAD, and the addition of fludarabine should be considered if the response to rituximab alone is suboptimal. Steroids do not have a role in CHAD, and splenectomy is usually avoided.

Patient care

Patients will need counselling and support for any of the medicines used. The patient should be informed of the unlicensed use of rituximab and that there is a risk of infusion reactions. Patients will also need advice on the use of corticosteroids, gastroprotection and osteoporosis prophylaxis. If a drug-induced subtype has been identified, they will need to be fully informed about the drug they should avoid and have it listed as an allergy in their medication records. They will need practical advice and support on avoiding cold exposure and maintaining a consistent ambient temperature.

Sickle cell anaemia

Epidemiology

Sickle cell anaemia is so named after the appearance of the red blood cells, which resemble the shape of a sickle, an agricultural tool. Sickle cell disease is a hereditary condition. Several

Fig. 50.2 Inheritance patterns in sickle cell trait and sickle cell disease.

different variants of sickle cell disease exist. It is common throughout Africa, the Middle East, parts of India and the Mediterranean. The carrier state is widespread, with a particularly high prevalence in West Africa of up to 30% (Hoffbrand and Moss, 2016).

Aetiology

Patients with sickle cell disease have a different form of haemoglobin. Patients with the most common variant of sickle cell disease have haemoglobin S (HbS). Normal haemoglobin is usually designated haemoglobin A (HbA). HbS has valine substituted for glutamic acid as the sixth amino acid in the β -polypeptide compared with normal haemoglobin. Patients with homozygous haemoglobin S develop many problems, including anaemia.

Sickle cell trait is where a person is a carrier of the gene (heterozygous for the sickle cell gene). These people are usually asymptomatic. Sickle cell trait provides some protection from malaria and is more common in those ethnic groups originating from geographical areas that are endemic for malaria. The offspring from a father with the trait and a mother with the trait has a one in four chance of having sickle cell disease (Fig. 50.2).

Pathophysiology

The membrane of red blood cells containing haemoglobin S is damaged, which leads to intracellular dehydration. In addition, when the patient's blood is deoxygenated, polymerisation of HbS occurs, forming a semisolid gel. These two processes lead to the formation of crescent-shaped cells known as sickle cells. Sickle cells are less flexible than normal cells (flexibility allows normal cells to pass through the microcirculation). The inflexibility leads to impaired blood flow through the microcirculation, resulting in local tissue hypoxia. Anaemia results from an increased destruction (haemolysis) of red blood cells in the spleen.

Clinical manifestations

Patients with severe variants of the disease have chronic anaemia, arthralgia, anorexia, fatigue and splenomegaly. They have crises more frequently than patients with other variants of the disease. A crisis can be precipitated by infection and fever, dehydration, hypoxia or acidosis. A combination of these factors is sometimes present. The clinical manifestation of a crisis can vary with the most common being an infarct crisis. Infarction of the long bones and larger joints or an infarction of a large organ, for example, the liver, lungs or brain, may all occur. Severe pain is a common feature, depending on the site of the infarction. Destructive bone and joint problems are frequently seen.

Infections carry a higher risk of morbidity and mortality due to compromised spleen function.

Investigations

The haemoglobin is typically 60–90 g/L. In healthy adults, there are different variants of haemoglobin; most of our haemoglobin is HbA (96–98%; [Hoffbrand and Moss, 2016](#)). The remaining portion consists of small amounts of HbA₂ and haemoglobin-F (HbF). The confirmation tests for sickle cell anaemia are based on the fact that in this condition, patients have a much higher proportion of HbF and have a haemoglobin unique to this condition.

Electrophoresis or high-performance liquid chromatography (HPLC) analysis of the haemoglobin would show HbS 80–99% with no normal. The HbF may also be elevated to about 15%. The background family history is also helpful. The presence of sickle cells in the blood film is also diagnostic. Reticulocytes could be increased as much as up to 10–20%, reflecting the excessive production of red blood cells by the bone marrow.

Treatment

Treatment is based around supportive care, managing pain, preventing infection and modifying HbS production or increasing HbF production and avoiding crises.

To help prevent infections *H. influenzae*, meningococcal and pneumococcal vaccinations are administered. Prophylactic use of penicillin V 250 mg twice a day is usual for adults with erythromycin prescribed for patients allergic to penicillin. Simple measures such as good general nutrition and handwashing are advised. All precipitating factors for a crisis should be avoided as far as possible, such as dehydration. Good daily hydration should be maintained. Folic acid is commonly used because of the high turnover of red blood cells.

Transfusions have been used in severe cases with the aim of suppressing HbS production. Hydroxycarbamide is also an option used in patients who experience frequent crises; it increases HbF, which has a positive effect on reducing symptoms. Erythropoietin may be used occasionally with the same rationale – to increase HbF. However, because erythropoietin levels are not normally low in sickle cell anaemia, its use is limited.

Beyond painful crises, some patients progress to chronic and severe pain. Therefore, such patients also need great attention focused on managing pain and supporting them to maintain a good quality of life.

Sickle cell crises require prompt and effective treatment. Removal of the trigger factor, hydration and effective pain relief are the mainstays of treatment. Appropriate antibiotic therapy should be started at the first signs of infection. Strong opioids are required for pain relief.

Patient care

Patients need to be encouraged to take their prophylactic penicillin and folic acid therapy regularly between crises. During a crisis, some health professionals worry about the patient developing opioid addiction. Although this may happen, it is also important to recognise that crises are extremely painful, and the patient requires effective analgesia.

Thalassaemias

Epidemiology

The thalassaemias are a group of inherited autosomal-recessive diseases. The α thalassaemias are most common in Africa, Afro-Caribbean regions, South and East Asia and in the Eastern Mediterranean. The β thalassaemias occur mainly in populations from around the Mediterranean, North and West Africa, Middle East and the Indian subcontinent.

Aetiology

The thalassaemias are a group of anaemias that result from either a reduced or absent production of one or more of the constituent globin chains in the haemoglobin.

In α thalassaemia the severity is associated with the number of the globin chains which are missing or dysfunctional and the type of deletion or mutation involved. It is generally the result of large deletions within an α globin complex. Haemoglobin Bart's hydrops fetalis is a variant of α thalassaemia and results in stillbirth of a newborn baby, as tissue oxygenation cannot be maintained. More than 100 β thalassaemia mutations have been identified. There are two copies of the β globin gene in each cell. If one is abnormal, this is called β thalassaemia trait. If both genes are affected, it is called β thalassaemia intermedia or major.

Pathophysiology

In β thalassaemias, there is a reduced or absent production of the globin β chain. This leads to a relative excess of α chain which when unpaired becomes unstable and precipitates in the red blood cell precursors. There is ineffective erythropoiesis, and those mature cells that reach the circulation have a shortened lifespan.

In α thalassaemias, the pathology is slightly different. The deficiency of α chains leads to an excess of γ or β chains. This time erythropoiesis is less affected, but the haemoglobin produced (haemoglobin Bart's or haemoglobin H) is unstable. This leads to a shortened lifespan, with the spleen trapping many of the cells.

Clinical manifestations

The anaemia causes erythropoietin production to increase and results in expansion of the bone marrow. In severe disease, this causes bone deformity and growth retardation. The spleen is actively involved in removing the abnormal mature cells from the circulation and becomes enlarged.

Investigations

In α thalassaemia, the MCV and the MCH are decreased and the red blood cell count, as well as reticulocytes, will be increased.

For β thalassaemia, the diagnosis is relatively straightforward: haemolytic anaemia from infancy and ethnicity. Haemoglobin electrophoresis is used to determine the amounts of abnormal haemoglobin. Haemoglobin is reduced but is not usually much less than 100 g/L. The MCV will also be reduced. It is also a microcytic and hypochromic anaemia.

Treatment

For both thalassaemias, there is currently no definitive treatment. Patients with thalassaemia minor (those who carry the thalassaemia gene but still make enough normal haemoglobin) and α thalassaemia usually do not require treatment. Patients with severe forms are dependent on blood transfusions. Iron chelation and avoidance of iron overload, as appropriate, are important. Folate supplementation as well as prompt treatment of infection are also important. Hydroxycarbamide could be used to increase HbF, which is helpful in β thalassaemias.

Patient care

Drug therapy does not currently play a significant role in treatment. If hydroxycarbamide becomes used more frequently, pharmacists will become involved in educating the patient particularly with regard to its cytotoxic effects.

Glucose-6-phosphate dehydrogenase deficiency

Epidemiology

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a recessive hereditary disease and affects approximately 400 million people worldwide (Nkhoma et al., 2009). There are more than 300 different forms of G6PD deficiency, only some of which cause anaemia. It occurs in West Africa, Southern Europe, the Middle East and South-East Asia. The impact of the deficiency varies between ethnic groups. Typically, the mildest form in black African people and the most severe in Mediterranean people. Severe deficiency occurs occasionally in white people.

Aetiology

Unlike some of the other types, this anaemia can only be genetically derived. The inheritance is sex linked. It is carried by females who show 50% normal G6PD activity and predominantly affects males.

Pathophysiology

A reduced form of glutathione (GSH) confers a protective effect on the cell membranes of haemoglobin and red blood cells from oxidant stress effects. G6PD is needed for the production of nicotinamide adenine dinucleotide phosphate (NADP). This in turn is needed for the production of GSH. In G6PD deficiency, the cells are therefore susceptible to oxidative stress. Exposure to an agent which causes overwhelming oxidative stress precipitates an acute haemolytic anaemia.

Clinical manifestation

Clinically, the two most important types of G6PD deficiency occur in the black population and in people originating from the Mediterranean. The black population has a milder form that results in an acute self-limiting haemolytic anaemia after exposure to an oxidising agent, for example, infection, acute illness, broad beans (fava) beans or drugs (Box 50.8). The haemolytic anaemia is self-limiting because the young cells produced by the bone marrow have higher levels of G6PD activity than old cells. After exposure to the oxidising agent, the old cells are haemolysed but the new cells produced in response are more capable of tolerating the insult until they grow old. In the Mediterranean form of the disorder, the enzyme activity is very low, haemolysis is not usually self-limiting and, indeed, some patients have a chronic haemolytic anaemia despite the absence of an obvious causative factor.

Investigations

The history and the clinical findings steer the diagnosis, which is then confirmed by measuring G6PD activity. Care must be taken during the acute phase because there are increased numbers of young cells with higher levels of activity that may be misleading. The increased numbers of young cells result from the selective destruction of older cells and the increased production of reticulocytes. The full blood count will be normal in between attacks of haemolytic anaemia.

Box 50.8 Common drugs implicated in causing haemolysis in G6PD deficiency

Drugs to be avoided in all variants

- Ciprofloxacin (and probably other quinolones)
- Dapsone
- Methylene blue
- Primaquine (reduced dose may be used in milder variants)
- Nalidixic acid
- Sulfonamides (including co-trimoxazole)

Drugs to be avoided in more severe variants

- Aspirin (low dose used under supervision)
- Chloramphenicol
- Chloroquine (may be acceptable in acute malaria)
- Menadione
- Probenecid
- Quinidine
- Quinine (acceptable in acute malaria)

Treatment

Prevention of haemolysis by avoiding trigger factors (drugs or food) is important. Vaccination against hepatitis A and hepatitis B may reduce attacks. In cases of acute haemolytic anaemia, the causative oxidising agent should be stopped and general supportive measures adopted. In chronic haemolytic anaemia, most patients become reasonably well adjusted to their anaemia. They need to avoid known precipitating factors to prevent acute episodes occurring on top of their chronic haemolytic anaemia.

There is no specific drug treatment. During acute episodes, the patient should be kept well hydrated to ensure good urine output to prevent haemoglobin damaging the kidney. Blood transfusions may be necessary.

Patient care

Patients should be educated and can be given a list of drugs to avoid. It is important that patients remind healthcare professionals of their condition. Pharmacists have a role in keeping healthcare staff informed of the high-risk drugs that can cause G6PD anaemia.

Case studies

Case 50.1

Mr HA, a 60-year-old single unemployed man, was admitted to hospital for investigation of anaemia. He presented with a 6-month history of lethargy, chest pain, dizziness and falls and a past history of having a gastrectomy 26 years ago. The drug history on admission showed that Mr HA was taking diazepam and GTN spray.

Review of systems revealed no vomiting and no melaena. He complained of some indigestion after meals and reported his appetite was fine if someone else cooked. On examination, he was pale, with a blood pressure of 140/80 mmHg, pulse 90 bpm and haemoglobin level of 25 g/L (normal range: 135–180 g/L). Endoscopy and colonoscopy were normal, and a biopsy showed no evidence of coeliac disease. A barium enema was also unremarkable.

Over the first 2 days, he was transfused with 8 units of blood and given furosemide 40 mg with alternate bags. On day 7 he was started on ferrous sulfate 200 mg three times a day, folic acid 5 mg daily and ascorbic acid 200 mg three times a day.

Questions

1. What additional questions should Mr HA have been asked at admission?
2. Comment on the use of vitamin C in Mr HA.
3. How long should Mr HA remain on ferrous sulphate?

Answers

1. Although Mr HA's prescribed drugs were documented, it is possible that he was taking purchased medication. On admission, he complained of indigestion over the last 3 months, and on questioning, he revealed that he was self-medicating with aluminium hydroxide mixture. From a theoretical point of view, antacids may

reduce the amount of iron absorbed by increasing the pH of the stomach and by reducing the solubility of ferrous salts. It is unlikely that this contributed significantly to the development of his anaemia, but if he intends to continue using an antacid after discharge, which should be discouraged, it would be better not to take a dose of the antacid within 1–2 hours of his ferrous sulfate. It would also be worth checking to see if he has been self-medicating with a purchased aspirin or ibuprofen-based product; both drugs have been implicated in causing gastro-intestinal blood loss, although in this case his gastro-intestinal investigations were normal.

2. Ascorbic acid increases the absorption of iron in some patients, probably by keeping iron in solution either in the ferrous form or by being a soluble chelate with the ferric form. Its benefit in correcting iron-deficiency anemia is unclear, and it is not routinely recommended. It may be an advantage in Mr HA because he may also benefit from a short course of multivitamins.
3. Mr HA needs to continue iron therapy until he has at least replenished his iron stores. This may take up to 6 months, after which time he should be reassessed. He should be counselled on the importance of an iron-rich diet and referred to a dietician if necessary. In practice, because his iron was dangerously low on admission, it may be quite reasonable to prescribe him iron for the rest of his life.

Case 50.2

Mr WK, a 46-year-old mechanic, is referred to hospital by his primary care doctor. He gave a history of diarrhoea and vomiting a week ago and now was complaining of headaches, abdominal pain and feeling 'lousy'. His doctor had given him metoclopramide and ferrous sulfate because his haemoglobin had dropped. Mr WK was pale but did not appear jaundiced, although he said he had noticed his urine was unusually dark a few weeks ago. On examination, he was obese, with a blood pressure of 120/80 mmHg and a pulse of 80 bpm. Rectal examination revealed black stools. He had a normal gastroscopy with three negative FOBs. His serum biochemistry showed a normal level of alanine transaminase and a slightly raised total bilirubin level. Mr WK's reticulocyte percentage was 13.5% (normal range: 0.5–1.5%). He was diagnosed with having G6PD deficiency, probably triggered by an infection.

Questions

1. How do you explain Mr WK's dark urine and dark stools?
2. Would Mr WK benefit from any medication after admission?
3. Why is it necessary to repeat his red blood cell G6PD levels after 2 months?

Answers

1. Mr WK's dark urine was a consequence of his haemolytic anaemia. Bilirubin is a breakdown product of haemoglobin that is transported to the liver and conjugated before being excreted in the bile. Bacteria in the intestine converts this to urobilinogen, most of which is excreted in the stools. Small amounts of urobilinogen are reabsorbed, and some of this appears in the urine. Urobilinogen is oxidised to urobilin, which is coloured. During episodes of haemolysis, erythrocytes are destroyed faster than normal, and hence there is an increase in the formation of bilirubin and increased excretion of urobilinogen in the urine. Also during haemolysis, free haemoglobin may be released into the blood. If the haemolysis is severe enough, the normal mechanism for removing haemoglobin from the circulation is overcome, and haemoglobin may appear in the urine.

Dark stools may indicate melaena and upper gastro-intestinal bleeding. In Mr WK's case, his gastroscopy was normal, and he had three negative FOBs. His dark stools were therefore likely to be due to the ferrous sulfate prescribed by the primary care doctor before admission.

- His raised reticulocyte count indicates he is rapidly replacing his lost red blood cells. Erythropoiesis consumes folate and iron, so it may be worth giving him a short course of folate supplements in addition to the oral iron already prescribed, until stores of both are normalised.
- Young red blood cells tend to have higher levels of enzyme activity than more mature cells. Determining G6PD levels during the acute phase may be misleading because there is a relatively high proportion of young cells. Mr WK's result 2 months later would more accurately represent his normal state.

Case 50.3

Ms PR, a 58-year-old lady, was admitted to the emergency department. She had fallen over and bruised herself but had no broken bones. On examination, it was noted that she appeared pale, with possibly a lemon-yellow tinge to her skin; she was slightly confused and had paresthesiae of the feet and fingers. She has a past history of heart failure. She was admitted for investigation and discovered to have a macrocytic anaemia; pernicious anaemia was suspected. Folate and vitamin B₁₂ levels were carried out before commencing treatment.

Questions

- What are the features that may lead you to consider a diagnosis of pernicious anaemia?
- Can Miss PR have a blood transfusion after samples have been taken for folate and vitamin B₁₂?
- The red blood cell folate is reported as 150 mg/L (reference range: 160–640 mg/L). Would Ms PR benefit from folate therapy?

Answers

- Macrocytic anaemia and paraesthesia are typical features, although not diagnostic, of pernicious anaemia. Patients may be mildly jaundiced, which is often described as lemon-yellow in colour. Interestingly, pernicious anaemia is more common in women than men and is associated with blue eyes and early greying of the hair. Miss PR may have other features of pernicious anaemia, which include glossitis, angular stomatitis and altered bowel habit.
- Patients with pernicious anaemia develop their anaemia over a long period of time and tend not to tolerate increases in blood volume very well. A transfusion may result in fluid overload and precipitate heart failure. Miss PR already has heart failure, so unless she becomes severely compromised by anaemia, a transfusion should not be given. In patients who have such pronounced anaemia that an urgent transfusion is required, an exchange transfusion of a small volume of packed cells may be appropriate.
- In vitamin B₁₂ deficiency, folate tends to leak from cells, and the red blood cell folate is often low (serum folate is sometimes raised). Many patients initially require both folate and vitamin B₁₂ although folate can usually be stopped after a short course. Folate therapy must never be given to patients who have not been fully investigated for vitamin B₁₂ deficiency. If vitamin B₁₂-deficient patients are given large doses of folate without hydroxocobalamin, the full blood count may appear to improve, but the peripheral neuropathy from the vitamin B₁₂ deficiency progresses.

Case 50.4

Mrs GN, a 76-year-old retired factory worker, was seen by her primary care doctor, complaining of tiredness. She had been seen 2 months earlier and started on ferrous sulfate for microcytic anaemia. Initially, she had felt better, but the tiredness soon returned. A bone marrow aspiration revealed increased erythropoiesis, iron stores and red blood cell precursors.

A diagnosis of sideroblastic anaemia was made, and it was decided to give her monthly transfusions. She was started on pyridoxine 50 mg three times a day in addition to ferrous sulfate.

Questions

- What are the potential problems with Mrs GN's treatment?
- After 3 months, there appeared to be little benefit to show from pyridoxine. How might management be improved?

Answers

- Mrs GN's bone marrow aspiration and serum ferritin level showed that she has high levels of stored iron. Repeated monthly transfusions will also contribute to further iron accumulation; each transfused unit contains around 200–250 mg of iron (Hoffbrand et al., 2012). In sideroblastic anaemia, the bone marrow appears to be inefficient at incorporating the iron into haem. The administration of iron leads to iron overload, which may result in damage to the heart, liver and endocrine organs. The ferrous sulfate must be stopped. If iron accumulation remains a problem, iron chelation therapy using deferoxamine or deferasirox would be necessary.
- Pyridoxine does not always improve the blood picture in patients with sideroblastic anaemia. In sideroblastic anaemia, the dose of pyridoxine required is usually 400 mg daily. Therefore, in the case of Mrs GN, an increase in dose should be tried. In addition, patients with sideroblastic anaemia may be unaware that pyridoxine is not just a simple vitamin but a specific treatment for anaemia. Counselling the patient would be essential to improve adherence.

Case 50.5

Mrs RO, a 70-year-old retired teacher, presented with a history of increased tiredness over the last 6 weeks. She has a past history of a partial gastrectomy 4 years ago. On questioning, her relevant symptoms included 'pins and needles' in her toes and loose bowels. She said that she had never been a good eater but ate red meat twice a week. On investigation, her serum vitamin B₁₂ level was found to be 27 ng/L (range 150–400 ng/L).

Questions

- Why was it 4 years after her gastrectomy before Mrs RO developed vitamin B₁₂ deficiency?
- How long will it take for Mrs RO to respond to treatment?
- What therapy will Mrs RO require?

Answers

- Vitamin B₁₂ requires intrinsic factor produced by the stomach for absorption. Patients with a total gastrectomy and some with a partial gastrectomy malabsorb vitamin B₁₂. Most patients have good body stores, and even if no new vitamin B₁₂ enters the body

- (e.g. after a total gastrectomy), it will take at least 2 years to deplete the stores.
- Many patients will feel better within days of starting treatment with hydroxocobalamin and before a change in their haemoglobin concentration can be detected. Mrs RO's blood picture may take a number of weeks to return to normal. However, her 'pins and needles' may be a sign of peripheral neuropathy, which can be irreversible and may not respond to the hydroxocobalamin treatment.
 - Mrs RO will require lifelong replacement therapy. The standard treatment for vitamin B₁₂ deficiency is hydroxocobalamin 1 mg intramuscularly three times a week for 2 weeks, then 1 mg every 3 months. If neurological involvement is identified, as in the case of Mrs RO, then a slightly higher dose regimen is recommended of 1 mg on alternate days until no further improvement, followed by 1 mg every 2 months thereafter. Unlike Mrs RO, in patients in whom vitamin B₁₂ deficiency is likely to be exclusively diet related, it may be possible to reduce the frequency of injections to twice yearly.

51 Leukaemia

Michelle Lannon and Gail Jones

Key points

- Leukaemias are uncommon malignancies.
- Acute lymphoblastic leukaemia (ALL) is the most common malignancy in childhood.
- With the exception of ALL, leukaemias are more common in the elderly.
- Age is one of the most important prognostic factors in the treatment of leukaemia. With the exception of neonates, older patients are less likely to be cured than younger patients.
- The treatment of leukaemia is continually improving with the introduction of more focused therapy and improvements in supportive care.
- The use of bone marrow transplantation in the treatment of all forms of leukaemia is increasing. Some of the results are exciting, but the short- and long-term problems of this type of intensive treatment need to be considered.

Leukaemias and lymphomas are the commonest forms of haematological malignancy. Although rare, they are of particular interest in that dramatic improvements in the prognosis of patients with these cancers have been achieved through the use of chemotherapy. Cure is now a possibility for many patients.

Many forms of leukaemia exist, but they are all characterised by the production of excessive numbers of abnormal white blood cells. The leukaemias can be broadly divided into four groups:

- acute myeloblastic leukaemia (AML),
- acute lymphoblastic leukaemia (ALL),
- chronic myelocytic leukaemia (CML),
- chronic lymphocytic leukaemia (CLL).

The adjectives *myeloid* and *lymphoid* refer to the predominant cell involved, and the suffixes *-cytic* and *-blastic* to mature and immature cells, respectively. These characteristics can be determined by a combination of cellular appearances, surface antigen expression, cytogenetic features and molecular markers. The international standard for leukaemia classification is the World Health Organization (WHO) system (Swerdlow et al., 2008).

Epidemiology

Haematological malignancies account for only 5% of all cancers; of these, CLL is the most common form of leukaemia. UK incidence data are presented in Table 51.1. CLL mainly affects an older

age group: 90% of patients are older than 50 years at diagnosis, and nearly two-thirds are older than 60 years. It rarely occurs in young people and is twice as common in men as in women. CML is primarily a disease of middle age, with the median onset in the 40- to 50-year-old age group, but it can occur in younger people.

Acute leukaemia is rare, with a total annual incidence of approximately 4 per 100,000 population. The most common form of the disease is AML, which accounts for 75% of cases. The incidence of AML rises steadily with age, occurring only rarely in young children. In contrast, ALL is predominantly a childhood disease, with the peak incidence in the 3- to 5-year-old age group, and is the most common childhood cancer.

Aetiology

In common with other cancers, the aetiology of leukaemia is not fully understood. Leukaemia is thought to result from a combination of factors that induce genetic mutations that allow mutated cells to proliferate faster than normal cells and/or to fail to die in response to normal apoptotic signals. Epidemiological studies have, however, identified a number of specific risk factors for the development of leukaemia, which are described as follows.

Radiation

The association between the ionising radiation and the development of leukaemia is evident from nuclear disasters such as Hiroshima and, more recently, Chernobyl. Long-term follow-up of survivors of Nagasaki and Hiroshima has shown an increase in all forms of leukaemia other than CLL. The link is also apparent for patients who received radiotherapy for the treatment of malignant and non-malignant conditions such as Hodgkin's disease or ankylosing spondylitis. The effect of chronic low-level exposure to radiation is less certain.

Exposure to chemicals and cytotoxic drugs

There is a small but definite risk of acute leukaemia occurring in patients successfully treated for other malignancies with cytotoxic and immunosuppressive agents. Combination treatment with chemotherapy, especially alkylating agents such as cyclophosphamide and radiotherapy, presents the highest risk. In addition, topoisomerase II inhibitors, such as etoposide, frequently

used in curative treatment for haematological and solid-organ malignancies, pose a risk of therapy-related acute leukaemia. This has practical implications as an increasing number of patients achieve a 'cure' as a result of combination therapy. Occupational exposure of health professionals to these agents is also an area of concern. Occupational exposures to paint, insecticides and solvents, in particular, the aromatic solvent benzene, have all been associated with the development of leukaemia, but it is difficult to be certain whether such exposures genuinely cause the disease.

Viruses

Human T-cell lymphotropic virus, an RNA retrovirus endemic in Japan and the West Indies, has been linked to a rare T-cell leukaemia/lymphoma.

Genetic factors

Down's syndrome, constitutional trisomy of chromosome 21, is associated with an increased risk of leukaemia. Disorders that predispose to chromosomal breaks such as Fanconi's anaemia

and ataxia telangiectasia are also associated with an increased risk of developing acute leukaemia. These alterations may permit the expression of oncogenes, which promote malignant transformation.

Haematological disorders

Many patients with other haematological disorders have a greatly increased risk of developing leukaemia, particularly AML. These disorders include the myelodysplastic syndromes, the non-leukaemic myeloproliferative disorders including myelofibrosis, aplastic anaemia and paroxysmal nocturnal haemoglobinuria.

Pathophysiology

In leukaemia, the normal process of haemopoiesis is altered (Fig. 51.1). Transformation to malignancy appears to occur in a single cell, usually at the pluripotential stem cell level, but it may occur in a committed stem cell with capacity for more limited differentiation. Accumulation of malignant cells leads to progressive impairment of the normal bone marrow function.

Acute leukaemias

In acute leukaemia, the normal bone marrow is replaced by a malignant clone of immature blast cells derived from the myeloid (in AML) or lymphoid (in ALL) series. More than 20% of the cellular elements of the bone marrow are replaced with blasts. This is usually associated with the appearance of blasts in the peripheral circulation accompanied by worsening pancytopenia as a result of the marrow's reduced ability to produce normal blood cells as the proportion of malignant cells increases. In ALL, the blasts may infiltrate lymph nodes and other tissues such as liver, spleen, testis and the meninges, in particular. In AML, blasts tend to infiltrate skin, gums, liver and spleen.

Table 51.1 Incidence 2014 of leukaemia in the UK (Cancer Research UK, 2017)

	New cases/year	Age-Standardised Incidence per 100,000 of the population
CLL	3515	6.0
CML	748	1.2
ALL	758	1.1
AML	3072	5.2

ALL, Acute lymphoblastic leukaemia; AML, acute myeloblastic leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myelocytic leukaemia.

Fig. 51.1 Haemopoiesis.

Table 51.2 World Health Organization classification of acute myeloblastic leukaemia (Swerdlow et al., 2008)

Subgroup	Examples
AML with recurrent genetic abnormalities	Inversion chromosome 16 (inv 16) t(15;17) t(8;21)
AML with multilineage dysplasia	
Therapy-related AML	
AML not otherwise classified	AML without maturation AML with granulocytic maturation AML with granulocytic and monocytic differentiation AML with monocytic differentiation AML with erythroid differentiation AML with megakaryocytic differentiation

AML, Acute myeloblastic leukaemia.

Classification of acute myeloblastic leukaemia

AML has traditionally been classified on the basis of morphological features of the disease. Subtypes displaying granulocytic, monocytic, erythroid and megakaryocytic differentiation can be demonstrated. The WHO has updated this system (Table 51.2). AML is now classified using a combination of morphological, genetic and immunological cell marker features (surface antigen expression) in an attempt to define disease groups of greater prognostic significance (Swerdlow et al., 2008).

Classification of acute lymphoblastic leukaemia

As with AML, the WHO classification system takes account of morphological, genetic and immunological features. The disease is, however, mainly classified immunologically, based on the presence or absence of B- or T-cell markers (Table 51.3). Each subtype displays different clinical presentations, response to treatment and, ultimately, prognosis, with pre-B having the best prognosis and T-ALL the worst. It is worth noting that Burkitt type B-ALL which is associated with translocations of the *myc* gene located on chromosome 8, seems to be a morphologically and biologically distinct form of leukaemia.

Chronic leukaemias

In chronic leukaemia, the normal bone marrow is replaced by a malignant clone of maturing haemopoietic cells.

Chronic lymphocytic leukaemia

CLL is characterised by a clonal expansion of morphologically mature lymphocytes of B-cell origin. These cells accumulate in

Table 51.3 Classification of acute lymphoblastic leukaemia (Swerdlow et al., 2008)

Pre-B ALL	Possessing the common ALL antigen CD10
B-cell type	B-ALL or Burkitt's type
T-cell type	T-ALL
Null	Non-B, non-T and lacking the common ALL antigen CD10

ALL, Acute lymphoblastic leukaemia.

the peripheral blood and give rise to a lymphocytosis that may be very marked. Lymphocytes accumulate in lymph nodes and can spread to the liver and spleen, which become enlarged. The bone marrow is progressively infiltrated. Although the malignant lymphocytes appear relatively normal morphologically, they are functionally deficient.

Chronic myelocytic leukaemia

The characteristic feature of CML is the predominance of maturing myeloid cells in blood, bone marrow, liver, spleen and other organs. CML was the first cancer to be associated with a specific chromosomal abnormality: the Philadelphia chromosome translocation (Ph) seen in more than 90% of cases. This is a translocation of genetic material between the long arms of chromosome 22 and chromosome 9. This results in the apposition of the BCR gene (chromosome 22) and the ABL gene (chromosome 9). This novel BCR-ABL gene encodes a fusion protein that has tyrosine kinase activity. This genetic event is believed to be crucial in the pathogenesis, or perhaps even to initiate the development, of CML because overactivity of the tyrosine kinase results in the uncontrolled growth characteristic of leukaemic cells (Cilloni and Saglio, 2009).

Clinical manifestations

Acute leukaemia

Most of the clinical manifestations of acute leukaemia are related to bone marrow failure. The disease commonly presents with a short history, and left untreated, it is rapidly fatal. Symptoms of infection, anaemia and bleeding are common and life-threatening presenting problems. Bleeding may be particularly severe in one subtype of AML, acute promyelocytic leukaemia (APL). This condition is most commonly associated with a translocation of genetic material between chromosomes 15 and 17, t(15;17). Disseminated intravascular coagulation (DIC) is commonly the presenting feature of this disease with patients often displaying life-threatening bleeding symptoms at presentation. Some patients with AML develop symptoms and signs due to infiltration of major organs by leukaemic cells.

The involvement of tissues such as spleen, liver, lymph nodes and meninges is more common in ALL than AML. Involvement

of the central nervous system (CNS) may give rise to headaches, vomiting and irritable behaviour. CNS disease is rare at presentation but develops in up to 75% of children with ALL unless specific prophylactic treatment is given. Less commonly, patients present with features of hypermetabolism, hyperuricaemia or generalised aches and pains.

Chronic leukaemia

Chronic myelocytic leukaemia

Patients with CML commonly present with non-specific symptoms, such as malaise, weight loss and night sweats. The most common physical sign is an enlarged spleen that may give rise to abdominal discomfort. Hepatomegaly is also detected in approximately 40% of newly diagnosed patients. Neutropenia and thrombocytopenia are uncommon at presentation. Thus, in contrast to the acute leukaemias, patients with CML rarely present with symptoms of infection or haemorrhage. In up to 30% of cases, patients are asymptomatic, and the disease is detected, by chance, as a result of a routine blood test performed for other reasons.

Historically CML was regarded as a triphasic disease. The initial chronic phase typically lasted from months to years, with a median of around 5 years. During this time, treatment was aimed at symptom alleviation with reduction of the white blood cell (WBC) count and spleen size. An accelerated phase typically followed, manifest by the presence of increasing numbers of immature cells in the blood and bone marrow associated with worsening symptoms: unexplained fevers, bone pain and anaemia. Finally, after a period of weeks or months, a blast crisis resembling fulminant acute leukaemia would ensue. In a small number of patients, this occurred abruptly with no prior accelerated phase. Whilst accelerated phase and blast crisis can still occur, the natural history of CML has been profoundly improved by the use of targeted therapies.

Chronic lymphocytic leukaemia

An increasing number of asymptomatic patients are diagnosed as having CLL purely by chance, when a full blood count is performed for an unrelated reason. Symptomatic patients often suffer B symptoms: night sweats, unexplained fever and weight loss. At diagnosis, findings may include generalised lymphadenopathy and some enlargement of the liver and spleen. The course of CLL is variable; in some patients, the disease may remain indolent for many years, whereas others experience a steady deterioration in their health. Survival typically varies from 2 to 20 years depending on the extent of disease. Patients are immunocompromised with a reduction in serum gammaglobulin and are at increased risk of bacterial and viral infections. There is an increased susceptibility to autoimmune disease, particularly immune haemolytic anaemias and thrombocytopenia. With progressive disease, bone marrow failure becomes apparent, resulting in fatigue, infection and bleeding, and the disease becomes less responsive to treatment. Patients with CLL also have an increased risk of developing a more aggressive malignancy, such as high-grade non-Hodgkin's

lymphoma (known as Richter's transformation) or prolymphocytic leukaemia (PLL).

Investigations

Traditionally examinations of peripheral blood and bone marrow are the key laboratory investigations carried out in cases of suspected leukaemia. However, some additional investigations can help in the diagnosis and classification of this group of diseases. With the wider general accessibility and understanding of molecular testing, the classification and prognostication of these diseases continue to evolve. Some of the main findings at diagnosis are presented in [Table 51.4](#).

In acute leukaemia, leukaemic blast cells are usually seen on the peripheral blood film. The blasts of ALL and AML are distinguished using morphology, cell surface antigen analysis and cytogenetics. In CML, the principal feature is a leucocytosis with WBC usually ranging from $10 \times 10^9/L$ to $250 \times 10^9/L$ and comprising the complete spectrum of myeloid cells from immature to mature. In CLL, it is lymphocytes, in particular, which are increased, with clonal lymphocyte counts exceeding $5 \times 10^9/L$. Non-random chromosome abnormalities are increasingly being identified in patients with leukaemia. The information obtained from cytogenetic analysis of bone marrow or peripheral blood cells can be used to confirm the diagnosis and classification of leukaemia and may provide a guide to treatment response and prognosis.

Treatment

Although significant progress has been made in the treatment of leukaemia, work continues to further improve prognosis. As leukaemias are rare malignancies, the most important studies are undertaken on a national or international basis. In addition to the specific anti-leukaemia treatment, general supportive therapy is vital to manage both the disease and the complications of therapy.

Acute leukaemia

At the outset, intensive combination chemotherapy is given in the hope of achieving a complete remission (CR). This initial phase of treatment is termed induction or remission induction chemotherapy. A CR can only be achieved by virtual ablation of the bone marrow, followed by recovery of normal haemopoiesis. If the induction regimen fails to induce CR, an alternative drug regimen can be used. Remission is defined as the absence of all clinical and microscopic signs of leukaemia, less than 5% blast forms in the bone marrow and return of normal cellularity and haemopoietic elements. Despite achieving CR, occult residual disease (also termed minimal residual disease or MRD) will persist, and further intensive therapy is given in an attempt to consolidate the remission. This post-remission consolidation therapy may comprise chemotherapy or a combination of chemotherapy and bone marrow transplantation.

Table 51.4 Findings at diagnosis in leukaemia

	AML	ALL	CML	CLL
WBC	↑ in 60%, may be N or ↓	↑ in 50%, may be N or ↓↓	↑↑ Commonly >100 × 10 ⁹	Commonly ↑↑
Differential WBC	Mainly myeloblasts	Mainly lymphoblasts	Granulocytes ↑↑, especially neutrophils, myelocytes, basophils and eosinophils <10% blasts present	>5 × 10 ⁹ /L monoclonal lymphocytes
RBC	Severe anaemia	Severe anaemia	Anaemia common	Anaemia in 50% of patients, generally mild
Platelets	↓↓	↓↓	Usually ↑ but may be N or ↓	↓ in 20–30%
Bone marrow aspiration and trephine	Predominantly blasts	Predominantly blasts	Hypercellular Blasts <10%	Lymphocytic infiltration
Cytogenetic analysis	Important abnormalities may be detected but can be N	Important abnormalities may be detected, Ph chromosome detected in 20% of adults	Presence of Ph chromosome	Important abnormalities including p53 deletion or mutation are prognostically significant
Lymphadenopathy	Rare	Common	Rare	Common
Splenomegaly	50%	60%	Usual and severe	Usual and moderate
Other features	DIC, high urate, gum infiltration	High urate, CNS involvement	High urate	Immunoparesis

↓, Reduced; ↑ increased; ALL, acute lymphoblastic leukaemia; AML, acute myeloblastic leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myelocytic leukaemia; CNS, central nervous system; N, normal; DIC, disseminated intravascular coagulation; Ph, Philadelphia; RBC, red blood cell; WBC, white blood cell.

Acute lymphoblastic leukaemia

Treatment of ALL in childhood has been one of the success stories of the past three decades. Nearly 90% of children will achieve a remission lasting more than 5 years, and current studies are often focused on trying to identify the 20% of children with poor-risk disease and treating them more aggressively (Pui et al., 2012). Poor risk is defined at presentation based on white cell count, age, underlying genetic conditions (e.g. Down syndrome) and the diagnosis of T-cell ALL. Thereafter, risk is determined by minimal residual disease measurements. This allows for patients with ALL to have risk-adapted therapy in the context of clinical trials.

Unfortunately, the results in adults are less impressive. The combination of vincristine, prednisolone, anthracyclines and asparaginase induces CR in about 90% of children with ALL and 80% of adults, although sadly relapse is far more common in adults. Table 51.5 demonstrates a possible schedule for induction and consolidation therapy for adults with ALL. Given the rarity of the disease, patients should be entered into clinical trials whenever possible where the addition of targeted therapies and comparison of the optimal scheduling of chemotherapy can hopefully be refined.

Patients with ALL are at a high risk of developing CNS infiltration. Cytotoxic drugs penetrate poorly into the CNS, which thus acts as a potential sanctuary site for leukaemic cells. For this reason, all patients with ALL receive CNS prophylaxis. Cranial irradiation, intrathecal methotrexate or high-dose systemic methotrexate can be used in isolation or in combination as part of the treatment schedules for both adults and children.

Maintenance treatment is important to sustain a CR. It is usually less myelotoxic than induction or consolidation chemotherapy but is given for at least 18 months. Treatment usually consists of weekly methotrexate and daily 6-mercaptopurine with intermittent vincristine and prednisolone and in some patients, intrathecal methotrexate.

The treatment of relapsed disease varies with the site of relapse. Isolated CNS or testicular relapse may be successfully treated with radiation and reinduction therapy. Cure can still be achieved for some patients. Bone marrow relapse is much more difficult to cure, especially if it occurs early.

A small proportion of paediatric patients and a larger proportion of adult patients have the Philadelphia chromosome translocation within their ALL blasts. Historically, such patients had a relatively poor prognosis but the use of targeted therapy, such as the tyrosine kinase inhibitor, imatinib, has considerably improved responses. Most adult patients with Philadelphia chromosome positive ALL are assessed for stem cell transplant to further consolidate an initial response.

Acute myeloblastic leukaemia (non-acute promyelocytic leukaemia)

As for ALL, the treatment of AML involves induction and consolidation chemotherapy. In AML therapy, however, the chemotherapy regimens used to achieve remission are typically more myelotoxic, and patients require intensive supportive care to survive periods

Table 51.5 Treatment of acute lymphoblastic leukaemia

	Dose	Route	Regimen
Phase I induction (4-week cycle)			
Daunorubicin	30 mg/m ²	i.v.	Weekly for 4 weeks
Vincristine	1.4 mg/m ² (max 2 mg)	i.v.	Weekly for 4 weeks
PEGylated Asparaginase	1000 IU/m ²	i.v.	Days 4 and 18 of the cycle (only if Ph-negative)
Dexamethasone	10 mg/m ²	p.o.	For 4 days each week
Methotrexate	12.5 mg	i.t.	Day 14 of the cycle
Phase II induction (4-week cycle)			
Cyclophosphamide	1000 mg/m ²	i.v.	Days 1 and 15 of the cycle
Cytarabine	75 mg/m ²	i.v.	Days 2–5, 9–12, 16–19 and 23–26
Mercaptopurine	60 mg/m ²	p.o.	Once daily
Methotrexate	12.5 mg	i.t.	Weekly for 4 weeks
Risk assessment – Many will proceed to allogeneic stem cell transplant, but the remainder will continue with consolidation (2 x 4 weekly cycles)			
Cytarabine	75 mg/m ²	i.v.	Days 1–5 of each cycle
Etoposide	1000 mg/m ²	i.v.	Days 1–5 of each cycle
PEGylated Asparaginase	1000 IU/m ²	i.v.	Day 5 of cycle 1 only
Methotrexate	12.5 mg	i.t.	Once per cycle
Delayed Intensification I			
Daunorubicin	25 mg/m ²	i.v.	Weekly for 4 weeks
Vincristine	1.4 mg/m ²	i.v.	Weekly for 4 weeks
PEGylated Asparaginase	1000 IU/m ²	i.v.	Day 4 of the cycle
Dexamethasone	10 mg/m ²	p.o.	For 4 days each week for 4 weeks
Methotrexate	12.5 mg	i.t.	Days 2 and 17 of the cycle
Cyclophosphamide	1000 mg/m ²	i.v.	Day 29 of the cycle
Cytarabine	75 mg/m ²	i.v.	Days 30–33 and 37–40 of the cycle
Mercaptopurine	60 mg/m ²	p.o.	Days 29–42 of the cycle
Further cycle the same as consolidation (4 weeks)			
Maintenance for 2 years			
Vincristine	1.4 mg/m ² (max 2 mg)	i.v.	Once every 3 months
Prednisolone	60 mg/m ²	p.o.	For 5 days every 3 monthsw
Mercaptopurine	75 mg/m ²	p.o.	Every day
Methotrexate	20 mg/m ²	p.o.	Once weekly
Methotrexate	12.5 mg	i.t.	Every 3 months

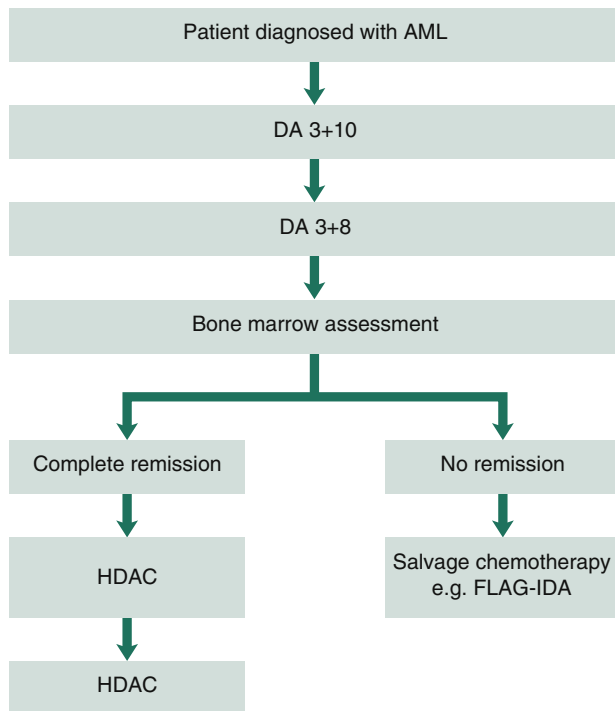

Fig. 51.2 One example of a possible treatment regimen for acute myeloblastic leukaemia (AML). The figure demonstrates that patients are treated with initial induction therapy, then remission is consolidated with at least two courses of chemotherapy. Patients are assessed for the necessity and their suitability for allogeneic stem cell transplant during this treatment. This figure provides a summary only and should not be used as a guide to prescribing or dispensing therapy. DA 3+10 and DA 3+8 are schedules of daunorubicin and cytarabine; HDAC, high-dose cytarabine; FLAG-IDA, fludarabine, cytarabine and granulocyte colony-stimulating factor combined with idarubicin.

of bone marrow aplasia (Fig. 51.2). The anthracycline, daunorubicin, and the pyrimidine analogue, cytarabine, have formed the backbone of AML therapy for more than 30 years. Sadly, this is an indicator of a lack of progress in the therapy of this disease over the years. Whilst it is possible to achieve 80% remission rates, relapse rates remain high, with 5-year survival of 35–40% in those younger than 60 years at diagnosis and 5–15% in those older than 60 years at diagnosis (Dohner et al., 2015). For this reason, many patients opt for treatment in the context of clinical trials.

For many years, cytogenetic abnormalities in AML blasts have been recognised as having fundamental importance in determining prognosis (Grimwade et al., 2010). They have been used to develop individualised risk-adapted treatment strategies, particularly influencing which patients (i.e. those at highest risk of relapse) potentially have most to gain from allogeneic bone marrow transplant in first remission, for instance. Unfortunately, the largest patient group identified comprised those with a normal karyotype; a standard cytogenetic approach does not allow further risk stratification in this group. Molecular studies, identifying specific gene mutations associated with AML, are now allowing better risk stratification particularly in this normal karyotype group (Grimwade et al., 2016). Molecular technologies are now beginning to aid in the understanding of the biology of AML and the identification potential targets for therapy. It is worth stating,

however, that our ability to detect mutations is improving very quickly; the current challenge is to understand the relative importance of such mutations, given that an individual patient may have several mutations, to be able to best apply this new knowledge for patient benefit. A parallel strand of thinking in AML is to develop robust techniques for MRD monitoring, thus allowing an individualised treatment approach based not on pre-existing molecular or genetic phenotype but on response to treatment. This strategy has been particularly successful in paediatric ALL and is now being better defined in AML (Ivey et al., 2016).

Fig. 51.2 shows a possible treatment schedule for an adult patient with AML. The backbone of daunorubicin and cytarabine remains. For many patients, consolidation chemotherapy, as shown in Fig. 51.2, may be considered the best treatment; an alternative approach to post-remission therapy is stem cell transplantation. In patients younger than 40 years, myeloablative allogeneic bone marrow transplantation has resulted in disease-free survival of 45–65% at 5 years post-transplant. These patients are considered cured of their disease. Only about 10% of patients are suitable for myeloablative allogeneic bone marrow transplants, although reduced-intensity conditioning regimens have a more general applicability. There is little evidence to suggest that autologous stem cell transplantation improves the outcome for patients with AML in first CR. It is always worth remembering that AML is most common in the elderly, and it is not always possible to deliver intensive intravenous chemotherapy regimens to this patient population. Alternative options in the elderly include less intensive, lower-dose daunorubicin and cytarabine, low-dose subcutaneous cytarabine and 5-azacytidine; 5-azacytidine is of recent interest, especially in older patients and those whose disease has evolved from myelodysplastic syndrome (MDS). This agent inhibits DNA methyltransferase, resulting in DNA hypomethylation. This process is thought to increase the activity of some tumour-suppressor genes, resulting in anti-tumour effects. The agent has been shown to slow the rate of progression to AML in patients with high-risk myelodysplastic syndrome and is currently the subject of clinical trials in AML and MDS.

Treatment of AML in relapse is difficult, and the prognosis is generally poor. Whenever possible, patients who enter remission should be offered an allogeneic bone marrow transplant, as chemotherapy alone is unlikely to cure relapsed disease. Encouraging results have been seen using a combination of fludarabine, cytosine arabinoside, idarubicin and granulocyte colony-stimulating factor (G-CSF) as a prelude to allogeneic transplant. Novel approaches in AML therapy are often piloted in this group of poor-risk patients. There are many novel agents currently being investigated in AML; we highlight just a few. Gemtuzumab ozogamicin is a humanised anti-CD33 monoclonal antibody, which targets myeloid blasts, bound to a potent anti-tumour anthracycline antibiotic, calicheamicin (Rowe and Löwenberg, 2013). This antibody, when used in combination with standard chemotherapy, seems to reduce relapse risk in all but the highest-risk patients. Concerns have been raised about possible toxicity in the form of veno-occlusive disease of the liver, and the dosing schedule is not yet optimised. Midostaurin is a multi-targeted FLT3 inhibitor and has been shown to improve survival in the subgroup of patients with FLT3-mutated AML. Increasing numbers of such targeted therapies are likely to be tested in the next few years.

Acute promyelocytic leukaemia

The acute promyelocytic leukaemia subtype of AML deserves special consideration because the approach to treatment and prognosis is quite different from that of other AML variants. APL is associated with the t(15;17) translocation, which involves a genetic translocation of material between chromosomes 15 and 17. The disease is clinically characterised by the presence of DIC at presentation. Because these patients are so prone to life-threatening haemorrhage at diagnosis, the management of a new case of APL is considered a medical emergency. The leukaemic cells are exquisitely sensitive to all-trans retinoic acid (ATRA), which induces blast maturation and can induce remission when used as a single agent (Coombs et al., 2015). Using a combination of ATRA and anthracycline chemotherapy, usually idarubicin, it is now possible to achieve long-term cure in greater than 80% patients. A number of studies have been published demonstrating the efficacy of arsenic trioxide (ATO) in treating relapsed or refractory APL. In the UK, ATO is currently regarded as the standard of care for relapsed APL. It is also effective in first-line therapy, although overall survival of patients treated up front with ATO and ATRA was no different from that of patients treated with anthracycline and ATRA. Given the significant differences in cost between the two regimens, the latter currently remains the standard of care (Burnett et al., 2015).

Chronic leukaemia

Chronic myelocytic leukaemia

Historically, the treatment of CML was essentially palliative in intent, producing modest increases in survival, but with the main aim of keeping patients asymptomatic by normalising the WBC. Traditionally, CML was treated with non-targeted therapies, but these were often poorly tolerated and did not provide a long-term solution. Historically, the only curative option for CML was an allogeneic stem cell transplant, but many patients were not suitable for this intensive treatment due to age and comorbidities.

Hydroxycarbamide was the most widely used drug in the management of CML in chronic phase. Treatment with hydroxycarbamide at a dose of 1.5–2 g/day can be used and usually brings the WBC under control within 1–2 weeks. The dose can then be reduced to a maintenance dose of 0.5–2 g/day. Withdrawing or reducing the dose abruptly can cause a rebound increase in WBC. The side effects of hydroxycarbamide are generally mild but include rashes and gastro-intestinal disturbances.

Interferon can be used to control the symptoms of CML but was also the first agent shown to modify the disease process. It promotes the expression of suppressed normal haemopoiesis at the expense of the malignant clone. Studies have shown that interferon- α therapy prolongs the chronic phase and improves the median survival of CML patients with its effects seemingly enhanced by the addition of low-dose cytarabine (Sawyers, 1999).

Therapeutic options for patients with CML have changed dramatically in the past 10–15 years due to the development of imatinib mesylate. This drug, which belongs to the tyrosine kinase inhibitor (TKI) class of drug, was specifically designed to target

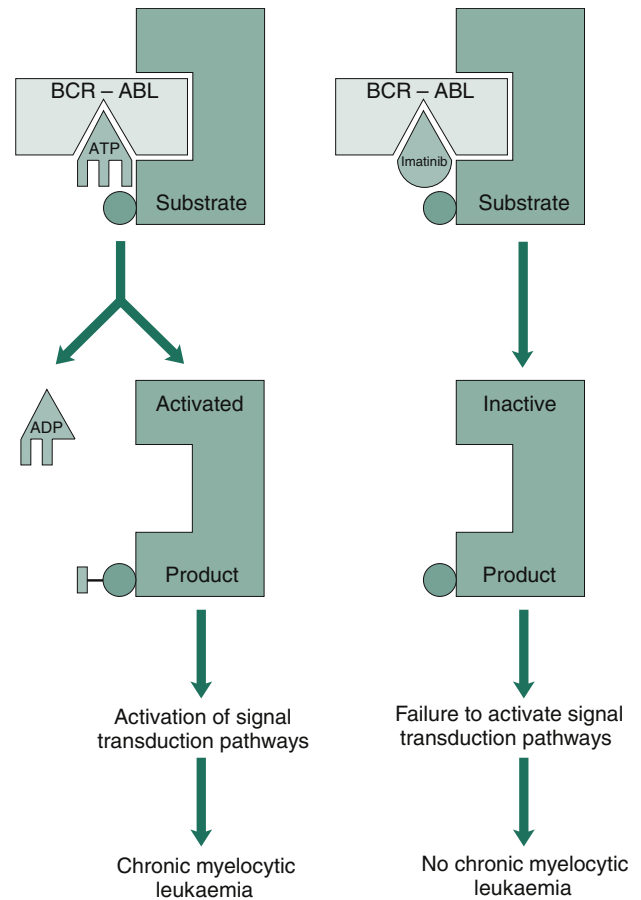

Fig. 51.3 Inhibition of BCR-ABL protein by imatinib. The protein product of the BCR-ABL fusion gene (BCR-ABL protein) acts as a constitutively active tyrosine kinase and uses adenosine triphosphate (ATP), bound within a kinase pocket in the molecule, to phosphorylate tyrosine (o) in a variety of substrates. In doing so, ATP is reduced to adenosine diphosphate (ADP), which falls out of the kinase pocket to be replaced by further ATP. Imatinib prevents the action of the BCR-ABL protein by blocking ATP entry into the kinase pocket.

the abnormal tyrosine kinase product of the BCR-ABL fusion gene (Fig. 51.3). TKIs are now the mainstay of treatment for CML.

In a large randomised controlled trial, patients were randomised to receive imatinib or a combination of interferon- α and cytarabine. Many patients were intolerant of the interferon and cytarabine combination and crossed over to receive imatinib after trial commencement. Despite this problem, progression-free survival at 1 year was 97% in the imatinib arm and 80% in the interferon and cytarabine arm in an intention-to-treat analysis (O'Brien et al., 2003). The Philadelphia chromosome became undetectable in 68% of imatinib recipients compared with 7% of those in the alternative arm (Hughes et al., 2003). However, more sensitive testing methods, such as real-time polymerase chain reaction (PCR), have now shown that many patients who are Philadelphia chromosome negative still possess very low levels of the abnormal BCR-ABL gene produced by the Philadelphia translocation. Complete molecular remission is seen in only a very small proportion of patients. In patients who achieve a cytogenetic or ideally

a molecular remission, current studies are underway to determine if TKIs can be stopped and what impact this will have on remission status and survival.

The use of imatinib has inevitably led to the demonstration of imatinib-resistant clones in some patients; second-generation TKIs are now available, such as nilotinib, dasatinib and bosutinib. In the UK, the National Institute for Health and Care Excellence (NICE) has approved imatinib and nilotinib for first-line therapy for chronic phase CML and dasatinib and nilotinib for the second-line treatment of CML in those who are refractory to or unable to tolerate imatinib (NICE, 2012a).

Due to the effectiveness of imatinib therapy and the development of second-generation agents, allogeneic stem cell transplantation is now rarely used to treat CML, but it is still a potentially curative option for patients with multi-drug-resistant disease.

Transformation of CML into acute leukaemia can be treated in the same manner as de novo acute leukaemia, in an effort to achieve a second chronic phase. Treatment is slightly more successful if transformation is lymphoid rather than myeloid. Imatinib, typically at higher doses than are used in chronic phase disease, can also be used to attempt to return patients to chronic phase disease. In general, remissions are rare, and the median survival is less than 6 months.

Chronic lymphocytic leukaemia

Currently, there is no cure for CLL. All treatment is, therefore, considered palliative. There is no evidence that early treatment of asymptomatic patients improves outcome. Indications for treatment are:

- rapidly increasing WBC,
- increasing or troublesome lymphadenopathy,
- systemic symptoms,
- marrow failure,
- autoimmune complications.

In the last 5 years, there have been very exciting developments in the management of CLL, such as new agents and new combination regimens, that have been adopted successfully into clinical practice.

Formerly, the alkylating agent chlorambucil was the most common agent used in the treatment of CLL. Corticosteroids can reduce the lymphocyte count without contributing to myelosuppression and are used to treat autoimmune phenomena such as haemolytic anaemia and immune thrombocytopenia. The use of purine analogues, particularly fludarabine, marked the beginning of an exciting phase in the treatment of CLL. Although CRs were unusual, good responses were seen even in patients whose leukaemia was resistant to alkylating agents. With regard to initial therapy of CLL, fludarabine-treated patients show a higher response rate than patients treated with chlorambucil. However, no survival advantage for the use of fludarabine has been demonstrated (Rai et al., 2000).

The addition of the anti-CD20 antibody rituximab to fludarabine and cyclophosphamide (FC-R) has been shown in randomised trials to have better overall responses than fludarabine

and cyclophosphamide (FC) alone, with 86% and 73%, respectively (Halleck et al., 2009). This combination of fludarabine, cyclophosphamide and rituximab has been adopted in the UK as the regimen of choice for first-line treatment of CLL as long as patients are considered fit enough and has been used as the comparator to novel drugs and novel combinations for the first-line treatment of CLL.

More recent studies have looked at the use of bendamustine, an intravenous alkylating agent. Studies have shown fludarabine, cyclophosphamide and rituximab (FC-R) and bendamustine and rituximab (BR) to have a similar overall response rate but with better complete responses in those receiving fludarabine, cyclophosphamide and rituximab (Eichhorst et al., 2013). Based on these data, bendamustine can be used as a first-line agent in CLL in those patients not fit for fludarabine, cyclophosphamide and rituximab.

Chlorambucil, alone or in combination with rituximab, remains an excellent choice for patients with significant comorbidities because the treatment is less immunosuppressive. As such, trials are ongoing to look at the effectiveness of chlorambucil in combination with other anti-CD20 agents to try to improve outcomes in the elderly. Obinutuzumab and ofatumumab have both been NICE approved in combination with chlorambucil for first-line treatment for those patients for whom neither fludarabine nor bendamustine is an option for first-line therapy (NICE, 2015a, 2015b).

Alemtuzumab is a humanised monoclonal anti-CD52 antibody. CD52 is present on most lymphocytes including malignant lymphocytes in CLL. Binding of this antibody induces both antibody-mediated and complement-mediated T-cell cytotoxicity against malignant B cells. In relapsed patients, the duration of response to alemtuzumab is relatively short but has shown more promise in those who have difficulty to treat disease, namely, those who are found to have a p53 mutation in their CLL clone.

The most recent advance in CLL has been the advent of molecular therapies which target the B-cell signalling pathway. The Bruton kinase inhibitor, ibrutinib, and the PI3K inhibitor, idelalisib, have shown promise. Both of these agents are oral drugs which have targeted action so as to avoid the systemic effects seen with conventional chemotherapy agents.

Splenic complications may necessitate splenectomy or splenic irradiation. Radiotherapy can also be used to control localised painful lymphadenopathy. Combination chemotherapy, such as cyclophosphamide, doxorubicin, vincristine and prednisolone (CHOP; see Chapter 52) used in lymphoma, may be beneficial in advanced disease.

Patients with CLL are very susceptible to infection. Herpes viruses, in particular herpes zoster, can cause significant problems. This susceptibility is increased because many treatments, such as campath-1H, fludarabine and bendamustine, have generalised anti-lymphocyte action and are not absolutely specific for malignant lymphocytes.

Stem cell transplantation

The potential role of stem cell transplantation is increasingly being explored in the management of all types of leukaemia.

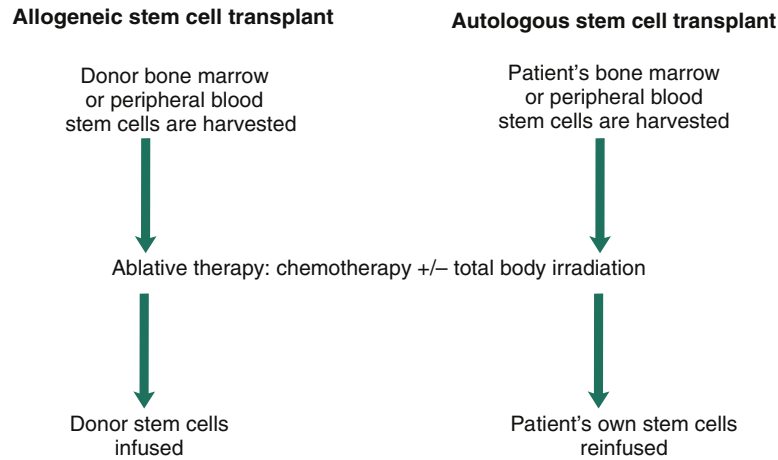

Fig. 51.4 Stem cell transplantation.

The basic principle

This technique provides a means of rescuing the patient from the potentially lethal effects on the bone marrow of ablative therapy given in an attempt to eradicate all traces of disease (Fig. 51.4). The conditioning regimen most commonly used is a combination of high-dose cyclophosphamide and total body irradiation. Other conditioning regimens include high-dose melphalan, fludarabine, busulphan or cytarabine.

After administration of conditioning therapy, 2–3 days elapse to allow its elimination from the body, and then previously harvested stem cells are reinfused peripherally. The stem cells will return to and repopulate the marrow, restoring normal haemopoiesis. Peripheral blood counts recover in 2–4 weeks. Throughout this time, patients require intensive supportive care and the procedure, particularly allogeneic stem cell transplantation, causes significant morbidity and has a mortality rate of 5–30% (Rezvani et al., 2016).

Over the last 30 years it has become clear that cure, after allogeneic bone marrow transplant, is not simply due to the very high doses of chemotherapy that are delivered but is instead an immunological function of a graft-versus-tumour effect that ensues after donor stem cell engraftment.

Allografts and autografts

During allogeneic stem cell transplantation (allograft), stem cells are obtained from a human leucocyte antigen (HLA)-matched donor who may be a sibling or an unrelated donor found through a national/international registry. These stem cells can be removed directly from the bone marrow, under general anaesthetic, or, more commonly, harvested from the peripheral blood. Under certain circumstances, an autologous bone marrow or peripheral blood stem cell transplant (autograft) may be preferred as the best treatment option. During an autologous transplant, the patient donates his or her own bone marrow or peripheral blood stem cells before receiving high-dose conditioning treatment. After conditioning, the patient's own stem cells are re-infused. There is a potential risk that stem cells obtained in this way may contain

undetected, residual disease. Attempts have been made to purge the bone marrow of disease *in vitro*, but these have generally been unsuccessful. In contrast to allograft recipients, patients receiving an autologous transplant will not benefit from any graft-versus-tumour effect. Autologous transplants are more commonly used to treat myeloma and lymphoma than leukaemia.

Peripheral blood stem cells versus marrow stem cells

Most patients and donors now donate haematopoietic stem cells using a technique of harvesting the cells from the peripheral blood. Donors receive the haematopoietic growth factor G-CSF, either alone or, in the case of patients donating for autologous transplant, after an infusion of high-dose chemotherapy such as high-dose cyclophosphamide. G-CSF is given for a period of about 7 days. This stimulates the release of stem cells into the peripheral circulation. Stem cells are then harvested from the peripheral circulation by a process of cell pheresis. The harvested cells can then be reinfused, fresh, into the patient after conditioning therapy or frozen and stored for later use. Peripheral blood stem cell transplantation offers some advantages over the conventional surgical technique of harvesting haematopoietic stem cells direct from the marrow cavity; collection of peripheral stem cells negates the need for general anaesthesia, and it has been found that the haematopoietic recovery period after transplantation is shortened by several days. This technique can also be used to harvest stem cells from allogeneic donors. In this case, G-CSF is used alone to stimulate stem cell release into the peripheral circulation. It is sometimes impossible to harvest enough stem cells from patients to allow an autologous transplant to be performed. The commonest reason for this is that the patient has been heavily pretreated with chemotherapy or radiotherapy. A new CXCR4 chemokine antagonist, plerixafor, is now available. This agent is thought to reduce the adhesion of stem cells within the bone marrow milieu. It can be given along with G-CSF and allows a proportion of patients who have failed to mobilise stem cells using G-CSF alone to mobilise cells for an autograft.

Complications of allogeneic bone marrow transplantation

Infection is almost inevitable in patients undergoing bone marrow transplantation. Other significant complications of allografting include interstitial pneumonitis and hepatic veno-occlusive disease (VOD), but the major life-threatening complication is graft-versus-host disease (GVHD). The likelihood of graft-versus-host disease occurring increases with recipient age and is one of the factors that explains the higher treatment-related mortality when transplanting older as compared with younger recipients. GVHD is caused by T-lymphocytes in the donated marrow reacting to host tissues. The severity of the reaction ranges from a mild maculopapular rash to multisystem organ failure with a high mortality rate. Acute GVHD is defined as occurring within 100 days of the bone marrow transplantation and typically presents with fever, rash, diarrhoea and liver dysfunction. Prophylactic immunosuppression is routinely given to prevent GVHD and is gradually weaned post-engraftment. The specific regimen depends on the nature of the transplant, but ciclosporin, the anti-CD52 antibody, alemtuzumab, and methotrexate can be used. Should acute GVHD develop, high-dose methylprednisolone, ciclosporin and, more recently, anticytokine monoclonal antibodies, for example, anti-tumour necrosis factor (anti-TNF) or anti-IL-6 antibodies, have been used to treat the condition.

Chronic GVHD is defined as GVHD occurring more than 100 days post-transplant. It is a multisystem disorder associated with chronic hepatitis, severe skin inflammation, gastrointestinal disturbance and profound immunosuppression. Treatment is successful in approximately 50% of patients and consists of immunosuppression with ciclosporin and prednisolone together with prophylactic antibiotics and antifungal agents. Tacrolimus, thalidomide, imatinib and extra-corporeal photopheresis (ECP) have also been used successfully in the treatment of chronic steroid-refractory GVHD. The main cause of death among patients with chronic GVHD is infection.

Reduced intensity allografting

Myeloablative, or full-intensity, allogeneic transplantation is a very intensive procedure associated with significant morbidity and mortality; hence, its application has to be restricted to younger, fitter patients. Attempts have been made to reduce the intensity of transplant conditioning regimens whilst using increased immunosuppression to facilitate marrow engraftment. Although such an approach reduces the intensity of therapy delivered to any residual tumour, the possible downside of this reduction is offset by an immunological graft-versus-tumour effect and by reduced early post-transplant mortality. This form of transplant is often offered to older patients who are considered unfit to receive a standard allograft. The long-term outcomes of this approach are under continual review. Several trials now suggest that the overall survival after myeloablative and reduced intensity transplants may be similar, although the causes of death in the two groups are different. More patients die of disease relapse after reduced intensity transplants, and more die of transplant-related complications in the myeloablative group (Sengsayadeth et al., 2015).

Table 51.6 Indications for allogeneic stem cell transplantation in leukaemia

AML	First remission for those with high-risk genetic or molecular characteristics and is a clinical option for those with standard-risk disease Second remission for relapsed patients
ALL	First remission in most adults Second remission in children
CML	Chronic phase but only if patients are intolerant of or refractory to first- and second-line tyrosine kinase inhibitors
CLL	Generally only considered in the setting of multiple-relapsed disease

ALL, Acute lymphoblastic leukaemia; AML, acute myeloblastic leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myelocytic leukaemia.

The place of stem cell transplantation

The place of stem cell transplantation in the management of a particular form of leukaemia depends very much on the prognosis of patients treated with conventional chemotherapy (Table 51.6). For example, the results of intensive chemotherapy in children with ALL are good, and bone marrow transplantation is generally only considered for children who have relapsed and in whom a second remission can be achieved. However, conventional treatment of adults is less successful, and allogeneic bone marrow transplantation may be offered to adults in first remission.

Patient care

Supportive care

The treatment of CLL and CML is largely carried out in a hospital outpatient setting, with patients taking oral medication at home or attending outpatient clinics for injections of chemotherapy. Patients are routinely monitored to follow the progress of disease and to observe treatment-related side effects. Supportive therapy, such as blood transfusions, can also be given on an outpatient basis. In contrast, the intensity of induction and consolidation regimens used in the management of patients with acute leukaemia renders patients severely pancytopenic. Therapy is usually given in an in-patient setting, with patients often remaining in hospital after treatment for 3–4 weeks until their bone marrow recovers sufficiently. Advanced leukaemia, bone marrow transplantation and aggressive chemotherapy for acute leukaemia all result in pancytopenia. Red blood cell transfusions are given to patients to maintain their haemoglobin at a level which prevents significant symptoms. Evidence of bleeding includes petechial haemorrhages in skin and mucous membranes, and patients receiving aggressive treatment must be examined frequently for any of these signs. Platelet concentrates are given to thrombocytopenic patients who have signs of bleeding and are given prophylactically should platelets fall to less than $10 \times 10^9/L$, although data are emerging to suggest

Fig. 51.5 Infection risk in immunocompromised patients.

that it is safe to transfuse platelets on the basis of symptoms rather than a platelet count per se (Stanworth et al., 2013). The probability of infection developing rises as the WBC count, specifically the neutrophil count, falls. With an absolute neutrophil count of less than $0.5 \times 10^9/L$, patients are at high risk of infection, with the risks being even greater if the period of neutropenia is prolonged. Atypical bacterial infections, as well as viral and fungal infections, can be troublesome in patients with prolonged neutropenia.

Chapters 52 and 53 examine many of the non-haematological toxicities which result from the use of cytotoxic drugs, and these are clearly pertinent to haematology patients. The major contributors to morbidity and mortality in patients with leukaemia are relapsed disease and infection.

Infection in the immunocompromised patient

A number of intrinsic and extrinsic factors all contribute to the risk of infection in this vulnerable group of patients (Fig. 51.5).

Although cross-infection can occur via staff, relatives, other patients or contaminated objects, the main sources of infection in this group of patients are endogenous, arising from commensal gut and skin organisms. The normal host defences to infection are broken down; damage to mucous membranes, particularly in the gastro-intestinal tract, occurs with chemotherapy and radiotherapy, allowing infecting organisms to enter the bloodstream. Most infections in neutropenic patients arise from three main sites: the gastro-intestinal and respiratory tracts, and the skin. Table 51.7 lists the main pathogens responsible for infection in this group of patients.

Preventive measures

Oral hygiene. Mouth care is important in all patients receiving chemotherapy but particularly neutropenic patients. Patients are generally asked to use mouthwashes regularly, and prophylactic antifungal therapy may also be given. Although it is important to avoid any sort of trauma to the oral mucosa, teeth should be cleaned regularly using a soft toothbrush. Attention must also be paid to the care of dentures. Patients require careful counselling on mouth care, stressing the importance of oral hygiene.

Table 51.7 Pathogens commonly causing infection in neutropenic patients

Gram-negative bacteria	<i>Pseudomonas</i> spp. <i>Escherichia coli</i> <i>Klebsiella</i> spp. <i>Enterobacter</i> spp. <i>Proteus</i> spp. <i>Serratia</i> spp. <i>Legionella pneumophila</i>
Gram-positive bacteria	<i>Streptococcus</i> spp. <i>Staphylococcus epidermidis</i> <i>Staphylococcus aureus</i>
Anaerobes	<i>Clostridium difficile</i> <i>Clostridium perfringens</i> <i>Bacteroides</i> spp.
Fungi	<i>Candida</i> spp. <i>Aspergillus</i> spp.
Viruses	Herpes simplex Herpes zoster Cytomegalovirus Epstein–Barr virus Hepatitis
Protozoa	<i>Pneumocystis carinii</i>

Table 51.8 Prophylactic anti-infectives

Gram-negative bacteria	Ciprofloxacin
Candidiasis	Nystatin Fluconazole Itraconazole Amphotericin B
Herpes simplex	Aciclovir
<i>Pneumocystis carinii</i>	Co-trimoxazole

Prophylactic anti-infectives. Although it is easy to see the potential advantages in using prophylactic anti-infective agents in severely immunosuppressed patients, the potential complications of drug resistance and, in the case of antibiotics, risks for hospital-acquired infections, such as *Clostridium difficile* and Meticillin-resistant *Staphylococcus aureus* (MRSA), also need to be considered. In the UK, the NICE currently recommends antibiotic prophylaxis for patients who will develop a neutrophil count less than $0.5 \times 10^9/L$ as a consequence of chemotherapy treatment (NICE, 2012b). Prophylactic antifungal agents are often given, and patients undergoing bone marrow transplantation, patients on therapy for ALL and some patients on therapy for CLL require prophylaxis against herpes virus and *Pneumocystis carinii* (Table 51.8). In patients with ALL, the choice of antifungals should be carefully thought out because the azole class of antifungals is contraindicated in those receiving vincristine due to the potential hepatotoxic effects.

Gut decontamination. Historically, gut decontamination using a combination of non-absorbable oral antibiotics and antifungal agents has been used to reduce the burden of potentially pathogenic organisms in the intestine. One such combination includes neomycin sulphate, colistin sulphate, nystatin and amphotericin. However, opinions are now divided over this practice because gut decontamination can lead to the overgrowth of resistant organisms, so some centres have chosen to avoid gut decontamination.

Growth factors. G-CSF can be used to reduce the time to neutrophil recovery after chemotherapy and has been shown to reduce infection risk and hospitalisation after certain chemotherapy regimens. Current international guidelines suggest that G-CSF should be considered for prophylactic administration if a patient has a risk of greater than 20% of developing febrile neutropenia as a consequence of the chemotherapy (Smith et al., 2015). G-CSF can also be used if patients develop febrile neutropenia and are designated as being at high risk of complications by standard criteria.

Aseptic technique. Careful attention should be paid to the care of intravenous cannulae, particularly central venous catheters. The increased incidence of staphylococcal infection in immunocompromised patients can largely be attributed to their use. Invasive procedures, such as venepuncture, must be carried out using strict aseptic technique. Similarly, urinary catheters are a major source of infection and their use should be avoided if at all possible.

Protective isolation. Reverse barrier isolation during periods of neutropenia, nursing in strict sterile environments and high-efficiency particulate air (HEPA) filtration have been used in an attempt to reduce infection rates. This is extremely demanding for staff and patients alike and is generally only appropriate after bone marrow transplantation.

Treatment of infection

Commonly, neutropenic patients show no signs of focal infection; they are unable to form pus. The only clinical manifestations of septicaemia might be general malaise, fever or hypotension. A patient's condition can deteriorate very rapidly, with collapse occurring within hours of the first signs of infection. Treatment should be instigated as soon as infection is suspected. After a clinically serious febrile episode (temperature: 37.5 °C for more than 1 hour or 38 °C or more on a single reading), samples are taken for culture; these may include blood, urine, sputum and stool cultures along with line and throat swabs. Intravenous antibiotics must be started empirically without delay (Sipsas et al., 2005). Standard empirical therapy varies from unit to unit but commonly comprises an anti-pseudomonal penicillin, such as piperacillin, to provide broad-spectrum bactericidal cover. In penicillin-allergic patients, meropenem may be substituted, but local resistance patterns are of paramount importance. Vancomycin or teicoplanin are often prescribed if an infected central venous catheter is suspected, to provide additional cover against Gram-positive organisms. Microbiological advice should be sought in cases of MRSA infection. Metronidazole may be added to the antibiotic regimen to cover anaerobes if the

clinical presentation suggests that the source of the infection may be oral, perineal or gut. Anti-infective therapy should subsequently be modified on the basis of cultures, but in the majority of neutropenic patients, a causative organism is never identified.

If the pyrexia persists for more than 4 days in spite of broad-spectrum antibiotics, or if the patient's condition is deteriorating, systemic fungal infection should be suspected. Empirical antifungal therapy for neutropenic patients with antibiotic-resistant fever reduces mortality and has historically been considered a standard of care. There is no doubt that some patients with persistent fever do have fungal infection, but it's also true that an entirely empiric approach will result in many patients receiving unnecessary treatment. Given the potential side effects of antifungal agents and their cost, many units now have a policy of systematic investigation of patients with ongoing fever including, early high-resolution computed tomography (CT) scanning of the chest and possible use of immunological or molecular tests to detect markers of fungal infection in the blood. This approach aims to target therapy more effectively. A number of broad-spectrum agents are now available for use in this setting, including standard amphotericin, lipid formulation of amphotericin, caspofungin, voriconazole and posaconazole. Intravenous amphotericin is often the first choice to ensure that *Aspergillus* and *Candida* are covered. The main limitation of amphotericin is its toxicity, in particular, nephrotoxicity. Lipid formulations of amphotericin may be appropriate in patients with pre-existing renal impairment or in cases where conventional amphotericin has induced nephrotoxicity. Voriconazole is a useful agent with a similarly broad spectrum of activity. Hepatotoxicity, visual disturbances and prolonged QT interval are the most common side effects of voriconazole. This agent has the advantage of being available as both intravenous and oral preparations, so the conversion from parenteral to oral therapy is straightforward. Posaconazole is only available orally but has a similar broad spectrum of activity.

Although the antifungal activity of the echinocandin caspofungin is more limited than that of amphotericin or voriconazole, it has been shown to be effective for empirical therapy because it has good efficacy against *Candida* and *Aspergillus* spp. It has the advantage of reduced toxicity in comparison with other available agents. The most common side effect is hepatotoxicity. Because this agent has a relatively limited spectrum of activity, it is probably best avoided in the setting of presumed fungal sinus or CNS infection, which are often caused by fungi other than *Aspergillus* or *Candida* spp. Table 51.9 lists some of the common problems encountered in the treatment of the leukaemias.

The following practice points should be used to control infection in immunocompromised patients:

- Measures to prevent infection are important.
- Particular attention should be paid to scrupulous handwashing, mouth care and the use of antifungal, antiviral and anti-pneumocystis prophylaxis for patients at high risk.
- Treatment of fever in a neutropenic patient is a medical emergency.
- Ongoing fever in neutropenic patients treated with antibiotics should prompt investigation for possible systemic fungal infection.

Table 51.9 Common therapeutic problems in the leukaemias

Problem	Cause	Solutions
Mucositis and oral ulceration	Chemotherapeutic agents directly toxic to mucosal epithelium Radiotherapy is directly toxic to the mucosa and also reduces saliva production by salivary glands Vulnerable mucosa is likely to be attacked by infective agents, e.g. herpes simplex, <i>Candida</i>	Regular mouth toilet including the use of antibacterial mouth-wash Prophylactic use of antiviral and antifungal agents for patients in whom myelosuppression is likely to be prolonged
Fever in neutropenic patients	Infection predominantly caused by bacteria and/or fungi	Prophylaxis with fluoroquinolone antibiotics for high-risk patients can be considered Broad-spectrum antibiotics must be commenced as soon as blood cultures have been taken A strategy of planned progressive therapy including use of an antifungal agent in non-responsive fever is appropriate alongside diagnostic testing
GVHD	T lymphocytes from the donor react against host tissues	Use a sibling donor if possible Use the donor most closely HLA matched to the patient Consider T-cell depletion of graft (although this may increase the risk of disease relapse) Prophylactic therapy with methotrexate or ciclosporin for example Treat GVHD with corticosteroids, ciclosporin, anti-thymocyte globulin, anticytokine monoclonal antibodies, imatinib, extracorporeal photopheresis Irradiate all blood products
Late complications of treatment	Risks of haemopoietic malignancy and non-haemopoietic malignancy are increased post-chemotherapy Late cardiotoxicity secondary to anthracyclines	Aim to tailor therapy to the underlying disease, i.e. do not over-treat and do not under-treat Do not exceed maximum cumulative doses of anthracyclines

GVHD, Graft-versus-host disease; HLA, human leucocyte antigen.

Case studies

Case 51.1

A 30-year-old woman, Ms PL, recently diagnosed with CML, attends the haematology clinic to discuss the options for treatment.

Questions

1. Which treatment options are available?
2. Which treatment is likely to be the best choice for Ms PL?
3. What treatment would be preferable if she was to become pregnant?

Answers

1. There are clearly a number of potential treatment options which need to be explored with the patient. The various treatment options are:
 - active management with targeted drug therapy:
 - imatinib or other tyrosine kinase inhibitors (e.g. nilotinib),

- treatment as part of a clinical trial, which is likely to involve imatinib or other TKIs in varying doses.
 - allogeneic stem cell transplant:
 - matched sibling donor transplant,
 - matched unrelated donor (MUD) transplantation if a matched sibling is not available.
 - other options:
 - interferon- α +/- cytosine,
 - palliative therapy with hydroxycarbamide to control cell counts.
2. Imatinib or other TKI would be the treatment of choice in a patient presenting at any age, as long as there are no contraindications. Ms PL may be offered treatment in a clinical trial, if available. Results with these agents, particularly for patients with newly diagnosed chronic phase disease, are excellent. Complete cytogenetic responses have been seen, although very sensitive quantitative PCR techniques can still detect the abnormal BCR-ABL gene in the vast majority of CML patients in whom the Philadelphia chromosome itself is undetectable. In addition, the drug has been shown to delay progression to accelerated phase disease or blast crisis. It is still not possible, however, to say that imatinib cures patients with CML. Although no randomised study has been undertaken, it is clear from historical data that, in the medium term, the mortality associated with allogeneic stem cell transplantation far exceeds that associated with TKIs. In addition to these very encouraging data,

which pertain to the effect of the drug on the disease, the side effects of TKIs are generally mild, and patients report this agent far easier to tolerate than interferon- α . The main side effects of imatinib are rash, cytopenias, fluid retention and abnormalities of liver function tests. Second generation TKIs carry some of the same side effect profiles but have other side effects which are unique to them; for example, dasatinib is associated with the development of pleural effusions and reversible pulmonary hypertension. Given the efficacy of imatinib and the fact that the drug is generally very well tolerated, imatinib is regarded as the initial treatment of choice for the vast majority of patients with CML. Ongoing management involves haematological and molecular monitoring of the patient to determine whether he or she has a good response to imatinib. In the event of a good response, the patient continues to take the drug. If at a later stage the molecular response to the agent begins to diminish, then a second-line TKI is considered. If a poor/incomplete response is seen to a second-line agent, then transplantation should be considered.

A purely palliative approach is unlikely to be acceptable to a young patient, thus excluding hydroxycarbamide as a single agent in a patient who is newly diagnosed with CML. Hydroxycarbamide, however, does have a role in the acute setting, where it can be used to control high cell counts before, or during, the commencement of a TKI. There is no doubt that use of interferon- α alone results in cytogenetic remission in a small percentage of patients, and this effect is enhanced by the addition of cytosine. The side effects of interferon- α include flu-like and affective symptoms, and the addition of cytosine increases myelosuppression and risk of mucositis. Although these treatments can induce cytogenetic remission, the duration of such responses is unclear, and only a minority of patients respond completely. The high risk of side effects and the low chance of complete cytogenetic response to interferon- α , with or without cytosine, are likely to make these therapeutic modalities unattractive to Ms PL.

It remains true that allogeneic stem cell transplantation is the only proven curative therapy for patients with CML at present but should be reserved for those who are intolerant of or refractory to multiple TKIs. The fundamental problem with allogeneic transplantation as an approach is that the mortality rate for transplant recipients remains high. The 1-year mortality rate for a 30-year-old patient transplanted using a sibling donor is approximately 10–15%, and this may rise to 20–25% if an unrelated donor has to be used. The major causes of death in this group are GVHD and infection. In addition to the high risk of mortality in the short-term, there is also a risk of long-term morbidity post-allograft. Chronic GVHD can have a significant impact on quality of life for many patients and requires long-term medical follow-up. Ironically, patients with a degree of chronic GVHD are at reduced risk of disease relapse because a GVHD response is associated with a graft-versus-leukaemia effect; some disparity between the immune systems of the transplant donor and recipient is helpful. In addition to these problems, all transplanted patients are at increased risk of a second malignancy as a consequence of the conditioning therapy received as part of the transplant and probably also as a consequence of deficiencies within the transplanted immune system.

Given the problems associated with the various therapeutic strategies discussed earlier, it is not surprising that there was great excitement surrounding the development of the TKI imatinib, and subsequent second-generation TKIs, which remain the agent of choice in first-line therapy.

3. Currently, there are no safety data for the use of TKIs before and during pregnancy. It is therefore more appropriate that disease control is gained with a TKI before pregnancy so that a 'drug holiday' can be undertaken during pregnancy, with the hope of ongoing disease control. If Ms PL required treatment, then safety data are available for the use of interferon- α , and this agent is therefore a reasonable therapeutic option in this rare situation.

Case 51.2

A patient, Mr RB, with AML is currently in first CR and has a fully HLA-matched brother who is medically fit. You have been asked to counsel Mr RB's brother, the potential transplant donor, about stem cell collection.

Questions

1. What methods are available for the collection of stem cells for haemopoietic stem cell transplantation?
2. What are the advantages and disadvantages of each of these stem cell collection methods for the transplant donor?
3. What are the advantages and disadvantages of each of these stem cell collection methods for the transplant recipient, Mr RB?

Answers

1. There are two main methods of collection of haemopoietic stem cells from a sibling donor:
 - Direct harvesting of cells from the bone marrow in the pelvis
 - Collection of circulating peripheral blood stem cells using an apheresis technique after stimulation of the stem cell compartment using G-CSF
2. Direct harvesting of marrow stem cell from the bone marrow is an operative procedure and is performed under general anaesthesia. Clearly, there are risks associated with the use of general anaesthesia, but the risk of death associated with this approach is less than 1 in 10,000 procedures. Marrow harvesting involves a hospital stay, usually for one night postoperatively, but some units also require donors to be admitted the night before surgery. Donors are likely to experience pain around the pelvis, and there is a risk of mechanical back pain in the short to medium term due to pressure applied to the pelvis during repeated needle insertions. This risk is increased in those with a history of back problems before the procedure. Indeed, such potential donors may prefer a peripheral blood stem cell harvesting approach. Donors, such as Mr RB's brother, must be warned about bruising and potential infection at the site of their wounds. One of the other potential problems associated with marrow harvesting is that it is impossible to select the type of blood cell harvested, and a large component of the volume of fluid collected comprises red blood cells. This can lead to a degree of anaemia in the donor, who may take several weeks to normalise his or her haemoglobin. It is usually possible to avoid blood transfusion in this situation because it is unusual for donors to be significantly symptomatic. Nonetheless, Mr RB's brother must be warned that the need for allogeneic blood transfusion is a possibility with this procedure. Peripheral blood stem cell harvesting has several advantages over direct marrow harvesting from the iliac crests. The procedure can be undertaken during hospital outpatient visits and does not require the use of a general anaesthetic. Because the stem cell harvesting procedure allows selective collection of mononuclear cells, significant anaemia is very unlikely after this procedure. Clearly, red blood cells do circulate within the apheresis circuit, and if the circuit clots off and has to be disconnected from the donor, then red blood cells will be lost. This is unlikely to be of clinical significance unless the donor is a child and hence has a relatively low blood volume. Disadvantages of this approach include the need for stimulation of donor haemopoiesis by the G-CSF. Marrow stimulation can result in significant pain especially around the shoulders, back and pelvic girdle. Most donors can manage this pain at home with simple analgesia, but very occasionally hospital admission is required for pain control. Very occasionally patients develop splenic pain, and there have been a couple of reports of splenic rupture in

normal donors after G-CSF stimulation, but this is very rare. One difficulty with the use of G-CSF is that it has only been in routine use for the past 20 years. This makes it impossible to categorically reassure potential stem cell donors, such as Mr RB's brother, that use of G-CSF in this way is absolutely safe in the long-term. There is, however, currently no evidence that acting as a peripheral blood stem cell donor increases one's risk of leukaemia development later in life. Some potential donors find this element of uncertainty difficult and prefer to undertake a marrow harvest in which the risks, although present, are better quantified.

The apheresis procedure itself will require Mr RB's brother to lie relatively still with a needle in one or both arms (depending upon the type of apheresis kit used) for approximately 4–5 hours. Some collections can be done in one procedure, but some donors will need to be harvested in two procedures, over 2 days. One prerequisite for peripheral blood stem cell donation is that the potential donor has good enough peripheral veins to allow reliable venous access. If this is not the case and the donor prefers to donate using this method, a temporary central venous line has to be inserted.

Most donors tolerate the apheresis procedure with few problems. One of the most common complications of the procedure is hypocalcaemia which results from calcium binding by the citrate anticoagulant used to prevent clotting within the apheresis circuit. Donors may notice perioral tingling or paraesthesia in other areas and are asked to report this immediately. The problem is easily treated by reducing the concentration of anticoagulant in the circuit and by asking the donor to drink a small amount of milk. If this problem is not picked up early, the consequences can be more severe, with the development of tetany, which would require intravenous calcium replacement.

In summary, Mr RB's brother should be advised that peripheral blood stem cell donation is generally a less invasive and better-tolerated procedure than direct stem cell harvest from the marrow space. However, the associated procedural risks are more easily quantifiable for the latter procedure.

- There are some potential advantages, to the transplant recipient, in the use of peripheral blood stem cells as opposed to bone marrow stem cells. Engraftment is quicker, so the recipient spends less time in the neutropenic phase, and hence the risk of infection is reduced. Similarly, there is evidence that duration of hospital stay is reduced when peripheral blood stem cells are used. One potential disadvantage of this approach is that the graft includes a larger dose of T-lymphocytes than a graft of stem cells derived directly from the marrow (approximately a 10-fold increase). There is some evidence that rates of chronic GVHD are increased among recipients of peripheral blood stem cells, but this observation has not been borne out in all studies. This potential disadvantage of peripheral blood stem cells is negated if a T-cell-depleted approach is used, as is the case for most matched unrelated procedures.

Case 51.3

A 68-year-old woman, Mrs BG, is admitted with newly diagnosed AML. Once her condition is stabilised, the consultant seeks her consent to start intensive chemotherapy.

Questions

- How should the consultant ensure the consent process is performed as well as possible?
- What are the treatment options available for Mrs BG?

Answers

- It is vital that consent is taken only after very careful discussions. Consent for such intensive chemotherapy usually requires several

conversations and should be regarded as a process not a single event. The final consent conversation should be done in a quiet private room if possible, and interruptions should be kept to a minimum. Mrs BG should be allowed to have a friend, partner or relative present if she wishes, and ideally, a clinical nurse specialist should be present too. If possible, Mrs BG should be given some written material on chemotherapy before consent even if it is important the treatment is started promptly. Patients should be given a clear explanation of their potential treatment options and should be informed of any clinical trials that may be available to them. It is vitally important to fully inform patients regarding their condition and its prognosis and about treatment options and their potential advantages and disadvantages. Only if patients have all the necessary information can they decide on the treatment option that is most appropriate/acceptable to their individual circumstances.

- Treatment options for older patients, such as Mrs BG, diagnosed with AML should take into consideration the fitness of the patient, their comorbidities and the characteristics of their leukaemia. These options should be clearly discussed with the patient and their relatives to make the best individualised treatment plan. Broadly speaking, the options are as follows:

- Intensive therapy:
 - Daunorubicin and cytarabine containing regimens (see Fig. 51.2) may be used in older patients with AML. The decision to treat intensively is largely based on an assessment of the patient's performance status and comorbidities. It must also take into account the disease characteristics and the fitness of the patient for a subsequent transplant procedure. Given that many older patients with AML have disease that displays high risk genetic and molecular characteristics, allogeneic marrow transplantation is often the only potentially curative therapeutic option. Complete remission can be achieved in 50–60% of older patients fit enough to be treated with an intensive approach, but unfortunately, the survival of these patients at 2 years is poor at approximately 15–20% (Lowenberg et al., 2009), due to high relapse rates. Whilst reduced intensity allogeneic transplantation can provide a potentially curative option, only a relatively small number of patients older than 60 years will be fit enough to tolerate this treatment.
 - Ongoing clinical trials are investigating the optimum scheduling, dosing and the addition of targeted therapies to improve the outcome for older patients with AML.
- Non-intensive therapy:
 - 5-Azacytidine has shown promise in the management of AML with a low disease burden. The 5-azacytidine regimen is delivered on an outpatient basis over 7 days and is less toxic than the intensive in-patient regimens previously described. This treatment may be preferable to those patients wishing for a less intense approach or for those who have comorbidities which may effectively exclude them from a high-dose treatment option. 5-Azacytidine has been shown to deliver complete responses in 18% of patients, with a median overall survival of 10.4 months (Dombret et al., 2015; Fenaux et al., 2010). In addition, this agent has delivered modest responses in reducing the transfusion requirements in those who have a background of myelodysplasia.
 - Low-dose subcutaneous cytarabine is another option which can be delivered in the outpatient setting and is given over 10 days. This option is aimed at reducing toxicity whilst achieving some disease control. Low-dose cytarabine has been shown to deliver complete responses in 18% of patients treated but with a median overall survival of only 5 months (Devillier et al., 2014). This treatment option is best reserved for those who do not have complex/adverse cytogenetics because no benefit has been seen in this group of patients.

- Best supportive care:
 - This approach aims to reduce the disease burden and alleviate symptoms but does not fundamentally alter the overall disease process/natural history. Transfusional support (red blood cells and platelets) is given to reduce the symptoms of anaemia and thrombocytopenia, antimicrobials are used to treat infection and hydroxycarbamide can be administered to reduce the peripheral blood blast percentage and thus minimise symptoms of gum swelling, headache and breathlessness. This treatment option focuses on maximising quality of life, typically over a few months.
 - For palliative management to be effective, regular review of the patient is necessary by team members who are skilled at managing any symptoms which may arise during the palliative phase of the disease.
 - Clinical trials: Mrs BG is in the older AML patient group, which is the focus of current clinical trials because the significant need in this population for effective and better tolerated treatment options is well recognised.

Case 51.4

A 24-year-old patient, Mr TH, with ALL is undergoing chemotherapy and needs intrathecal chemotherapy to prevent relapse in the meninges. Giving drugs by this route is extremely dangerous. Several patients have died as a result of the inadvertent administration of vinca alkaloids into the CSF.

Question

What steps have been taken nationally to try to prevent the inadvertent intrathecal injection of vincristine and other agents not suitable for intrathecal use?

Answer

In the UK, there are now strict guidelines for administration of intrathecal chemotherapy. The procedure can only be performed in hospital units which have been deemed fit for purpose by assessment as part of a rigorous peer-review process. The procedure must be undertaken in a specially designated area which is only used for the purpose of administering intrathecal drugs. To minimise the possibility of the wrong drug being administered, intravenous drugs must not be given in this area. Intrathecal drugs must only be prescribed by a consultant or specialist registrar who has been trained to prescribe or give intrathecal chemotherapy and whose name appears on a locally held register. Drugs for intrathecal administration must only be prescribed on a designated prescription sheet. Once the prescription has arrived in pharmacy, the drugs must be manufactured and checked by pharmacists trained in the manufacture and checking of intrathecal prescriptions. The drugs must be positively labelled 'for intrathecal use only' and must be dispensed by a trained pharmacist. They can only be dispensed once Mr TH has been given any intravenous drugs that are due that day; ideally intrathecal and intravenous chemotherapy should not be given to a patient on the same day. Intrathecal drugs must only be dispensed to a doctor trained and on the register for giving intrathecal drugs who will, in the presence of the dispensing pharmacist, check the details of the drug against the prescription before transporting the intrathecal drugs. The intrathecal drugs must be transported in a specially designated container, and if they need to be stored, then it must be in a separate, specially designated lockable fridge, that is separate from any intravenous chemotherapy. Once the procedure is underway, the intrathecal drugs must be checked by the registered

doctor and by a nurse who has been trained and appears on a register of nurses trained to check intrathecal drugs. The drugs should also be checked by Mr TH or his representative. Intrathecal drugs must not be given in hospitals not approved for the procedure, in non-designated areas, outside office hours or at the weekend unless there are exceptional circumstances. All staff working on oncology or haematology units should be taught about the rules for giving intrathecal therapy.

In addition, to prevent inadvertent vincristine administration into the intrathecal space, hospitals giving intrathecal chemotherapy should follow special rules for labelling vinca alkaloid prescriptions, and vinca alkaloids should be made up in a minimum volume of 20 mL to prevent intrathecal administration. More recent practice has seen hospitals replace their intrathecal syringes with ones which will only lock into intrathecal lumbar puncture needles; this ensures that no other syringes, containing the wrong drugs, can be inadvertently attached or administered.

Case 51.5

A 37-year-old dental technician, Mr SG, presented with acute promyelocytic leukaemia (APL). He had a number of bleeding problems at presentation. Mr SG was commenced on all-trans retinoic acid (ATRA) at presentation but was causing much concern to the treating team because he had a white cell count of $80 \times 10^9/L$ ($4.0\text{--}11.0 \times 10^9/L$) and severe bleeding problems.

Questions

1. Why is ATRA used in this circumstance, and what are its side effects?
2. What options are there for induction management of APL?

Answers

1. APL is a variant of AML which presents with disseminated intravascular coagulation (DIC). This is manifest by coagulation defects, low platelet counts and severe bleeding. Patients, such as Mr SG, are at risk of severe haemorrhage at presentation but have a very good prognosis with chemotherapy if they survive the induction phase. ATRA can rapidly correct the coagulopathy found at presentation by promoting differentiation of the abnormal promyelocytes typical in this condition and thus reducing the trigger for DIC development. ATRA also increases the likelihood of the patient entering remission, when combined with standard high-dose chemotherapy. It is also used as a maintenance agent because it increases the number of patients who remain in long-term remission. In the acute setting, ATRA can cause a severe and life-threatening sterile pneumonitis, otherwise referred to as 'differentiation syndrome'. This causes a rapid onset respiratory distress associated with hypotension and leucocytosis. This normally occurs within 1 week of commencement of ATRA, and it is important to recognise this syndrome quickly because it often responds to withdrawal of the drug and administration of high-dose dexamethasone. If left untreated, differentiation syndrome can lead to respiratory failure and death. The longer-term side effects of ATRA include dry eyes and a dry mouth.
2. Idarubicin and ATRA induction followed by consolidation with idarubicin and mitoxantrone, both combined with ATRA, are the chemotherapy options of choice in the UK at present. A combination of idarubicin and ATRA as induction has been shown to result in a complete response rate of up to 94% (Lo-Coco et al., 2010). This has been used in combination with cytarabine, but a number of

large clinical trials have shown that the addition of cytarabine does not significantly improve the outcomes and is given at the expense of additional toxicity.

Idarubicin, like other anthracyclines, carries the same side-effect profile: anaemia, low platelets resulting in bleeding, neutropenia resulting in severe infections, nausea/vomiting, diarrhoea, hair loss and hepatotoxicity. In addition, there are the long-term toxicities which are of concern, namely, cardiotoxicity and, later, secondary malignancies. Despite very good outcomes in APL, clinical trials have been moving towards using non-chemotoxic agents to minimise toxicity without compromising on response rates and survival.

Arsenic trioxide (ATO) has been the subject of recent clinical trials. When given with ATRA, ATO has been shown to bring about remission in patients who have APL in association with the 15;17 chromosomal translocation and the PML:RARA genetic abnormality. Efficacy has been demonstrated to be non-inferior to idarubicin and ATRA (Burnett et al., 2015), and the need for supportive care was reduced in the ATO group.

Side effects include differentiation syndrome. ATO can cause QT interval prolongation and complete atrioventricular block in some patients. QT prolongation can lead to a torsade de pointes ventricular arrhythmia, which can be fatal. The risk of torsade de pointes is related to the extent of QT prolongation, concomitant administration of QT prolonging drugs, a history of torsade de pointes, pre-existing QT interval prolongation, congestive heart failure, administration of potassium-wasting diuretics or other conditions that result in hypokalemia or hypomagnesemia. Before initiating therapy with ATO, a 12-lead electrocardiogram (ECG) should be performed and serum electrolytes (potassium, calcium and magnesium) and creatinine should be assessed; pre-existing electrolyte abnormalities should be corrected and, if possible, drugs that are known to prolong the QT interval should be discontinued. For QTc greater than 500 ms, corrective measures should be completed and the QTc reassessed with serial ECGs before considering using ATO. ATO is not currently available in the UK for first-line treatment of APL.

Case 51.6

A 57-year-old man, Mr AV, with a 6-year history of CLL presented with a rising white cell count, worsening lymphadenopathy and hepatosplenomegaly. Treatment was commenced with oral fludarabine 40 mg/m² and oral cyclophosphamide 250 mg/m² daily for 3 days with rituximab given on day 1 (FC-R).

Questions

1. What additional precautions would you advise the doctor to take and why?
2. Mr AV relapses after 18 months. What treatment options would you discuss with the patient?

Answers

1. The combination of fludarabine, cyclophosphamide and rituximab (FC-R) is very powerful for the initial treatment of CLL. It has been used as a second-line therapy, although recent data support its use as a first-line therapy. It has been associated with more frequent and deeper remissions which are typically longer than those attained after single-agent therapy. It is thus currently regarded as the gold standard of treatment in non-p53-mutated CLL patients. It is nonetheless a highly

immunosuppressive combination with activity against both T- and B-cells. Patients treated with this regimen are at high risk of developing *Pneumocystis pneumonia*. It is important that patients are given prophylaxis against this severe infection. Herpes virus infections including herpes simplex and herpes zoster are also common, and most patients are given aciclovir prophylaxis.

As patients are immunosuppressed, they are also at risk of developing transfusion-related GVHD. This is a complication of blood product transfusion, caused by engraftment of lymphocytes from the transfused product. This complication is now very rare in the era of leuco-depleted blood, but where it occurs, it is typically fatal. This complication can be prevented by irradiation of blood products before transfusion. Rituximab is an antibody-based therapy and can be associated with significant reactions which can occasionally be severe and life threatening (see Chapter 52). Paracetamol, chlorphenamine and hydrocortisone are administered to prevent acute reactions to the drug.

Fludarabine-based chemotherapy agents are less effective when used in patients who have deletion or mutations in the p53 gene, and so Mr AV should be tested for this before commencing therapy because it may affect current and future options for therapy.

2. There are many approaches that could be undertaken. The potential treatment options are as follows:

- Repeat treatment with FC-R. This can be considered given that Mr AV had a reasonable duration of remission with the first course. Again, if any mutations in the p53 gene were detected, then this option would be less favourable.
- The combination of bendamustine and rituximab (BR) has been shown to be effective in the management of CLL either as first-line or as subsequent therapy. BR has been shown to deliver overall response rates and progression-free survival rates similar to that of FC-R but has achieved higher complete response rates. It is an intravenous treatment delivered as an outpatient and is generally well tolerated. Many of the side effects are shared with FC-R and prophylaxis against *Pneumocystis pneumonia* and herpes viruses should be given.
- Chlorambucil and rituximab or other novel anti-CD20 agents (e.g. ofatumumab or obinutuzumab) are less intensive regimens which have shown promising results in patients, such as Mr AV, with advancing age or significant comorbidities. Oral chlorambucil in combination with an intravenous anti-CD20 agent is delivered in the outpatient setting. Trial data have shown that progression-free survival for chlorambucil- and obinutuzumab-treated patients exceeds that for chlorambucil- and rituximab-treated patients (median PFS 26 months vs. 16.3 months). The combination of chlorambucil and obinutuzumab has been approved for use in the UK (Goede et al., 2014). Similarly, ofatumumab and chlorambucil have shown enhanced progression-free survival when compared with chlorambucil alone (22 months vs. 13 months) (Hillmen et al., 2013)
- Alemtuzumab is usually reserved for CLL that is proving difficult to treat, especially in those patients who have p53 mutations/deletions. It is delivered as a subcutaneous injection with dose escalations on the first cycle. Like other agents, alemtuzumab is also associated with increased risk of opportunistic infections; prophylaxis with co-trimoxazole and aciclovir is advised. Patients receiving alemtuzumab should also receive irradiated blood products. Patients are at risk of allergic reactions given that it is a monoclonal antibody, and so prophylaxis to prevent this should be given. In addition, patients are at particular risk of primary cytomegalovirus (CMV) infection or CMV reactivation. It is therefore advised that CMV levels are monitored twice weekly whilst on therapy

- Targeted drug therapies, ibrutinib (Bcr-1 kinase inhibitor) or idelalisib (PI3K inhibitor) should be considered, if available, or in the context of a clinical trial. These agents are oral drugs which effectively target the essential points in the B-cell signalling pathway to block the production of clonal, and other, B cells. Some of the most common, early side effects associated with ibrutinib are diarrhoea, rashes, low platelet counts and an early rise in non-clonal lymphocyte counts which does not seem to be harmful and returns to the normal range after several months of treatment.
- Idelalisib is the only PI3K inhibitor available currently in the UK outside the context of a clinical trial. The main reported side effects are diarrhoea, low blood counts and hepatotoxicity.
- Once started, these drugs should be continued. Their use, although very promising, is expensive. Ongoing studies will be needed to determine the correct sequencing of these highly effective agents.

52 Lymphomas

Laura Cameron and Catherine Loughran

Key points

- Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL) are aggressive diseases that are fatal if untreated.
- In early-stage HL, patients are treated with combined modality treatment usually consisting of two to four cycles of ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) and involved field radiotherapy (IFRT) (20–30 Gy); a relapse-free survival rate of 85–90% at 5–10 years is achieved.
- Combination chemotherapy is the current gold-standard regimen for advanced HL, and overall survival at 5 years is 75–80%.
- Low-grade NHL may be treated using R-CVP (rituximab, cyclophosphamide, vincristine, prednisolone) or R-CHOP (rituximab, cyclophosphamide, hydroxydaunorubicin [doxorubicin [Adriamycin]], vincristine [Oncovin], prednisolone) or bendamustine and rituximab (BR) chemotherapy or by adopting a policy of 'watch and wait'.
- R-CHOP chemotherapy is the standard for the treatment of aggressive (intermediate- and high-grade) NHL, curing 60% of patients.
- Relapsed HL and NHL may be treated with further chemotherapy followed by high-dose chemotherapy with bone marrow or peripheral stem cell transplantation.
- Patients receiving chemotherapy for HL and NHL should have full blood count (FBC) and blood biochemistry monitored at frequent intervals.
- Complications such as nausea and vomiting, tumour lysis syndrome (TLS), mucositis and bone marrow suppression may occur as a result of chemotherapy and are significant factors in morbidity.
- Supportive care of the patient undergoing chemotherapy includes appropriate drug therapy to minimise the adverse effects of the treatment.

Lymphoma is cancer of the lymphatic system and accounts for approximately 5% of new cases of cancer reported in the UK each year. The primary cancerous cell of origin is the lymphocyte; as a result, there is often considerable overlap between lymphomas and lymphoid leukaemias. Lymphomas are subdivided into two main categories: Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL). Both HL and NHL can be further classified based on histology.

The site of malignancy is usually a lymph node. Extranodal disease, most frequently of the stomach, skin, oral cavity and pharynx, small intestine and central nervous system (CNS), can occur and is more common in NHL than HL.

Hodgkin's lymphoma

Hodgkin's disease, now known as HL, was first described by Thomas Hodgkin in 1832. HL accounts for 13% of all lymphomas, and there are approximately 2000 new cases per year in the UK. HL incidence demonstrates a bimodal age distribution, with the first peak in incidence in young adults aged 20–24 years and a second peak in older men and women. Nearly 50% of patients diagnosed with HL in the UK are aged 45 years and older ([Cancer Research UK, 2016a](#)).

Aetiology

The cause of HL is unknown, but a number of risk factors have been identified. Epstein–Barr (glandular fever) virus has been identified in 50% of HL cases and is likely to be associated with an increase in the risk of developing HL. Certain associations have been identified which suggest a genetic link with HL; for example, same-sex siblings of patients with HL have a 10 times higher risk of developing the disease. Patients with reduced immunity, for example, acquired immune deficiency syndrome (AIDS) or those taking immunosuppressants, and those with a history of autoimmune disorders are at increased risk of developing HL.

Pathology

The diagnosis is made by histological examination of an excised lymph node biopsy. HL, as classified by the World Health Organization (WHO), has two distinct entities: classic HL (cHL) and nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL) ([Swerdlow et al., 2008](#)). The characteristic pathological finding in cHL is the identification of Hodgkin and Reed–Sternberg (HRS) cells in an inflammatory background. NLPHL accounts for 5–10% of HL cases and is histologically distinct from cHL with no HRS cells. Reed–Sternberg, but not lymphocyte-predominant (LP) cells express CD-30. Classic Hodgkin's is further subdivided into four histological types:

- nodular sclerosis,
- mixed cellularity,
- lymphocyte depleted,
- lymphocyte rich.

Signs and symptoms

HL usually presents with painless enlargement of lymph nodes, often in the neck. About 25% of patients will present

Table 52.1 Cotswolds modification of the Ann Arbor classification system for Hodgkin's lymphoma (Lister et al., 1989)

Clinical stage	Defining features
I	Involvement of a single lymph node region or lymphoid structure
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph node regions or structures on both sides of the diaphragm: III ₁ - with or without involvement of splenic, hilar, coeliac or portal nodes III ₂ - with involvement of para-aortic, iliac or mesenteric nodes
IV	Involvement of extranodal site(s) beyond that designated E
Modifying characteristics: A: no symptoms B: fever, drenching sweats, weight loss X: bulky disease >one-third width of the mediastinum >10 cm maximal dimension of nodal mass E: involvement of a single extranodal site, contiguous or proximal to known nodal site CS: clinical stage PS: pathological stage	

with unexplained fever, drenching night sweats and/or unexplained weight loss (>10% of body weight). These have prognostic significance and are designated B symptoms; others include malaise, itching or pain at the site of enlarged nodes after drinking alcohol. Bone pain may result from skeletal involvement. Primary involvement of the gut, CNS or bone marrow is rare.

If lymph nodes in the chest are involved, patients may present with breathlessness. There is often a disturbance of immune function due to a progressive loss of immunologically competent T-lymphocytes, with patients becoming particularly prone to viral and fungal infections.

Laboratory findings

Laboratory findings include normochromic, normocytic anaemia, a raised erythrocyte sedimentation rate (ESR) and eosinophilia. One-third of patients have a leucocytosis due to an increase in neutrophils. Advanced disease is associated with lymphopenia (lymphocytes $<0.6 \times 10^9/L$). Plasma lactate dehydrogenase (LDH) is raised in 30–40% of patients at diagnosis and has been associated with a poor prognosis.

Investigations and staging

Once the diagnosis has been made on biopsy, further investigations are needed to assess disease activity and the extent of its spread through the lymphoid system or other body sites. This is called staging and is essential for assessing prognosis, with cure rates for localised tumours (stage I or II) being much higher than those for widespread disease (stage IV). The staging of HL is assessed by the Cotswolds modification of the Ann Arbor classification system (Table 52.1). Information about prognostic factors, such as mediastinal mass and bulky disease, is included in the classification system. The tests

required to establish the stage include a complete history, physical examination, full blood count (FBC), urea and electrolytes (U and Es), chest X-ray, positron emission tomography (PET) and computed tomography (CT). Other useful tests include ESR, serum LDH, liver function tests (LFTs) and viral screening for hepatitis B, hepatitis C and human immunodeficiency virus (HIV). After staging, patients are usually classified as having early-stage favourable, early-stage unfavourable or advanced disease (Table 52.2). Advanced-stage disease patients should have their International Prognostic Score (IPS) or Hasenclever score calculated (see Box 52.1). Each risk factor scores 1, with the number of risk factors predicting 5-year freedom from progression (FFP) rates and overall survival (OS). For example, the FFP rate is 84% and OS 89% for patients with a score of 0, whereas FFP is 42% and OS 56% for a score of 5 or more.

Management

HL is potentially curable and, in general, sensitive to both chemotherapy and radiotherapy; therefore, the two main goals of treatment are to maximise the likelihood of cure whilst minimising the risk of late toxicity such as infertility.

Nodular lymphocyte-predominant Hodgkin's lymphoma

Localised NLPHL frequently involves one isolated lymph node, tends to be indolent (slow growing) and can be treated with surgery if resectable. Early-stage patients can be treated with involved-field radiation therapy (IFRT) alone (30 Gy; Eichenauer et al., 2014). Advanced-stage patients should be treated with combination chemotherapy, and because LP cells express CD20, the addition of rituximab can improve the efficacy of treatment (Eichenauer et al., 2014).

Table 52.2 Definition of Hodgkin’s lymphoma risk groups according to the European Organisation for Research and Treatment of Cancer /Lymphoma Study Association and the German Hodgkin Study Group (Follows et al., 2014)

	A. Early-stage favourable (patients must have all features)	B. Early-stage unfavourable	C. Advanced disease
European Organisation for Research and Treatment of Cancer disease	Clinical stage 1 or 2 Maximum of three nodal areas involved Age <50 years of age ESR <50 mm/h without B symptoms or <30 mm/h with B symptoms ^a No mediastinal adenopathy	Clinical stage 1 or 2 with one or more of the following: Four or more nodal areas involved Age >50 years of age ESR >50 mm/h without B symptoms or >30 mm/h with B symptoms Large mediastinal adenopathy	Clinical stage 3 or 4
German Hodgkin Study Group	Clinical stage 1 or 2 Maximum of two nodal areas involved No mediastinal adenopathy ESR <50 mm/h without B symptoms or <30 mm/h with B symptoms No extranodal disease	Clinical stage 1 or 2 with one or more of the following: Three or more lymph node sites of involvement Large mediastinal adenopathy ESR >30 mm/h with B symptoms or ESR >50 mm/h without B symptoms Extranodal disease	Clinical stage 3 or 4 or clinical stage 2B with risk factors (large mediastinal mass and extranodal disease)

^aB symptoms include unexplained fever, drenching night sweats and/or unexplained weight loss (>10% of body weight). ESR, Erythrocyte sedimentation rate.

Box 52.1 Hasenclever/International Prognostic Score for advanced Hodgkin lymphoma (Hasenclever and Diehl, 1998)

Prognostic risk factors

1. Age >45 years of age
 2. Male gender
 3. Serum albumin <40 g/L
 4. Haemoglobin <10.5 g/dL
 5. Stage 4 disease
 6. Leucocytosis, i.e. WCC >15 × 10⁹/L
 7. Lymphopenia, i.e. <0.6 × 10⁹/L or <8% of total WCC
- Score 1 for each of the risk factors present at diagnosis.

WCC, White blood cell count.

Classical Hodgkin’s Lymphoma

There is no difference in the management of the four subtypes of classical HL. Management is based on risk group and is summarised in Fig. 52.1.

Early-stage (favourable) disease. The cure rate for patients with stages I and IIA disease is greater than 90%. Patients with stages I and IIA disease may be cured with radiotherapy alone (wide or extended field irradiation). However, due to radiation-related late effects, cardiac toxicity and secondary malignancy, most receive combined modality treatment (chemotherapy and radiotherapy). This usually consists of two cycles of ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) chemotherapy followed by IFRT of 20 Gy (Follows et al., 2014). The aim of chemotherapy is to destroy subclinical disease outside the field of radiotherapy. Involved-site radiation therapy (ISRT) is increasingly used as an alternative to IFRT to further minimise the exposure of uninvolved tissue and organs.

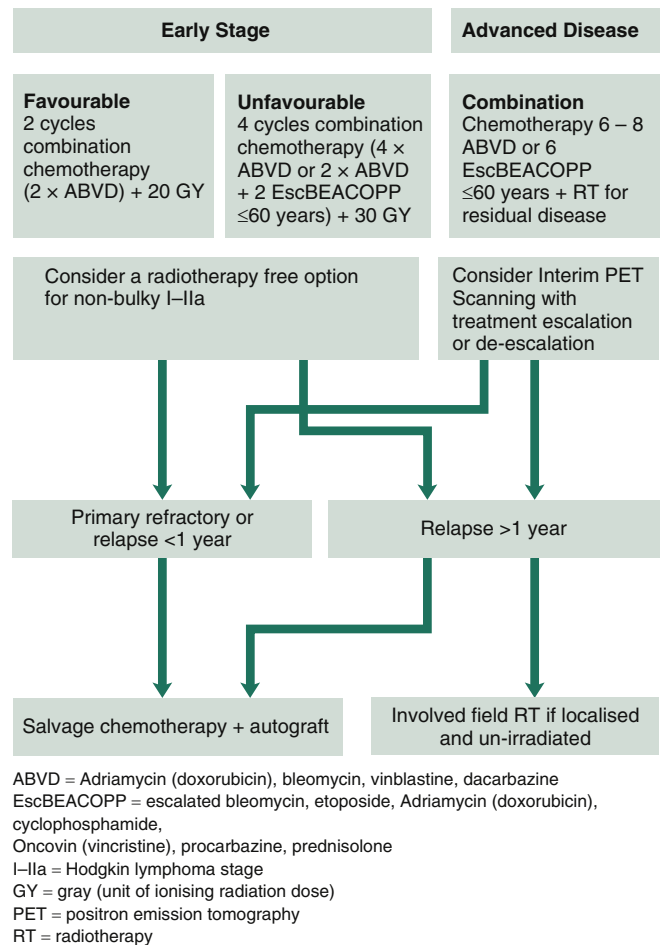

Fig. 52.1 Treatment algorithm for classic Hodgkin lymphoma. (Adapted from Eichenauer et al., 2014.)

Box 52.2 Deauville scale (Meignan et al., 2009)

1. No uptake or no residual uptake (when used interim)
2. Slight uptake but below blood pool (mediastinum)
3. Uptake above mediastinal but below or equal to uptake in the liver
4. Uptake slightly to moderately higher than liver
5. Markedly increased uptake or any new lesion (on response evaluation)

Given the high cure rates seen in HL, there has been a drive to minimise radiation toxicity by using chemotherapy alone. The recently published RAPID study investigated whether interim PET scanning after three cycles can identify patients who can avoid radiotherapy and be treated with chemotherapy alone. Those patients with a negative PET scan after three cycles of chemotherapy, as defined by 1 or 2 on the Deauville score (Box 52.2), were randomised to receive IFRT or no further treatment (Radford et al., 2015). At 3-year follow-up, the combined modality group had a lower rate of disease progression, but patients with a negative PET after 3 cycles and no radiotherapy still had an excellent prognosis (3-year progression-free survival 90.8%).

Early-stage (unfavourable) disease. Patients with stage I or II presenting with bulky disease, B symptoms or with more than two sites of disease are considered to be poor risk if treated with radiotherapy alone. These patients are treated with four cycles of combination chemotherapy, usually ABVD, and radiotherapy (30 Gy) to sites of bulky disease (Eichenauer et al., 2014; Follows et al., 2014). The HD14 study compared two cycles of escalated BEACOPP (escBEACOPP; bleomycin, etoposide, doxorubicin [Adriamycin], cyclophosphamide, vincristine [Oncovin], procarbazine, prednisolone) plus two cycles of ABVD with four cycles of ABVD (von Tresckow et al., 2012). The escBEACOPP patients had better disease control and were less likely to relapse but had significant acute toxicities from their chemotherapy. Therefore, escBEACOPP can be considered as a treatment option in younger, fitter patients.

Chemotherapy alone may be considered in selected patients with non-bulky disease to avoid radiation-related late effects, but patients must be counselled on their increased risk of relapse.

Advanced disease. Patients with advanced disease (stages III and IV) are treated with combination chemotherapy. ABVD has been the standard regimen for several decades because 80% of patients will achieve a complete response but experience less toxicity in terms of fertility, haematological toxicity and the development of acute leukaemia and myelodysplasia compared with older regimens, such as MOPP (Mustargen, vincristine [Oncovin], procarbazine, prednisolone) (Table 52.3).

As with unfavourable early-stage disease, escBEACOPP in the advanced setting is associated with fewer progressions and relapses compared with ABVD-based therapy but is more toxic and has not demonstrated an overall survival benefit.

Six to eight cycles of ABVD or six cycles of escBEACOPP is considered the current standard treatment for advanced disease in patients who are 60 years or younger. Patients with a high IPS/Hasenclever score (see Box 52.1) are at a higher risk of relapse and may benefit from more intensive treatment. Recently, the results of the phase 3 HD18 study have been published

Table 52.3 Combination chemotherapy regimens effective in the treatment of Hodgkin's lymphoma

Regimen	Dose and route	Frequency
ABVD (28-day cycle)		
Doxorubicin	25 mg/m ² i.v.	Days 1 and 15
Bleomycin	10,000 iu/m ² i.v.	Days 1 and 15
Vinblastine	6 mg/m ² i.v.	Days 1 and 15
Dacarbazine	375 mg/m ² i.v.	Days 1 and 15
BEACOPP escalated (21-day cycle)		
Bleomycin	10,000 iu/m ² i.v.	Day 8
Etoposide	200 mg/m ² i.v.	Days 1–3
Adriamycin (doxorubicin)	35 mg/m ² i.v.	Day 1
Cyclophosphamide	1250 mg/m ² i.v.	Day 1
Oncovin (vincristine)	1.4 mg/m ² i.v. (max. 2 mg)	Day 8
Procarbazine	100 mg/m ² orally	Days 1–7
Prednisolone	40 mg/m ² orally	Days 1–14
ChIVPP (28-day cycle)		
Chlorambucil	6 mg/m ² orally	Days 1–14
Vinblastine	6 mg/m ² i.v.	Days 1 and 8
Procarbazine	100 mg/m ² orally	Days 1–14
Prednisolone	40 mg/m ² orally (max 60 mg)	Days 1–14
VEPEMB (28-day cycle)		
Vinblastine	6 mg/m ² (max: 10 mg) i.v.	Day 1
Endoxan (cyclophosphamide)	500 mg/m ² i.v.	Day 1
Prednisolone	30 mg/m ² orally	Days 1–5
Procarbazine	100 mg/m ² orally	Days 1–5
Etoposide	60 mg/m ² orally	Days 15–19
Mitoxantrone	6 mg/m ² i.v.	Day 15
Bleomycin	10,000 iu/m ² i.v.	Day 15

(Borchmann et al 2018). In this study patients who achieved PET negativity after two cycles of escBEACOPP were assigned to receive either a total of four cycles or a total of 6 or 8 cycles. An impressive 5 year progression free survival of 92% was achieved in the 4 cycle cohort (i.e. after only 12 weeks of treatment)

with reduced toxicity compared with a 5-year progression-free survival of 90.8% in the extended treatment arm. This has the potential to become a new standard of care. Patients should be involved in evaluating the risk benefits with respect to efficacy and treatment toxicity. Radiotherapy in advanced disease is given only to those patients with residual disease after chemotherapy (Eichenauer et al., 2014).

For older patients (>60 years), ABVD is the preferred regimen as treatment toxicity is more likely to be tolerated. Options for elderly patients or those unlikely to tolerate ABVD include CH1VPP (chlorambucil, vinblastine, procarbazine, prednisolone) and VEPEMB (vinblastine, cyclophosphamide [Endoxan], prednisolone procarbazine, etoposide, mitoxantrone and bleomycin).

The management of cHL is becoming increasingly individualised to the patient. Studies are ongoing to determine if interim PET scanning after initial therapy may help identify poor responders who are more likely to relapse and require treatment escalation and good responders who can be cured with less intensive therapy (Eichenauer et al., 2014). Recently the Response-Adapted Therapy in Hodgkin Lymphoma (RATHL) study has shown that bleomycin can be omitted, reducing pulmonary toxicity, from ABVD (AVD) in patients achieving a negative PET scan after two cycles of ABVD (Johnson et al., 2016).

Attempts to improve the efficacy of ABVD or reduce the toxicity of escBEACOPP are being made by incorporating new drugs into the backbone of these regimens. For example, brentuximab vedotin, an anti-CD30 monoclonal antibody conjugated to monomethyl auristatin E (MMAE), is being combined with doxorubicin, vinblastine and dacarbazine (A+AVD) and compared with ABVD (Ansell et al., 2014).

Salvage therapy for relapsed disease. Despite advances in HL, 25% of patients progress or relapse. Relapsed disease refers to disease progression after completion of primary treatment which resulted in a complete remission. Depending on previous treatment, options include salvage radiotherapy, salvage chemotherapy or high-dose chemotherapy with autologous stem cell support. In this procedure, stem cells are collected from the patient and returned after high-dose chemotherapy. Patients who relapse after initial radiotherapy alone have a good chance of cure with combination chemotherapy, at least equal to that of patients initially treated with chemotherapy for advanced disease. Occasionally, radiotherapy is used if the disease is localised and previously non-irradiated. Those who relapse after combination chemotherapy have a worse prognosis, although durable remissions can be obtained with further conventional therapy.

Length of remission after first-line chemotherapy influences the success of subsequent salvage therapy, and so the failure of chemotherapy can be used to classify the disease and determine appropriate therapy. If the duration of remission was greater than 12 months (late relapse), then the patient can be re-treated with the initial chemotherapy, salvage regimen or considered for high-dose chemotherapy with autologous transplantation.

Commonly used chemotherapy salvage regimens are listed in Table 52.4. If relapse occurs less than a year after treatment (early relapse), then high-dose chemotherapy with autologous stem cell support should be considered. A patient who has never achieved complete remission (primary refractory disease) should receive high-dose chemotherapy with autologous stem cell support.

Table 52.4 Salvage chemotherapy regimens effective in the treatment of lymphoma

Regimen	Dose and route	Frequency
DHAP		
Cisplatin	100 mg/m ² i.v.	Days 1
Cytarabine	2000 mg/m ² i.v. 12 hourly	Day 2
Dexamethasone	40 mg orally	Days 1–4
ESHAP		
Etoposide	40 mg/m ² i.v.	Days 1–4
Methylprednisolone	500 mg/m ² i.v.	Days 1–5
Cytarabine	2000 mg/m ² i.v.	Day 1
Cisplatin	25 mg/m ² i.v.	Days 1–4
ICE		
Ifosfamide	5000 mg/m ² i.v.	Day 2
Carboplatin ^a	AUC 5 i.v.	Day 2
Etoposide	100 mg/m ² i.v.	Days 1–3
IVE		
Epirubicin	50 mg/m ² i.v.	Days 1
Etoposide	200 mg/m ² i.v.	Days 1–3
Ifosfamide	3000 mg/m ² i.v.	Days 1–3
IGEV		
Ifosfamide (+ Mesna)	2000 mg/m ² i.v.	Days 1–4
Gemcitabine	800 mg/m ² i.v.	Days 1 and 4
Vinorelbine	20 mg/m ² i.v.	Day 1
Prednisolone	100 mg oral	Days 1–4

^aCarboplatin dose (mg) = target AUC (mg/mL × min) × (GFR [mL/min] + 25). AUC, Area under the curve; GFR, glomerular filtration rate.

High-dose chemotherapy plus autologous stem cell support is associated with a 40–50% 5-year survival rate. However, the significant toxicity of autologous stem cell transplantation means that it should be reserved for patients in whom there is a clear increase in the chance of cure. Allogeneic transplant is an option in patients relapsing after autologous transplant (Brusamolino et al., 2009).

Brentuximab vedotin is licensed for the treatment of relapsed or refractory CD30+ HL where patients have had an autologous stem cell transplant (ASCT) or at least two prior therapies when ASCT or combination chemotherapy are not treatment options.

New agents

The programmed death 1 (PD-1) pathway serves as an immune checkpoint to dampen T-cell-mediated immune responses. Nivolumab, a monoclonal antibody, which blocks the PD1 protein receptor is an option for treating relapsed or refractory HL (NICE 2017).

Other novel agents under investigation include panobinostat, an oral histone deacetylase (HDAC) inhibitor, and everolimus, a mammalian target of rapamycin (mTOR) inhibitor. Studies are underway to evaluate combinations of novel agents including brentuximab vedotin (Stathis and Younes, 2015).

Non-Hodgkin's lymphoma

The NHLs are a heterogeneous group of lymphoid malignancies ranging from indolent, slow-growing tumours to aggressive, rapidly fatal disease. Paradoxically, the more aggressive NHLs are more susceptible to anticancer therapy. The incidence of NHL in the UK is 23.6 per 100,000 per year for males and 18.6 per 100,000 per year for females. NHL accounts for approximately 4% of all cancers in the UK (Cancer Research UK, 2016b). The disease is rare in subjects younger than 30 years, and the incidence steadily increases with increasing age; the median age at presentation is about 70 years.

Aetiology

The aetiology is unclear, although immunosuppression, for example, after organ transplantation, may predispose to the development of lymphoma. Viruses have been implicated in the pathogenesis of NHL. For example, Burkitt's lymphoma is one of the most common neoplasms to develop in HIV-related immunosuppressed patients; human T-lymphotropic virus type 1 (HTLV-1) is associated with a rare type of T-cell lymphoma, adult T-cell leukaemia/lymphoma (ATLL); and Epstein-Barr virus (EBV) is associated with post-transplant lymphoproliferative disorder (PTLD). Exposure to certain chemicals such as pesticides and solvents can increase the risk of developing NHL. There is an increased incidence of gastro-intestinal lymphomas in patients with inflammatory bowel disease and *Helicobacter pylori* infection.

Signs and symptoms

The most common presentation of NHL is painless lymphadenopathy, frequently in the neck area in the supraclavicular and cervical regions. The spread of disease is haematogenously (via the blood), so extranodal sites may be involved. Signs and symptoms of infection, anaemia or thrombocytopenia may be present in patients with bone marrow involvement. Hepatosplenomegaly may also be present. Patients may also present with any of the following symptoms: unexplained loss of weight, unexplained fever and drenching night sweats. These symptoms are described as B symptoms, and patients without these symptoms are classified as category A. B symptoms are more commonly seen in advanced or aggressive NHL but may be present in all stages and histological subtypes.

Laboratory findings

Laboratory examinations may reveal anaemia, a raised ESR and a raised serum LDH level. There may be a reduction in circulating immunoglobulins, and a monoclonal paraprotein may be seen in a small number of cases. The immune disruption caused by the disease may also result in an increased susceptibility to viral infection or autoimmune haemolytic anaemia or thrombocytopenia. Peripheral blood lymphocytosis (increased lymphocytes) with circulating malignant cells is common in low-grade and mantle cell lymphomas.

Histopathology and classification

There have been many attempts to classify the NHLs into histological categories that have clinical significance. Despite this, many problems and areas of confusion remain. Approximately 85% of NHLs are of B-cell origin, whereas 15% are of T-cell origin or are unclassifiable.

There are two classification systems in common use. The Working formulation, developed in 1982, divides the lymphomas into low, intermediate and high grade. The revised European-American lymphoma (REAL) classification system was developed in 1994 (Table 52.5) and then modified by WHO (Box 52.3)

Table 52.5 Clinical grade and frequency of lymphomas in the REAL classification (Smith et al., 2015)

Diagnosis	% of all cases
Indolent lymphomas	
Follicular lymphoma	22
Marginal zone B-cell, mucosa-associated lymphoid tissue	8
Chronic lymphocytic leukaemia/small lymphocytic lymphoma	7
Marginal zone B-cell nodal	2
Lymphoplasmacytic lymphoma	1
Aggressive lymphomas	
Diffuse large B-cell lymphoma	31
Mature (peripheral) T-cell lymphomas	8
Mantle cell lymphoma	7
Mediastinal large B-cell lymphoma	2
Anaplastic large cell lymphoma	2
Very aggressive lymphomas	
Burkitt's lymphoma	2
Precursor T-lymphoblastic	2
Other lymphomas	7

to further classify lymphomas (Harris et al., 1994; Swerdlow et al., 2008). The REAL/WHO classification incorporates some diagnoses not included in the Working formulation and is a list of lymphomas using morphology, immunophenotype, genotype, molecular and clinical behavior. It recognises the three major categories of lymphoid malignancies: B-cell neoplasms, T-cell/natural killer cell neoplasms and HL. However, in practice, the clinical behaviour of lymphomas informs the treatment strategies employed as these are based on the initial classification into indolent (low-grade) or aggressive (intermediate- and high-grade) NHL. A more biologically relevant classification of lymphoma is done using the WHO modification of the REAL classification together with immunological and molecular characteristics. This increases the diagnostic specificity and improves selection and targeting of therapy (Swerdlow et al., 2008).

Diagnosis

Diagnosis is based on a thorough history, physical examination, laboratory findings and investigation of a lymph node. A definitive

Box 52.3 World Health Organization (WHO) modification of the Revised European–American lymphoma classification (REAL/WHO classification) (Swerdlow et al., 2008)

Precursor B-cell neoplasm

- Precursor B-cell acute lymphoblastic leukaemia or lymphoma

Mature (peripheral) B-cell neoplasm

- B-cell chronic lymphocytic leukaemia or small lymphocytic lymphoma
- B-cell prolymphocytic leukaemia
- Lymphoplasmacytic lymphoma
- Splenic marginal zone B-cell lymphoma (with or without villous lymphocytes)
- Hairy cell leukaemia
- Plasma cell myeloma or plasmacytoma
- Extranodal marginal zone B-cell lymphoma (with or without monocytoid B-cells)
- Follicular lymphoma
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma
- Mediastinal large B-cell lymphoma
- Primary effusion lymphoma
- Burkitt's lymphoma or Burkitt cell leukaemia

Precursor T-cell neoplasm

- Precursor T-cell acute lymphoblastic leukaemia or lymphoma

Mature (peripheral) T-cell and natural killer neoplasms

- T-cell prolymphocytic leukaemia
- T-cell granular lymphocytic leukaemia
- Aggressive natural killer cell leukaemia
- Adult T-cell lymphoma or leukaemia
- Extranodal natural killer/T-cell lymphoma
- Enteropathy type T-cell lymphoma
- Hepatoplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides/Sézary syndrome
- Primary cutaneous anaplastic large cell lymphoma
- Peripheral T-cell lymphoma
- Angio-immunoblastic T-cell lymphoma
- Primary systemic anaplastic large cell lymphoma

diagnosis of NHL can only be made by biopsy of pathological lymph nodes or tumour tissue. An expert histopathologist may need to utilise techniques, such as immunocytochemistry (e.g. CD20) or flow cytometry or a combination of both, to obtain an accurate subclassification. Chromosomal abnormalities are of diagnostic importance. Most translocations involve genes associated with either proliferation (e.g. c-MYC) or apoptosis (e.g. BCL-2).

Investigations are also performed to accurately stage the disease and exclude other disease. Fluorodeoxyglucose (FDG)-PET or CT scan of the chest, abdomen and pelvis is the standard for staging. A bone marrow aspirate and trephine are required to exclude leukaemia and will detect bone marrow involvement, which is more common than in HL. Lumbar punctures should be performed for patients at high risk of CNS involvement, for example, Burkitt's lymphoma.

Molecular subtypes

Progress in the knowledge of the molecular pathology of diffuse large B-cell lymphomas (DLBCL) has led to the identification of two molecular subtypes. Studies have shown that the activated B-cell-like (ABC) subtype has a worse prognosis than the germinal center B-cell-like (GCB) subtype. Up to now, patients with DLBCL have been managed in the same way. However, the identification of these subtypes has led to studies investigating whether patients with the ABC subtype benefit from receiving novel agents as part of their treatment (Tilley et al., 2015).

Staging

Determining the extent of disease in patients with NHL provides prognostic information and is useful in treatment planning. Patients with extensive disease usually require different therapy from those with limited disease. The NHLs can be staged according to the Ann Arbor classification (see Table 52.1). In this system, NHL is defined as stage I, II, III or IV, stage I being disease limited to a single lymph node and stage IV being advanced disease, with involvement of extralymphatic sites. The International Prognostic Index (IPI) (Table 52.6) uses the following factors as predictors of poor prognosis: elevated LDH, stage III or IV

Table 52.6 International prognostic index for aggressive non-Hodgkin's lymphoma (International Non-Hodgkin's Lymphoma Prognostic Factors Project, 1993)

Factor	Adverse prognosis
Age	≥60 years
Ann Arbor stage	III or IV
Plasma lactate dehydrogenase level	Above normal
Number of extranodal sites of involvement	≥2
Performance status	≥ECOG 2 or equivalent

ECOG, Eastern Co-operative Oncology Group.

disease, greater than 60 years of age, the higher the number of extranodal sites involved and the Eastern Co-operative Oncology Group (ECOG) performance status of 2 or higher. Other prognostic factors include bulky disease, presence of B symptoms and transformation from low- to high-grade disease. Prognostic indicators are important because they inform the treatment plan to avoid over-treating those with good prognosis and under-treating those with poor prognosis.

Treatment

When designing a treatment plan for an individual patient, various factors must be taken into account. These include the patient's age and general health, the extent or stage of the lymphoma and the particular histological subtype. Indolent (low-grade) lymphoma tends to run a slow course, and although it is not curable, patients survive for prolonged periods with minimal symptoms. Aggressive (high-grade) lymphomas result in death within weeks or months if untreated. However, these lymphomas are very responsive to chemotherapy, and up to 50–60% may be cured with combination chemotherapy (Fig. 52.2).

CD20 is essential for cell cycle regulation and cell differentiation. It is expressed on normal B-cells and the majority of malignant B-cell lymphomas. The introduction of rituximab, a monoclonal antibody with specificity for CD20, has changed the way patients with NHL are treated and is now incorporated into most chemotherapy regimens. The mechanism of action of rituximab is not fully understood but is thought to involve complement-mediated lysis of B-cells and antibody-dependent cellular cytotoxicity. Other potential mechanisms include induction of apoptosis and inhibition of cell cycle progression.

Indolent non-Hodgkin's lymphoma

The median age at which patients present with indolent NHLs is 50–60 years, and generally patients have a good performance status. If left untreated, indolent NHL has a comparatively long survival (median: 9 years). Follicular lymphoma is the most common of the indolent lymphomas. Management is summarised in Fig. 52.3. The majority (80%) of patients present with advanced disease (stages II–IV) where the aim of treatment is to reduce disease bulk and offer symptom relief. Bendamustine and rituximab (BR) or the combination of rituximab, cyclophosphamide, vincristine, prednisolone (R-CVP) or R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisolone) is used as the first-line treatment for advanced (stage III or IV) follicular lymphoma. After the response to first-line induction treatment, patients should go on to receive rituximab maintenance (one dose every 2 months) for 2 years.

For patients who are asymptomatic at diagnosis, adopting a policy of 'watch and wait' with active monitoring and initiating treatment when symptomatic is an option.

Relapsed indolent non-Hodgkin's lymphoma. Relapsed patients may be re-treated with rituximab and combination chemotherapy if the time to relapse post-rituximab is greater than 6 months. Assuming response, these patients should receive

rituximab maintenance (a dose every 3 months) for 2 years. For some resistant or relapsing patients, particularly if their condition is too poor to merit further radical chemotherapy, palliation will be appropriate. Radiotherapy may be an option in this situation, and this is being evaluated through an ongoing clinical trial. Idelalisib, a small-molecule inhibitor of PI3K, may also have a role in managing patients who are refractory to two lines of treatment.

Aggressive non-Hodgkin's lymphoma

The median age of presentation of aggressive NHL is 60–70 years when 50–60% of patients will present with an advanced stage of the disease. The most common presentation is diffuse large B-cell lymphoma (DLBCL), and therefore the treatment strategies described later refer to this alone. Other aggressive lymphomas, for example, mantle cell, are managed differently. The most important strategy when treating this group of patients is to maintain the dose intensity of chemotherapy and minimise any delay in chemotherapy administration. Treatment is given with curative intent and is summarised in Fig. 52.4.

The treatment for DLBCL is six cycles of the combination of R-CHOP chemotherapy. Doxorubicin can cause cardiotoxicity, and patients with a reduced cardiac ejection fraction may not tolerate R-CHOP. In this situation, doxorubicin may be substituted by gemcitabine (R-GCVP). There is currently an ongoing clinical trial to establish if inotuzumab ozogamicin is an option for this group of patients. For patients with comorbidities or worse performance status, R-mini-CHOP (dose-attenuated R-CHOP) may be used. The addition of bortezomib to R-CHOP in DLBCL is being investigated as a clinical trial, to determine if bortezomib provides any benefit for the ABC or GBC subtypes.

Central nervous system prophylaxis. CNS relapse in patients with DLBCL occurs in approximately 5% of patients. Patients with high IPI, which includes involvement of more than one extranodal site and with an elevated LDH, appear to have a higher risk of CNS relapse. Prophylactic strategies include intrathecal methotrexate or systemic high-dose methotrexate, which are administered in addition to R-CHOP.

National guidance for the safe administration of intrathecal chemotherapy sets out the minimum requirements of a hospital providing an intrathecal chemotherapy service (Department of Health, 2008).

Relapsed aggressive non-Hodgkin's lymphoma. Combination chemotherapy with R-CHOP probably cures 60%. This, therefore, implies that greater than one-third of all patients have refractory disease or relapse after the first treatment.

In younger patients with aggressive NHL, the aim will be to introduce remission with further chemotherapy, using an alternative, salvage regimen, and then to consolidate remission with high-dose therapy (HDT). HDT is usually supported by mobilised peripheral blood stem cells (PBSCs) and an autologous PBSC transplantation (auto-PBSCT). HDT, with autologous stem cell support, is also used as part of primary treatment for younger patients with indolent lymphoma. Patients who receive

 NICE TA 137 – National Institute for Health and Clinical Excellence 2008

Fig. 52.3 Treatment algorithm for follicular lymphoma.

HDT after their initial treatment can have progression-free survival rates of around 50% at 5 years (Nournier et al., 2012; Philip et al., 1995; Sureda et al., 2015).

To induce a remission in patients with aggressive lymphoma and relapsed disease, it may be reasonable to use the same or a similar regimen as used for front-line chemotherapy. However, in most cases, the regimen chosen introduces new agents that are potentially not cross-resistant with those used in the initial treatment regimen. There are several salvage regimens in use, and they generally have response rates of between 40% and 70%. Examples of salvage regimens are ICE (ifosfamide, carboplatin, etoposide), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin) and DHAP (cisplatin, cytarabine, dexamethasone) (see Table 52.4). Gemcitabine, a pyrimidine analogue, may be of benefit for patients with relapsed or refractory disease after two lines of treatment. Gemcitabine is used in combination with other agents, such as cisplatin and methylprednisolone. Rituximab can also be added to these salvage regimens. PBSCs are usually harvested after the

second course of the salvage regimen. Patients then receive a high-dose regimen such as BEAM (carmustine, etoposide, cytarabine, melphalan) (Table 52.7) conditioning before stem cell infusion (autograft). Patients should only undergo an autograft if they have demonstrated a response to salvage chemotherapy.

For patients who are not suitable for autologous transplant, entry into a clinical trial should be considered. There are currently studies investigating the use of lenalidomide in combination with rituximab and the use of selinexor.

Very aggressive lymphoma

Burkitt's lymphoma is a rare form of B-cell NHL which occurs most commonly in children and young adults. The median age of adult patients is 30 years. Untreated, survival is measurable in days or weeks, and it is widely accepted that combination chemotherapy should be urgently commenced. Intensive chemotherapy is necessary, together with CNS prophylaxis, and cure is possible in a high proportion of cases.

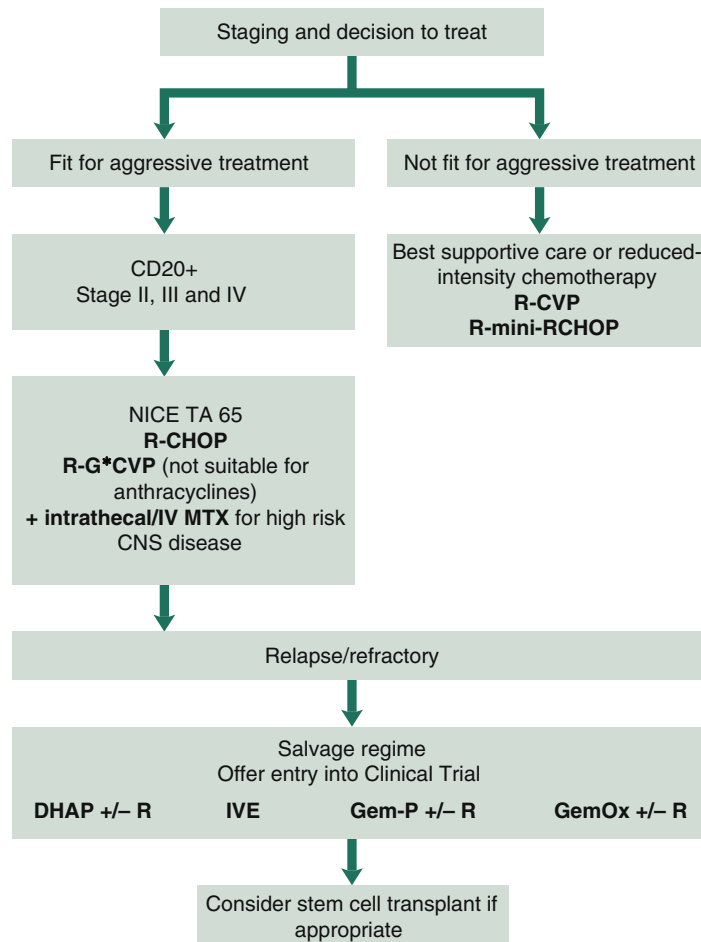

Multi-agent chemotherapy regimens including high-dose methotrexate, high-dose cytarabine, etoposide and ifosfamide are used. A schedule such as CODOX-M (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate)/IVAC (ifosfamide, etoposide, high-dose cytarabine) in combination with rituximab is common.

Lymphoblastic lymphomas/leukaemia

Lymphoblastic lymphomas comprise about 2% of adult NHLs. Patients are often treated with the same regimens used in acute lymphoblastic leukaemia (ALL). Despite a very high rate of complete responders, long-term survival remains poor. Patients who fail after first-line chemotherapy have a long-term disease-free survival of less than 10% (Fielding et al., 2007). These cases are subsequently treated as leukaemias (see Chapter 51).

Patient care

The chemotherapy regimens used to treat HL and NHL (see Tables 52.3 and 52.8) are usually administered on a hospital outpatient basis with the patient visiting the clinic regularly for assessment and treatment. The patient is monitored by FBCs carried out before each cycle of chemotherapy and at the 'nadir' between cycles. The nadir is when the blood count is at its lowest point, usually 10–14 days after the first day of chemotherapy. The interval between each cycle of chemotherapy enables normal body cells to recover before the patient receives further treatment. Disease response to treatment is monitored by repeating some of the diagnostic investigations, such as CT, at suitable intervals and the use of PET. If there is little or no response to treatment, a different chemotherapy regimen will be used, or a decision will be made to withdraw from active therapy and provide optimum supportive care.

R-CHOP = rituximab, cyclophosphamide, hydroxydaunorubicin (doxorubicin), vincristine (Oncovin), prednisolone
 R-G*CVP = rituximab, gemcitabine, cyclophosphamide, vincristine (Oncovin), prednisolone
 IV MTX = iv methotrexate

Counselling and support

Counselling is an essential part of the care of the cancer patient and involves not only the explanation of drug therapy and investigations but also the provision of psychological support for the patient and family. Before treatment with chemotherapy, the patient will be counselled by the doctor, chemotherapy nurse and, increasingly, oncology pharmacists and pharmacy technicians. It is necessary to explain how the chemotherapy is to be given and discuss both potential and inevitable side effects. The probability of successful treatment must be weighed against the prospect of serious and life-threatening adverse effects. Patients must be made aware of the long-term complications of chemotherapy and radiotherapy, such as secondary malignancy. If appropriate, patients should discuss options for fertility preservation.

The support available to the cancer patient, to help cope with both the illness and its treatment, has improved dramatically in recent years. Multidisciplinary teams working within specialised units have become skilled in anticipating the problems of lymphomas and their treatment. In addition, many charities provide care, support and advice, such as Macmillan Cancer Support (<http://www.macmillan.org.uk>) and the Lymphoma Association (<http://www.lymphoma.org.uk>).

Patient-specific treatment modifications

The selection of appropriate therapy must also take into consideration the individual patient. Factors include the patient's age, renal and hepatic function and underlying medical conditions,

Table 52.7 Conditioning chemotherapy for autologous transplantation

Drug	Dose and route	Day of administration
BEAM		
Carmustine	300 mg/m ² i.v.	6 days before reinfusion
Etoposide	200 mg/m ² i.v.	5–2 days before reinfusion
Cytarabine	200 mg/m ² 12 h i.v.	5–2 days before reinfusion
Melphalan	140 mg/m ² i.v.	1 day before reinfusion
Reinfusion of stem cells		Day 0
LACE		
Lomustine	200 mg/m ² orally	7 days before reinfusion
Etoposide	1000 mg/m ² i.v.	7 days before reinfusion
Cytarabine	2000 mg/m ²	6–5 days before reinfusion
Cyclophosphamide	1800 mg/m ² i.v.	4–2 days before reinfusion
Reinfusion of stem cells		Day 0

such as heart disease, diabetes or chronic pulmonary disease. The patient's tolerance of side effects and complications of therapy may then be predicted. The decision is based on an understanding of the pharmacodynamics and pharmacokinetics of the drugs being used, as well as the clinical condition of the patient.

Supportive care

During a course of chemotherapy, the patient requires supportive care to minimise the adverse effects of treatment. The common adverse effects of the chemotherapy regimens discussed in this chapter are outlined in [Table 52.9](#). These will occur to varying degrees depending on the combination of drugs and the doses used, as well as individual patient factors. Practice points to support patient care are described in [Box 52.4](#).

Nausea and vomiting

Nausea and vomiting is the most distressing and most feared adverse effect of chemotherapy. Its effect on the patient should not be underestimated, and its treatment is an important part of supportive care. The severity will depend on the combination of

Table 52.8 Chemotherapy regimens effective in the treatment of non-Hodgkin's lymphoma

Drug	Dose and route	Day of administration
R-CHOP (21-day cycle)		
Cyclophosphamide	750 mg/m ² i.v.	Day 1
Doxorubicin (hydroxydaunorubicin)	50 mg/m ² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m ² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5
Rituximab	375 mg/m ² i.v.	Day 1
R-CVP (21-day cycle)		
Cyclophosphamide	750 mg/m ² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m ² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5
Rituximab	375 mg/m ² i.v.	Day 1
FC (28-day cycle)		
Fludarabine	40 mg/m ² orally	Days 1–3
Cyclophosphamide	250 mg/m ² daily orally	Days 1–3
CHOP (21-day cycle)		
Cyclophosphamide	750 mg/m ² i.v.	Day 1
Doxorubicin (hydroxydaunorubicin)	50 mg/m ² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m ² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5
BR (28-day cycle)		
Bendamustine	90 mg/m ² i.v.	Days 1–2
Rituximab	375 mg/m ² i.v.	Day 1

drugs used. For example, oral chlorambucil is generally well tolerated by almost all patients and requires no antiemetic cover. Regimens such as ABVD, which is highly emetic, will make most patients vomit if no antiemetics are given. Aprepitant, an NK1 receptor antagonist, is licensed for cisplatin chemotherapy regimens and may be useful for managing emesis with DHAP, ESHAP and other regimens. The patient should be counselled on the appropriate use of prescribed antiemetics (see [Table 52.9](#)).

Table 52.9 Adverse effects associated with chemotherapy regimens used in the lymphomas with supportive measures and counselling points

Adverse effect	Cytotoxics implicated	Supportive measures	Counselling points
Bone marrow suppression	Chlorambucil Cyclophosphamide Dacarbazine Etoposide Doxorubicin Vinblastine Fludarabine	Blood transfusion Platelet transfusions Mouth care Granulocyte-colony stimulating factor Antibiotic therapy for febrile episodes	Expect tiredness Report bleeding or unusual bruises Adhere to mouth care regimen Avoid people with infections Importance of good personal hygiene Monitor temperature Report febrile episodes or signs of infection immediately
Nausea and vomiting	Doxorubicin Dacarbazine Procarbazine Cyclophosphamide	Antiemetic therapy	Emphasise regular use; a short course is more effective than 'as-required' treatment Report episodes of vomiting (especially if taking oral cytotoxics) For dexamethasone, emphasise short course not to be continued to ensure the patient does not receive repeat prescriptions from primary care doctor Take tablets before meals
Mucositis	Doxorubicin	Mouth care regimen	Importance of good oral hygiene; stress importance of regular mouth care
Tumour lysis syndrome	All cytotoxic drugs and corticosteroids in patients with a high tumour load sensitive to chemotherapy	Hydration, allopurinol, rasburicase	Stress importance of regular allopurinol until appropriate to stop Drink plenty of fluids
Alopecia	Cyclophosphamide Doxorubicin, etoposide	Provision of wig if wanted	Hair usually regrows on completion of therapy
Impaired gonadal function	Alkylating agents Procarbazine, doxorubicin (to a lesser degree)	Sperm storage	Depends on regimen Should be discussed as part of consent to treatment
Neuropathy	Vincristine Vinblastine, Vinorelbine	Reduce dose if continued use of vincristine Because vincristine is more neurotoxic than vinblastine, consider substituting with vinblastine as an alternative to dose reduction	Report tingling sensations or difficulty with buttons, constipation, jaw pain or stiffness
Constipation	Vincristine, bortezomib		Do not self-treat but refer to doctor
Cardiomyopathy	Doxorubicin		Report breathlessness, tiredness
Lung fibrosis	Bleomycin		Report breathlessness

Tumour lysis syndrome

The lymphomas are, in general, highly sensitive to chemotherapy. The resulting lysis of cells which occurs after initiation of chemotherapy may lead to hyperuricaemia, hyperkalaemia and hypocalcaemia in patients with bulky disease and may result in urate nephropathy. There is a high incidence of tumour lysis syndrome (TLS) in tumours with high proliferation rates and tumour burden such as Burkitt's lymphoma and T-lymphoblastic lymphoma. The mainstay of TLS prevention is hydration, with the patient encouraged to maintain a high fluid intake. Hyperuricaemia is controlled

with allopurinol and close monitoring of renal function, serum urate levels and electrolytes. Fig. 52.5 describes the purine catabolism pathway and explains the action of allopurinol and rasburicase. Allopurinol must be commenced before chemotherapy and continued until the tumour load has reduced and serum urate levels are normal. In aggressive forms of NHL, rasburicase, a recombinant urate oxidase, may be indicated as prophylaxis.

Rasburicase can also be used to treat TLS but will only correct hyperuricaemia. Treatment of TLS should include hydration at approximately 3 L/m² per day unless the patient has renal

insufficiency or oliguria (Cairo et al., 2010). Hypocalcaemia should be corrected if the patient is symptomatic, but this may increase calcium phosphate deposition. Hyperkalaemia and hyperphosphataemia should be corrected; patients may require haemofiltration or dialysis.

Mucositis

Chemotherapy may cause mucositis, which is inflammation of or damage to the surface of the gastro-intestinal tract. In the mouth, this may lead to painful ulceration, local infection and difficulty in swallowing. Dependent on the severity of mucositis, patients may require analgesia ranging from benzydamine mouthwash to systemic opiates. Disruption of the mucosal barrier will give bacteria and fungi easier systemic access. A mouth care regimen should therefore be instituted with myelosuppressive therapy. This involves good oral

Box 52.4 Practice points

Neutropenic sepsis

- The usual inflammatory signs of infection (redness, pain, swelling) are often absent due to a lack of neutrophils, and not all patients will present with a fever. Consider neutropenic sepsis in any patient who has received chemotherapy in the past 30 days.
- Neutropenic sepsis is a medical emergency; broad-spectrum antibiotics should be administered within 1 h of presentation. Do not wait for a full blood count to confirm neutropenia.

HL treatment

- Patients with HL should receive irradiated blood products for life.
- HL patients receiving bleomycin should be assessed carefully for signs and symptoms of pulmonary toxicity before each dose.

Tumour lysis syndrome

- Allopurinol should not be prescribed concurrently with rasburicase because it inhibits the production of uric acid, the substrate for rasburicase (see Fig. 52.5).
- Prednisolone and other steroids used to treat lymphoma can also cause tumour lysis syndrome. At-risk patients should receive a hypouricaemic agent before the first dose.
- When treating tumour lysis syndrome, potassium must not be added to the hydration fluid.

HL, Hodgkin's lymphoma.

hygiene, for example, gentle brushing with a toothbrush to remove plaque or rinsing with saline to remove debris.

Bone marrow suppression

Myelosuppression is usually the dose-limiting factor with these regimens, and it is necessary to carry out FBCs before treatment to confirm that recovery has occurred. Each chemotherapy protocol should be referred to so as to ensure appropriate management. Generally, if the platelet count is less than $100 \times 10^9/L$ and/or the absolute neutrophil count (ANC) is less than $1 \times 10^9/L$, the subsequent dose may be reduced or treatment delayed by a week.

Anaemia is treated with blood transfusions and thrombocytopenia with platelet transfusions as necessary. Erythropoietin administration reduces blood transfusion requirements and can improve quality of life. However, the evidence suggesting improvement in patient survival is inconclusive.

Neutropenia is the most life-threatening acute toxicity; the neutropenic patient is at constant risk from infections. Seemingly minor infections such as cold sores can spread rapidly, and infections not seen in the normal population (e.g. systemic fungal infections) can occur. Supportive measures involve reducing the risks and the aggressive treatment of any infectious episodes. The patient is counselled to avoid contact with people with infection or those who may be carriers. Most infections, however, are from an endogenous source such as the gut or skin. The patient is educated on the importance of good personal hygiene, mouth care, how to monitor body temperature and to report any febrile episodes immediately. Co-trimoxazole 960 mg once daily may be prescribed as prophylaxis against *Pneumocystis* pneumonia in patients receiving chemotherapy for lymphomas, particularly in those receiving a regimen containing fludarabine or bendamustine. Thorough and frequent handwashing helps prevent the transmission of opportunistic infection to the neutropenic patient.

Neutropenic sepsis

Neutropenic sepsis should be managed as a medical emergency. Susceptibility to infection is likely when the neutrophil count is less than $1 \times 10^9/L$, with increasing risk at levels less than

Fig. 52.5 Purine catabolism pathway.

$0.5 \times 10^9/L$ and $0.01 \times 10^9/L$. Risk of infection also increases with duration of neutropenia. Fever, usually defined as a temperature greater than $38^\circ C$, may be the only sign of infection. The patient should be assessed to determine the site of infection. Blood cultures from all venous access ports and any other appropriate cultures, for example, midstream urine sample and stool sample, should be taken. Cultures are taken before starting antibiotics to increase the likelihood of obtaining a positive culture. Infection with Gram-negative bacilli, for example, *Escherichia coli*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*, and Gram-positive cocci, for example, coagulase-negative staphylococci, β -haemolytic streptococci, enterococci and *Staphylococcus aureus*, is probable in this situation. First-line empiric therapy should cover these common pathogens. Options include carbapenems, a third-generation cephalosporin or antipseudomonal penicillin with or without an aminoglycoside.

Gram-positive infections are becoming more common with the use of indwelling intravenous catheters. If positive microbiological cultures are found, the appropriate antibiotic can be prescribed on the basis of sensitivities; however, if the patient is responding to empiric therapy, the antibiotics should not be changed. Only one-third of suspected infections are ever confirmed, and the pathogen may not be isolated. The febrile episode may not be due to infection; non-infectious causes include blood transfusion, drug administration and underlying disease.

Growth factor support

Patients with persistent neutropenia or those who have repeated admissions for neutropenic sepsis may be supported with granulocyte-colony-stimulating factor (G-CSF). There is evidence that patients with lymphomas receiving a reduced dose of chemotherapy as a consequence of myelosuppression have a worse prognosis compared with patients who receive full doses. G-CSF is indicated as primary prophylaxis, before any episode of febrile neutropenia, for regimens in which there is a high (>40%) incidence of febrile neutropenia. G-CSF has been investigated as a prophylactic measure to increase the dose intensity of chemotherapy in regimens such as CHOP-14 (cyclophosphamide, hydroxydaunorubicin [doxorubicin], vincristine [Oncovin], prednisolone at 14-day intervals).

Case studies

Case 52.1

Mr RB is a 50-year-old man receiving bendamustine and rituximab for follicular lymphoma. He has no other medical problems and has normal renal and hepatic function.

Questions

1. What are the key counselling points for patients receiving bendamustine?
2. What antibacterial agent would you expect to see prescribed with bendamustine?

Answers

1. Immunocompromised patients, for example, those receiving purine analogues, fludarabine, cladribine, pentostatin, and alkylating agents such as bendamustine, are at risk of developing transfusion-associated graft versus host disease (TAGVHD), a rare but usually fatal complication of transfusion. Viable T-lymphocytes in donated blood can recognise the recipient as 'foreign', leading to fever, skin rash, hepatitis and bone marrow involvement. Death occurs in 90% of cases, predominantly due to infection (Kopolovic et al., 2015).
 γ -Irradiation of cellular blood components is the mainstay of TAGVHD prevention. Patients, such as Mr RB, should be given an appropriate patient information leaflet and an alert card. The risk of TAGVHD is minimised by informing transfusion staff and the patient of their need for irradiated blood products.
2. Mr RB should be prescribed co-trimoxazole prophylactically, to prevent *P. carinii* (previously *P. jiroveci*) infection.

Case 52.2

Mrs BC is a 72-year-old widow who has been newly diagnosed with advanced HL. She has been seen in the haematology clinic before starting VEPEMB chemotherapy. She has brought a prescription to the pharmacy for prednisolone, procarbazine, etoposide, and supportive medications. When Mrs BC hands in her prescription, she expresses concern about the side effects of the tablets. The doctor who saw her had spent a lot of time talking to her about her treatment, but she feels confused with all the information given.

Questions

1. What are the side effects of prednisolone, procarbazine and etoposide?
2. How would you counsel Mrs BC?

Answers

1. Prednisolone-related side effects include mood changes, difficulty sleeping, increased appetite, stomach irritation, immunosuppression and hyperglycaemia. Side effects are less common with short courses, but Mrs BC will be taking a moderately high dose (30 mg/m² per day).
 The most common side effects of procarbazine are nausea, vomiting and myelosuppression. As procarbazine is a weak monoamine oxidase inhibitor that crosses the blood-brain barrier rapidly, patients can uncommonly suffer with drowsiness, confusion, pins and needles or nightmares.
 Etoposide is associated with dose-limiting myelosuppression which is dose-related. It can cause a sore mouth and hair loss.
 Mrs BC is an elderly patient and is thus more likely to experience toxicity because of deteriorating renal and hepatic function and underlying medical conditions.
 Usually, an H₂ antagonist or proton pump inhibitor, 5HT₃ anti-emetic and anti-infectives (which may include aciclovir, fluconazole, co-trimoxazole and a quinolone) will be prescribed to counteract these side effects.
2. Mrs BC may be distressed by her diagnosis and may not have been able to absorb all the information she was given in the clinic. In addition, VEPEMB is a complicated regimen, and she may also be seeking confirmation of information. Mrs BC should have been allocated a specialist nurse or key worker who will be able to give her ongoing support.

She should be told that she will probably feel tired and be more prone to infection because the tablets lower the blood count and resistance to infection. She should be advised to inform the haematologist or her specialist nurse if she feels unwell.

Other counselling points include the following:

- Complete the course of tablets as prescribed.
- Procarbazine should be swallowed whole with water.
- Avoid drinking alcohol while taking procarbazine (risk of disulfiram-type reaction).
- Etoposide should be swallowed whole on an empty stomach or an hour before food.

Mrs BC should be advised to take her prednisolone with breakfast in the morning to reduce gastric side effects.

Case 52.3

Mr FP is 56-years-old and was diagnosed with stage III high-grade NHL (DLBCL) over 10 weeks ago. Since then, he has received three cycles of R-CHOP and has come to the hospital for his nadir blood count. He complains of painful mouth ulcers and a sore throat. On examination, he has mucositis and oropharyngeal candidiasis. He has a white blood cell count (WCC) of 3.2 (normal range: $3.5\text{--}11 \times 10^9/\text{L}$) with an ANC of $0.8 \times 10^9/\text{L}$.

Questions

1. How would you treat Mr FP's candida infection?
2. What advice would you give Mr FP?

Answers

1. Mr FP has an ANC of $0.8 \times 10^9/\text{L}$ and is therefore neutropenic (ANC $<1.0 \times 10^9/\text{L}$). Localised candida infections can spread rapidly in the immunosuppressed patient, so local therapy with an antifungal mouthwash will be inadequate therapy. A course of fluconazole, 100 mg daily for at least 7 days, should be prescribed. Therapy should continue for a further 7 days if Mr FP is still neutropenic or if the thrush has not completely resolved. Because Mr F is complaining of pain, an analgesic should be added. Benzylamine mouthwash, a locally acting analgesic, could be prescribed initially. If this does not give adequate pain relief, then systemic analgesics should be given.
2. Regular mouth care reduces the risk of infection but does not entirely remove it. It is not necessarily a reflection of how well Mr FP has adhered to his mouth care regimen. The benzydamine mouthwash should be used before meals because Mr FP will probably find eating painful. He should be advised to use a soft toothbrush, to eat soft foods and to avoid hot and spicy dishes. Mr FP may be reassured that once his blood count recovers, his mouth ulcers should resolve and that the fluconazole should relieve his sore throat.

Case 52.4

Mr DG, 38-year-old with advanced HL, is admitted to the haematology ward at the local hospital as an emergency. He had a temperature of 39°C on the morning of admission and feels generally unwell but has no specific symptoms. It has been 10 days since Mr DG started his second cycle of ABVD.

Blood cultures are taken and piperacillin + tazobactam 4.5 g i.v. three times daily and gentamicin 420 mg i.v. once daily are prescribed, to be commenced immediately. Mr DG weighs 84 kg

and is 186 cm tall. His blood biochemistry results are normal; his FBC is as follows:

	Value	Reference range
Haemoglobin	108 g/L	(13.5–18.0 g/dL for men)
White cell count	$2.5 \times 10^9/\text{L}$	($3.5\text{--}11 \times 10^9/\text{L}$)
Neutrophil count	$0.5 \times 10^9/\text{L}$	($1.5\text{--}7.5 \times 10^9/\text{L}$)
Platelets	$150 \times 10^9/\text{L}$	($150\text{--}400 \times 10^9/\text{L}$)

Questions

1. Comment on the rationale for the antibiotic therapy prescribed.
2. How would you monitor this patient?
3. What would be an appropriate second-line regimen if Mr DG remains pyrexial?
4. What modifications would need to be made to subsequent cycles of chemotherapy?

Answers

1. Mr DG's FBC is probably at its nadir after his last course of chemotherapy. He is neutropenic and febrile. Immunosuppression is also a feature of HL and contributes to his susceptibility to infection. Treatment should commence immediately after cultures have been taken because infection can be rapidly fatal in these patients. The antibiotics selected should provide broad-spectrum cover and follow local policy because there are institutional variations in predominant pathogens and antimicrobial sensitivities. Because Gram-negative infections are more rapidly fatal, first-line therapy should be biased towards these infections. Monotherapy with an antipseudomonal agent (e.g. piperacillin + tazobactam) is sufficient in most cases of uncomplicated neutropenic sepsis. The addition of gentamicin to Mr DG's therapy may be warranted based on local microbial resistance, prior infection history or evidence of severe sepsis (e.g. hypotension). The dose of piperacillin + tazobactam is appropriate. Single-daily-dose gentamicin is at least as effective as multiple dosing and less nephrotoxic; it is more convenient and cost-effective and overcomes deficiencies of the traditional method such as sub-therapeutic dosing and inadequate monitoring. The dose is 5–7 mg/kg once daily and has been calculated correctly for Mr DG. He has normal renal function, so no dose modifications are necessary.
2. Monitor Mr DG's temperature, pulse and blood pressure and any symptoms for signs of improvement or deterioration. Blood biochemistry should be checked daily to detect any deterioration in renal function. Microbiology reports should be checked and antibiotics reviewed if any micro-organisms have been cultured. However, no change should be made to antibiotics if Mr DG shows signs of improvement. The administration of gentamicin should be monitored, checking both administration and sampling time for drug levels.
3. If Mr DG remains pyrexial 24–48 hours after the first-line antibiotics have been commenced, but he is clinically stable, empiric antibiotics should not be modified. Consideration should be given to broadening cover, for example, adding vancomycin if the patient has mucositis or evidence of line infection. If blood cultures show growth, found in only 30–40% of neutropenic patients, the choice of antibiotics should be on the basis of sensitivities. Clinical improvement is often seen with the recovery of neutrophil count. Mr DG should recover by day 14, but neutrophil recovery may be delayed by this infection. If Mr DG is still pyrexial at 96 hours, then the likelihood of fungal infection must be considered and an intravenous amphotericin-based product or caspofungin commenced if appropriate.
4. Because Mr DG is being treated with curative intent, it is appropriate to give GCSF and maintain the dose intensity of his chemotherapy.

Case 52.5

Mr RT is 26-year-old man with Burkitt's lymphoma. Mr RT is due to start chemotherapy with rituximab + CODOX-M. His LDH is 960 U/L (normal range 240–480 U/L), and his eGFR is greater than 90 mL/min (normal value ≥ 90 mL/min per 1.73 m²).

Questions

1. Which complications is Mr RT at risk of?
2. How would you treat Mr RT?

Answers

1. Mr RT is at high risk of developing tumour lysis syndrome because he has a diagnosis of Burkitt's lymphoma. In addition, his LDH is two times greater than the upper limit of normal.

2. Mr RT should receive prophylactic rasburicase along with appropriate hydration. Hydration should be given at approximately 3 L/m² per day because Mr RT does not have renal insufficiency or oliguria (Cairo et al., 2010). His urine output should be maintained at greater than 100 mL/m² per hour.

The licensed dose of rasburicase is 0.2 mg/kg for up to 7 days, but a single dose repeated only if clinically necessary has been recommended by a panel of experts (Cairo et al., 2010). Rasburicase metabolises uric acid to allantoin, which is more easily excreted. Allopurinol should not be administered concurrently because this may reduce the efficacy of rasburicase; allopurinol inhibits the production of uric acid, the substrate for rasburicase (see Fig. 52.5).

Mr RT's urate should be measured daily. The sample must be sent to the laboratory on ice to prevent false assay results because rasburicase will otherwise continue to metabolise the uric acid in the sample tube. His serum creatinine, potassium, calcium, phosphate and uric acid should be checked at baseline and repeated as clinically indicated.

53 Solid Tumours

Netty (Annette) Cracknell and Alan Lamont

Key points

- Cancer involves a group of relatively normal cells dividing without the controls that usually prevent cells from growing beyond their normal size, site and nutritional base.
- Certain cancers are now considered a long-term illness with many subgroups.
- *Cancer* is a collective term for several diseases, each with its own characteristics and natural history according to where it started. Even for a single site of origin, such as breast cancer, major biological and histological differences can be shown compared with other sites of cancer origin.
- Before treatment, patients must be carefully 'staged' to establish the type and extent of disease.
- Depending on the stage of disease, the aim of treatment may be cure, prolongation of survival or symptom control.
- Cytotoxic chemotherapy remains the main treatment for disseminated disease for most cancers.
- Treatment options depend not only on the 'gold standard' of treatment but also on patient factors and preferences.
- Targeted medical therapies are becoming more common, generally have fewer side effects and are given over a longer-term than conventional chemotherapy

The term *cancer* is used to describe more than 200 different diseases, including those affecting discrete organs (solid tumours) and haematological malignancies (which are not localised in the same way). Whereas some tumours are benign and may be harmless, this chapter focuses on the management of patients with solid malignancies which require some form of treatment. Treatment is generally carried out in specialised cancer centres, cancer units or, for some agents, in the patient's home. Therapy may include surgery, radiotherapy, chemotherapy and biological or targeted therapy as single modalities or in combination. Care of the patient with cancer demands a broad range of services involving a multidisciplinary team working across the hospital, community and hospice network. The cost of systemic anticancer therapeutic agents is now in some cases so high that healthcare systems, such as the UK National Health Service (NHS), are restricting access to funding of individual products or to specific indications.

Epidemiology

Cancer is a common disease, with more than one-third of 1 million people developing cancer each year in the UK (352,197 new UK cancer cases in 2013). This equates to someone in the UK being diagnosed with cancer every 2 minutes. It is predicted that one in two people born after 1960 will be diagnosed with some form of cancer during their lifetime. Of all deaths in the UK, one in four is due to cancer. The most common cancers are lung, breast, bowel and prostate cancers, which make up more than half (53%) of all new cancers in the UK ([Cancer Research UK, 2016a](#)).

In 2013 prostate cancer became the most common cancer in men (26%), followed by lung cancer (14%) and bowel cancer (13%). For the same period, in women, breast cancer was the most common (31%), followed by lung cancer (12%) and bowel cancer (11%). However, there are regional variations ([Cancer Research UK, 2016a](#)).

Aetiology

The causes of cancer may be categorised as either environmental or genetic, although these may be interrelated, and the causes of some cancers may be multifactorial.

Environmental factors

Increasingly, lifestyle factors play a large part in the development of many cancers. Cigarette smoking has been identified as the single most important cause of preventable disease and premature death in the UK. The beneficial effect of stopping smoking on the cumulative risk of death from lung cancer reduces with increasing age ([Doll et al., 2004](#)). Tobacco (both active smoking and environmental tobacco smoke) causes almost one-fifth (19%) of all cancer cases in the UK each year, with the link between tobacco and cancer having been established more than 50 years ago.

The most important lifestyle factor for bowel cancer is diet, whereas cervical cancer is primarily linked to sexual behaviour through the transmissible agent human papilloma virus (HPV) and secondarily to smoking.

Table 53.1 A–K of factors associated with specific cancer sites: An empirical basis for recommending lifestyle changes (Jankowski and Boulton, 2005)

Factor	Associated cancer
Alcohol consumption >3 units a day	Most squamous cancers, especially bladder and oesophagus
Body mass index >25 and certainly >30	All solid cancers
Cigarette smoking at any level (even passive smoking)	Bladder, lung, head and neck, oesophagus and oropharyngeal cancers
Diet, especially one that is high in fat	All solid cancers
Exercising <30 min a day	All solid cancers
Family history of cancer (in at least one first-degree relative and at least three people in two or more generations)	Inherited cancer syndromes, including breast, colorectal, diffuse gastric, ovarian, prostate and uterine cancers
Genital and sexual health (sexually transmitted infections)	Cervical cancer
Health-promoting drugs that may decrease global cancer risks (but need a careful risk/benefit analysis)	Colonic adenomas can be treated with low-dose aspirin but can have serious side effects Hormone replacement therapy linked with breast cancer
Intense sunburn	Melanoma
Job-related factors	Lung cancer (exposure to asbestos and particulates), skin cancer (contact with arsenic)
Known disease associations	Colorectal cancer has predisposing mucosal pathology – adenomas, coeliac disease, ulcerative colitis

Table 53.1 lists other factors which have been associated with cancer development.

Genetic factors

Some rare tumours are known to be associated with an inherited predisposition, where an individual is born with a marked susceptibility to cancer. This is due to the inheritance of a single genetic mutation which may be sufficient to greatly increase the risk of one or more types of cancer. Examples include the paediatric malignancies, Wilms' tumour of the kidney and bilateral retinoblastoma, a rare cancer of the eye. Some common cancers, such as breast, ovarian and colorectal cancers, may also show a tendency to occur in families, but these represent a small proportion of the overall presentation of common cancers where identifiable risk factors are relevant in only 5–10% of cases, although when the genetic factor is present, the cancers tend to have their onset at a younger age (Garber and Offit, 2005).

Screening and prevention

Screening

Screening programmes aim to detect pre-malignant changes or early-stage cancer in asymptomatic individuals in the general population to provide earlier and thus more effective treatment. Any screening test must be simple, reliable, highly specific (to exclude healthy individuals) and highly sensitive (detection:

90–95%). For a screening programme to be effective in reducing morbidity and mortality, there must also be an available, effective, safe and economically viable treatment that can be applied to the abnormalities detected by the screening test. Screening is well established for cancers of the breast, cervix and bowel. Population screening for prostate cancer using the prostate-specific antigen (PSA) blood test remains more controversial due to the lack of specificity and sensitivity of the test and because of the limited evidence on the viability and effectiveness of the treatment options in early-stage disease. It is currently not recommended for use in screening programmes in the UK but is used in the USA. The evidence base for ovarian cancer screening using the blood test CA 125 and pelvic ultrasound is evolving through clinical trials.

Prevention

The strong association between cancer risk and lifestyle factors means there is great potential for the primary prevention of cancer through:

- avoiding tobacco use, especially exposure to cigarette smoke;
- moderate alcohol consumption;
- healthier eating;
- limiting exposure to sunlight and artificial tanning UV exposure;
- encouraging physical exercise;
- maintaining a healthy body weight;
- maintaining adequate protection from asbestos fibres, radon and other occupational and environmental risk factors.

Chemoprevention

Chemoprevention is the prevention of cancer by using medication. The most common example is tamoxifen (pre-menopausal women) or an aromatase inhibitor (post-menopausal women) prescribed daily for 5 years to reduce the risk of developing breast cancer in high-risk women. However, these treatments are not without their side effects, such as menopausal symptoms and increased risk of thromboembolic events. Therefore, the risk/benefit ratio for each patient needs to be carefully assessed.

Another potential future development is the effect of aspirin as a chemopreventive agent for colorectal cancer. Maximal effect requires long-term use of high-dose aspirin that may increase the risk of gastro-intestinal bleeding. Non-steroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitors may also be candidates for chemoprevention. However, the regular use of these drugs may also cause gastro-intestinal bleeding and increase the risk of cardiovascular events (Herszényi et al., 2008).

Cancer at the cellular level

Cancer arises from the changes in genes that regulate cell growth. For a normal cell to transform into a cancer cell, genetic changes must occur in the genes that regulate cell growth and differentiation. The nature of the genetic change may be a single-point change to a DNA nucleotide or the complete loss/gain of an entire chromosome. However, the most important factor is that a gene which regulates cell growth and/or differentiation must be altered to allow the cell to grow in an uncontrolled manner. Most cancers require a series of genetic mutations in a cell before an invasive tumour results.

Oncogenes

Oncogenes are where the normal gene, called a proto-oncogene, mutates and is then expressed at inappropriately high levels, therefore increasing the function of that gene. Examples of proto-oncogenes are genes that encode growth factors, signal transducers and transcription factors.

Tumour-suppressor genes

Tumour-suppressor genes are normal genes which have a protective effect against oncogenes and are also known as 'anti-oncogenes'. The tumour-suppressor gene's normal function is usually to control the cell cycle or act as a checkpoint in division. When this function becomes lost due to mutations affecting both copies of the gene in a potentially malignant cell, other genetic mutations have a greater likelihood of progressing to cancer. An example is the *TP53* gene which codes for the suppressor protein product p53.

The p53 protein acts as a regulator of cell growth and proliferation and controls passage from G1 to S phase in cell division (see Fig. 53.1). Agents that damage DNA cause p53 to accumulate. This accumulation of p53 switches off replication in the cell,

Fig. 53.1 Normal cell cycle.

arresting the cell cycle and allowing time to repair. If repair fails, p53 may trigger cell suicide by apoptosis. Thus, p53 controls and halts the proliferation of abnormal cell growth.

The cancer cell

Cancer cells differ from normal cells in that they function differently. Inherently unstable, they may display different protein or enzyme content and chromosomal abnormalities (such as translocations or deletions), which may be associated with differences in their susceptibility to chemotherapy or radiotherapy. The changes in internal structure and function lead to changes in their appearance which are visible under light microscopy, for example, larger and more varied appearance of the cell nuclei and loss of the appearance of specialised cell functions such as gland formation. This allows them to be easily detected, particularly when these lead to changes in the way clusters of cells form structures as a group and relate to normal cells in a tissue or organ.

Tumour growth

A solid tumour represents a population of dividing and non-dividing cells. The time it takes for a tumour mass to double is known, unsurprisingly, as the doubling time. The latter will vary depending on the type of disease, but for most solid tumours it is about 2–3 months. In most solid tumours, the growth rate is very rapid initially (exponential growth) and then slows as the tumour increases in size and age, a pattern described as Gompertzian growth (Fig. 53.2). The growth fraction is the percentage of actively dividing cells in the tumour, and this decreases with increasing tumour size. Not all of the dividing cells' 'daughters' will continue to grow, divide and add to the cell population of a growing tumour. The balance between the production of new cells and the 'cell loss factor' results in a much lower rate of growth than might be expected from the individual malignant cell's potential for division.

Fig. 53.2 Example of Gompertzian growth of cancer cells.

This pattern of tumour growth kinetics has implications for chemotherapy treatment. Generally, chemotherapy is most successful when the number of tumour cells is low and the growth fraction high, which is the situation in the very early stages of cancer.

Tumour spread

As a primary tumour grows, it both pushes the normal surrounding cells aside and invades between them into normal tissue. It is this property of invasion that characterises a malignant tumour and leads to distant spread of the disease because the abnormal cells often infiltrate through the walls of blood vessels and the lymphatic system. Malignant cells are then released from the infiltrating cluster of tumour cells and are transported by the blood or lymphatic fluid to other organs of the body, where they can subsequently form secondary cancers or metastases. The pattern of spread tends to be predictable for different tumour types, influenced by the anatomy of the primary site and by differences in the local factors affecting the viability of malignant cells when they become deposited elsewhere. For example, breast cancer usually metastasises to the lymph nodes under the arm, lungs and central nervous system, whereas prostate cancer tends to metastasise to bone. Generally, when the primary is first detected, the larger the tumour mass, the more likely that it has metastasised to other sites. It is often possible, using specialised research techniques, to detect circulating tumour cells or DNA in the peripheral blood of patients with even small primary tumours with no evidence of metastatic spread. This is a field of great interest in research for developing methods of early detection of active disease but also indicates that most cells released into the blood by primary tumours do not result in viable secondary tumours.

Patient management

Clinical assessment

Presentation

The clinical features of cancer vary with tumour type. Generally, patients most commonly present with either (1) non-specific

complaints, which include weight loss, unexplained anaemia, malaise, lethargy or pain; (2) a specific localising symptom such as bleeding from an identifiable site, a non-healing ulcer, a minor symptom such as a cough or hoarseness not resolving in the usual way or the presence of a painful lump; or more commonly (3) a painless lump. In general, solid tumours are first clinically detectable when there are approximately 10^8 – 10^9 tumour cells present in a tumour mass in the range of 1–10 g. The patient is usually in the terminal stages of the disease when there are 10^{12} cells present and a tumour burden of around 1 kg. Less commonly, a tumour may be detected by chance during a routine physical examination or by screening or through identification of early symptoms. However, if this does not occur or these symptoms are not present or not recognised, then the disease at presentation is commonly at a stage where there is a high risk that metastatic spread has already occurred at a microscopic level even if that is not clinically detectable.

Before treatment, each patient must undergo a thorough assessment to establish diagnosis, stage of disease and general fitness level. These factors will influence the choice of treatment and give a guide to prognosis.

Diagnosis

An accurate diagnosis is usually made from a tissue sample taken from a suspected primary or secondary tumour, according to the initial clinical investigations. This sampling procedure, known as a biopsy, may be obtained by an open operation, or less invasively by endoscopy or image-guided techniques. Such samples may be obtained, for example, during bronchoscopy when lung cancer is suspected or, as in the case of a patient presenting with a breast lump, aspiration through a fine needle under ultrasound guidance.

Malignant tumours vary in their sensitivity to chemotherapy. For example, there are two major groups of lung cancer: small-cell and non-small-cell lung cancer. Each of these groups is treated with different combinations of surgery, radiotherapy and chemotherapy drugs. Therefore, precise histopathology is important.

Tumour markers

Tumour markers are usually proteins associated with a malignancy and are clinically useful in:

- diagnosing or at least helping indicate a specific tumour;
- monitoring response to treatment;
- estimating prognosis, usually as part of a prognostic index calculation;
- detecting recurrent disease;
- screening a healthy population or a high-risk population for the presence of cancer.

They may be detected in a solid tumour, in circulating tumour cells in peripheral blood, in lymph nodes, in bone marrow or in other body fluids. Some of the tumour markers are presented in Table 53.2.

Staging investigations

Because the cancer is often disseminated at the time of presentation, it is vital that patients undergo thorough staging investigations to establish the extent and nature of disease. This will

Table 53.2 Examples of tumour markers used in detection, diagnosis and monitoring

Tumour marker	Indicative cancer
CA 125	Ovarian cancer, although non-specific
CA 19-9	Upper gastro-intestinal/pancreas though non-specific
CA 15-3	Breast cancer, though limited utility
CEA	Lower gastro-intestinal tumours, although non-specific
α -Fetoprotein β -Human chorionic gonadotrophin	Testicular tumour
5-Hydroxyindole acetic acid, chromogranins A and B	Carcinoid tumours
Thyroglobulin	Thyroid cancer (limited utility unless thyroid-stimulating hormone is suppressed post-thyroidectomy)
α -Fetoprotein	Hepatocellular carcinoma
Prostate-specific antigen	Prostate cancer
Human chorionic gonadotrophin	Gestational trophoblastic tumours
β -2-Microglobulin	Myeloma and some related hematological malignancies

determine the most appropriate treatment offered to the patient. Baseline investigations range from clinical examination, blood tests and liver function tests to diagnostic imaging such as chest and skeletal X-rays, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET), depending on the disease type and likely pattern of spread. Clinical guidelines for staging and management of malignancies of the various body systems have been produced at local and national levels in most developed countries, with relatively minor variations according to local custom and practice. For example, guidelines have been developed by the National Institute for Health and Care Excellence (NICE) in the UK (see <http://www.nice.org.uk/> for guidance) and the National Cancer Institute (NCI) in the USA (see <http://www.cancer.gov/> for guidance).

Staging classification

Staging is essentially a measure of how far a tumour has progressed in its development at the time of diagnosis, whereas grading is a measure of how aggressive its behaviour is likely to be in future, based on the microscopic appearance of the cells of the tumour. Both measures are relevant to the patient and clinical team in planning the management.

Box 53.1 Performance status scales

Karnofsky performance index

- 100** Normal, no complaints, no evidence of disease
- 90** Able to carry on normal activity, minor signs or symptoms of disease
- 80** Normal activity with effort, some signs or symptoms of disease
- 70** Cares for self, unable to carry on normal activity or do active work
- 60** Requires occasional assistance but is able to care for most of own needs
- 50** Requires considerable assistance and frequent medical care
- 40** Disabled, requires special care and assistance
- 30** Severely disabled, hospitalisation is indicated, although death is not imminent
- 20** Very sick, hospitalisation necessary, active supportive treatment is necessary
- 10** Moribund, fatal processes progressing rapidly

World Health Organization performance scale

- 0.** Able to carry out all normal activity without restriction
- 1.** Restricted in physically strenuous activity but ambulatory and able to carry out light work
- 2.** Ambulatory and capable of all self-care but unable to carry out any work; up and about more than 50% of waking hours
- 3.** Capable of only limited self-care; confined to bed more than 50% of waking hours
- 4.** Completely disabled; cannot carry on any self-care; totally confined to bed or chair

Most tumours are classified according to the TNM (tumour–nodes–metastases) system, where T (0–4) indicates the size of the primary tumour, N (0–3) the extent of lymph node involvement and M (0–1) the presence or absence of distant metastases. Each solid tumour site has a specific grading and staging classification such as Dukes-based staging in colorectal cancer ([Cancer Research UK, 2009](#)) and Gleason scoring for grading prostate cancer ([Berney, 2007](#)), although these are being superseded by TNM in many healthcare systems, and other prognostic scoring and predictive tools are sometimes used, especially in research trials to stratify into subgroups.

Performance status

The patient's general level of fitness (performance status) at the time of diagnosis is often a surprisingly reliable indicator of prognosis, independent of disease-related factors, and will help determine whether the patient is likely to withstand intensive chemotherapy; this therefore influences the choice of treatment. Various physical rating scales have been devised to assess performance status, including the Karnofsky Performance Index ([Karnofsky and Burchenal, 1949](#)) and the World Health Organization (WHO-ECOG) performance scale ([Oken et al., 1982](#)) ([Box 53.1](#)).

Prognostic factors

Prognostic factors are those that can predict how the disease is likely to behave and determine an outcome in individual patients. For example, [Table 53.3](#) lists prognostic factors in patients with colorectal cancer.

Table 53.3 Prognostic factors in patients with colorectal cancer

Favourable	Unfavourable
Good performance status	Presence of nodal involvement
No penetration of the tumour through the bowel wall	Presence of distant metastases
Absence of nodal involvement	Bowel obstruction and bowel perforation
Absence of distant metastases	

Treatment

Treatment goals

After the diagnosis of cancer has been confirmed and the extent of disease fully investigated, the goals of treatment have to be considered. Depending on the stage of disease, the goal can be the following (and this may change throughout treatment):

- Cure – Patients are said to be ‘cured’ of cancer when they are completely disease-free and have a normal life expectancy. The smaller the tumour bulk when treatment is given, the greater the potential of achieving cure. A common measure of ‘cure’ is the 5-year disease-free survival rate.
- Prolong survival while maintaining patient’s quality of life.
- Provide palliative relief of symptoms such as pain.

Childhood malignancies, choriocarcinoma and testicular tumours in adults are most responsive to chemotherapy, and these patients are frequently cured, even with advanced disease. However, for most patients treated with chemotherapy, cure is less likely, and treatment will be given to maximise the probability of cure, prolong survival or be purely palliative. The decision is influenced by factors such as the extent of the disease, as well as co-existing symptoms, concurrent medical conditions, performance status and, importantly, the patient’s wishes. The possibility of medium- to long-term survival justifies aggressive treatment, but with palliative therapy, it is particularly important that the toxicity of treatment is carefully weighed against the potential benefits.

Treatment guidelines

Consensus on the best approach to managing each particular type of cancer is continually evolving based on the evidence from clinical research, most reliably in the form of randomised controlled trials. National guidelines aim to promote equity for patients and ensure a consistent treatment approach that takes account of the boundaries of affordability for the healthcare system. In the absence of clinical consensus, patients should be encouraged to participate in clinical trials.

Treatment methods

Four main options are available for the treatment of patients with solid tumours: surgery, radiotherapy, conventional chemotherapy and targeted/biological therapies. Each treatment may play a number of roles, either alone or in combination, depending on the disease, stage and grade.

Role of surgery. Surgery can be curative when solid tumours are confined to one primary anatomical site or region as in localised disease. It can also be used to remove isolated metastatic masses with curative intent in rare circumstances or to deal with anatomical consequences of a tumour as a palliative procedure, such as relief of bowel obstruction by defunctioning colostomy. Surgical techniques may be used to support chemotherapy administration when given by continuous infusion or by the intraperitoneal route. Surgery plays a major role in diagnosis through tissue biopsy or in staging to ascertain the extent of tumour involvement such as in ovarian cancer. In the latter, it may also be used to debulk or reduce the size of the tumour to effect pain relief or to improve the effectiveness of subsequent radiation or chemotherapy. However, with more widespread disease, systemic treatment becomes the mainstay of management, with chemotherapy playing a major role.

Role of radiotherapy. Radiotherapy can be used to cure cancer, reduce the symptoms of the tumour, reduce the size of the tumour ready for surgery or to prevent re-occurrence of the tumour after surgical removal. It can be used alone or in combination with surgery and/or chemotherapy. A full exposition of the role of radiotherapy is beyond the scope of this chapter, which concentrates on the role of systemic agents. However, the combination of radiotherapy and systemic treatment is becoming increasingly employed as research shows the benefit to disease control and long-term survival, for example, in carcinoma of the uterine cervix (Green et al., 2009).

Systemic therapy. This encompasses cytotoxic chemotherapy, hormonal, biological and targeted therapies, but the term does not usually encompass the modalities of nutritional, complementary, alternative or other ‘holistic’ interventions, even if employed within a conventional medical environment.

Cytotoxic chemotherapy

Chemotherapy regimen

Although chemotherapy is sometimes administered as a single agent, it is more usual to combine two or more drugs to achieve additive or synergistic effects. Generally, drugs used in combination should have established efficacy as single agents, different mechanisms of action and differing toxicity profiles to allow their use at optimal doses.

Chemotherapy scheduling

Because chemotherapy does not specifically target malignant cells, any actively proliferating normal cell will be at potential risk of damage, in particular the cells of the bone marrow. This causes a fall in the white blood cell count, and with many cytotoxic drugs, the white blood count is at its lowest level (nadir) around 10 days after treatment. Recovery generally occurs by day 20 post-treatment, and therefore chemotherapy treatment is usually repeated every 3–4 weeks. With agents such as mitomycin and lomustine, haematological recovery may be delayed for 42–50 days after treatment, in which case the interval between treatment cycles needs to be increased. In most cases, a course of treatment will comprise a maximum of six cycles of

Fig. 53.3 The effect of chemotherapy on tumour mass and healthy cells.

chemotherapy, although in some less common cancers, such as sarcomas, leukaemias and in paediatrics, the regimen may continue with a much longer period of adjuvant or consolidation therapy. Targeted agents may be continued for long periods, in some cases indefinitely until either tolerance is lost or until disease progression.

Fig. 53.3 demonstrates the tumour cell kill for each cycle of chemotherapy together with the healthy normal cell kill. Chemotherapy works in situations where the healthy normal cells recover faster or more completely from the effects of chemotherapy compared with the tumour cells. This allows the tumour cells to be progressively killed off, whilst not having a detrimental effect on the patient.

Chemotherapy dose

The dose of most chemotherapy agents is calculated using the patient's body surface area (BSA) as a surrogate estimate analogous to lean body mass, or weight (kg), and is usually prescribed in the form of milligrams per square metre or per kilogram. Body surface area may be calculated from the height and weight of the patient using a nomogram or standard formula and may need to be recalculated for subsequent cycles of chemotherapy if the patient experiences significant weight changes. Table 53.4 gives an example of a chemotherapy regimen used in breast cancer. The reliability of body surface area as a predictor of the effective safe dose is diminished for patients who are either very thin (cachectic), grossly overweight (morbidly obese) or in the case of limb deformities or loss because it does not then reflect a reasonable estimate of lean body mass.

Adjuvant chemotherapy

Adjuvant chemotherapy means literally 'additional treatment' and is usually given after surgery or radiotherapy when all

Table 53.4 Example of a chemotherapy regimen FEC-T (fluorouracil, epirubicin, cyclophosphamide, docetaxel [Taxotere]) for breast cancer

Indication	Adjuvant breast cancer	
Length of cycle	21 days	
No. of cycles	Three cycles of FEC followed by three cycles of Taxotere (Docetaxel)	
FEC		
Fluorouracil	IVB	500 mg/m ² day 1
Epirubicin	IVB	100 mg/m ² day 1
Cyclophosphamide	IVB	500 mg/m ² day 1
T		
Docetaxel	IVI over 1 h	100 mg/m ² day 1

IVB, i.v. bolus; IVI, i.v. infusion.

detectable disease has been removed, but where there remains a statistical risk of relapse due to undetectable disease. Adjuvant therapy is, therefore, used to increase the likelihood of cure. Only patients whose cancers have a high or intermediate risk of recurrence tend to be selected for adjuvant chemotherapy because it is not desirable to expose patients whose disease may already have been cured by surgery or radiotherapy to the toxicity of chemotherapy treatment.

In colorectal cancer, for example, adjuvant chemotherapy provides significant disease-free survival benefit by reducing the recurrence rate and also increases overall survival. This indicates the curative role of chemotherapy in the adjuvant setting (Sargent et al., 2009). Similarly, in breast cancer, adjuvant treatment has been shown to increase recurrence-free survival (Levine and Whelan, 2006), and trials are underway to determine which agents and in what combination further improvements in overall survival will be obtained. One trial has shown that three-weekly AC/T (doxorubicin, cyclophosphamide, docetaxel [Taxotere]) is significantly inferior to CEF (cyclophosphamide, epirubicin, 5-fluorouracil) or EC/T (epirubicin, cyclophosphamide, docetaxel [Taxotere]) in terms of recurrence-free survival (Burnell et al., 2010). This is important for development of healthcare system therapeutic management planning because standard treatment choices should move to the superior regimen.

Neo-adjuvant chemotherapy

In neo-adjuvant chemotherapy, chemotherapy is given before local therapy, often preoperatively, to reduce tumour size and facilitate surgical removal. Neo-adjuvant chemotherapy has been of particular value in cases of breast cancer, non-small-cell lung cancer, advanced head and neck cancer, and bone tumours. In Ewing's sarcoma, it allows limb-sparing surgery as an alternative to amputation. It also improves survival with reduced morbidity in osteosarcoma.

Synchronous chemoradiation

In several cancers, chemotherapy alongside radical radiotherapy is now established. Agents such as cisplatin are commonly used as a 'radiosensitiser' in head and neck, oesophageal and cervical cancers. The use of cetuximab in combination with radiotherapy for a certain type of head and neck cancer is also recommended (NICE, 2008). Although in common use, the use of the term *radiosensitiser* in this context is somewhat inaccurate and is distinct from the 'true' radiosensitising drugs such as nimorazole, which interact at a chemical level with very short-lived radiation-induced free radicals, and the effect is more appropriately termed 'combined modality therapy'.

Adverse effects of cytotoxic drugs

Most cytotoxic drugs have been developed because of their effect on dividing cells. Consequently, and as previously mentioned under chemotherapy scheduling, proliferating normal tissue such as bone marrow is at risk. Myelosuppression is frequently the dose-limiting toxicity with these compounds. Neutropenia and thrombocytopenia place patients at risk of life-threatening infection and bleeding, respectively.

The other acute adverse effects occurring most frequently include nausea and vomiting, mucositis, anorexia and alopecia. Individual drugs will also give rise to specific adverse effects, some of which may not be reversible on stopping treatment. Cardiotoxicity, nephrotoxicity and pulmonary toxicity, which are specific to the chemotherapeutic agent or class, may depend on cumulative drug exposure, the schedule of administration and previous therapy. Long-term side effects include infertility due to suppression of ovarian and testicular function and occasionally the induction of a second malignancy.

Chemotherapy-related toxicity is an important issue. Not only can it result in prolonged hospitalisation and a reduction in patients' quality of life, but also successful treatment can be compromised. A reduction in dose intensity, that is, the dose of cytotoxic delivered per unit time, because of dose reductions or treatment delays, can result in reduced response rates and survival. The use of granulocyte-colony-stimulating factors (G-CSFs) to prevent dose-limiting toxicity of myelosuppression can help reduce dose reductions or treatment delays. This is often used in treatments where the dose intensity given is paramount, and the goal of treatment is cure, for example in testicular germ-cell cancer.

Chemotherapy-specific adjunctive treatments

Both ifosfamide and cyclophosphamide are metabolised to the inactive acrolein which is responsible for bladder toxicity. The co-administration of mesna, a sulfhydryl-containing compound which binds to acrolein, has reduced the incidence of haemorrhagic cystitis associated with intravenous regimens of ifosfamide and high-dose cyclophosphamide.

Calcium leucovorin or folinic acid is a reduced form of folic acid and is in effect an 'antidote' to the cytotoxic methotrexate. Folinic acid is effectively used as a form of 'rescue' when high

doses of intravenous methotrexate are used, to limit the exposure to the cytotoxic effect to a defined period of time, usually 24 hours.

Targeted therapies

In recent years, there has been a greatly increased understanding of biochemical signalling pathways involved in the growth and progression of tumours. This has allowed the development of therapies targeted specifically at the cell receptors involved. Because they are targeted at tumour cells, they can suppress disease without inflicting the non-selective toxic effects of cytotoxic chemotherapy on the patient.

Epidermal growth factor receptor

The epidermal growth factor receptor (EGFR) is a transmembrane protein with an intracellular tyrosine kinase domain. Extracellular binding of the epidermal growth factor receptor induces tyrosine phosphorylation which activates signal cascade pathways. These ultimately lead to cellular proliferation and metastasis. Epidermal growth factor receptor expression is low in normal tissues, and overexpression is associated with a variety of tumours, including non-small-cell lung cancer, colon cancer and head and neck cancer.

Inhibitors of epidermal growth factor receptor (also known as human epidermal growth factor receptor type 1 [HER1]) include the following:

- Small molecules such as the orally administered erlotinib, gefitinib and adatinib used in the treatment of non-small-cell lung cancer and afatinib used in the treatment of gastrointestinal stromal tumours (GIST) specifically inhibit tyrosine kinase.
- Monoclonal antibodies, such as cetuximab and panitumumab, bind to the epidermal growth factor receptor. Cetuximab has demonstrated synergy when given in combination with irinotecan chemotherapy, offering prolonged survival in selected patients with metastatic colorectal cancer and improved disease control when given in combination with radiotherapy in selected cases of head and neck cancer.

Vascular endothelial growth factor receptor

Angiogenesis is the formation of new blood vessels on which tumour growth depends. Vascular endothelial growth factor (VEGF) is key in angiogenesis, and its overexpression has been associated with increased vasculature, aggressive disease and poor prognosis. The monoclonal antibody bevacizumab inhibits VEGF, thereby reducing new blood vessel growth and interstitial pressure within the tumour, allowing improved chemotherapy access. Studies have demonstrated meaningful survival benefits when bevacizumab is administered in conjunction with chemotherapy in patients with advanced or metastatic colorectal cancer (Hurwitz et al., 2004). Pazopanib is a tyrosine kinase inhibitor and inhibits VEGF. It is used in the treatment of renal cell carcinoma.

Human epidermal growth factor receptor type 2

Overexpression of human epidermal growth factor receptor type 2 (HER2) is associated with a particularly aggressive form of breast cancer (about 20% cases are HER2 positive) and 7–34% of gastric cancers. Trastuzumab, a humanised monoclonal antibody, specifically targets HER2 and is only effective in patients with elevated levels. It is used widely in metastatic and early breast cancer (NICE, 2002, 2006a) and HER2 positive metastatic gastric cancer (NICE, 2010). Pertuzumab, a humanised monoclonal antibody, inhibits dimerisation of HER2 receptors and is used in combination with trastuzumab for breast cancer.

Trastuzumab emtansine is a HER2-targeted antibody–drug conjugate which contains trastuzumab, covalently linked to the microtubule inhibitor DM1. When trastuzumab attaches to the HER2 receptor it releases emtansine into the cancer cell. Emtansine binds to tubulin and inhibits tubulin polymerisation; both DM1 and trastuzumab emtansine cause the cancer cells to arrest in the G2/M phase of the cell cycle, leading to apoptotic cell death.

Capecitabine

Although capecitabine does not target a particular receptor, it is mentioned in this section because it preferentially targets tumour cells.

Capecitabine is a fluoropyrimidine carbamate precursor of 5-fluorouracil (5FU). Given orally, it is converted via enzyme pathways to 5-FU. Because these enzymes are found in higher concentrations in tumour cells, treatment is effectively targeted. Capecitabine has been shown to be at least as effective as intravenous 5-FU (Twelves et al., 2012), and it is widely used in practice. This is of a particular benefit where the total regimen can then be given orally rather than intravenously. Clinical use of capecitabine requires caution because although it is very easy to administer as an apparently simple oral tablet, the toxicity is comparable to intravenous fluoropyrimidine therapy, and a small proportion of the population are exceedingly sensitive due to an inherited defect in the enzyme dihydropyrimidine dehydrogenase (DPD; Cancer Research UK, 2016b).

Management of patients receiving cytotoxic chemotherapy

Prescription verification

Over the years, there has been considerable effort to improve the quality and safety of chemotherapy services for adult patients. In particular, the importance of all chemotherapy prescriptions being checked by appropriately trained and competent pharmacists is now recognised. The British Oncology Pharmacy Association (BOPA) has published standards for pharmacy verification of prescription for cancer medicines (BOPA, 2013). These BOPA standards are summarised in Box 53.2. These were supplemented in 2015 by standards for associated e-prescribing systems (BOPA, 2015).

Box 53.2 Standards for pharmacy verification of prescriptions for cancer medicines (BOPA, 2013)

1. Check the prescription.

- Has the drug or regimen been prescribed in line with legislation and local prescribing policy?
- Check that the prescriber's details and signature are present, and confirm the prescriber is authorised to prescribe SACT as appropriate
- Check that the prescription is clear, legible, unambiguous and includes all details required for dispensing, labelling and administration

2. Check the prescription against the protocol and treatment plan.

This will include as appropriate/relevant:

- Ensuring the regimen has been through local approval processes (e.g. clinical governance and financial approval) and/or is included on a list of locally approved regimens
- Where there is access to either clinical notes, treatment plan or electronic record on first cycle, check that the regimen is intended treatment and is appropriate for patient's diagnosis, medical history, performance status and chemotherapy history

3. Check patient details.

- Check that patient demographics (age, height and weight) have been correctly recorded on prescription as appropriate

4. Check administration details.

This will include the following as appropriate/relevant:

- Checking that there are no known drug interactions (including with food) or conflicts with patient allergies and other medication(s)
- Checking that the timing of administration is appropriate (i.e. interval since last treatment and/or start and stop dates for oral chemotherapy)
- Checking that appropriate supportive care is prescribed
- Checking that the method of administration is appropriate

5. Check calculations: are the BSA and dose calculations correct?

- Check that all dose calculations and dose units are correct and have been calculated correctly according to the protocol and any other relevant local guidance (e.g. dose rounding/banding) as appropriate.
- Check that prescribed dose is in line with previous dose reductions
- Check that BSA is correctly calculated if needed for dose calculation. There should be local agreement for frequency of monitoring and checking patient's weight.

6. Check laboratory results as appropriate.

- Check that laboratory values, FBC, U&Es and LFTs are within accepted limits if appropriate.
- Check that doses are appropriate with respect to renal and hepatic function and any experienced toxicities.
- Check that other essential tests have been undertaken if appropriate.

7. Sign and date prescription as a record of verification.

BSA, Body surface area; FBC, full blood count; LFTs, liver function tests; SACT, systemic anticancer therapy; U&Es, urea and electrolytes.

Cumulative dosing

The use of doxorubicin is limited by a dose-dependent cardiomyopathy. Various other factors have been implicated, including treatment schedule, patient age and pre-existing cardiac disease, but dose is the most important. The maximum recommended cumulative dose is 550 mg/m², reducing to 400 mg/m²

for patients who have received radiotherapy to the mediastinum. Therefore, treatment should be monitored closely to make sure the cumulative dose is not exceeded throughout the patient's lifetime. All other anthracycline antibiotics also have a lifetime cumulative dose limit.

Dose modification or delay

Appropriate investigations must be carried out before each treatment to ensure that patients are fit for chemotherapy. In particular, the patient's haematological, renal and hepatic function should be determined by blood testing and further investigation as indicated. For some cytotoxic drugs, it may be necessary to adjust the dose, or even stop treatment, in the presence of renal or hepatic impairment to ensure that delayed excretion or reduced metabolism does not result in excess toxicity. Therefore, the individual summary of product characteristics (SPC) for the chemotherapy agent should be consulted; SPCs can be found at <http://www.medicines.org.uk>.

If the bone marrow does not recover sufficiently between cycles of treatment, then a dose reduction or a delay in treatment may be necessary. In general, patients with a neutrophil level less than $1 \times 10^9/L$ or a platelet count less than $100 \times 10^9/L$ should not be given myelosuppressive cytotoxics at full doses (note that different ranges will apply for hematological malignancies and when specified in solid-tumour schedules such as germ-cell malignancy).

Drug interactions

Prescriptions for cancer chemotherapy are often complex, sometimes involving combinations of both parenteral and oral cytotoxic drugs, intravenous fluids and other supportive therapies. The potential for drug interactions to arise is considerable. However, care is required when assessing the clinical significance of potential drug interactions. A documented interaction does not necessarily imply that drugs should not be used in combination but can necessitate close monitoring of the patient.

Patient information and counselling

All patients must be provided with information about their treatment, including any anticipated side effects. Patients should be encouraged by health professionals to ask questions about their treatment.

Patients must understand the different medication, the specific role of each medicine and the duration of treatment. Duration of treatment is particularly important to prevent highly potent medicines from being inadvertently continued beyond their intended course.

Symptom control

Nausea and vomiting

Chemotherapy-induced nausea and vomiting (CINV) is one of the most frequently experienced side effects encountered by chemotherapy patients and is considered to be the most distressing. In extreme cases, poor symptom control can result in patients refusing further treatment.

In selecting an appropriate antiemetic regimen, relevant factors include the emetogenic potential of the chemotherapy drugs prescribed, the putative mechanism(s) of inducing emesis, and the likely onset and duration of symptoms. Individual patient characteristics also have to be taken into consideration. For example, predisposing factors which increase a patient's susceptibility to emesis as a result of chemotherapy treatment are as follows:

- Poor control with prior chemotherapy
- female sex
- younger age <50 years
- a current or prior history of low chronic alcohol intake
- history of sickness: pregnancy/travelling/surgery
- anxiety
- smoking
- radiation to gastro-intestinal tract, liver or brain
- other medications: various medications can cause nausea and vomiting such as anaesthetic agents, antidepressants, antimicrobials, antifungals, iron, levodopa, carbidopa, NSAIDs

Differences in the severity of emesis can also occur between patients receiving the same type of chemotherapy and even between treatment cycles in the same patient; however, modern drug treatment can successfully control CINV for the majority of patients.

The 5-hydroxytryptamine type 3 (5HT₃) receptor antagonists, which include dolasetron, granisetron, ondansetron, palonosetron and tropisetron, have become the standard management of acute CINV when treating patients with moderately emetogenic chemotherapy regimens. For highly emetogenic chemotherapy regimens such as those including cisplatin, the use of the NK₁ inhibitor, aprepitant or netupitant, together with a 5HT₃ antagonist is becoming the gold standard. These agents are most effective in dealing with acute emesis (duration of <24 hours) when combined with a potent steroid such as dexamethasone.

It is important to achieve optimal control of nausea and vomiting at the outset to avoid subsequent anticipatory symptoms which can prove very difficult to treat.

The route of administration for antiemetics is an important consideration. With intravenous chemotherapy, it may be simpler to administer all treatments by the intravenous route. Alternatives to the oral route may be useful when vomiting occurs and include the rectal and buccal route.

Pain control

Drug therapy remains one of the cornerstones of effective pain management, but it is often underprescribed, thus highlighting the importance of regular patient assessment and appropriate dose or drug treatment changes. For example, patients experiencing intolerable side effects to morphine may be transferred to oxycodone or transdermal fentanyl skin patches. Analgesia should be prescribed both regularly and for breakthrough pain, and stimulant laxatives should be prescribed to prevent opioid-related constipation. Combinations of analgesics which have synergistic activity, for example, opiates plus NSAIDs, can be highly effective whilst minimising the dose-related side effects of each agent.

The route of administration is also important. When patients are unable to manage oral medication, it is important to assess the use of alternative routes such as the rectal, subcutaneous, epidural and transdermal routes.

Table 53.5 National Cancer Institute Common Terminology Criteria for Adverse Events v4.0: anaemia (haemoglobin) (NCI, 2010).

Adverse event, grade	0	1	2	3	4
Haemoglobin (Hgb)	WNL	<LLN–10.0 g/dL	8.0–<10.0 g/dL	6.5–<8.0 g/dL	<6.5 g/dL
	<LLN–100 g/L	80–<100 g/L	65–<80 g/L	<65 g/L	<LLN–100 g/L
	<LLN–6.2 mmol/L	4.9–<6.2 mmol/L	4.0–<4.9 mmol/L	<4.0 mmol/L	<LLN–6.2 mmol/L

LLN, Lower limit of normal; WNL, within normal limits.

Bone marrow suppression

Myelosuppression after chemotherapy is common, and for some patients profound. The risk of systemic infection can be reduced by good oral hygiene and mouth care using antiseptic mouthwashes and antifungal prophylaxis. Patients must be advised to immediately report symptoms of infection and bruising. Platelet transfusions may be required, but fever or other evidence of infection occurring in a neutropenic patient when the neutrophil count is less than $1.0 \times 10^9/L$ must be aggressively treated with broad-spectrum intravenous antibiotics to prevent overwhelming infection. Most treatment centres will have developed and implemented a local policy for management of suspected ‘neutropenic sepsis’ with a recommended antibacterial schedule.

The duration and depth of neutropenia can be dramatically reduced by the administration of G-CSFs, which stimulate neutrophil production and, in cases of severe neutropenia, effectively rescue the patient. Once the patient’s neutrophil count has recovered sufficiently, their use may be safely discontinued. These agents may also be used prophylactically in patients with a high risk of febrile neutropenia before receiving chemotherapy.

Blood transfusions are commonly required by patients at some stage of their treatment due to anaemia. Alternatively, erythropoietin may be useful in some patients receiving chemotherapy to shorten the period of anaemia and to improve the patient’s quality of life where blood transfusions are not possible.

Extravasation

Extreme care must be taken when administering cytotoxic drugs parenterally because of the dangers of extravasation. Extravasation, which is the accidental leakage of an intravenous drug into the surrounding tissue, can cause pain, erythema and severe local necrosis, resulting in permanent tissue damage. The patient must be asked to immediately report any pain or a stinging sensation at the injection site because the degree of damage is determined by the amount of drug extravasated and the speed at which it is detected. If extravasation is suspected, the administration of further chemotherapy must stop, and remedial treatment must commence as soon as possible. The effectiveness of such therapy varies according to the agent extravasated. Most treatment facilities will have developed and implemented a policy for the management of extravasation according to the agent involved.

In-patient or outpatient treatment

The majority of patients receive chemotherapy in the outpatient clinic or day-care setting, where cytotoxics are administered mainly by short intravenous infusion at 3- or 4-week intervals.

Other treatments include monoclonal antibodies, which usually require close monitoring of the patient for several hours in case of anaphylactic reactions. More complex treatments, such as cisplatin-containing regimens which require prehydration with intravenous fluids, need the patient to attend all day.

Currently, in-patient treatment of chemotherapy only occurs for the small minority of treatments, and this number is declining further as novel ways of administering long infusions are being developed.

Domiciliary treatment

Oral cytotoxic drugs can safely be taken at home so long as the patient is informed and able to monitor side effects. Availability of a 24-hour helpline is essential for these patients should they encounter problems whilst on treatment. In the future, administration of intravenous treatments, such as the monoclonal antibody trastuzumab, may be carried out more frequently in the home setting, particularly when safety permits and where patient preference becomes an influential factor.

Monitoring anticancer therapy

In addition to desirable outcomes, treatment with chemotherapy may result in a variety of undesirable outcomes; both require careful monitoring.

Toxicity

The toxicity resulting from treatment is routinely assessed after each cycle of chemotherapy and may result in therapy being modified on subsequent cycles, for example, a dose reduction, a delay in treatment or, in some cases, an alternative treatment. A number of international rating scales are available for rating predictable acute reactions arising from chemotherapy, including that of the National Cancer Institute Common Toxicity Criteria (NCI, 2010). For an example, see Table 53.5. Standardising the assessment of treatment-related toxicity in this way allows comparison to be made between published reports of clinical trials.

Response to treatment

Throughout treatment, the response to therapy is closely monitored, noting changes in performance status, symptoms and objective measurements of the tumour. This may necessitate repeating some or all of the initial staging investigations. Should the initial treatment prove ineffective, an alternative can then be considered without delay. Assessment of response should be formally documented before proceeding to further therapy.

Definitions of response. Definitions of response have been standardised by WHO:

- **Complete response or remission (CR).** The disappearance of all recognisable tumour masses and/or biochemical changes directly related to the tumour and resolution of symptoms determined by two observations at least a month apart.
- **Partial response (PR).** Decrease by 50% or more in all tumour masses, measured by the product of the longest \times the widest perpendicular diameters for at least a month.
- **Stable disease (SD) or no change (NC).** Changes smaller than those described for PR or less than for progressive disease for at least a month.
- **Progressive disease (PD).** The occurrence of any new lesion or increase in the longest \times widest perpendicular diameters of measurable disease by at least 25%.

Again, this allows comparison of results between different reported studies. An update of the WHO guidelines has been published (Therasse et al., 2000) called Response Evaluation Criteria in Solid Tumours (RECIST). To avoid confusion, it is important to stipulate in trial protocols which system will be used. Although clinical response indicates tumour sensitivity, it may not necessarily predict long-term survival, nor does it measure other benefits such as quality of life.

Case studies

Case 53.1

Mrs BH, a 53-year-old post-menopausal mother of two teenage children, has recently completed six cycles of FEC(100)-T (5-fluorouracil, epirubicin, cyclophosphamide, docetaxel) as adjuvant chemotherapy for her node-positive early breast cancer. She tolerated her chemotherapy well and did not require any dose reductions or delays.

Her receptor status at diagnosis was oestrogen receptor positive and progesterone receptor positive (ER+/PR+); she was also HER2 positive.

Her oncologist has recommended that she commences adjuvant treatment with trastuzumab.

Questions

1. What treatment regimen for trastuzumab should be followed?
2. How long will Mrs BH have to continue treatment with trastuzumab?
3. What other treatments should be considered for this patient?

Answers

1. Trastuzumab targets the epidermal growth factor receptor (EGFR) and is indicated for the treatment of early breast cancer overexpressing HER2 after surgery, chemotherapy (neo-adjuvant or adjuvant) and radiotherapy if applicable as recommended by NICE (2006a). The product license for trastuzumab recommends the dosing schedule used in the HERA study (Piccart-Gebhart et al., 2005), that is loading dose of 8 mg/kg body weight, followed by 6 mg/kg body weight 3 weeks later and then 6 mg/kg repeated at three-weekly intervals administered as infusions over approximately 90 minutes.

2. It is recommended to continue for 12 months, stopping sooner if disease reoccurs, or if unacceptable toxicity appears.
3. In view of her receptor status, this patient should be offered hormonal treatment. Depending on the perceived level of risk of recurrence as estimated using a model such as the Nottingham Prognostic Index (Galea et al., 1992), she should be offered either 5 years' treatment with an aromatase inhibitor or planned sequential treatment with tamoxifen, switching to an aromatase inhibitor after 2–3 years' therapy. The long-term effect on cardiovascular health (tamoxifen) or bone health (aromatase inhibitors) together with the expected level of benefits should be used to guide the choice of treatment. Further information can be found in national guidance for the early management of breast cancer with hormonal treatments (NICE, 2006a).

Case 53.2

Mr BS, a 67-year-old man with a history of localised prostate cancer, is reviewed by his oncologist. Mr BS was previously treated with radical radiotherapy and more recently several lines of hormonal therapy.

His PSA has risen over the last 6 months and is now 80 ng/mL. It was 0.1 ng/mL on completion of radical radiation therapy. He also complains that his longstanding back pain controlled by low-dose NSAIDs has now become much worse and is out of control.

Questions

1. What is the most likely cause of Mr BS's back pain and raised PSA?
2. What treatment options should be discussed with the patient?
3. Why should he be referred for a dental examination before commencing any further treatment?

Answers

1. The fact that the PSA is markedly raised suggests a recurrence of prostate cancer. Moderate rises in the PSA would have warranted a change in hormonal therapy. The elevated PSA together with the increased back pain suggests metastatic bone disease as a result of distant recurrence of his prostate cancer. This could be confirmed with plain film X-rays or by bone scan. The risk of both local and distant recurrence depends on the stage at presentation.
2. Treatment options for recurrent prostate cancer include further hormonal therapy, chemotherapy with or without corticosteroids, and best supportive care. Localised radiotherapy to specific bone lesions could improve his back pain; this would depend on the distribution of treatable lesions identified. The choice of therapy depends on the symptoms, the site of relapse, performance status of the patient and the presence of other comorbidities. Best supportive care can be provided with radiotherapy, bisphosphonates, steroids and analgesics and is the only option for patients who are too ill to tolerate further systemic intervention. Tolerability of chemotherapy is of concern, particularly because most patients with prostate cancer are elderly and many have other medical problems. Mr BS has already received more than one line of hormonal therapy; his tumour is unlikely to respond to further hormonal manipulation. An alternative strategy that is available is the use of radioactive isotopes such as Strontium 89 for systemic treatment of multiple bone metastases. The use of chemotherapy in the treatment of hormone-refractory prostate cancer should be considered in patients with a Karnofsky performance status of 60% or greater. Further information on the use of docetaxel for the treatment of hormone-refractory metastatic prostate cancer is available (NICE, 2006b).

- Future treatment options for this patient may include the use of bisphosphonates to stabilise his bone lesions and reduce his pain. Long-term use of bisphosphonates has been associated with osteonecrosis of the jaw; the risk is exacerbated by poor dental hygiene, concurrent dental procedures, chemotherapy, corticosteroids and malignant disease. Examination and preventive dental treatment should be considered for patients before commencing therapy with bisphosphonates to avoid any invasive procedures, for instance, dental extraction, during bisphosphonate therapy.

Case 53.3

Mr SG, a 46-year-old patient, was diagnosed with colon cancer several months ago. Since then, he has undergone a left hemicolectomy. He is currently receiving capecitabine monotherapy as adjuvant treatment. He telephones the pharmacy department for advice on how to cope with the side effects he is currently experiencing.

Questions

- What side effects are commonly associated with capecitabine?
- How do these differ from those associated with intravenous 5FU?
- What advice should Mr SG be given?

Answers

- Side effects most commonly associated with capecitabine treatment are mainly related to the skin and the gastro-intestinal tract:
 - palmar–plantar erythema (hand–foot syndrome), 57%;
 - diarrhoea, 47%;
 - nausea, 35%;
 - stomatitis, 23%;
 - vomiting, 18%;
 - fatigue, 16%;
- Although capecitabine is converted enzymatically to 5FU, there is a difference in the frequency with which specific side effects are experienced, making it more akin to continuous infusions of 5FU. Patients receiving intermittent bolus therapy with 5FU are more likely to experience the gastro-intestinal side effects, particularly diarrhoea or stomatitis, rather than the cutaneous reactions. Myelosuppression may also infrequently be a problem encountered by these patients.
- Mr SG should be instructed to contact the emergency telephone number he would have been given with his treatment from the hospital looking after him, especially if there is any reason to suspect infection (e.g. feverishness). If detected early, side effects usually improve within 2–3 days. Treatment may be reinstated at the same dose if side effects are moderate, or at a reduced dose if more severe. Symptomatic relief for palmar–plantar erythema may be provided by the use of emollients. There is little evidence to support the use of specific antidotes.

Case 53.4

Mrs PQ, a 59-year-old woman, has non-small-cell lung cancer. She has had a course of gemcitabine combined with carboplatin and now requires second-line chemotherapy. The doctor has suggested erlotinib.

Questions

- What type of treatment is erlotinib, and how is it given?
- What common side effects should Mrs PQ be informed about when she is giving consent for treatment?
- What other treatments should be considered for Mrs PQ?

Answers

- Erlotinib is an epidermal growth factor receptor/human epidermal growth factor receptor type 1 (EGFR; also known as HER1) tyrosine kinase inhibitor. Erlotinib potently inhibits the intracellular phosphorylation of EGFR. Epidermal growth factor receptor is expressed on the cell surface of normal cells and cancer cells. In non-clinical models, inhibition of EGFR phosphotyrosine results in cell stasis and/or death. It is an oral tablet given once a day until disease progression or unacceptable toxicity.
- Rash (75%) and diarrhoea (54%) were the most commonly reported adverse drug reactions (ADRs). In general, rash manifests as a mild or moderate erythematous and papulopustular rash, which may occur or worsen in skin areas exposed to the sun. For patients who are exposed to the sun, protective clothing, and/or use of sun screen (with minimum SPF 15, e.g. mineral-containing) may be advisable. The rash generally starts about 8–10 days after starting treatment but usually improves after a few weeks. Diarrhoea is usually mild and can be controlled with anti-diarrhoeal drugs. Fatigue, nausea and vomiting and sore mouth are also quite common. Some people also develop sore, red eyes (conjunctivitis) or dry eyes.
- Cytotoxic therapy with docetaxel is an alternative second-line treatment currently available for the treatment of non-small-cell lung cancer, although the use of alternative targeted agents may also be available in some health-care systems.

Case 53.5

Mrs GH is a 64-year-old woman with lung cancer. She has had several cycles of chemotherapy and had her third cycle of cisplatin/vinorelbine 7 days ago. She is due her day 8 vinorelbine tomorrow. Mrs GH is feeling 'a bit unwell', and her husband thinks she is not at all her usual self and is, therefore, worried about her.

Questions

- What side effect may Mrs GH be suffering from?
- How would you explain to Mrs GH how to take her oral vinorelbine?
- What are the possible patient safety concerns regarding oral chemotherapy?

Answers

- Mrs GH may be suffering from neutropenic sepsis. The signs can be difficult to identify with a small elevation in temperature and a general feeling of not being well. If she is suffering from neutropenic sepsis, it is important that Mrs GH is prescribed i.v. antibiotics as soon as possible before she succumbs to an infection. Chemotherapy patients are all at varying degrees of risk of neutropenic sepsis due to the marked decrease in neutrophils in the body due to the chemotherapy. She should also have a blood test to check her neutrophil level, but the administration of antibiotics should not wait for these results. Each hospital will have guidelines or a protocol in place to treat neutropenic sepsis in patients receiving chemotherapy. She will need to call the hospital emergency chemotherapy number.
- Take the vinorelbine dose on day 8 with a glass of water.

- Healthcare workers and their staff must be made aware that the prescribing, dispensing and administering of oral anticancer medicines should be carried out and monitored to the same standard as injected therapy. This requires the following:
 - Healthcare organisations are to prepare local policies and procedures that describe the safe use of these oral medicines.
 - Treatment is to be initiated by a cancer specialist.
 - All oral anticancer medicines are to be prescribed only in the context of a written protocol and treatment plan
- Non-specialists who prescribe or administer ongoing oral anticancer medication must have ready access to appropriate written protocols and treatment plans.
- Staff dispensing oral anticancer medicines must be able to confirm that the prescribed dose is appropriate for the patient.
- Patients are to be fully informed and receive verbal and up-to-date written information about their oral anticancer therapy from the initiating hospital.

54 Rheumatoid Arthritis and Osteoarthritis

Tina Hawkins

Key points

Rheumatoid arthritis

- Approximately 1% of the population worldwide is affected by rheumatoid arthritis.
- The peak age of onset in the UK is between 40 and 70 years.
- Rheumatoid arthritis is about two to four times more prevalent in women than in men.
- The cause of rheumatoid arthritis remains unclear.
- Disease-modifying anti-rheumatic drugs (DMARDs) should be commenced as soon as a diagnosis is made.
- Disease-modifying drugs include conventional DMARDs (e.g. methotrexate), biologic DMARDs (e.g. tumour necrosis factor inhibitors) and targeted synthetic agents (e.g. baricitinib and tofacitinib).
- Glucocorticoids are initiated while awaiting the onset of action of DMARDs.
- The ideal is clinical remission, or if this is not achievable low disease activity.
- Uncontrolled disease is associated with significant morbidity and early mortality.

Osteoarthritis

- Osteoarthritis is a degenerative disorder of the joints that commonly affects the knee, hip, hands and spine.
- It is the most common musculoskeletal condition in older people.
- The cause of osteoarthritis is unknown.
- Risk factors for the development of osteoarthritis include increasing age, obesity, gender, bone density, joint injury, occupation and genetics.
- No medical treatments are proven to prevent or delay the onset of osteoarthritis.
- Non-pharmacological measures such as weight loss, structured exercise programmes and supportive aids form the cornerstone of management.
- Pharmacological treatments such as paracetamol and topical or oral non-steroidal anti-inflammatory drugs are used as adjuncts to provide moderate symptomatic relief.

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic autoimmune condition characterised by inflammation of the synovium of joints combined with a number of additional systemic effect features resulting from abnormal immune response and secondary inflammation. Common joints affected include the proximal

interphalangeal joints (PIPs) and metacarpophalangeal joints (MCPs) of the hands, wrists, knees, ankles and small joints of the feet. It is not purely a disease of the joints; extra-articular manifestations may affect the lungs, skin, blood, eyes and other organs of the body. There is no cure for RA. In early disease, management aims to suppress disease activity and induce remission, prevent loss of function, control joint damage, control pain and enhance self-management. Disease-modifying anti-rheumatic drugs (DMARDs) should be commenced upon diagnosis and adjusted in a timely manner to achieve the aim of clinical remission. In established disease, management should address complications and associated comorbidity, as well as the effect of the condition on the person's quality of life.

Epidemiology

Approximately 1% of the population worldwide is affected by RA. It is estimated that there are around 400,000 people with RA in the UK, and of these, approximately 15% have severe disease ([National Institute for Health and Care Excellence \[NICE\], 2015a](#)). RA is about two to four times more prevalent in women than in men. It can develop at any age, but the peak age of onset in the UK is between 40 and 70 years. Patients with RA have a shortened life expectancy and an increased risk of other diseases including cardiovascular and malignant disease (e.g. lymphoma). A poorer prognosis is associated with a positive rheumatoid factor (RF), raised inflammatory markers, early radiographic joint damage and the presence of tender/swollen joints. Early referral to a rheumatologist is essential.

Aetiology and pathophysiology

The cause of RA remains unclear, with hormonal, genetic and environmental factors playing a key role. Genetic factors contribute 53–65% of the risk of development of this disease. The HLA-DR4 allele is associated with both the development and severity of RA. There is now a large body of work that has identified a link between smoking and the incidence of RA. Smoking has been shown to reduce remission rates in men and women, but it causes a greater reduction in response to treatment in the male RA population ([Inoue et al., 2015](#)).

Fig. 54.1 Joint affected by rheumatoid arthritis. The inflamed synovium spread across the joint surface forming a 'panus'. There is subsequent thinning of the cartilage and bone erosion. (Reproduced from Arthritis Research UK, with permission.)

More recent research has identified a relationship between periodontal inflammation and RA, although it is unclear whether periodontal disease is a trigger for RA, a propagating factor, a target of circulating autoimmunity or all three of these (Payne et al., 2015). An association has also been found between the microbiome of the gut (and other mucosal areas) and RA activity in Chinese patients; specifically, certain organisms were associated with changes in disease activity (Zhang et al., 2015).

Pathologically, RA is characterised by the infiltration of a variety of inflammatory cells into the joint. The synovial membrane, which is normally acellular, becomes highly vascularised and hypertrophied, creating a so-called pannus formation, as shown in Fig. 54.1. There is proliferation of synovial fibroblasts and an increase in the number of inflammatory cells present within the joint. The inflammatory cells involved in RA include T cells (predominantly CD4 helper cells), B cells, macrophages and plasma cells. Cytokines are released by these cells which cause the synovium to release proteolytic enzymes, resulting in the destruction of bone and cartilage. Key cytokines involved in RA include tumour necrosis factor (TNF)- α , interleukin-1 (IL-1), IL-6 and granulocyte macrophage colony-stimulating factor. These play a crucial role in the pro-inflammatory reaction.

Clinical manifestations

There are different patterns of clinical presentation of RA. The disease may present as a polyarticular arthritis with a gradual onset, intermittent or migratory joint involvement, or a monoarticular onset. In addition, extra-articular manifestations may be present (Box 54.1). Extra-articular features are associated with a poorer prognosis, but they are less commonly encountered now because of earlier diagnosis of the disease and earlier introduction of appropriate DMARD therapy.

Box 54.1 Examples of the extra-articular features of rheumatoid arthritis

- Amyloidosis
- Carpal tunnel syndrome
- Episcleritis
- Felty's syndrome
- Fever
- Lymphadenopathy
- Nodules; may be subcutaneous or within the lungs, eyes or heart
- Osteoporosis
- Pericarditis
- Pleural and pericardial effusions
- Scleritis
- Vasculitis

Rheumatoid arthritis (late stage)

Boutonnière deformity of thumb

Ulnar deviation of metacarpophalangeal joints

Swan-neck deformity of fingers

Boutonnière deformity

Fig. 54.2 Typical ulnar deviation, swan neck and boutonnière deformities.

Disease onset is usually insidious with the predominant symptoms being pain, stiffness and swelling. Typically, the metacarpophalangeal interphalangeal joints and PIPs of the fingers, interphalangeal joints of the thumbs, the wrists and metatarsophalangeal joints of the toes are affected during the early stages of the disease. RA-associated deformities affecting multiple joints of the hands are shown in Fig. 54.2. Other joints of the upper and lower limbs, such as the elbows, shoulders and knees, are also affected. Morning stiffness may last for 30 minutes to several hours and usually reflects the severity of joint inflammation. Up to one-third of patients also suffer from prominent myalgia, fatigue, low-grade fever, weight loss and depression at disease onset.

RA shows a marked variation of clinical expression in individual patients both in the number and pattern of joints affected, disease progression and the rapidity of joint damage. Disease activity may not abate in 10–20% of cases. Remission has been reported in a small proportion of patients but usually is rare without DMARDs.

Diagnosis

A clinical diagnosis of RA is made based on the patient's history, presenting symptoms and clinical findings. Family history is useful, as well as investigations including blood tests, ultrasound for the presence of synovitis and X-rays. The presence of joint destruction indicates that the disease may have been active for a period of time before a formal diagnosis being made.

Emphasis on early diagnosis and treatment is extremely important to prevent disease activity, duration and ultimately joint destruction. The American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) use a score-based algorithm in diagnosing RA. The scoring system consists of four categories, A–D (Table 54.1), and a score of at least 6 out of 10 is required for a classification of RA. Parameters include the number and type of joints affected, the patient's serology (RF and anti-citrullinated antibodies), the presence of raised acute-phase reactants (C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]) and symptom duration.

Investigations

Inflammatory markers

Inflammatory markers, including CRP and ESR, are usually, but not always, elevated in active disease and are useful for monitoring response to treatment. It should be noted that CRP and ESR are non-specific and may be elevated as a consequence of other pathologies including infection and malignancy.

Serology

RF was the initial defining auto-antibody in RA. It is an antibody against the Fc portion of immunoglobulin G (IgG). RF and IgG combine to form complexes that contribute to the disease process. Although used as a test in the diagnosis of RA, a positive result may be due to another cause and a negative result does not rule out a diagnosis of RA. Approximately 80% of individuals with RA will be positive for RF, and it may precede symptom onset by years. The presence of RF in RA is associated with a poorer prognosis. Other conditions associated with an elevated RF include chronic hepatitis, primary biliary cirrhosis, chronic viral infection, bacterial endocarditis, leukaemia, dermatomyositis, infectious mononucleosis, systemic sclerosis and systemic lupus erythematosus (SLE).

Raised anti-citrullinated peptide antibodies (ACPAs), also referred to as anti-citrullinated protein antibodies (anti-CCPs), are a marker of RA. Post translational modification of arginine residues to citrulline is the antigen recognised, and it has a higher specificity for distinguishing RA from other rheumatic disease. The presence of ACPA/anti-CCP, like RF, often precedes symptom onset by years. The presence of ACPAs/anti-CCPs appears to be highly predictive of the future development of RA in both healthy individuals and patients with undifferentiated arthritis. Individuals who have ACPAs/anti-CCPs tend to have a poorer

Table 54.1 American College of Rheumatology/European League Against Rheumatism scoring algorithm for diagnosing rheumatoid arthritis (Kay and Upchurch, 2012)

Classification criteria for rheumatoid arthritis (score-based algorithm: add score of categories A–D)
A score of 6/10 is needed for classification of a patient as having definite rheumatoid arthritis

A	Joint Involvement	Score
	1 large joint	0
	2–10 large joints	1
	1–3 small joints (with or without involvement of large joints)	2
	4–10 small joints (with or without involvement of large joints)	3
	>10 joints (at least 1 small joint)	5
B	Serology (At Least 1 Test Result Is Needed for Classification)	Score
	Negative RF and negative ACPA	0
	Low-positive rheumatoid arthritis or low-positive ACPA	2
	High-positive rheumatoid arthritis or high-positive ACPA	3
C	Acute-Phase Reactants (At Least 1 Test Result Is Needed for Classification)	Score
	Normal CRP and normal ESR	0
	Abnormal CRP or abnormal ESR	1
D	Duration of Symptoms	Score
	<6 weeks	0
	≥6 weeks	1

ACPA, Anti-citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

prognosis with an increased level of joint damage and lower remission rates compared with people who are not positive for these antibodies.

Auto-antibodies

Anti-nuclear antibodies (ANAs) are a prominent feature of auto-immune rheumatic diseases. Detection of these antibodies and their differing profiles plays an important part of the diagnostic process. ANAs are a diverse group of antibodies, often directed to large cellular complexes containing protein and nucleic acid components. The most frequently occurring ANAs react with components of deoxyribonucleic acid (DNA)–protein or ribonucleic

acid (RNA)–protein complexes. Auto-antibodies are of value in situations where clinical expression of a disease such as SLE is incomplete; the presence of a particular ANA profile can be diagnostic of SLE.

Other blood parameters

Other abnormal laboratory tests include an elevated alkaline phosphatase, an elevated platelet count, raised plasma viscosity, a decreased serum albumin and a normochromic, normocytic anaemia. The white cell count, particularly neutrophils, is elevated in patients with infected joints and is elevated whilst the patient is on corticosteroids.

Disease activity

A patient's level of disease activity can be assessed with the Disease Activity Score of 28 joints (DAS28) (Box 54.2). The value is calculated from the number of tender and swollen joints, the patient's ESR or CRP, and a self-determined patient assessment of general health status according to a 100-mm visual analogue scale. A score >5.1 indicates high disease activity, ≥ 3.2 and up to 5.1 indicates moderate disease activity, between 3.2 and 2.6 indicates low disease activity, whereas <2.6 indicates remission. The DAS28 score is often used to determine when treatment with a biologic medicine should be commenced and to evaluate the patient's response to that treatment. In the UK the NICE requires the patient's DAS28 to be greater than 5.1

Box 54.2 Summary of DAS28 criteria in the assessment of rheumatoid arthritis

DAS28 is a composite formula. Four parameters are used to calculate a disease severity score:

1. number of swollen joints out of a total of 28 specified joints;
2. number of tender joints out of a total of 28 specified joints;
3. ESR or CRP level;
4. patient's interpretation of well-being, with 0 being at their best and 100 their worst.

Programmed calculators are used to determine the final DAS28. DAS28 does not take into account other features of a patient's disease, such as synovitis and other clinical symptoms.

High disease activity: DAS28 >5.1

Moderate disease activity: DAS28 >3.2 – 5.1

Low disease activity: DAS28 2.6 – 3.2

Remission: DAS28 <2.6

before treatment is permitted with a biologic therapy (NICE, 2016). However, drawbacks associated with using the DAS28 exist: some patients may not have particularly high inflammatory markers but still have severe disease, different patients may vary in their perception and reporting of their general health status, and secondary non-inflammatory factors such as the presence of degenerative disease can overestimate the DAS28.

The EULAR has developed criteria to assess the degree of change in DAS28 to determine good, moderate or non-response to treatment (Table 54.2). NICE permits continuation of treatment with a biologic therapy only if there is a moderate EULAR response 6 months after starting therapy.

Clinical trials assessing the efficacy of treatments for the management of RA often use the ACR response criteria (Box 54.3). This requires a specified improvement in tender joint count, swollen joint count, global assessments, pain, disability and an acute-phase reactant, for example, ESR or CRP. The ACR20 represents a 20% improvement in the patient's baseline ACR score. This is usually the minimum efficacy criteria for a medicine to achieve in a clinical trial for RA when compared with placebo or a comparative drug therapy. The ACR50 and ACR70 may also be assessed and represent a relative improvement from a baseline of 50% and 70%, respectively.

Treatment

There are four primary goals in the treatment of RA:

- symptom relief including pain control,
- slowing or prevention of joint damage,
- preserving and improving functional ability,
- achieving and maintaining disease remission.

Treatment should be aimed at reaching a target of remission or low disease activity in every patient; ideally this should be achieved within the first 6 months of starting treatment. Clinical remission is indicated by the absence of signs and symptoms of significant inflammatory disease activity. The ACR/EULAR have proposed two definitions for defining remission in RA for utilisation in clinical trials. One is a Boolean-based definition, as shown in Box 54.3; the other is a composite index of RA, the Simple Disease Activity Index (Felson et al., 2015).

A disease activity target should be set in all patients at the start of therapy and adaptations made to achieve this target. It can take up to 6 months to see the full benefit of disease-modifying

Table 54.2 EULAR response criteria (Fransen and van Riel, 2005)

DAS28 improvement →			
Present DAS28 ↓	>1.2	>0.6 – 1.2	≤ 0.6
≤ 3.2	Good response	Moderate response	No response
>3.2 – 5.1	Moderate response	Moderate response	No response
>5.1	Moderate response	No response	No response

Box 54.3 American College of Rheumatology/European League Against Rheumatism definitions of remission in rheumatoid arthritis clinical trials (Felson et al., 2015)

Boolean-based definition at any time point, patient must satisfy all of the following:

- tender joint count ≤ 1 ,
- swollen joint count ≤ 1 ,
- CRP ≤ 1 mg/dL,
- patient global assessment ≤ 1 (on a 0–10 scale).

A Simple Disease Activity Index score ≤ 3.3 at any time point: The simple sum of the tender joint count (using 28 joints), swollen joint count (using 28 joints), patient global assessment (0–10 scale), physician global assessment (0–10 scale), and CRP level (mg/dL).

medicines, but assessment of initial response is recommended at the 3-month stage (Smolen et al., 2017). If the individual has had only a minor response or no response at the 3-month stage, then he or she is unlikely to reach the target of remission at 6 months (Aletaha et al., 2016; Smolen et al., 2017).

Patients should have access to a multidisciplinary team (MDT) to address the pharmacological and non-pharmacological aspects of disease management. Education is extremely important because patients cope better if they understand their condition and have realistic expectations of the benefits and disadvantages of their treatment strategies. It is important that any therapeutic decision is jointly agreed with the patient. Shared decision making includes the need to inform the patient of the risks of RA and the benefits of reaching the targeted disease activity states, as well as the advantages and disadvantages of respective therapies. The individual should be empowered to make active decisions about his or her treatment and therapeutic goals in conjunction with the MDT.

Patients may need psychological support and employment counselling to help them adjust to living with their condition. Occupational therapy aims to provide support and aid to allow patients to improve function and limit disability in their activities of daily living. This includes devices to alleviate tasks that may be troublesome for those with restricted manual dexterity, such as twisting lids to open bottles. Physiotherapy involves assessment of function and designing a programme to aid pain relief and rehabilitation. The programme should aim to improve general fitness through regular exercise, and tailor exercises to the individual patient to enhance joint flexibility and muscle strength.

Drug treatment

The term DMARD is used to describe medicines used in the management of RA. For a medicine to be classified as a DMARD it should be able to demonstrate the capacity to inhibit structural damage to cartilage and bone. Historically there was only one category of DMARD, but due to the introduction of biologic medicines that alter the disease process and the newer targeted synthetic agents, there are now three categories of DMARD. The first category is conventional synthetic DMARDs (csDMARDs), such as methotrexate, hydroxychloroquine, sulfasalazine and leflunomide, which have been used for decades to

manage RA. The second category of DMARDs is the biologic medicines (bDMARDs), such as the tumour necrosis factor inhibitors (TNFi's), abatacept, rituximab and the IL-6 inhibitors (tocilizumab and sarilumab). More recently a new group of medicines has been introduced (the third category), which inhibit the enzyme JAK-Kinase (baricitinib and tofacitinib). These have been defined as targeted synthetic DMARDs (tsDMARDs).

Low-dose corticosteroids may be used as part of the initial treatment strategy (first 6 months), in combination with csDMARDs, while awaiting the therapeutic onset of the csDMARD(s). The role of non-steroidal anti-inflammatory drugs (NSAIDs) in the management of RA has considerably changed over the last decade. Traditionally the therapeutic pyramid was employed whereby initial treatment was conservative, with the use of NSAIDs for several years and progression on to DMARDs when the disease was not controlled. This approach has been replaced now by early treatment with csDMARDs followed by bDMARDs, because there is evidence that most patients develop joint destruction within the first 2 years of their disease. Despite this, NSAIDs still continue to be prescribed as DMARDs are still not used optimally. Where there is residual inflammatory pain NSAIDs are effective in reducing stiffness and swelling associated with this. It is important that any NSAID use does not mask the need for modification of DMARDs.

Research is ongoing with regard to the dose tapering of DMARDs once the target of disease remission has been achieved. Findings suggest that therapies may be reduced and remission maintained in a subset of patients. If the individual has achieved a prolonged period of remission on combined csDMARDs and bDMARDs, in the absence of glucocorticoids, the dose tapering of the bDMARDs may be considered (Smolen et al., 2017). The rheumatologist in consultation with the patient may agree an individualised tapering plan.

Disease-modifying anti-rheumatic drugs (conventional/synthetic)

Early therapeutic intervention with csDMARDs can improve patient outcomes and reduce disease progression. All patients with a confirmed diagnosis of RA should be commenced on a csDMARD. csDMARDs commonly used in the management of RA include methotrexate, leflunomide, sulfasalazine and hydroxychloroquine (Table 54.3).

csDMARDs do not provide pain relief but do suppress the disease process. They have a delayed onset of action; it can be 4–6 weeks before the patient starts to see a response, and up to 4–6 months before a full response is achieved. The precise mechanism of action of these drugs is unclear. There is good evidence that csDMARDs inhibit the activity of inflammatory cytokines. Methotrexate and leflunomide have been shown to also inhibit T cells.

Practice may differ regarding the use of combination or csDMARD monotherapy following diagnosis. NICE encourages the use of combination csDMARD therapy, including methotrexate, in newly diagnosed RA. Where combination csDMARD therapy is not possible due to comorbidities, csDMARD monotherapy may be initiated with fast escalation to a clinically effective dose (NICE, 2015a). EULAR guidance states that both monotherapy

Table 54.3 Conventional synthetic disease-modifying anti-rheumatic drugs (csDMARDs) used in the treatment of rheumatoid arthritis

Name	Dosage	Adverse reactions	Monitoring		Time period to benefit
			Baseline	Long-term	
Hydroxychloroquine	200–400 mg daily	Ocular toxicity, GI and visual disturbances	FBC eGFR LFT Visual acuity	Annual review with optometrist	2–3 months
Leflunomide	10–20 mg daily Loading dose is not commonly used in practice because of GI side effects	Weight loss, hypertension, GI disturbances, myelosuppression	FBC eGFR LFTs BP Weight	FBC, LFTs and eGFR every 2 weeks until patient has been on a stable dose for 6 weeks. Then monthly for 3 months and thereafter if stable 12 weekly. Monthly blood tests should be continued long-term if co-prescribed with another immunosuppressant or potentially hepatotoxic agent Regular BP and weight checks	8–12 weeks, although longer if the loading dose is not given
Methotrexate	7.5–25 mg once weekly	Hepatotoxicity, myelosuppression, pneumonitis, nausea and vomiting	FBC eGFR LFTs Chest X-ray	FBC, eGFR, LFTs every 2 weeks until methotrexate dose and monitoring stable for 6 weeks, then monthly thereafter until dose and disease stable for 1 year. Following this, reduction in frequency of monitoring may be considered depending on various patient factors, e.g. renal impairment	6 weeks to 3 months
Sodium aurothiomalate (IM gold)	10 mg test dose, then 50 mg weekly until significant response or total dose of 1000 mg has been given	Rash, oral ulceration, proteinuria, myelosuppression	FBC Urinalysis eGFR LFTs	FBC and urinalysis every 4 weeks	Usually when 500 mg cumulative dose has been reached
Sulfasalazine	500 mg to 3 g daily	GI disturbances, myelosuppression, hepatotoxicity	FBC eGFR LFTs	FBC and LFTs monthly for first 3 months, then every 3 months thereafter. Reduce frequency after first year if dose and results are stable	3 months

BP, Blood pressure; eGFR, estimated glomerular filtration rate; FBC, full blood count; GI, gastro-intestinal; IM, intramuscular; LFT, liver function test.

and combination therapy with csDMARDs are effective, and that patient preferences and expectations of adverse events should be considered when discussing treatment options (Smolen et al., 2017). Ideally combination therapy with csDMARDs should include methotrexate, because other combinations have not been sufficiently studied. Whether using combination or monotherapy, it is important that there is frequent monitoring of disease activity, with timely dose titration and the introduction of new therapies to reach the ideal therapeutic target for disease remission.

Methotrexate. Methotrexate is highly effective in the management of RA both as a monotherapy and on the basis of its ability to increase the efficacy of biologic medicines when used

in combination. It is therefore considered the ‘anchor drug’ in RA (Smolen et al., 2014). No other csDMARD has shown superiority in terms of clinical efficacy; meta-analyses have confirmed TNFi monotherapy is not superior to methotrexate in improving signs and symptoms, although they do have a superior effect on radiographic progression (Smolen et al., 2014).

Methotrexate is generally used as a first-line agent, unless comorbidity precludes. It has an onset of action of approximately 1 month and can be given either orally or by subcutaneous or intramuscular injection. It tends to be given by injection when patients are unable to tolerate oral doses because of gastric side effects, or where doses of 25 mg or more weekly are being given.

Box 54.4 Important points to cover when counselling a patient who is receiving methotrexate

- Why the patient is taking methotrexate
- How long it will take for methotrexate to work
- The dose and the frequency
- For oral methotrexate the strength and number of tablets
- The importance of regular blood monitoring
- The side effects including warnings symptoms for urgent referral to the doctor
- Interactions with other medicine, including over-the-counter and herbal remedies
- The need for adequate contraception in males and females
- Inform healthcare professionals that methotrexate is prescribed

The starting dose varies according to clinician preference and patient tolerability. Common starting doses are 10 or 15 mg/week, but where there are concerns about tolerability the lower starting dose of 7.5 mg/week may be prescribed. Ideally the optimal dose of methotrexate (25–30 mg weekly) or maximum tolerated dose should be achieved within a few weeks and maintained for at least 8 weeks, because maximum effect of methotrexate is attained only after 4–6 months. Common side effects include mouth ulcers (stomatitis) and nausea. Methotrexate reversibly inhibits the enzyme dihydrofolate reductase, resulting in a lowering of serum folate; supplementation with folic acid is given to counteract this side effect. Folic acid tends to be given as a 5 mg once-daily dose, although other regimens are used including a once-weekly dose. Most regimens omit the folic acid dose on the day of methotrexate therapy to avoid any potential impact on the latter's efficacy.

The use of methotrexate has been associated with haematological, hepatic and pulmonary toxicity. Because of methotrexate's potential to suppress bone marrow and cause liver toxicity it is essential that certain blood tests be performed regularly on patients who are taking methotrexate. All patients should have the following baseline blood tests: full blood count (FBC), estimate of glomerular filtration rate (eGFR), and albumin and liver function tests (LFTs). These should then be performed regularly throughout the course of treatment (see [Table 54.3](#)). Lower doses and slower dose titration are indicated in the presence of moderate renal impairment, and in the presence of severe impairment the use of methotrexate should be avoided.

Although methotrexate is a safe medicine when used appropriately, deaths have occurred as a consequence of patients taking this medicine incorrectly. The patient must understand how and when to take the medicine, plus the need for regular blood monitoring. It must be quite clear that the medicine is taken only once a week. The patient should also be re-counselled every time they are issued with a prescription for methotrexate irrespective of how long they have been receiving treatment ([Box 54.4](#)).

The National Patient Safety Agency (NPSA) in England has issued guidance on the prescribing and dispensing of oral methotrexate ([NPSA, 2004](#)). The guidance recommends that all patients who are taking methotrexate should be issued with a core patient information leaflet and a handheld methotrexate

monitoring booklet. The prescriber should provide the patient with information about the benefits and risks of treatment with methotrexate. The term 'as directed' should not be used on a prescription, and patients should be quite clear on the number of tablets they are taking and on which day of the week. There should also be consistency on the strength of the tablet issued; ideally patients should remain on the 2.5 mg strength to avoid confusion. When issuing the medication to the patient, clearly explain which is the methotrexate container and which is the folic acid container, so the patient is able to differentiate between the two. Patients should be aware of certain signs and symptoms that may suggest toxicity, such as increased breathlessness, a dry, persistent cough, unexplained sore throat, or vomiting and diarrhoea, and who to contact if they experience these side effects. Most rheumatology departments operate a telephone helpline, staffed by specialist nurses, which patients can contact if they are experiencing side effects because of their rheumatology medication.

Leflunomide. In cases of methotrexate contraindications (or early intolerance), leflunomide or sulfasalazine may be considered as alternatives to methotrexate as part of the initial treatment strategy. Both sulfasalazine and leflunomide have shown clinical, functional and structural efficacy, and although methotrexate doses in respective comparative trials may not have been optimal, both have shown efficacies similar to methotrexate ([Smolen et al., 2014](#)).

Leflunomide has both immunomodulatory and immunosuppressive characteristics. It inhibits the synthesis of pyrimidine nucleotides in response cells (particularly T cells) and reduces pro-inflammatory cytokines (TNF and IL-6). Studies have shown it to be at least as effective as sulfasalazine and methotrexate, and for quality-of-life measures some evidence suggests superiority. When given as a loading dose of 100 mg daily for 3 days followed by a maintenance dosage of 10–20 mg daily its therapeutic effect starts after 4–6 weeks, and further improvement may be seen for up to 4–6 months. However, many centres do not use this loading dose regimen, because patients are unable to tolerate the gastro-intestinal side effects associated with it. The use of leflunomide has been associated with both haematological and hepatotoxic side effects. FBC, eGFR, albumin and LFTs must be performed before therapy is initiated and then every 2 weeks until on a stable dose for 6 weeks, then once monthly for 3 months and then every 12 weeks ([Ledingham et al., 2017](#)). When leflunomide and methotrexate are used in combination extra caution is advised, and patients should be monitored closely because of the increased risk of hepatotoxicity. Leflunomide can also cause hypertension: blood pressure should be checked before commencing leflunomide and periodically thereafter. Both men and women who are taking leflunomide are required to use adequate contraceptive measures during treatment and for at least 2 years after treatment in women and at least 3 months after treatment in men. If the individual plans to conceive before completion of this period, then a washout protocol must be followed. This involves treatment with cholestyramine or activated charcoal and measuring the concentration of the active metabolite. A washout protocol may also be used if a patient develops a toxic side effect caused by treatment with leflunomide or there is a need to switch to a different DMARD.

Sulfasalazine. Sulfasalazine (enteric coated) is indicated in mild-to-moderate disease. It has an onset of action of 6–12 weeks. To reduce the side effect of nausea, the dose is usually titrated upwards from 500 mg daily, increasing at weekly intervals to 1 g twice daily. Haematological abnormalities have occurred rarely with the use of sulfasalazine, and patients should be counselled to report unexplained bleeding, bruising, purpura, sore throat, fever or malaise. Patients should also be warned that sulfasalazine can colour urine red and stain contact lenses. Baseline FBCs and LFTs should be performed on patients taking sulfasalazine and repeated intermittently throughout the course of treatment (see Table 54.3). Sulfasalazine is considered safe in pregnancy when given in combination with folic acid. In males it may cause oligospermia, which can be reversed within 2–3 months of stopping treatment.

Hydroxychloroquine and chloroquine. The antimalarial drugs hydroxychloroquine and chloroquine may be used in milder disease. They show some efficacy as a monotherapy with respect to the signs and symptoms of RA, but they have not been shown to inhibit structural damage sufficiently when compared with other csDMARDs. They are often combined with other csDMARDs in the management of RA (Katz and Russell, 2011). There is a rare risk of retinopathy associated with their use, so patients should have an annual eye check and be informed to report any changes in vision or how they perceive colours.

Other conventional synthetic disease-modifying anti-rheumatic drugs. Injectable gold (sodium aurothiomalate) has been shown to be efficacious in the management of RA, but its use is limited because of an unfavourable side-effect profile. Due to the risk of anaphylaxis, an initial 10 mg test dose should be given in the first week of treatment followed by a maintenance dose of 50 mg the following week. Administration is by deep intramuscular injection. Patients should be monitored for 30 minutes following each dose. FBC and urine should be checked before giving the next full dose of 50 mg intramuscularly. The maintenance dose of 50 mg every week is given until the first signs of remission occur. At this point the interval between injections is extended to 2 weeks until full remission occurs. The interval between injections can then be increased progressively to 3 weeks, 4 weeks, and then, after 18 months to 2 years, to 6 weeks.

Penicillamine is no longer used in the management of RA because of its poor side-effect profile and lack of efficacy compared with other agents.

Azathioprine and ciclosporin may be used occasionally for progressive disease refractory to other csDMARDs or where a biologic agent is contraindicated. Azathioprine may also be used as a steroid-sparing agent. Azathioprine is an oral purine analogue that inhibits lymphocyte proliferation. It becomes biologically active after metabolism by the liver to 6-mercaptopurine. Bone marrow suppression and liver toxicity are associated with its use, and FBCs and LFTs should be performed during treatment. Renal function should also be monitored because the drug is renally excreted. Ciclosporin works by impairing the function of B and T lymphocytes. Dose-related hypertension and nephrotoxicity are common side effects. FBCs should be performed during treatment, and liver and renal function monitored. Ciclosporin drug levels are not routinely measured when it is used for the management of RA.

Glucocorticoids

Glucocorticoids act by inhibiting cytokine release and give rapid relief of symptoms and decrease inflammation. Depending on the number of affected joints, corticosteroids may be injected directly into the joint (intra-articular), given as an intramuscular depot injection or given as short-term oral therapy. The standard intramuscular dose used is 120 mg methylprednisolone, and oral starting doses can be up to 30 mg once a day of prednisolone. For very severe disease, particularly where there are extra-articular manifestations, pulsed intravenous infusions of methylprednisolone (e.g. 250 mg) may be given in rare instances, but this approach is less common now because of the availability of more modern therapies.

Glucocorticoids are often used as a bridging therapy to reduce symptoms and disease activity when waiting for the therapeutic onset of a csDMARD or when changing from one csDMARD to another. In addition they have been shown to be effective adjunctive treatments with the main csDMARD therapy to more efficiently achieve the desired target (usually clinical remission). Treatment with glucocorticoids should ideally be short-term, and they should be gradually withdrawn as soon as it is clinically feasible according to disease activity. Ideally treatment should be gradually reduced and stopped by 3 months (Smolen et al., 2017). In more refractory cases it may be more difficult to withdraw treatment with glucocorticoids because the individual's disease tends to flare as the dose is reduced. A reducing rate as slow as 1 mg/month may even be necessary in some patients. In rare instances where there is intolerance, contraindications or therapeutic failure with DMARDs, it may be necessary to continue with a small maintenance dose of glucocorticoid.

The long-term side effects of corticosteroids include osteoporosis, peptic ulceration, diabetes mellitus and hypertension. Oral glucocorticoid treatment with greater than 5 mg prednisolone daily can lead to a reduction in bone mineral density and a rapid dose-dependent increase in the risk of fracture (van Staa, 2006). The risks are highest during the initial stages of treatment. In patients exposed to high-dose and/or long-term corticosteroid, consideration should be given to the need for bone protection with a bisphosphonate and calcium plus vitamin D supplementation. Gastric protection, such as a proton pump inhibitor, should be co-prescribed with glucocorticoids in patients with risk factors for peptic ulcer disease, for example, the elderly and concomitant NSAID use. Although hypothalamic–pituitary–adrenal axis suppression may vary greatly from person to person, it should be anticipated in any patient receiving more than 7.5 mg prednisolone or equivalent daily for more than 3 weeks (Cooper and Stewart, 2003). The importance of not stopping glucocorticoid therapy suddenly should be explained to the patient. Health professionals should also consider the need for replacement therapy during acute illness in patients with RA who have received glucocorticoids for a prolonged period.

Non-steroidal anti-inflammatory drugs

NSAIDs are effective in reducing the pain, swelling and stiffness associated with RA; however, it is important that their use does not mask the need for optimisation of DMARD therapy.

The mechanism of action of NSAIDs involves the inhibition of cyclo-oxygenase-1 (COX-1) and/or COX-2. COX-1 catalyses the production of prostaglandins involved in various physiological functions, that is, the maintenance of renal function, mucosal protection in the gastro-intestinal tract and platelet activation. COX-2 is expressed as part of the inflammatory response, resulting in vasodilation, platelet inhibition and inhibition of smooth cell proliferation. The inhibition of COX-2 by NSAIDs plays a role in mediating pain, fever and inflammation. Non-selective NSAIDs inhibit both COX-1 and COX-2 enzymes. Inhibition of COX-1 results in an increased risk of gastro-intestinal bleeding. COX-2 selective NSAIDs were developed to maintain analgesic efficacy while minimising gastro-intestinal side effects associated with COX-1 inhibition. Two licensed COX-2 inhibitors are available in the UK: celecoxib and etoricoxib. Despite the potential gastro-intestinal benefit of COX-2 selective NSAIDs, they have been shown to have a higher risk of cardiovascular events. A large meta-analysis found that compared with placebo, the risk of major vascular events was increased by 33% in patients taking COX-2 selective agents or diclofenac (Bhala et al., 2013). The proposed mechanism of cardiovascular toxicity associated with NSAIDs is inhibition of the cardioprotective prostaglandin I₂ that is generated by COX-2. Naproxen is proposed to have a lower cardiovascular risk compared with the other licensed NSAIDs (Trelle et al., 2011). The use of NSAIDs increases the risk of gastro-intestinal toxicity, such as the development of peptic ulcer disease, upper gastro-intestinal haemorrhage or perforation. The risk of these complications may vary among NSAIDs. Agents such as ibuprofen and celecoxib have a lower relative risk of gastro-intestinal complications, while piroxicam and ketoprofen have been shown to have a higher relative risk (Castellsague et al., 2012). Chronic NSAID use can lead to kidney impairment due to direct and indirect effects on the kidney. The use of NSAIDs can increase blood pressure, cause fluid retention and decrease kidney function in patients with kidney disease. It should also be noted that 10% of total drug-induced hepatotoxicity is NSAID related (Bessone, 2010).

NICE guidance on the management of RA recommends that both non-selective NSAIDs and COX-2 inhibitors are prescribed at their lowest effective dose for the shortest period of time. Whether the NSAID is selective or non-selective, a proton pump inhibitor should always be co-prescribed. As the analgesic effect of NSAIDs is the same, selection should be based upon the patient's individual risk factors. If a person with RA needs to be prescribed low-dose aspirin, prescribers should consider other analgesics before substituting or adding an NSAID or a COX-2 inhibitor (with a proton pump inhibitor) if pain relief is ineffective or insufficient (NICE, 2015a).

Biologic disease-modifying anti-rheumatic drugs

Biologic therapies used in RA target specific immune-mediated pathways involved in the pathophysiology of the condition. They are derived from living cells through highly complex manufacturing processes. Biologic medicines used in RA may exist as a whole antibody (e.g. monoclonal antibody) or a specific fragment of an antibody, usually the binding site portion (e.g. fusion

protein). Monoclonal antibodies may also be fully humanised (fully humanised monoclonal antibody) or partially humanised, where they consist of a combination of both animal and human proteins (chimeric monoclonal antibody).

bDMARDs have markedly changed the management and outcome of RA. Current biologic therapies available for the management of RA include the TNFi's, as well as abatacept, tocilizumab and rituximab. These medicines now form part of the standard treatment strategy for RA, and NICE recommends the use of a biologic medicine in patients with a DAS28 greater than 5.1 whose disease has not responded to intensive therapy with a combination of csDMARDs (NICE, 2016).

Biosimilars. As patents for biologic medicines near their expiry, pharmaceutical manufacturers have taken steps to develop medicines with equivalent therapeutic effect to their branded counterparts, but with a considerably lower acquisition cost. These new medicines have been classified as 'biosimilars'. NHS England (2015, p. 5) defines biosimilar medicines as: 'a biological medicine which is highly similar to another biological medicine already licensed for use. It is a biological medicine which has been shown not to have any clinical meaningful differences from the originator biological medicine in terms of quality, safety and efficacy'. Biosimilar medicines have specific European Union (EU) regulatory pathways that differ from the authorisation process applied to generic medicines. The licensing process for biosimilars includes a head-to-head comparison of randomised controlled trial (RCT) data. There should be no clinically significant difference between the biosimilar and the original reference product. Biosimilar medicines are not required to have comparative phase III clinical trial data for all the indications of the original product. The information submitted to the European Medicines Authority (EMA) by the manufacturer of the biosimilar should be of sufficient quality and quantity to allow 'extrapolation' by the EMA to all the indications of the original reference product.

Biosimilar products for the management of RA have already been introduced into the UK market. The TNFi's infliximab and etanercept are now available as biosimilars. Biosimilar medicines are also in clinical development for other biologics including adalimumab and rituximab. Multiple branded products will become available for each biologic medicine. It is important that all prescriptions for a biologic medicine available as both the original reference drug and as a biosimilar specifically state the brand name of the desired product to avoid confusion. Due to the complex nature of these medicines there is a risk that small differences between the products could potentially affect response. Prescribing by brand ensures the patient is maintained on the same product.

Tumour necrosis factor inhibitors. TNF- α and IL-1 are pro-inflammatory cytokines that are present in the synovial fluid and tissue. In RA they are produced in excess. Blocking of TNF- α by TNFi agents results in dampening of the inflammatory cascade and blocking of IL-1 activity. TNFi therapy has been shown to reduce the signs and symptoms of RA, improve physical function and slow the progression of joint damage. Five originator TNFi's are currently available in the UK: adalimumab, certolizumab, etanercept, golimumab and infliximab. At the time of writing this chapter, three biosimilar infliximab products plus two etanercept biosimilar are available (Table 54.4).

Table 54.4 Current licensed tumour necrosis factor inhibitors available in the UK for rheumatoid arthritis

Adalimumab (Humira)	Etanercept (Enbrel, Benepali)	Certolizumab (Cimzia)	Golimumab (Simponi)	Infliximab (Remicade, Inflectra, Remsima, Flixabi)

AS, Ankylosing spondylitis; HS, hidradenitis suppurativa; JIA, juvenile idiopathic arthritis; MTX, methotrexate; PsA, psoriatic arthritis; RA, rheumatoid arthritis; UC, ulcerative colitis.

The market authorisations for adalimumab, etanercept and certolizumab approve use in combination with methotrexate or as monotherapy. However, infliximab and golimumab should be administered in combination with methotrexate for the management of RA. At present TNFi monotherapy has failed to demonstrate superiority over methotrexate alone, whereas combination therapy has. Current European guidance suggests a dosage of 10 mg or more weekly of methotrexate (where not contraindicated) with all TNFi's until additional evidence becomes available (Smolen et al., 2014). NICE permits the use of adalimumab, etanercept, and certolizumab pegol as monotherapy where methotrexate is contraindicated or not tolerated (NICE, 2016).

Adalimumab is a recombinant human monoclonal antibody that binds specifically to TNF- α and neutralises its biological function by blocking its interaction with cell surface TNF- α receptors. Due to it being a fully humanised monoclonal antibody, it is less likely to engender an immune response in the recipient than agents that contain non-human or artificial sequences. It is used in combination with methotrexate in patients with moderate-to-severe active RA who have had an inadequate response to csDMARDs, including methotrexate. Adalimumab is administered as a 40 mg subcutaneous injection every other week. It can be used as monotherapy in patients who are intolerant of methotrexate, or where methotrexate is contraindicated. When given as monotherapy, the dose may be increased to 40 mg once a week where there is a decrease in response.

Certolizumab pegol consists of a portion of a recombinant, humanised monoclonal antibody (fab fragment) bound to polyethylene glycol (PEG). The PEG portion increases the half-life to approximately 14 days, which is that of a whole antibody, and is much longer than the half-life of unconjugated fab fragments. The formulation was developed to address concerns that some of

the toxicity associated with infliximab and adalimumab might be caused by the effects of the Fc portion of the antibody such as complement activation and antibody-dependent cell-mediated cytotoxicity. Certolizumab pegol, in combination with methotrexate, is indicated for the treatment of moderate-to-severe active RA in adult patients when the response to csDMARDs, including methotrexate, has been inadequate. Certolizumab pegol can be given as monotherapy in case of intolerance to methotrexate or when continued treatment with methotrexate is inappropriate. The recommended starting dose of certolizumab pegol for adult patients with RA is 400 mg (as two subcutaneous injections of 200 mg each on one day) at weeks 0, 2 and 4, followed by a maintenance dose of 200 mg every 2 weeks. Full clinical response to certolizumab pegol should be achieved within the first 12 weeks of treatment. If the desired therapeutic response has not been achieved at this point, then treatment with certolizumab pegol should be discontinued.

Etanercept is a recombinant human soluble TNF- α receptor. It competitively inhibits the activity of TNF- α by binding to its cell surface receptors. It can be used as monotherapy or in combination with methotrexate for the treatment of moderate-to-severe active RA. It is given by subcutaneous injection, either 25 mg twice weekly or 50 mg once weekly. The patent for the original reference drug (Enbrel) has now expired, and etanercept is now available as a biosimilar (Benepali and Erelzi). Etanercept should therefore be prescribed according to its brand name.

Golimumab is a human monoclonal antibody that forms high-affinity, stable complexes with both the soluble and transmembrane bioactive forms of human TNF- α , thus preventing the binding of TNF- α to its receptors. It must be administered in combination with methotrexate, and it is licensed for the treatment of moderate-to-severe active RA, following an inadequate response

Box 54.5 Screening tests to be performed before commencing biologic disease-modifying anti-rheumatic drugs

- Full clinical/infection screen to exclude the presence of infection
- Urea and electrolytes plus urinalysis
- FBC
- Chest radiograph to exclude infection, TB or lung fibrosis
- QuantiFERON-TB or T Spot to establish TB status
- Hepatitis B and C screening
- Assess risk factors for HIV and consider screening
- Check vaccination status
- Check family/patient history with regards to demyelinating disease
- Previous history of malignancy
- Antibody profile: ANAs and DNA
- Check blood pressure and review cardiac function

ANA, Anti-nuclear antibodies; DNA, deoxyribonucleic acid; FBC, full blood count; HIV, human immunodeficiency virus; TB, tuberculosis.

to csDMARDs or following failure or intolerance to other TNFi's. In RCTs it has demonstrated efficacy in patients with RA who have not responded positively to one to two previous TNFi's. Clinical response is usually seen after 12–14 weeks of treatment. It requires less frequent administration than the other subcutaneous TNFi's and is given once a month. The starting dosage is 50 mg by subcutaneous injection once a month; patients who weigh more than 100 kg should have their dose increased to 100 mg/month if they have not achieved an adequate response after three or four doses. If an adequate response is not achieved following administration of three or four doses of 100 mg, treatment should be discontinued.

Infliximab is a chimeric human–murine monoclonal antibody that binds with high affinity to both soluble and transmembrane forms of TNF- α , leading to inhibition of its functional activity. Infliximab is the only TNFi that is given by intravenous infusion. It must be given concomitantly with methotrexate. The recommended dosage in RA is 3 mg/kg. The initial infusion is given over a 2-hour period; subsequent infusions are given 2 and 6 weeks after the first. The patient is then maintained on 8-weekly maintenance infusions. Due to it being not fully humanised there is a higher risk of the development of human anti-chimeric antibodies (HACAs) against infliximab. The development of HACAs may result in a loss of therapeutic effect and an increased risk of infusion reaction. Methotrexate is co-administered to reduce the risk of development of HACA. Blood tests are now available for determination of infliximab plasma blood levels; a drop in the plasma level may be indicative of the development of antibodies to infliximab. Due to the availability of biosimilar infliximab, all prescriptions for infliximab should include the brand name of the product to avoid inadvertently switching to an alternative product.

Screening and safety issues associated with tumour necrosis factor inhibitors. Before commencing a TNFi, a number of important screening tests should be performed (Box 54.5) and a risk–benefit assessment be made (Box 54.6). The use of TNFi's has been associated with an increased incidence of infection and reactivation of latent tuberculosis (TB). Tests to establish TB immune status (QuantiFERON-TB or T Spot) should be performed in addition to a chest radiograph. A small minority of

Box 54.6 Factors that influence biologic disease-modifying anti-rheumatic drug selection

Perform a risk–benefit assessment taking into account the following factors:

1. Disease characteristics: serological status (RF +ve or –v) and CRP level
2. Concomitant methotrexate or monotherapy
3. Comorbidities: relative versus absolute contraindications to biologics
4. Concomitant immune-mediated inflammatory diseases, e.g. psoriasis and IBD
5. The ability to self-inject

CRP, C-reactive protein; IBD, inflammatory bowel disease; RF, rheumatoid factor.

patients have experienced lupus-like symptoms while receiving TNFi, and it is important to test for the presence of auto-antibodies that may predispose the individual to development of a lupus-type reaction. Live vaccinations are not permitted while receiving TNFi's; therefore, the individual's vaccine status should be evaluated before commencing treatment and appropriate vaccines given. It should be noted that the influenza and pneumococcal vaccines can be administered while receiving treatment with a TNFi because these are non-live vaccines. In rare instances neurological complications have been associated with TNFi use, and it is therefore important to establish any background history of demyelinating disorders before treatment commences.

The presence of infection should be excluded before commencing a patient on a TNFi. In addition, the risks and benefits of commencing TNFi in certain patient groups should be carefully considered. TNFi's may be avoided in circumstances such as patients with chronic leg ulcers, septic arthritis in a native joint within the last 12 months, sepsis in a prosthetic joint in the last 12 months (if the joint remains in situ), persistent or recurrent chest infections, or indwelling urinary catheter and bronchiectasis (associated with frequent chest infection). Although data from RCTs and the British Society for Rheumatology (BSR) Biologic Registry failed to demonstrate an increase in treatment-related serious infections, data from the meta-analysis of RCTs and the German registries suggest that TNFi use is associated with an increased risk of serious infections, particularly early on in the course of therapy (Humphreys et al., 2016). An increased incidence of opportunistic and fungal infections has also been associated with treatment with a TNFi.

There is a well-established increased risk of TB associated with TNFi therapy, with registry data (from the British and French registries) demonstrating a greater risk associated with anti-TNF monoclonal antibodies as opposed to fusion protein (Humphreys et al., 2016). Before commencing treatment with TNFi therapy, all patients should be screened for mycobacterial infection. Active mycobacterial infection needs to be adequately treated before TNFi can be started. Where there is evidence of potential latent TB, the need for prophylactic treatment should be considered. Patients should be continued to be monitored for the development of mycobacterial infections during treatment and for 6 months after stopping.

Conflicting data exist on the role of TNFi and heart failure. Demonstration of worsening of moderate-to-severe heart failure

in initial trials that evaluated TNFi for heart failure (Chung et al., 2003; Mann et al., 2004) underlines the need for accurate assessment of cardiac function in all patients with pre-existing heart failure before considering treatment with TNFi. Treatment is contraindicated in moderate-to-severe impairment (New York Heart Association [NYHA] class III/IV) and should be used with caution in patients with mild heart failure (NYHA class I/II). Treatment with anti-TNF should be discontinued in patients who develop new or worsening symptoms of congestive heart failure.

Rare cases of SLE and vasculitis (ANCA associated) have been reported in association with TNFi treatment. SLE symptoms occurred 3–6 months after starting therapy and included fever, malaise, arthritis, discoid lupus rash, erythematous facial rash and hypertension. These resolved 6–14 weeks after stopping therapy. TNFi therapy should be stopped if symptoms of an SLE-like syndrome develop.

There are a number of reports of demyelination and acute neurological complications associated with TNFi therapy (although registry data have not led to a clear signal); nevertheless, because of this, TNFi therapy should not be given to patients with a history of demyelinating disease and should be carefully considered if there is a strong family history of demyelination. Therapy should be stopped if signs or symptoms suggestive of demyelination develop.

Concerns have previously been raised about the increased risk of cancer associated with anti-TNF therapy. It is important to be aware that RA itself and continued disease activity is associated with a greater risk of cancer (particularly lymphoma) than the general population. For TNFi, overall long-term registry data have been reassuring, with no conclusive evidence for an increase in solid tumours or lymphoproliferative disease with the anti-TNF therapies above that which would be expected for the rest of the RA population. However, this continues to be monitored closely (Ding et al., 2010). There does appear to be

an increased risk of non-melanoma skin cancers with anti-TNF therapies, and patients should be counselled on appropriate skin protection (Ding et al., 2010).

It should be noted that limited data are available on the newer licensed TNFi, certolizumab pegol and golimumab, but information collected so far suggests that their side-effect profile does not differ significantly from the older agents.

Non-TNFi biologic medicines. Currently, five non-TNFi biologic medicines are available for the management of RA in the UK: abatacept, rituximab, tocilizumab, sarilumab and anakinra (Table 54.5). Tocilizumab and sarilumab are monoclonal antibodies which block the actions of IL-6. Elevated IL-6 levels have been found in the synovial fluid of patients with RA, and the cytokine is thought to play an important role in the inflammation and joint destruction associated with RA. Both IL-6 inhibitors are licensed following treatment failure with csDMARDs. Use is recommended in combination with methotrexate, but monotherapy can be considered where there is intolerance or a contraindication to methotrexate. Abatacept is a fusion protein that modulates T-lymphocyte-dependent antibody responses and inflammation. Use is recommended only in combination with methotrexate. Indications include highly active disease in patients without prior treatment with methotrexate or following treatment failure with one or more csDMARDs (including methotrexate) or a TNFi. Rituximab is a monoclonal antibody that binds specifically to the transmembrane antigen CD20, which ultimately results in B cell lysis. It is available as both the original reference drug and as biosimilar formulations. It is given as an intermittent intravenous infusion in combination with a weekly dose of methotrexate and is used following treatment failure with both csDMARDs and bDMARDs. Anakinra is a human IL-1 receptor antagonist licensed for the management of RA. It is given as a once-daily

Table 54.5 Non-tumour necrosis factor inhibitor biologic medicines licensed in rheumatoid arthritis

Abatacept (Orencia)	Rituximab (MabThera, Rixathon, Truxima)	Tocilizumab (RoActemra)	Sarilumab (Kevzara)
Fusion protein: blocks T cell activation	Monoclonal antibody: CD20 B-cell depletion	Humanised monoclonal antibody against soluble and membrane IL-6 receptor	Human monoclonal antibody selective for soluble and membrane IL-6 receptor
Dose in RA Intravenous infusion: at weeks 0, 2 and 4, then 4 weekly (<60 kg = 500 mg, 60–100 kg = 750 mg, >100 kg = 1000 mg) or Subcutaneous injection: 125 mg once a week	Dose in RA Intravenous infusion: two infusions of 1000 mg given 2 weeks apart, repeat as clinically indicated (no more than 6 monthly) (Only available as an intravenous infusion for RA)	Dose in RA Intravenous infusion: 8 mg/kg 4 weekly (maximum dose 800 mg) or Subcutaneous injection: 162 mg once a week	Dose in RA 200 mg once every 2 weeks by subcutaneous injection
Licensed: Moderate-to-severe RA following csDMARD or TNFi failure (with MTX) Polyarticular JIA	Licensed: RA (with MTX) following csDMARD + TNFi failure GPA with glucocorticoids NHL CLL	Licensed: RA (+/– MTX) following csDMARD failure sJIA (+/– MTX) JIA	Licensed: RA (+/– MTX) following csDMARD failure

CLL, Chronic lymphocytic leukaemia; DMARD, disease-modifying anti-rheumatic drug; GPA, granulomatosis with polyangiitis and microscopic polyangiitis; IL-6, interleukin-6; JIA, juvenile idiopathic arthritis; MTX, methotrexate; NHL, non-Hodgkin's lymphoma; RA, rheumatoid arthritis; sJIA, systemic juvenile idiopathic arthritis; TNFi, tumour necrosis factor inhibitor.

subcutaneous injection in combination with weekly methotrexate. Its use is not supported for the management of RA because it is clinically less effective than the other agents currently available (NICE, 2015a).

Rituximab. Rituximab is a genetically engineered monoclonal antibody which binds to CD20, a protein expressed on B lymphocytes. It is available as the original reference drug MabThera and also as the biosimilar brands Rixathon and Truxima. The three products are licensed in combination with methotrexate for the treatment of severe active RA in patients who have had an inadequate response or intolerance to other DMARDs, including one or more TNFi therapies. Rituximab works by a variety of methods including depleting B cells, affecting B- and T-cell interaction, antigen presentation and cytokine production. In RA, B cells can be found in the synovium. They produce antibodies that contribute to the disease and inflammatory cytokines. B cells also affect the function of other cells involved in inflammation. A course of rituximab consists of 1000 mg by intravenous infusion at week 0 followed by a second 1000 mg intravenous infusion 2 weeks later. Intravenous methylprednisolone is administered with each infusion to prevent infusion reaction along with an antihistamine and oral paracetamol. The need for further courses should be evaluated 24 weeks following the previous course. Available data suggest that clinical response is usually achieved within 16–24 weeks of an initial treatment course. All patients treated with rituximab should be given a patient alert card at each infusion. Contraindications to rituximab include hypersensitivity to rituximab or other murine proteins, active severe infections and severe heart failure (NYHA class IV).

In the UK, NICE recommends treatment with rituximab, in combination with methotrexate, as an option for the treatment of adults with severe active RA who have had an inadequate response to, or are intolerant of, DMARDs, including at least one TNFi (NICE, 2010). Treatment is permitted no more frequently than every 6 months. EULAR guidance on the management of RA states that in the presence of certain contraindications for other biologic medicines, such as a recent history of lymphoma, latent TB with contraindications to the use of chemoprophylaxis, living in a TB-endemic region or a previous history of demyelinating disease, then rituximab may be considered as a first-line biological agent (Smolen et al., 2017). Some rheumatologists also give preference to rituximab in patients with a recent history of any malignancy because there are no indications that rituximab use is associated with the occurrence of cancers (Smolen et al., 2017).

Recently, pooled data from two phase III studies in methotrexate-inadequate responder populations, as well as a substudy from the IMAGE study that evaluated methotrexate-naïve patients, have all reinforced the view that seropositive patients (ACPA/anti-CCP, RF or both) demonstrate a more robust response to rituximab (Tak et al., 2011). In the IMAGE study, there was evidence of significantly greater joint protection in the seropositive subpopulation treated with rituximab and methotrexate; whereas in the seronegative group, inhibition of the progression of damage in each treatment group was comparable and generally low even in the placebo/methotrexate group (Tak et al., 2011). As a consequence of this, some rheumatologists may prefer to use an alternative biologic to rituximab in seronegative patients. In seronegative patients with refractory disease who have not responded positively to multiple biologic DMARDs, rituximab may be considered if there are limited treatment options. The

SMART study (Sellam et al., 2011) found that those with evidence of erosive disease, those with a high DAS28 (i.e. those with high joint counts and inflammatory markers) had greatest benefit from rituximab. The presence of these factors may override serological status in patients with difficult to treat disease.

There have been a number of reported cases of hepatitis B virus reactivation in oncology patients treated with rituximab, although reports in the RA population are very low. All patients should be screened for hepatitis B (surface antigen and core) and hepatitis C before commencing rituximab. At present, there is no evidence of an increased frequency of TB in patients with lymphoma treated with rituximab, and prescreening for TB is not warranted (Buch et al., 2011). Patients considered for rituximab therapy should receive all indicated vaccines (hepatitis B for at-risk population, pneumococcus, tetanus toxoid every 10 years, influenza annually) before treatment. Ideally, vaccination should be undertaken at least 4 weeks before rituximab therapy.

A reduced baseline level of the IgG has been shown to be a risk factor for severe infections with rituximab (Gottenberg et al., 2010). On all of these grounds, rituximab treatment in patients with RA with hypogammaglobulinaemia (below the lower limit of normal) should be considered with caution. It is recommended that patients have their baseline IgG measured before starting rituximab and before each cycle of rituximab (Buch et al., 2011).

The most frequent adverse event with rituximab is infusion reaction (30–35% with the first infusion with concomitant glucocorticoids). Fewer reactions are observed with the second and subsequent infusions (Buch et al., 2011). In a recent pooled analysis of safety data from rituximab in combination with methotrexate, the rate of adverse events and serious events, including infections and serious infections, remained stable across several courses (van Vollenhoven et al., 2010).

Tocilizumab. IL-6 is a multifunction cytokine that has a wide range of biological activities in various target cells and regulates immune responses, acute-phase reactions, haematopoiesis and bone metabolism (Adachi et al., 2008). Because IL-6 is involved in a number of important physiological roles, deregulated overproduction of IL-6 causes various pathological conditions, including autoimmune, inflammatory and lymphoproliferative disorders. In RA, elevated production of IL-6 is observed in the synovial fluid and blood, with levels correlating with disease activity. Some of the clinical aspects of RA, such as overproduction of acute-phase proteins, raised platelet counts, induction of osteoclasts, production of auto-antibodies and decreased albumin, can be explained by activities of IL-6 (Nishimoto et al., 2008).

Tocilizumab is a monoclonal antibody that binds specifically to both soluble and membrane-bound IL-6 receptors (sIL-6Rs and mIL-6Rs) resulting in the inhibition of sIL-6Rs and mIL-6R-mediated signalling. Tocilizumab is indicated for the treatment of moderate-to-severe RA in patients who have not previously received methotrexate and in patients who have failed or been intolerant to one or more csDMARDs or TNFi's. Its license permits its use in combination with methotrexate or as monotherapy where methotrexate is contraindicated or not been tolerated. It can be administered as a once-weekly 162 mg subcutaneous injection or given as an intravenous infusion of 8 mg/kg (maximum 800 mg) every 4 weeks.

Tocilizumab is the only biologic therapy to repeatedly demonstrate superiority over methotrexate monotherapy or other

csDMARDs (Jones et al., 2010; Nishimoto et al., 2007). A study involving 2057 participants with RA assessing changes in Clinical Disease Activity Index and DAS28, as well as the likelihood to be in remission, showed no significant difference whether tocilizumab was used as monotherapy or in combination with csDMARDs (Gabay et al., 2016). However, tocilizumab retention was more prolonged when tocilizumab was prescribed in combination with csDMARDs. EULAR supports the combination of all biologic medicines with methotrexate, but where there is intolerance or a contraindication to use of methotrexate, then preference is given to tocilizumab monotherapy (Smolen et al., 2014).

NICE recommends the use of tocilizumab either in combination with methotrexate or as monotherapy when a patient's DAS 28 is greater than 5.1 and they have not responded to intensive therapy with a combination of csDMARDs (NICE, 2016). It can also be prescribed when csDMARDs and a TNFi have not been effective, the individual cannot have rituximab for medical reasons or because of a bad reaction, or when treatment with rituximab has failed (NICE, 2012).

Due to tocilizumab's mode of action, its use may be associated with a decline in neutrophil and platelet counts, a change in lipid profiles and abnormal LFTs. Its use is also associated with a number of significant drug interactions. Treatment should not be commenced in patients with an absolute neutrophil count (ANC) less than $2 \times 10^9/L$. Neutrophils and platelets should be monitored 4–8 weeks after start of therapy and thereafter according to standard clinical practice. The licensed datasheet provides specific recommendations with regards to dosage reduction or delaying treatment according to platelet and neutrophil levels. Elevated lipid levels including total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL) and triglycerides have been reported in studies following treatment with tocilizumab. Patients receiving tocilizumab should have their lipid parameters checked 4–8 weeks following the initiation of tocilizumab therapy. Patients with raised cholesterol levels should be managed according to local clinical guidelines for the management of hyperlipidaemia. In view of the elevated hepatic transaminases commonly associated with treatment, aspartate transaminase (AST) and alanine transaminase (ALT) levels should be monitored every 4–8 weeks for the first 6 months of treatment followed by every 12 weeks thereafter. Caution should be exercised in commencing treatment in patients whose ALT or AST level is greater than $1.5 \times$ the upper limit of normal (ULN). Consideration should be given to adjusting the dose of methotrexate if AST/ALT level is one to three times the ULN. Persistent elevation following on from this may warrant dose reduction or treatment interruption or termination.

Pro-inflammatory cytokines, such as IL-6, have been associated with suppression of hepatic cytochrome P450 (CYP450) enzymes. Reduction in these cytokines following the administration of a biologic therapy may lead to normalisation of enzyme expression and improved drug metabolism. In vitro studies have shown that IL-6 caused a reduction in CYP1A2, CYP2C9, CYP2C19, and CYP3A4 enzyme expression. These enzymes are responsible for the metabolism of a number of medicines including atorvastatin, calcium channel blockers, theophylline, warfarin, phenytoin, ciclosporin and benzodiazepines. Following the administration of tocilizumab, the function of these enzymes

normalised, resulting in the need for a dosage increase of these medicines in some patients. Following discontinuation of tocilizumab, enzyme activity may be affected for a number of weeks because of the long half-life of the drug. Live vaccines should not be administered to people who are receiving treatment with tocilizumab. It is recommended that all patients be brought up to date with all immunisations, in agreement with current immunisation guidelines, before initiating tocilizumab therapy. Annual influenza vaccination and pneumococcal vaccines may be given to patients who are receiving tocilizumab.

Sarilumab. Sarilumab is a subcutaneous IL-6 inhibitor licensed in combination with methotrexate for the treatment of moderately to severely active RA in adult patients who have responded inadequately to, or who are intolerant to, one or more csDMARDs. It can be given as monotherapy in case of intolerance to methotrexate or when treatment with methotrexate is inappropriate. Sarilumab is a fully human monoclonal antibody, whereas tocilizumab is a 'humanised' monoclonal, meaning its protein sequence has been modified to increase its similarity to antibody variants produced naturally by humans. Contraindications, side effects and drug interactions are similar between the two IL-6 inhibitors, and both require regular blood monitoring including neutrophils, platelets and liver transaminases. The recommended dose of sarilumab is 200 mg once every 2 weeks administered as a subcutaneous injection. Dose reduction to 150 mg once every 2 weeks or omission of the drug is recommended according to neutrophil, platelet and liver enzyme levels. NICE recommends the use of sarilumab, with or without methotrexate, in individuals with a DAS28 score of 5.1 or greater despite treatment with combination csDMARDs. It is also approved where other bDMARDs and csDMARDs have failed or are contraindicated and the person cannot have rituximab. Individuals failing to respond to rituximab may also have sarilumab provided they have also been treated with at least one other bDMARD (NICE, 2017c).

Abatacept. Abatacept is a recombinant human fusion protein that binds to proteins naturally expressed on the surface of activated T cells, causing attenuation of T-cell activity by blocking a costimulatory signal. T cells are central to the immune response and are found in the synovium of patients with RA. In the synovium, T cells express activation markers, secrete cytokines and stimulate macrophages, thereby contributing to the development of inflammation and joint destruction. Abatacept, in combination with methotrexate, is indicated for the treatment of moderate-to-severe active RA in adult patients who responded inadequately to previous therapy with one or more csDMARDs including methotrexate or TNFi's. Its benefit is not seemingly different between seropositive and seronegative RA, and may therefore be particularly considered in place of rituximab in such patients who have not responded positively to TNFi therapy. It can be administered as an intravenous infusion according to weight (<60 kg = 500 mg; 60–100 kg = 750 mg; >100 kg = 1000 mg). Following the initial infusion it is given 2 and 4 weeks later, then every 4 weeks thereafter. The infusions are generally well tolerated and administered efficiently (30 minutes). Alternatively, it can be administered as a 125 mg subcutaneous injection once a week.

In the UK, abatacept in combination with methotrexate is recommended as a first-line biologic treatment option in patients with a DAS28 greater than 5.1 who have not responded to intensive

therapy with a combination of csDMARDs (NICE, 2016). It is also recommended, in combination with methotrexate, as a second-line treatment option for adults with severe active RA who have had an inadequate response to or have an intolerance of other DMARDs, including at least one TNFi, and who cannot receive rituximab therapy because they have a contraindication to it, or when rituximab is withdrawn because of an adverse event (NICE, 2010).

Common adverse reactions ($\geq 10\%$) among abatacept-treated patients include headache, nausea and upper respiratory tract infections. The frequencies of serious infection and malignancy relative to placebo among abatacept-treated patients older than 65 years were higher than among those younger than 65 years. Because there is a higher incidence of infections and malignancies in the elderly in general, caution should be used when treating elderly patients. Live vaccines should not be given concurrently with abatacept or within 3 months of its discontinuation.

The GDH-PQQ-based glucose monitoring systems may react with the maltose present in abatacept infusion, resulting in falsely elevated blood glucose readings on the day of infusion. When receiving abatacept infusions, patients who require blood glucose monitoring should be advised to consider methods that do not react with maltose, such as those based on glucose dehydrogenase nicotinic adenine dinucleotide (GDH-NAD), glucose oxidase or glucose hexokinase test methods.

Targeted synthetic disease-modifying anti-rheumatic drugs

In 2017 a new class of DMARD became available for the management of moderate-to-severe RA, the Janus Kinase Inhibitors (also known as JAK inhibitors or Jakinibs). Due to their differing mode of action to existing oral DMARDs they have been given the classification of tsDMARDs. Janus Kinase Inhibitors inhibit the activity of one or more of the Janus Kinase family of enzymes (JAK1, JAK2, JAK3 and TYK2). These enzymes transduce intracellular signals from cell surface receptors for a number of cytokines and growth factors involved in haematopoiesis, inflammation and immune function. Within the intracellular signalling pathway, JAKs phosphorylate and activate signal transducers and activators of transcription (STATs), which activate gene expression within the cell. Inhibition of the JAK-STAT pathway results in a reduction in cytokine signaling.

Baricitinib (Olumiant) and tofacitinib (Xeljanz) are licensed for the treatment of moderate-to-severe active RA in adult patients who have responded inadequately to or who are intolerant to one or more DMARDs. Use is recommended in combination with methotrexate, but they can also be given as monotherapy where there is a contraindication or intolerance to methotrexate. NICE recommends the use of baricitinib (Olumiant) or tofacitinib (Xeljanz) in patients with a DAS28 greater than 5.1 and where there has been previous treatment failure with a combination of csDMARDs (NICE, 2017a, 2017b). Use is also permitted in patients with a DAS28 greater than 5.1 whose disease has responded inadequately to, or who cannot have, other DMARDs, including at least one biological DMARD and in whom treatment with rituximab is not appropriate. Ideally they should be given in combination with methotrexate, but NICE permits monotherapy

where there is a contraindication or intolerance to methotrexate. All use is under the proviso that the manufacturers provide baricitinib and tofacitinib at a discounted price as per the agreed patient access scheme. EULAR recommends the use of either JAK Kinase inhibitor when there is high disease activity despite treatment with a csDMARD or where treatment with a bDMARD or first JAK kinase inhibitor has failed (Smolen et al., 2017).

Baricitinib (Olumiant) partially inhibits the JAK1 and JAK2 enzymic activity, thus affecting interferon- γ and IL-6 signaling, and consequently T helper cell 1 cell differentiation. A non-inferiority study comparing baricitinib with adalimumab demonstrated baricitinib 4 mg was superior to adalimumab for the ACR20 response (Taylor et al., 2017).

All patients should be screened for TB, hepatitis B and hepatitis C plus the presence of infection before considering treatment with a JAK Kinase inhibitor. It is taken as a 4 mg once-daily dose with or without food. The dose should be reduced to 2 mg once daily in patients older than 75 years or where there is a history of chronic/recurrent infection, or creatinine clearance is between 30 and 60 mL/min. Use is not recommended where the creatinine clearance is less than 30 mL/min or in the presence of severe hepatic impairment. Dose reduction is also recommended in patients who are taking Organic Anion Transporter 3 (OAT3) medicines because these medicines can cause a significant rise in the plasma concentration of baricitinib (Olumiant), for example, probenecid. It should not be used in conjunction with bDMARDs or other JAK Kinase inhibitors because of the risk of increased immunosuppression and risk of infection.

Events of deep venous thrombosis (DVT) and pulmonary embolism (PE) have been reported in patients who are receiving baricitinib (Olumiant). It should be used with caution in patients with risk factors for DVT/PE, such as older age, obesity, a medical history of DVT/PE or patients undergoing surgery and immobilisation. If clinical features of DVT/PE occur, baricitinib (Olumiant) treatment should be temporarily interrupted and patients should be evaluated promptly, followed by appropriate treatment. Regular blood monitoring of haemoglobin, neutrophils, lymphocytes and hepatic transaminases is recommended throughout treatment according to local practice. Use has been associated with abnormal lipid profiles. Lipids should be checked at baseline and 12 weeks after initiation of treatment with any abnormality being managed in accordance with national guidance for the management of hyperlipidaemia.

In human cells, tofacitinib (Xeljanz) preferentially inhibits signalling by heterodimeric cytokine receptors that associate with JAK3 and/or JAK1 with functional selectivity over cytokine receptors that signal via pairs of JAK2. Inhibition of JAK1 and JAK3 by tofacitinib attenuates signalling of ILs (IL-2, -4, -6, -7, -9, -15, -21) and type I and type II interferons, which will result in modulation of the immune and inflammatory response. Clinical trial data showed non-inferiority when tofacitinib with methotrexate was compared with adalimumab in combination with methotrexate (Fleischmann et al., 2017). The standard dosage is 5 mg twice a day orally with or without food. No dose reduction is required in the elderly or in patients with mild-to-moderate renal function (creatinine clearance 30–49 mL/min). In severe renal impairment (creatinine clearance less than 30 mL/min) the dose should be reduced to 5 mg once a day. In moderate hepatic impairment (Child-Pugh B) the dose should be reduced

to 5 mg once a day, and use is not permitted in severe impairment (Child-Pugh C). Tofacitinib (Xeljanz) is metabolised through the CYP450 system; the dosage should be reduced to 5 mg once a day in the presence of strong inhibitors of CYP450 3A4 (e.g. ketoconazole). Dosage reduction is also warranted in patients who are receiving one or more concomitant medicinal products that result in both moderate inhibition of CYP3A4, as well as potent inhibition of CYP2C19 (e.g. fluconazole). Co-administration of potent inducers of CYP450 3A4 (e.g. rifampicin) is not recommended because it may result in a loss of clinical efficacy. The manufacturer of tofacitinib (Xeljanz) states that it should not be combined with bDMARDs, other JAK Kinase inhibitors, azathioprine, ciclosporin or tacrolimus because of increased risk of infection when these medicines are combined.

As with baricitinib (Olumiant), the use of tofacitinib (Xeljanz) has been associated with a decline in haemoglobin, neutrophil and lymphocyte levels. An FBC should be performed at baseline, after 4–8 weeks and then regularly at 3-monthly intervals. Abnormal lipid profiles have been observed within 6 weeks of commencing treatment. Assessment of lipid parameters is recommended at baseline and 8 weeks after commencing treatment. Due to adverse events noted in clinical trials, caution should also be exercised in patients with a history of malignancy, chronic lung disease and in patients at increased risk of gastro-intestinal perforation (history of diverticulitis, concomitant use of corticosteroids and/or nonsteroidal anti-inflammatory drugs).

Rheumatoid arthritis treatment pathway

The initial treatment strategy involves the use of csDMARDs in combination with short-term glucocorticoids. In the UK a combined csDMARD approach is recommended (NICE, 2016), whereas EULAR recommends initial csDMARD monotherapy (Smolen et al., 2017). Following treatment failure with combined csDMARDs in patients with a DAS28 greater than 5.1, NICE recommends a combination of methotrexate with either a TNFi or abatacept, tocilizumab or baricitinib (NICE, 2016). Where methotrexate is contraindicated or not tolerated, adalimumab, certolizumab, etanercept, tocilizumab or baricitinib can be used as monotherapy (NICE, 2016). In contrast, EULAR proposes treatment escalation to a bDMARD or tsDMARD, in combination with methotrexate, following treatment failure with the first csDMARD in the presence of poor prognostic factors (e.g. moderate to high disease activity after csDMARD, high acute-phase reactant levels, high swollen joint counts, the presence of RF and/or ACPA, and the presence of early erosions). In the absence of poor prognostic factors, a trial of a second csDMARD is recommended (Smolen et al., 2017) before considering a bDMARD or tsDMARD.

EULAR gives preference to bDMARDs over tsDMARDs because of greater availability of long-term registry data on their safety. None of the bDMARDs are given hierarchical ranking over another by either EULAR or NICE. However, EULAR does propose the use of an IL-6 inhibitor (e.g. tocilizumab) or a tsDMARD (e.g. baricitinib) over a bDMARD when csDMARDs cannot be given in combination (Smolen et al., 2017). The rheumatologist when making a decision in conjunction with the patient will evaluate the individual's risk–benefit profile and propose a particular biologic medicine based on this assessment (see Box 54.6). Factors that will be considered include the patient's

serology, comorbidities (e.g. heart disease), history of malignancy, the presence of lung disease, concomitant methotrexate, the presence of other autoimmune diseases (e.g. psoriasis and inflammatory bowel disease [IBD]), auto-antibody status and the ability to self-inject.

The TNFi should be avoided in patients who are positive for auto-antibodies suggestive of an overlying connective tissue disease such as SLE. This is due to the potential risk of worsening pre-existing lupus or triggering a lupus-type reaction. It may therefore be preferable to use tocilizumab or abatacept in individuals who have shown positivity for auto-antibodies linked to lupus. Other immune-mediated diseases, such as psoriasis and IBD, may co-exist with RA. Where the patient suffers from both RA and psoriasis or IBD it may be preferable to use an agent that is licensed for management of both conditions such as a TNFi.

Patients vary in their response to biologic medicines; they may fail to clinically respond to the first biologic they are given defined as a 'primary non-response'. In addition, some patients after initially having a good response to a particular biologic medicine may subsequently lose clinical response; this may be classified as a 'secondary non-response'. There is variation in patient tolerability to different biologic medicines; for example, an individual may experience an adverse reaction to one TNFi leading to discontinuation and then be able to tolerate another TNFi with good clinical effect. To maintain adequate disease control, patients may be switched to an alternative biologic; this is known as biologic sequencing. No comparative studies have been conducted to date offering clear guidance on biologic sequencing in RA (Smolen et al., 2014).

NICE recommends the use of rituximab, in combination with methotrexate, where there has been a primary non-response or a secondary loss of response with the first prescribed biologic medicine (NICE, 2010). Adalimumab, etanercept, infliximab, tocilizumab and baricitinib are recommended as alternatives to rituximab, where there is a contraindication to rituximab or rituximab is withdrawn because of an adverse reaction (NICE, 2010, 2017). The use of rituximab is supported only in combination with methotrexate; where methotrexate cannot be given, then either adalimumab, etanercept, tocilizumab or baricitinib monotherapy can be given. EULAR gives no preference to a particular bDMARD following a primary non-response or secondary loss of response to the first bDMARD. Following treatment failure with the original reference, bDMARD use of its corresponding biosimilar is not recommended.

It should be noted that class adverse drug reactions, such as lupus-type reactions or a neurological side effect with a TNFi, would preclude the use of another TNFi. The same risk–benefit assessment applied to the selection of the first biologic medicine is applied in biologic sequencing. In addition the rheumatologist will consider the therapeutic response to the first biologic medicine. It is important that the patient is involved throughout the decision-making process. NICE also permits the use of tocilizumab following primary treatment failure with rituximab or a loss of response to rituximab (NICE, 2012).

Rheumatoid arthritis and pregnancy

Although disease activity may improve during pregnancy, it is important that pregnant patients with RA are not deprived

appropriate disease-ameliorating therapies. Active disease during pregnancy is associated with adverse pregnancy outcomes (Østensen et al., 2015). There is growing drug safety evidence to support shared decision making regarding the safe use of medicines during pregnancy. The BSR deems prednisolone to be compatible with each trimester of pregnancy and during breastfeeding (Flint et al., 2016a). Hydroxychloroquine is the anti-malarial of choice in females planning a pregnancy and should be continued post-conception. Guidance also deems it to be compatible with breastfeeding (Flint et al., 2016a). Sulfasalazine is permitted during pregnancy. Oral sulfasalazine inhibits the absorption and metabolism of folic acid and may cause folic acid deficiency; therefore, folic acid 5 mg once daily should be administered in conjunction with sulfasalazine throughout the pregnancy (Flint et al., 2016a). It is important that the DMARDs methotrexate and leflunomide are not taken by females who are trying to conceive, and both medicines are contraindicated during pregnancy and breastfeeding. Females of childbearing age should be counselled on the importance of not getting pregnant while taking either methotrexate or leflunomide and using appropriate contraceptive measures during treatment with these medicines. Methotrexate should be stopped at least 3 months before conception. Leflunomide has an extended half-life, and female patients should use appropriate contraceptive measures for at least 2 years after stopping leflunomide or undergo an appropriate wash-out regimen and have verification by at least two blood tests that the plasma level of drug has dropped below 0.02 mg/L. It should be noted that males wanting to start a family should also stop leflunomide therapy and undergo an appropriate wash-out regimen, with verification of plasma levels.

The current licensed datasheets for the biologic therapies in RA often do not support continuation during conception and pregnancy. However, more recent evidence from biologic registries support the use of certain biologic medicines during pregnancy in patients whose disease activity warrants continuation. Infliximab may be continued for up to the first 16 weeks of pregnancy, whereas etanercept and adalimumab may be continued until the second trimester. Stopping the TNFi at these time points ensures low or no drug level in cord blood at the time of delivery. If infliximab, etanercept or adalimumab is continued beyond the recommended period, then live vaccinations should not be given to the infant until he or she reaches 7 months of age. Due to reduced placental transfer, certolizumab is deemed appropriate in all three trimesters. Golimumab is unlikely to cause harm in the first trimester. Other biologics such as rituximab, tocilizumab and abatacept should be avoided in pregnancy and breastfeeding at present because there are insufficient safety data to support their use.

BSR recommendations on analgesics support the intermittent use of paracetamol throughout pregnancy. However, regular consumption should be avoided especially during weeks 8–14 of pregnancy because of a small reported risk of cryptorchidism (Flint et al., 2016b). Codeine is compatible pre-conception and throughout pregnancy. Caution is advised with the use of codeine in breastfeeding because of the risk of central nervous system depression in the infant. Discordant findings from retrospective, large studies with population controls on the use of non-selective NSAIDs in the first trimester of pregnancy raise the possibility of a low risk of miscarriage and malformation

(Flint et al., 2016b). Caution is therefore advised with regard to using non-selective NSAIDs in the first trimester. All non-selective NSAIDs should be withdrawn at gestational week 32 to avoid premature closure of the ductus arteriosus. Avoidance of COX-2 inhibitors is recommended throughout pregnancy (Flint et al., 2016b).

Patient care

People with RA should have access to and be offered patient education throughout the course of their disease including as a minimum: at diagnosis, at pharmacological treatment change and when required by the patient's physical or psychological condition (Zangi et al., 2015). The content and delivery of patient education should be individually tailored. Ideally both individual and/or group sessions should be provided through face-to-face or online interactions, and supplemented by telephone calls, written material or multimedia material. Information provided should include knowledge and management of the disease, knowledge of side effects and risk factors, non-pharmacological treatment, pain control and self-help methods, as well as activity regulation, physical exercises and behaviour change. Effective communication and education is essential to enable patients with RA to make correct decisions about their treatment in conjunction with their rheumatologist and other members of the MDT. Medicine information sheets are available from the Arthritis Research UK with further information available on their website (<http://www.arthritisresearchuk.org>).

Many of the treatments used in the management of RA require regular blood monitoring, and hence the rationale for blood tests and the importance of attending for these tests should be clearly explained to the patient. In addition, patients should be reminded of the warning symptoms that must trigger them to contact a healthcare professional. Shared care agreements between secondary and primary care are often employed for csDMARD therapy. This involves a primary care clinician continuing to prescribe and monitor drug treatment that has been initiated by a hospital specialist. Clear guidelines stating the responsibilities of both parties and the action required in the event of toxicity is defined within the document. The main advantage of shared care is that the patient will not be required to attend regular hospital appointments for blood tests and will be managed in primary care.

Counselling about medication should incorporate the need to inform all healthcare professionals involved in the patient's care about the medicines the individual is taking for his or her RA. This is especially important when seeing healthcare practitioners outside of rheumatology who may wish to initiate a new medicine or when purchasing over-the-counter products and herbal/complementary therapies.

Osteoarthritis

Osteoarthritis is a degenerative disorder of the joints that most commonly affects the knee, hip, spine and small joints of the hand. It is the most common musculoskeletal condition in

older people (Arthritis Research UK, 2013). The exact aetiology of osteoarthritis is unknown, and at present there are no medical treatments proven to prevent or delay its onset. Risk factors for the development of osteoarthritis include increasing age, obesity, gender, bone density, joint injury, occupation and genetics. Symptomatic presentation does not usually occur until middle age. More than two-thirds of people with osteoarthritis are in constant pain, and it is the 11th highest contributor to global disability (Cross et al., 2014). The diagnosis and management of osteoarthritis is dependent upon the type and number of joints affected. Non-pharmacological measures, such as weight loss, structured exercise programmes and supportive aids, form the cornerstone of management. Pharmacological treatments are used as adjuncts to provide moderate symptomatic relief. Joint replacement surgery may be considered in osteoarthritis of the knee or hip when an individual suffers persistent debilitating symptoms despite appropriate management.

Epidemiology

Osteoarthritis is the most common musculoskeletal condition in older people. It involves inflammation and major structural changes to the whole joint, causing pain and functional disability. In the UK around one-third of people aged 45 years and older have sought treatment for osteoarthritis, an estimated 8.75 million (Arthritis Research UK, 2013). Osteoarthritis is more common in women than men, and the prevalence increases steeply with age.

The knee is the most common site in the body to have osteoarthritis in people aged 45 and older. In the UK nearly one in five adults older than 45 years may have symptoms of osteoarthritis of the knee (Arthritis Research UK, 2013). The global prevalence of radiographically confirmed knee osteoarthritis in 2010 was estimated to be 3.8%. The prevalence of knee osteoarthritis is higher in females than in males, 4.8% versus 2.8%, respectively (Cross et al., 2014). Epidemiological studies suggest the prevalence of knee osteoarthritis peaks at 50 years of age, and there are worldwide geographical variations with the highest prevalence in the Asia Pacific high-income region (Cross et al., 2014).

Hip osteoarthritis is less common than knee osteoarthritis, with the global age-standardised prevalence rate of symptomatic radiographically confirmed osteoarthritis estimated to be 0.85%. In the UK, 8% of people aged 45 and older have sought treatment for osteoarthritis of the hip (Arthritis Research UK, 2013). As with osteoarthritis of the knee, prevalence of hip osteoarthritis has been shown to be higher in females than males. Prevalence increases consistently with age, and hip osteoarthritis has the highest prevalence in North American high-income regions (Cross et al., 2014).

Symptomatic osteoarthritis of the hand affects 8% of people aged 60 years or older, and 26% of women and 13% of men aged 70 years and older (Zhang et al., 2002). More recent research in the UK has shown that 6% of people aged older than 45 years have sought treatment for osteoarthritis of the hand and wrist

(Arthritis Research UK, 2013). The most commonly affected joints in the hand are the distal interphalangeal joints and PIPs, followed by the base of the thumb. People with hand osteoarthritis have difficulty in performing daily tasks such as gripping and writing, and functional impairment may be as severe as that associated with RA.

Pathophysiology

In osteoarthritis the whole joint is involved in the pathogenesis. In healthy joints, two bones articulate with one another, and the surface of each bone within the joint is covered by shock-absorbing cartilage. Both the bone and cartilage are important in dissipating the load placed through joints every day. When the bone or cartilage is damaged as a consequence of large loads to the joint or some form of impact, numerous repair mechanisms attempt to restore normal function within the damaged joint to ensure the joint continues to dissipate the load correctly. This includes cell-mediated remodelling within the architecture of the cartilage and subchondral bone tissues (Goldring and Goldring, 2010). When the rate of damage exceeds the rate of repair, degeneration of the bone and cartilage ensues and the joint fails to effectively dissipate the load. This then results in a cycle of biomechanical and biochemical degeneration where the shock-absorbing cartilage is progressively destroyed, thus exposing the bone to a greater load with subsequent bone damage (bone marrow lesions) (Suri and Walsh, 2012). This then leads to further loss of cartilage, bone overgrowth with the formation of bony spurs (osteophytes) and narrowing of the joint space. The joint degeneration results in painful and tender inflammation of the synovial lining of the joint (synovitis) and swelling of the joint (effusion). Synovitis may be present in early cartilage changes to the joint, and there is cellular infiltration with macrophages, activated T and B cells, and accompanying vascular proliferation (Roemer et al., 2015; Yusuf et al., 2011). Inflammatory cytokine levels may also be elevated within the joint, but to a lesser extent than seen with RA.

Aetiology

Osteoarthritis may be classified as either primary or secondary osteoarthritis. In primary osteoarthritis the exact cause is unknown (idiopathic), while in secondary osteoarthritis there is a link to a specific cause such as previous injury to the joint, a pre-existing congenital abnormality (congenital hip dysplasia) or inflammatory arthritis such as gout or RA. Osteoarthritis can affect weight-bearing and non-weight-bearing joints, and may involve single or multiple joints.

The exact aetiology of osteoarthritis is unknown; however, a combination of risk factors may predispose an individual to its development. The main risk factors for osteoarthritis include age, gender, obesity, bone density, joint injury or disease, occupation, joint abnormalities and genetics (Box 54.7). At present there is no validated risk tool for quantitative prediction of the development of osteoarthritis.

Box 54.7 Osteoarthritis risk factors

- Age older than 50 years
- Female sex
- Increased body mass index (>25)
- Bone density
- Joint injury or joint disease (e.g. rheumatoid arthritis and gout)
- Occupation—physically demanding work
- Abnormal joint development (e.g. congenital hip dysplasia)
- Genetic factors

Increasing age and female gender have been associated with an increased risk of development of osteoarthritis. The effect of female gender on risk of hand osteoarthritis peaks around menopause, with more than 3.5-fold higher rates in women aged 50–60 years when compared with men of similar age (Prieto-Alhambra et al., 2014). It has been hypothesised that sex hormones may influence the development of hand osteoarthritis in young women (Zhang et al., 2010). However, research involving hormone replacement therapy has failed to support this hypothesis, and studies are required to further evaluate the relationship between female hormones and osteoarthritis. Being overweight increases loading on the joints and the risk of osteoarthritis, especially in the knee (Zhang et al., 2010).

Inheritance studies in twins and other family-based studies have assessed the estimated heritability for osteoarthritis in the range of 40–65% depending on the joint site (Jonsson et al., 2003; Kraus et al., 2007). Genome-wide association studies have identified at least 11 loci associated with osteoarthritis (Evangelou et al., 2014). The effect size of individual identified loci is small, and the genetic architecture of osteoarthritis is likely to consist of multiple variants of similar magnitude (Glyn-Jones et al., 2015).

Diagnosis

The diagnosis of osteoarthritis is based on the combination of typical mechanical pain symptoms and physical joint findings in an individual with risk factors for the development of osteoarthritis. No diagnostic tool for osteoarthritis has been validated for use in routine clinical practice. The individual may present with pain in more than one joint. The pain associated with osteoarthritis is of gradual onset and is worsened by activity; unlike RA there is only a short period of early-morning stiffness. People with osteoarthritis frequently present with muscle wasting around the affected joint(s) due to the avoidance of movement as a consequence of pain (disuse atrophy). In osteoarthritis of the hip people may encounter difficulty when putting on shoes, getting in and out of the car, or going up and down stairs. Pain related to hip osteoarthritis can occur in different locations than the thigh area, including the groin, buttocks and knees. The individual may be not aware that the pain is originating from the hip. The intensity of pain increases when the hip joint is moved. People with osteoarthritis of the knee typically experience activity-related pain, which is often worse towards the end of the day. The pain is relieved by rest, and there is only mild morning or inactivity-related stiffness. Symptoms may be episodic

Box 54.8 Management of osteoarthritis

- Appropriate information and education
- Activity and exercise
- Interventions to achieve weight loss
- Pharmacological adjuncts to provide symptomatic relief

and vary in severity, but as the osteoarthritis of the knee becomes more advanced the pain can become persistent and occur during rest and during the night.

Osteoarthritis of the hand is characterised by Heberden's and Bouchard's nodes. Heberden's nodes are visible hard, bony swellings occurring at the distal interphalangeal joints at the end of the fingers. They are a consequence of bony outgrowths (osteophytes) that form in the articular cartilage as part of the joint repair mechanism. Bouchard's nodes are less common in hand osteoarthritis and are hard, bony outgrowths in the PIP joints.

Occasionally X-rays may be used to aid diagnosis in osteoarthritis. Typical features seen on X-ray include joint space narrowing, bone spurs (osteophytes), subchondral sclerosis and subchondral cysts. There may be poor correlation between the pain experienced by an individual and the extent of change demonstrated on X-ray. Blood tests and X-rays are not required for a diagnosis of osteoarthritis but may be performed to exclude other diseases such as psoriatic arthritis, RA and gout.

Management

The pain and disability associated with osteoarthritis can have significant impact on mood and may impair participation in both work and recreational activities. Patients should be educated about their osteoarthritis and be provided with a tailored self-management plan to maintain physical function and fitness, reduce pain and prevent further deterioration (Box 54.8). Pharmacological treatments are used as adjuncts, and the key to management is lifestyle change. People with osteoarthritis who experience joint symptoms (pain, stiffness and reduced function) that have a substantial impact on their quality of life and are refractory to non-surgical management should be referred for consideration of joint replacement surgery (NICE, 2014).

Non-pharmacological treatment

Weight loss

It is important that overweight patients are encouraged to lose weight because obesity is a known risk factor for the development of osteoarthritis (Bijlsma et al., 2011). Studies in patients with knee osteoarthritis have shown that supervised weight-loss programmes demonstrate small but significant improvements in pain and physical function (Fernandes et al., 2013; McAlindon et al., 2014). Overweight patients with osteoarthritis should be educated on weight loss and provided with support to achieve and maintain their target weight.

Exercise

Exercise can reduce pain and improve overall function in people with hip or knee osteoarthritis. NICE recommends exercise as a core treatment of osteoarthritis irrespective of age, comorbidity, pain severity or disability (NICE, 2015b). Exercise regimens should include local muscle strengthening, for example, quadriceps exercises for knee osteoarthritis, combined with general aerobic exercise. EULAR recommends patients with osteoarthritis perform moderate-intensity aerobic training for at least 30 minutes/day and progressive strength training involving the major muscle groups at least 2 days/week at moderate to vigorous intensity for 10 repetitions (Jordan et al., 2003). The regimen needs to be continued long-term and become part of the patient's usual lifestyle rather than an additional task they are required to perform.

Physical aids

Appropriate footwear can help reduce pain and improve physical function in people with osteoarthritis of the hip and knee. Studies involving patients with knee osteoarthritis have demonstrated that shock-absorbing insoles worn for 1 month reduced pain and improved physical function (Turpin et al., 2012). Athletic shoes with custom-made insoles and conventional athletic shoes have both been found to reduce pain in patients with knee osteoarthritis (Erhart et al., 2010). Specialised footwear is not required; EULAR recommends footwear with no raised heel and thick, shock-absorbing soles with support for the arches and of sufficient size to give comfortable space for the toes (Fernandes et al., 2013).

The Osteoarthritis Research Society International recommends the use of walking sticks in the management of knee osteoarthritis, but states there is a lack of evidence to support their use in multiple joint osteoarthritis (McAlindon et al., 2014). A single RCT concluded that using a walking stick, in comparison with usual disease management, can diminish pain and improve function and some aspects of quality of life in participants with knee osteoarthritis (Jones et al., 2012). In addition to walking sticks EULAR recommends walking frames or wheeled walkers in people with osteoarthritis of the hip or knee. Adaptive measures in the home, such as raising the height of chairs, beds and toilet seats or adding hand rails to stairs, may also be of benefit (Fernandes et al., 2013).

Joint protection is recommended in people with hand osteoarthritis. This consists of using the hands in a different way to avoid adverse pressure on the joints (Hochberg et al., 2012; Zhang et al., 2007). People with osteoarthritis of the hand should avoid gripping things too tightly and also positions that push the joint towards deformity. The Arthritis Research UK website (<http://www.arthritisresearchuk.org>) provides clear guidance on how to protect the hand joints when performing simple daily activities. Splints may be used for thumb base osteoarthritis.

Joint surgery

Joint surgery can be divided into arthroscopic (keyhole) surgery and joint replacement. Arthroscopic surgery is not recommended as part of osteoarthritis treatment unless a person with knee

osteoarthritis has a clear history of true mechanical locking; this is where the knee suddenly cannot be fully straightened from a position of knee bend. This surgery does not otherwise improve clinical outcomes of knee osteoarthritis, even with symptoms of 'giving way' (typically a symptom of muscle weakness) or evidence of loose bodies on X-rays (Zhang et al., 2010). Joint replacement surgery should be considered when a patient with osteoarthritis suffers persistent debilitating symptoms despite treatment (NICE, 2014). Patients with osteoarthritis can be referred for a surgical opinion irrespective of age, gender, comorbidities, obesity and smoking status. Referral should occur before severe pain or established functional limitation develops.

Pharmacological management

The key management strategy for osteoarthritis is lifestyle change. Medication should be seen as an adjunct and not a replacement for appropriate exercise and diet. Paracetamol or topical NSAIDs should be used as first-line pharmacological treatments in patients with hand or knee osteoarthritis. Where either agent alone provides insufficient symptomatic benefit, the two medicines may be used in combination before progressing to the next step of pharmacological management. It is important to confirm that persistent pain is not being caused by non-adherence to a recommended exercise regimen.

Recommended treatments for osteoarthritis

Topical non-steroidal anti-inflammatory drugs. NICE (2014) supports the use of topical NSAIDs in the management of osteoarthritis. None of the current recognised international guidelines on the management of osteoarthritis give preference to a particular topical NSAID. A Cochrane review on the use of topical NSAIDs for chronic musculoskeletal pain in adults concluded that topical NSAIDs provide a good level of pain relief in osteoarthritis (Derry et al., 2016). In the review topical diclofenac solution was found to be equivalent to oral NSAIDs in knee and hand osteoarthritis, but there was no evidence for other painful conditions. For every six participants treated with diclofenac solution in the assessed studies, only one experienced a good level of pain relief over a period of 8–12 weeks. Diclofenac solution was shown to be more effective than diclofenac gel in the review (Derry et al., 2016). Gastro-intestinal side effects for topical NSAIDs did not differ from placebo, but there was an increase in localised skin reaction. Pain relief with topical NSAIDs may not be instant and is likely to increase over a period of several days; treatment should be discontinued if there is a lack of benefit after 4 weeks.

Paracetamol. Paracetamol monotherapy on a as required basis may be tried as an alternative first-line strategy to a topical NSAID in osteoarthritis. If intermittent consumption does not provide sufficient pain relief, then paracetamol may be given on a regular basis. It should be noted that both a systematic review and a meta-analysis have found paracetamol to be less effective in osteoarthritis than originally thought (Towheed et al., 2006; Zhang et al., 2010). In addition, toxicity associated with paracetamol use is greater than previously perceived at upper-end doses, with a dose-related increased incidence of mortality,

cardiovascular, gastro-intestinal and renal adverse events (Craig et al., 2012; Roberts et al., 2016). It is important that all patients are advised not to exceed the recommended dose in a 24-hour period.

Oral non-steroidal anti-inflammatory drugs. NICE (2014) recommends the use of oral NSAIDs when initial treatment with a topical NSAID and/or paracetamol has provided no symptomatic relief or the relief provided by using these agents is insufficient. Where there has been no relief with topical NSAID and/or paracetamol these medicines should be stopped and the patient should be commenced on either a non-selective NSAID or a COX-2 inhibitor. Where partial relief has been achieved with the initial therapeutic strategy, it is recommended paracetamol be continued and the topical NSAID be switched to either a non-selective NSAID or a COX-2 inhibitor. No preference is made for either type of NSAID; the choice should be based on any additional comorbidities the patient may have (e.g. cardiovascular disease, renal disease, history of peptic ulcer disease), concomitant medication, patient preference and the side-effect profile of the individual NSAID. A meta-analysis has demonstrated an increased cardiovascular risk in all NSAID users, irrespective of their baseline risk or duration of use (Trelle et al., 2011). A higher risk was demonstrated where there was chronic, high-dose consumption, particularly in the case of COX-2 inhibitors and diclofenac (Bhala et al., 2013). Naproxen was shown to have a lower thrombotic risk compared with other assessed NSAIDs. It is recommended that the lowest effective dose of NSAID should be used and the duration kept to a minimum. Gastric protection in the form of a proton pump inhibitor should be co-prescribed with all NSAIDs including the COX-2 inhibitors in patients with osteoarthritis. Patients vary in their clinical response to NSAIDs; if no clinical response is seen after 3–4 weeks, then it may be beneficial to switch the patient to an alternative NSAID.

Opioid analgesics. In patients with osteoarthritis who are taking low-dose aspirin it may be preferable to use an opioid analgesic in combination with paracetamol in place of an oral NSAID. Opioid analgesics may also be used where there is a contraindication to the use of an oral NSAID and initial management with a topical NSAID and/or paracetamol has been ineffective. NICE (2014) supports the use of opioids in its guidance, but makes no recommendation with regard to the type of opioid analgesic to be used. A Cochrane review evaluating the benefit of oral (excluding tramadol) or transdermal opioids for osteoarthritis of the knee or hip found a small mean benefit, but a significant increase in adverse effects associated with opioid use (da Costa et al., 2014). The ACR guidance on the management of osteoarthritis supports the use of tramadol, but not other opioids (Hochberg et al., 2012).

Care should be taken when prescribing opioids in elderly patients because they are particularly sensitive to the side effects associated with opioid consumption. Laxatives should be provided where appropriate to prevent constipation. The risk of a fall may be increased due to sedation and/or dizziness associated with opioid consumption, especially in the presence of other medicines known to cause sedation. A medication review should be performed and previous tolerance to opioid side effects evaluated before commencing an opioid analgesic in an elderly patient.

Topical capsaicin. Topical capsaicin cream is derived from capsicum extract, which comes from the pepper family of plants. Its mechanism of action is not fully understood, but it has been proposed to exert its analgesic effect by depleting and preventing the re-accumulation of substance P in peripheral sensory neurones. Substance P is thought to be involved in the transfer of pain impulses from the peripheral nervous system to the central nervous system. The 0.025% cream is licensed for the management of osteoarthritis in the UK, and NICE (2014) recommends it as an adjunct therapy for knee and hand osteoarthritis. Its use can be considered at any stage of treatment. It is important that the cream is applied at regular intervals, up to four times a day, to ensure the patient gains tolerance to the burning sensation associated with the initial use of capsaicin. Relief of pain usually starts within the first week of treatment, but this gradually builds if the cream is applied regularly for 2–8 weeks.

Intra-articular corticosteroids. In osteoarthritis of the knee, intra-articular injections of corticosteroids into the joint may relieve inflammation and reduce pain and disability (Bannuru et al., 2009). NICE guidance on the management of osteoarthritis suggests intra-articular corticosteroids should be considered as adjuncts to core treatment for the relief of moderate-to-severe pain (NICE, 2015b).

Other therapies available for osteoarthritis management

Chondroitin and glucosamine. Supplements containing chondroitin and/or glucosamine are proposed to provide relief of pain in musculoskeletal conditions such as osteoarthritis. Chondroitin sulphate belongs to a class of very large molecules called glycosaminoglycans, which are made up of glucuronic acid and galactosamine. It is manufactured from natural sources such as shark and bovine cartilage. The rationale for taking this supplement in osteoarthritis is that chondroitin is found endogenously in the cartilaginous tissues of most mammals and serves as a substrate for the formation of the joint matrix structure. A published meta-analysis showed no statistically significant benefit of chondroitin when compared with placebo (McAlindon et al., 2014). In addition, in a stratified analysis of larger, high-quality trials the effects sizes for pain were small to non-existent for chondroitin (Reichenbach et al., 2007).

Glucosamine is available in three forms: glucosamine hydrochloride, glucosamine sulphate and *N*-acetylglucosamine. Glucosamine is required for the synthesis of mucopolysaccharides; these are carbohydrate-containing compounds found in tendons, ligaments, cartilage, synovial fluid, mucous membranes, structures in the eye, blood vessels and heart valves. Meta-analyses have failed to demonstrate a benefit in terms of pain relief or disease modification (Lee et al., 2010; Wandel et al., 2010).

NICE currently states that glucosamine and chondroitin products should not be offered for the management of osteoarthritis (NICE, 2014). The ACR also does not support the use of glucosamine and/or chondroitin in osteoarthritis of the hip or knee (Hochberg et al., 2012).

Hyaluronic acid intra-articular injections. Hyaluronan is a natural substance found in the body and is present in high amounts in the synovial fluid of joints. It acts as a lubricant and shock absorber within the joint. Synthesised hyaluronic acid is gel-like in nature and is injected intra-articularly into the knee joint to supplement the natural hyaluronan in the joint and reduce the pain associated with osteoarthritis of the knee. The injection may reduce pain over 1–6 months, but there may be an increase in knee inflammation in the short-term. Inconsistent conclusions from meta-analyses and conflicting results regarding safety have led to reluctance to support its use in the management of knee osteoarthritis. A systematic review found a small, but significant effect on knee pain by week 4 and a peak at week 8 (moderate clinical significance), with effect lasting up to 24 weeks (Bannuru et al., 2011). Other reviews have found only moderate benefit (Rutjes et al., 2012). In the UK the routine use of hyaluronic intra-articular injections is not supported (NICE, 2014). Current ACR recommendations support use in people older than 74 years with knee osteoarthritis that is refractory to standard pharmacological treatments (Hochberg et al., 2012).

Future management

Disease-modifying anti-rheumatic drugs. Biopsy studies have demonstrated histological synovitis in the early stages of chondral damage in osteoarthritis with cellular infiltration with macrophages, activated T and B cells, and vascular proliferation. Elevated cytokine levels have been demonstrated, but to a less extent than those seen in RA. Ongoing osteoarthritis methotrexate studies, including the PROMOTE study, are evaluating the benefits of oral methotrexate in knee osteoarthritis (Kingsbury et al., 2015). The analgesic and structural benefit of hydroxychloroquine in osteoarthritis is also being studied (Kingsbury et al., 2013). Current guidance on the management of osteoarthritis does not incorporate the use of DMARDs; further research is required to clearly define their role in osteoarthritis.

In vitro blocking TNF action decreases production of enzymes and pro-inflammatory mediators in osteoarthritis cartilage explants (Kobayashi et al., 2005). The use of TNFi has therefore been proposed in refractory osteoarthritis. A recent French study evaluating the symptomatic efficacy of adalimumab in patients suffering from hand osteoarthritis with a high level of pain and no response to analgesics and NSAIDs failed to show superiority over placebo (Chevalier et al., 2015). Other biologic therapies being evaluated include anti-nerve growth factor (anti-NGF) monoclonal antibodies. They work by selectively targeting, binding to and inhibiting NGF. NGF levels increase in the body as a result of injury, inflammation or in chronic pain states. The NGF monoclonal antibody tanezumab is the first medicine of this kind given US Food and Drug Administration fast-track approval for the treatment of chronic pain in osteoarthritis.

Patient Care

No pharmacological treatments are known to prevent or cure osteoarthritis. Pharmacological treatments are adjuncts that offer at best moderate symptom relief, and the key to

management is promoting lifestyle change. The limited role that medication plays should be explained to the patient, and that it is not a substitution for lifestyle modification. Patients should be encouraged to lose weight and eat a healthy diet. Exercise should become part of their daily routine, and the ideal regimen should include local muscle strengthening (e.g. quadriceps muscle exercise for knee osteoarthritis) combined with general aerobic fitness.

Case studies

Case 54.1

Mrs SM is a 56-year-old woman who has been referred to the hospital rheumatologist by her primary care clinician. Mrs SM has an 8-week history of painful joints in her fingers (mainly the PIP and MCP) and in the joints of her lower limbs. She initially thought her symptoms were due to her working hard in the garden, but they have gradually worsened over the past few weeks despite resting. She also complains of feeling tired all the time. The primary care clinician initially thought it was musculoskeletal pain and prescribed a short course of NSAIDs in combination with paracetamol. However, when her symptoms failed to resolve and there was evidence of swelling in the small joints of her hands he decided to perform some blood tests including inflammatory markers and refer her to a rheumatologist. Blood tests showed a CRP level of 20 mg/L. She has a medical history of hypertension, and current medication consists of amlodipine 5 mg once daily, naproxen 500 mg twice a day and paracetamol 500 mg four times a day. In clinic, the hospital doctor takes a brief medical history from the patient and performs a physical examination. On examination there is active synovitis in the wrists, MCP joints and PIP joints of both hands and synovitis in both ankles. Mrs SM complains of early-morning stiffness persisting for up to 2 hours each morning. Her hands and wrists of both arms have been tender and swollen for the last 2 weeks, and she has found it difficult to walk because of swelling and pain in both knee joints and in her feet. The hospital doctor following blood tests, X-rays and physical examination makes a provisional diagnosis of RA.

Questions

1. What common signs and symptoms of RA does Mrs SM present with?
2. What treatments would be recommended for the initial management of Mrs SM's RA?

Answers

1. Mrs SM presented with swelling and pain in the small joints of the hands (PIPs and MCPs). Examination of the hand joints by the doctor indicated the presence of active inflammation (synovitis). There was also active synovitis in the ankle joints and she had a raised CRP level. Morning stiffness is a common early feature of RA. Mrs SM complained of stiffness lasting up to 2 hours each morning. Patients may experience fatigue and widespread musculoskeletal pain before there is visible swelling of the joints. There is no specific test to confirm the presence of RA. Presenting symptoms, X-ray images and blood tests including non-specific inflammatory markers (CRP, ESR) and auto-antibodies (RF, ACPA) are used in the diagnosis of RA. The presence or absence of these features is used to generate a score using the ACR and the EULAR diagnostic algorithm. A score of at least 6 out of 10 is required for a diagnosis of RA.

2. It is recommended that treatment with either combination or csDMARD monotherapy is commenced as soon as a diagnosis of RA is made. The agent of choice is methotrexate, and it can either be combined with other csDMARDs or given as monotherapy according to clinician and patient preference. Where methotrexate is contraindicated either leflunomide or sulfasalazine may be considered. Hydroxychloroquine tends to be used in mild disease or in combination with other csDMARDs because it has not been shown to inhibit structural damage sufficiently when compared with other csDMARDs. Response to treatment with csDMARD therapy should be closely monitored using a disease activity scoring system such as the DAS28. If there is a lack of clinical response at 3 months, then the therapeutic strategy should be altered. The aim is to achieve the therapeutic target of clinical remission at 6 months or where this is not possible low disease activity.

DMARDs have a delayed onset of action: it may take 4–6 weeks before the patient starts to see a response, and up to 4–6 months before a full response is achieved. The use of low-dose glucocorticosteroids is recommended as part of the initial treatment strategy because they are effective in reducing symptoms and disease activity when waiting for the therapeutic onset of a DMARD. In addition they have been shown to be effective adjunctive treatments with the main DMARD therapy to more efficiently achieve the desired target (usually clinical remission). When oral corticosteroids are used as part of the initial treatment strategy they should be tapered off as rapidly as clinically feasible and ideally within 6 months. Due to the effect of corticosteroids on bone mineral density, the need for calcium and vitamin D supplementation in combination with a bisphosphonate should be considered during treatment with corticosteroids.

Mrs SM is already taking the NSAID naproxen. NSAIDs may be prescribed in addition to csDMARD and glucocorticoids because they can help relieve pain and stiffness. They should be used in short courses at the lowest effective dose to provide symptomatic relief. Persistent pain and stiffness, despite the introduction of csDMARDs, indicates active disease and the need to change or step up treatment with DMARDs. No NSAID has demonstrated superiority over another in RA, but they differ in their side-effect profiles. The basis of selection should be according to patient preference and comorbidities. An increased cardiovascular risk is associated with all NSAIDs, irrespective of their baseline risk, and not only in chronic users. The greatest concern relates to chronic users of high-dose NSAIDs, especially the COX-2 selective agents and diclofenac. Evidence suggests that naproxen is associated with a lower thrombotic risk than the COX-2 selective agents. A gastro-protective agent should be prescribed with an NSAID whether it is non-selective or COX-2 selective.

Paracetamol used in combination with a weak opiate such as dihydrocodeine can be beneficial in providing simple pain relief. Although the combination has no anti-inflammatory properties and will not affect the disease process, simple analgesic combinations such as this do have a place in both early and late stages of the disease.

Case 54.2

Mr PB is a 58-year-old man who was diagnosed as having RA 6 months ago. He has been on combination DMARD therapy with injectable methotrexate 25 mg subcutaneously once a week, and hydroxychloroquine 200 mg twice a day. At his hospital appointment with the rheumatologist he is still symptomatic with active synovitis demonstrated by ultrasound in the small joints of his hand. He reports significant fatigue and feeling unwell. His calculated DAS28 is 5.2. After a discussion with the rheumatologist, a decision is made to start a biologic DMARD.

The rheumatologist discusses the various biologic medicines available with the patient and provides the patient with a number of leaflets about these medicines prepared by Arthritis Research UK. He asks the patient to have a think about which therapy he would prefer while important screening tests are performed.

Questions

1. Does Mr PB meet the UK criteria for commencement of a biologic medicine in RA?
2. What first-line biologic medicines are likely to be offered to Mr PB by his rheumatologist?
3. What blood tests should be performed before Mr PB is commenced on a biologic medicine?

Answers

1. Mr PB's RA has failed to respond to combined treatment with two csDMARDs, methotrexate and hydroxychloroquine. His calculated DAS28 score is also greater than 5.1. Biologic medicines now form part of the standard treatment strategy for RA, and NICE recommends the use of a biologic medicine in RA in patients with a DAS28 greater than 5.1 whose disease has not responded to intensive therapy with a combination of conventional DMARDs (NICE, 2016).
2. In the UK NICE supports the use of adalimumab, etanercept, infliximab, certolizumab pegol, golimumab, tocilizumab and abatacept, all in combination with methotrexate (NICE, 2016). In patients who cannot take methotrexate, adalimumab, etanercept, certolizumab pegol or tocilizumab can be given as monotherapy. At present there is no evidence to support one biologic over another as a first-line option. NICE proposes that the least expensive biologic medicine should be prescribed, but consideration should be given to the patient's preferred mode of administration and treatment schedules which do not interfere with work and home commitments. Other factors which will be considered by the rheumatologist include the presence of comorbidities such as heart disease, lung disease, previous malignancy, co-existing autoimmune diseases (IBD and psoriasis) and the presence of auto-antibodies associated with connective tissue diseases such as SLE.
3. The use of biologic medicines is associated with an increased risk of serious infection including TB and hepatitis B/C. The presence of these diseases must be excluded before a biologic medicine is commenced. Mr PB will be asked to have blood test to evaluate the presence of TB (Quantiferon-TB) and antibodies associated with past hepatitis B and C infection. An FBC, chest X-ray and urinalysis will be performed to exclude the presence of other types of infections. The TNFi may activate or worsen SLE. Mr PB will be screened for the presence of auto-antibodies which are associated with the development of SLE; this can be done using a simple blood test. Baseline LFT should be performed because the TNFi, abatacept and tocilizumab can cause a rise in transaminases. Particular care should be taken with tocilizumab in patients with elevated ALT or AST greater than 1.5 times ULN because of the increased incidence of significant rises in transaminases associated with the use of tocilizumab. None of the first-line recommended biologics have been studied in moderate-to-severe renal disease, and there are no specific recommendations regarding dose reduction. Renal function should be evaluated at baseline and intermittently throughout treatment. The use of tocilizumab has been associated with abnormal lipid profiles; if Mr PB has a background history of cardiovascular disease the rheumatologist may also assess Mr PB's lipid profile.

Case 54.3

Mrs JT is a 65-year-old woman who is referred by her primary care clinician for progressive left knee pain. She has little morning stiffness and significant swelling towards the end of the day. She is taking paracetamol, but this is not particularly helpful. She has been gaining weight (body mass index is now 36), and more recently her knee is giving way when she is walking.

Questions

What measures would you recommend to manage Mrs JT's symptoms of osteoarthritis?

Answers

The measures to be undertaken as listed below:

- Provide advice and support on achieving weight loss. Weight loss has been shown to have a dose-dependent effect on pain relief,

and ideally 10% of body weight should be lost. This may be best achieved by walking in the swimming pool first, so that it is not too painful for Mrs JT.

- Review Mrs JT's analgesia. Mrs JT is already taking paracetamol; a trial of topical capsaicin 0.025% cream four times a day for 1 month or a topical NSAID should be tried. If a trial of topical therapies is not beneficial, then treatment may be stepped up to an oral NSAID provided there are no contraindications.
- Recommend use of a knee brace because this can help reduce pain and further structural damage.
- Encourage exercise and seek the support of the physiotherapy service. They will assess Mrs JT's current muscle strength and provide her with an exercise programme which will include exercises to improve and maintain quadriceps strength. Quadriceps exercises should be maintained lifelong to stabilise the joints and reduce pain.
- In spite of all of the above recommendations Mrs JT still has persistent activity-related pain that is starting to affect other parts of her body (e.g. shoulders, hips), then referral for knee replacement surgery will be considered.

55 Gout and Hyperuricaemia

Tina Hawkins

Key points

- Gout is the most common inflammatory joint disease in men and is strongly age related.
- The prevalence and burden of gout has increased over recent decades.
- It is caused by the deposition of monosodium urate crystals within articular and periarticular tissue.
- The degree of elevation of uric acid levels above the saturation point for urate crystal formation is a major determinant in precipitating an attack.
- Not all people with hyperuricaemia experience development of gout.
- Gout is normally the result of an interaction between genetic, constitutional and environmental risk factors.
- The aim of long-term therapy is to reduce the serum uric acid level sufficiently so that crystals can no longer form and existing crystals are dissolved.
- Non-pharmacological measures such as lifestyle and dietary modification play an important role in the management of gout.
- Unmanaged recurrent attacks can result in progressive cartilage and bone erosion, deposition of tophi, secondary osteoarthritis and disability.
- Despite the introduction of modern therapies and treatment guidelines, the management of gout remains suboptimal.

The global burden of gout is rising and it is now the most common cause of inflammatory arthritis (Kuo et al., 2015a; Smith et al., 2014). Gout results from the deposition of monosodium urate crystals in peripheral joints and soft tissues due to persistent elevation of uric acid levels above the saturation point for crystal deposition. Chronic hyperuricaemia is associated with disorders of purine metabolism caused by underexcretion or overproduction of uric acid, the final metabolite of endogenous and dietary purine metabolism. Gout usually presents as a monoarthritis in the foot or ankle, especially in the first metatarsophalangeal joint (big toe), and is often referred to as podagra (from the Greek 'seizing the foot'). Subsequent attacks may be in the same or other joints, or involve multiple joints. Other commonly affected joints include the knee, wrist, elbow and finger joints.

Although an acute attack is extremely painful, it is usually self-limiting, resolving spontaneously in 1–2 weeks. Acute attacks are managed with rest, sometimes ice and one or more of the following pharmacological agents: colchicine, non-steroidal anti-inflammatory

drugs (NSAIDs), corticosteroids and, in severe refractory disease, the interleukin-1 (IL-1) receptor antagonists. Some patients may only ever experience one attack, but once a second attack occurs (often within 6–12 months), there is an increased risk of subsequent attacks. Patients with recurrent attacks require long-term prophylaxis with drugs that lower the serum urate level. The drug of choice is usually allopurinol; however, a small percentage of patients are unable to tolerate allopurinol and require treatment with an alternative urate-lowering agent, such as febuxostat, or a uricosuric agent such as benzbromarone, lesinurad, sulfapyrazone or probenecid. Recombinant forms of the enzyme uricase may be used to lower serum urate levels in individuals with severe tophaceous gout. It is essential that pharmacological measures are combined with non-pharmacological measures, such as dietary and lifestyle modification, to prevent recurrent attacks. Inappropriate management of gout can result in chronic tophaceous gout with polyarticular, destructive low-grade joint inflammation, joint deformity and tophi. Gout is not only an inflammatory arthritis of the joints, it is also associated with obesity, hypertension, metabolic syndrome and an increased future risk of major cardiovascular events and premature mortality (Rho et al., 2016).

Epidemiology

Gout is one of the oldest recognised diseases and was identified by the Egyptians in 2460 BC. Hippocrates described it as 'arthritis of the rich' because of the association with certain foods and alcohol. Due to an ageing population and rising obesity, the burden of gout is increasing around the world, especially in high-income countries (Smith et al., 2014). The reported prevalence of gout worldwide ranges from 0.1% to approximately 10%, and the incidence from 0.3 to 6 cases per 1000 person-years (Kuo et al., 2015b). Recent studies have demonstrated both an increase in the prevalence and the incidence of gout in the UK (Kuo et al., 2015a). A study evaluating data up to 2012 has estimated the UK prevalence rate of gout to be 2.49%, with an incidence of 1.77 per 1000 patient-years (Kuo et al., 2015a). Before this, the UK prevalence rate was estimated to be 1.4% and remained fairly static between the period of 1999–2005 (Annemans et al., 2008). Prevalence estimates for Spain and the Netherlands are similar to the UK, whereas Greece has the highest reported prevalence rate of gout in Europe at 4.75% in the adult population. In the USA,

gout has overtaken rheumatoid arthritis to become the most common inflammatory arthritis (Smith et al., 2014).

Gout before the age of 20 years is rare, but prevalence progressively increases from the age of 30 regardless of gender and tends to reach a plateau after the age of 70 years. Worldwide the prevalence of gout is significantly higher in men than women, and the male-to-female ratio is estimated to be 3–4:1 (Kuo et al., 2015b). It is important to note that the prevalence of gout is low in females before the age of 45 years, and this is thought to be due to a link between the menopause and gout (Hak et al., 2010).

A genetic predisposition, increasing age and changes in lifestyle have contributed to the increasing prevalence of gout in many developed countries. The Maori population has been shown to have a genetic predisposition to gout, but before 1700 they did not experience this inflammatory joint disease. Maori now have a threefold greater risk of gout than New Zealanders of European descent (Winnard et al., 2012). It is thought that adaptation to a European diet and lifestyle by the Maori has led to the appearance and increasing prevalence of gout in New Zealand.

Pathophysiology

Uric acid is mainly formed as a by-product from the breakdown of cellular nucleoproteins within the body and purine nucleotides synthesised de novo (Fig. 55.1). The remaining third of uric acid production comes from purine ingestion as part of an individual's diet. The enzyme xanthine oxidase catalyses the oxidation of hypoxanthine, the breakdown product resulting from the catabolism of cellular nucleoproteins, dietary purine and purine nucleotides, to xanthine and xanthine to uric acid (see Fig. 55.1). Uric acid, produced as a consequence of this process, is a weak organic acid with a pK_a of 5.75, and at the physiological pH of the extra-cellular compartment 98% of uric acid is in the ionised form of urate. This is mainly present as monosodium urate due to the high concentration of sodium in the extra-cellular compartment. Monosodium urate has a solubility limit of 380 mmol/L; when the concentration exceeds 380 mmol/L, as in hyperuricaemia, there is a risk of precipitation and the formation of monosodium urate crystals.

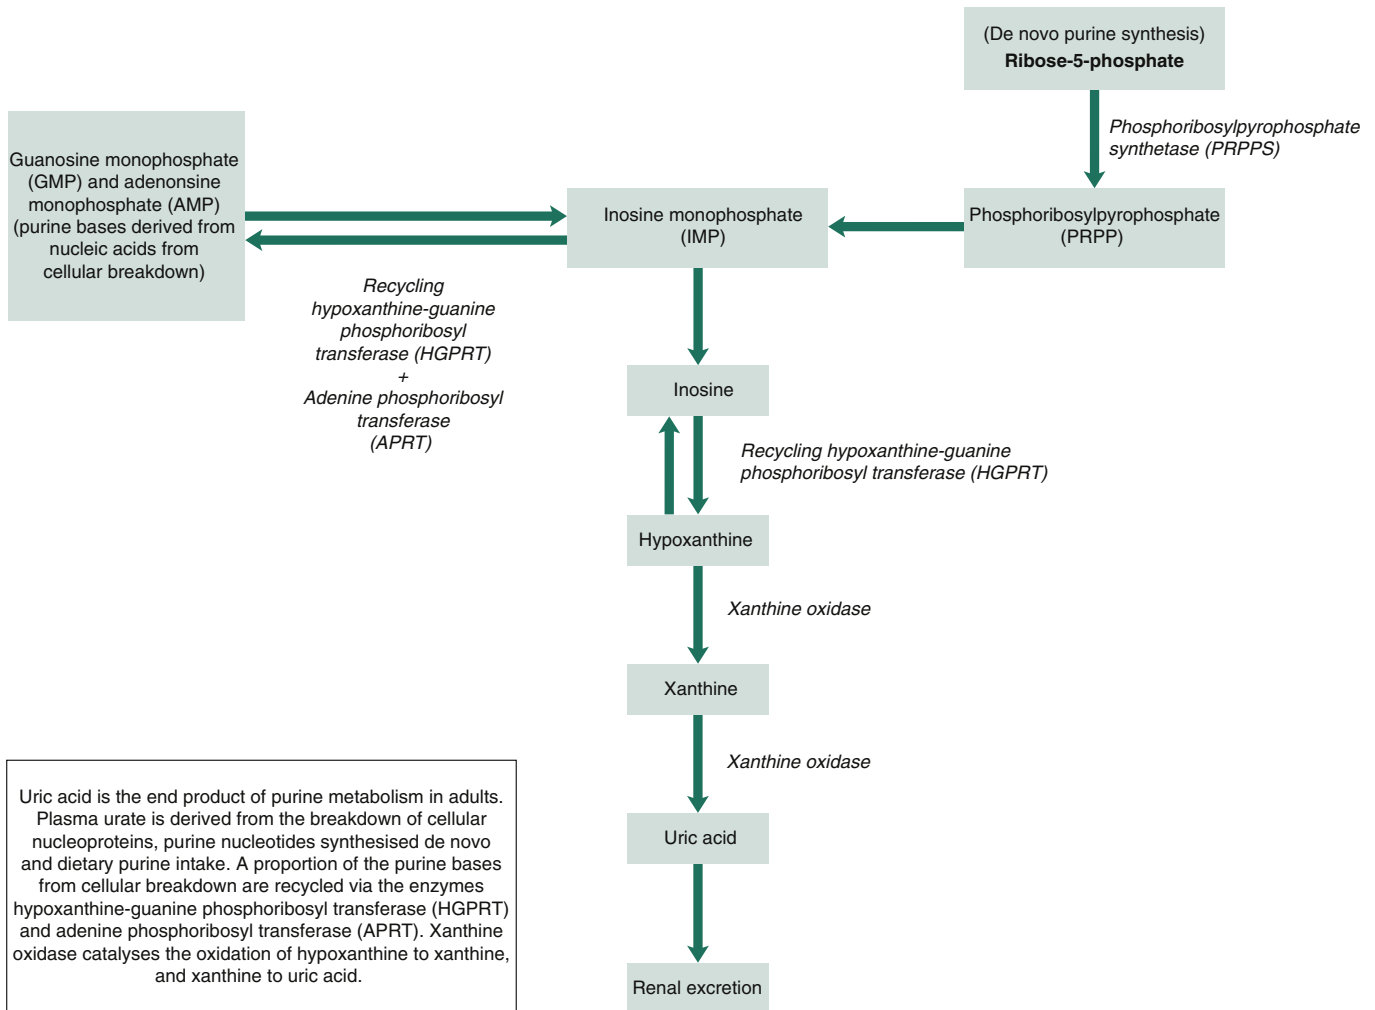

Fig. 55.1 Purine pathway.

Urate haemostasis depends upon the balance between production and complex processes of secretion and reabsorption in the kidney tubule and excretion in the intestine. It is estimated that approximately 30% of uric acid excretion is by the intestine, while renal mechanisms account for the other 70% (Roddy and Doherty, 2010). In the human kidney, urate handling involves urate glomerular filtration followed by a complex array of resorptive and secretory mechanisms taking place in the renal proximal tubule. The urate reabsorption pathway involves a number of important anion transport proteins which are located in the renal proximal tubule; these include URAT1, OAT4 and OAT10 (So and Thorens, 2010). The URAT-1 transporter is targeted by a number of drugs including lesinurad, benzbromarone, probenecid, losartan and sulfinpyrazone (Bernal et al., 2016). GLUT9 is a member of the glucose transporter family and is highly expressed in the kidney proximal tubules of humans. Studies have shown that GLUT9 may play an important role in renal urate reabsorption (Matsuo et al., 2016). Renal mechanisms are responsible for the majority of hyperuricaemia in individuals, with overproduction representing less than 10% of patients with gout.

Gout can be classified as primary or secondary, depending on the presence or absence of an identified cause of hyperuricaemia. Primary gout is not a consequence of an acquired disorder, but is associated with rare inborn errors of metabolism and isolated renal tubular defects in the fractional clearance of uric acid. A rare group of enzyme defects result in an increased de novo purine synthesis such as hypoxanthine-guanine phosphoribosyl transferase deficiency (Lesch–Nyhan syndrome), phosphoribosyl pyrophosphate synthetase super activity, glucose-6-phosphatase deficiency and myogenic hyperuricaemia (Table 55.1).

Secondary gout is the consequence of the use of specific drugs or develops as a consequence of other disorders such as chronic kidney disease or cardiovascular disease. Certain diseases are associated with enhanced nucleic acid turnover, for example, myeloproliferative and lymphoproliferative disorders, psoriasis and haemolytic anaemia, and can lead to hyperuricaemia (see Table 55.1).

Risk factors

Hyperuricaemia

Hyperuricaemia is considered the most important risk factor for the development of gout. A community-based, cross-sectional Taiwanese study involving 3185 adults older than 30 years reported an odds ratio for prevalent gout of 3.65 between men with and without hyperuricaemia (Lin et al., 2000a). The 5-year cumulative incidence of gout was 18.8% in the 223 men who had asymptomatic hyperuricaemia at baseline (Lin et al., 2000b). Another study in Germany reported a 32-fold increased risk of gout in patients with hyperuricaemia compared with those with normal serum uric acid (SUA) levels (Duskin-Bitan et al., 2014). The Framingham Heart Study and Normative Aging Study in the USA also reported a relationship between increased SUA and the risk of gout (Campion et al., 1987; Hall et al., 1967). It is

important to note that hyperuricaemia alone is not an indicator of gout; a number of contributing factors may result in gout developing in an individual (Box 55.1).

Genetics

The involvement of genetics in the development of gout has been supported by both clinical and epidemiological evidence, combined with recent advances in genetic studies. The varying prevalence of gout worldwide suggests both ethnic and genetic differences. A population study in Taiwan demonstrated an aggregation of gout within families with an inheritability of 35.1% in men and 17% in women (Kuo et al., 2015b). As previously discussed, the urate reabsorption pathway involves a number of important anion transport proteins which are located in the renal proximal tubule. Genome-wide association studies have identified single nucleotide polymorphisms in the genes that encode these transport proteins. The SLC22A12

gene codes for the urate transporter 1 (URAT1). URAT1 is important in controlling the reabsorption of uric acid from the proximal renal tubules and is the site of action for a number of drugs including lesinurad, benzbromarone and probenecid. A polymorphism of the SLC22A12 gene has been associated with relative underexcretion of uric acid and hyperuricaemia in German Caucasians (Graessler et al., 2006). The SLC2A9 gene encodes for the glucose and fructose transporter GLUT9, and polymorphisms in these gene have been associated with increased SUA and self-reported gout (Dehghan et al., 2008). Genome-wide studies have also identified a number of other important genes that may be implicated in urate metabolism including ABCG2, which is associated with an urate efflux transporter in the proximal collecting ducts (Matsuo et al., 2016). Ongoing studies are likely to identify other important genes that influence urate levels and the development of gout.

Age, sex and socioeconomic

The prevalence of gout is much higher in men, and the risk of gout steadily increases in men as they age. Females have a low prevalence of gout up to the age of 45 years, but the risk of gout sharply rises after menopause. The rapid rise after menopause is thought to be due to the loss of the uricosuric effects associated with oestrogen. In the Nurse's Health Study, the use of hormone replacement therapy in menopausal women was shown to reduce the risk of the development of gout (Hak et al., 2010). Geographical location may also play a role in the development of gout; European studies have shown that rural residents have a much lower risk of gout compared with their urban counterparts (Kuo et al., 2015b). Historically gout was considered a disease of affluence, but recent research in the UK has demonstrated higher rates of gout in less affluent areas (Kuo et al., 2015a).

Renal disease

Experts have emphasised the importance of screening for renal disease in individuals with gout and/or hyperuricaemia because of the strong association between the two conditions (Sivera et al., 2014). An increased incidence of end-stage renal disease has been found in patients with hyperuricaemia, but gout has not been found to be an independent predictor for this disease (Iseki et al., 2004). However, studies have shown a fourfold increase in mortality due to kidney disease in patients with gout compared with their non-gout counterparts (Hsu et al., 2009). A retrospective study in the USA involving 259,209 patients registered on a renal database found the incidence rate of gout to be 5.4% in the first year of dialysis and 15.4% in the first 5 years (Cohen et al., 2008). UK studies have also demonstrated an increased risk of gout in patients with renal transplant (Mikuls et al., 2005). Men with gout have a twofold greater risk of kidney stones than patients without gout (Jordan et al., 2007). The likelihood of stones increases with serum urate concentration, extent of urinary acid secretion and low urine pH.

Comorbidities

Metabolic syndrome is a multiplex risk factor for atherosclerotic cardiovascular disease that consists of atherogenic dyslipidaemia,

raised blood pressure, increased blood glucose, and both pro-thrombotic and pro-inflammatory states. In the USA, metabolic syndrome is present in 63% of those with gout compared with 25% of those without gout (Choi et al., 2007a). Other studies have shown obesity, weight gain and hypertension all to be independent risk factors for the development of gout (Choi et al., 2005). The skin disease psoriasis, as well as certain types of anaemia (sickle cell anaemia), has also been associated with an increased incidence of gout (Kuo et al., 2015b). Osteoarthritis has been linked to gout rather than being an actual risk factor because of the increased propensity for nucleation and growth of monosodium urate crystals in osteoarthritic cartilage (Roddy and Doherty, 2010).

Diet

Studies have demonstrated that a purine-rich diet increases the risk of gout. In the Health Professional Follow-up Study in the USA the incidence of gout was higher in individuals who consumed greater quantities of meat or seafood (Choi et al., 2004). In contrast, a diet high in purine-rich vegetables does not increase the risk, and the consumption of low-fat dairy products reduces the relative risk of gout with each additional dairy serving. The consumption of soft drinks sweetened with sugar (not diet drinks) has also been linked to an increase in the number of gout cases, particularly in the USA (Choi and Curham, 2008). A study in New Zealand found that the consumption of four sugar-sweetened soft drinks per day was associated with a sevenfold increase in prevalent gout in European descendants and a fivefold increase in Maori (Batt et al., 2014). Fructose contained in commercial sweetened soft drinks increases the degradation of purine nucleotides that act as a substrate for uric acid production. Vitamin C (ascorbic acid) has been shown to have a modest uricosuric effect (Huang et al., 2005), and coffee consumption may reduce the risk of the development of gout (Choi et al., 2007b). The consumption of cherries, but no other fruits, has been shown to decrease uric acid levels (Zhang et al., 2006).

Alcohol

Increased daily consumption of alcohol is associated with a higher risk of gout. Beer carries the greatest risk, probably because of its high purine content, followed by spirits. However, a moderate consumption of wine is not associated with an increased risk of the development of gout (Jordan et al., 2007). The mechanism of action involved is thought to be the metabolism of ethanol to acetyl coenzyme A leading to adenine nucleotide degradation, with resultant increased formation of adenosine monophosphate, a precursor of uric acid. Alcohol also raises lactic acid levels in blood, which inhibits uric acid excretion.

Medication

A number of drugs are associated with increased uric acid levels (Box 55.2). The use of both loop and thiazide diuretics is the most common modifiable risk factor for secondary gout, especially in

Box 55.2 Examples of drugs known to raise serum urate levels

 Ciclosporin
 Cytotoxic chemotherapy
 Diuretics (both loop and thiazide)
 Ethambutol
 Levodopa
 Pyrazinamide
 Ribavirin and interferon
 Ritonavir
 Teriparatide

the elderly. It is thought that loop and thiazide diuretics may precipitate an attack via volume depletion and reduced renal tubular secretion of uric acid. Aspirin has a bimodal effect; low doses inhibit uric acid excretion and increase urate levels, while doses greater than 3 g/day are uricosuric.

The prescribing of ciclosporin in organ transplant patients is an independent risk factor for new-onset gout in this group. The proposed mechanism of action is the interaction of ciclosporin with the hOAT10 transporter that mediates urate/glutathione exchange in the kidney (Bahn et al., 2008). Radiotherapy and chemotherapy in patients with neoplastic disorders can cause hyperuricaemia because of increased cell breakdown; to overcome this, prophylactic treatment may be given with allopurinol, commencing 3 days before therapy. Patients with HIV have been proposed to have a higher risk of gout; this has partly been linked to the use of ritonavir that can cause hyperuricaemia (Creighton et al., 2005).

Presentation and diagnosis

An acute attack of gout has a rapid onset, with pain being maximal at 6–24 hours of onset and spontaneously resolving within several days or weeks. The first attack usually affects a single joint in the lower limbs in 85–90% of cases, most commonly the first metatarsophalangeal joint (big toe). The next most frequent joints to be affected are the mid-tarsi, ankles, knees and arms. The affected joint is hot, red and swollen with shiny overlying skin. Even the touch of a sheet on the affected joint is too painful for the patient to bear. The patient may also have a fever, leukocytosis, raised erythrocyte sedimentation rate or C-reactive protein (CRP), and the attack may also be preceded by prodromal symptoms such as anorexia, nausea or change in mood. After resolution of the attack, there may be pruritus and desquamation of the overlying skin on the affected joint.

Monosodium urate crystals preferentially form in cartilage and fibrous tissues, where they are protected from contact with inflammatory mediators. The deposition of crystals may continue for months or years without causing symptoms; it is only when the crystals are shed into the joint space or bursa that inflammatory reaction occurs precipitating an acute attack of gout. The shedding of crystals can be triggered by a number of factors including direct trauma, dehydration, acidosis or

rapid weight loss. The acute-phase response associated with intercurrent illness or surgery may also precipitate an attack; during this phase, there is increased urinary urate excretion with a lowering of SUA that leads to partial dissolution of monosodium urate crystals and subsequent shedding of crystals into the joint space.

The shed crystals are phagocytosed by monocytes and macrophages, activating the NACHT–LRR–PYD-containing protein-3 (NALP3) inflammasome and triggering the release of IL-1 β and other cytokines, a subsequent infiltration of neutrophils and the symptoms of an acute attack (Dalbeth and Haskard, 2005). The NALP3 inflammasome (cryopyrin) is a complex of intracellular proteins that is activated on exposure to microbial elements, such as bacterial RNA and toxins. Activation of NALP3 leads to the release of caspase-1, which is required for cleavage of pro-IL-1 β to active IL-1 β (Richette and Bardin, 2009). IL-1 β has been shown to be critically associated with the inflammatory response induced by monosodium urate crystals (Rider and Jordan, 2010).

The presence of hyperuricaemia alone is insufficient to confirm a diagnosis of gout, and approximately one-third of patients will have normal uric acid concentrations during an acute attack of gout because of increased urinary urate excretion. The most appropriate time to measure serum urate for monitoring purposes is when the attack has completely resolved. The gold standard for the diagnosis of gout is the demonstration of urate crystals in synovial fluid or in a tophus by polarised light microscopy (Sivera et al., 2014). Crystals may be found in fluid aspirated from non-inflamed joints, even in those joints that have not previously experienced an attack. The crystals are large (10–20 micrometres) and needle shaped with a strong, intense, characteristic light pattern under polarised light. In contrast, the calcium pyrophosphate dehydrate crystals associated with pseudo-gout are small, rhomboid crystals of low intensity. In some clinical settings it may not be possible to aspirate monosodium urate crystals. Under these circumstances the European League Against Rheumatism (EULAR) recommends a diagnosis based on the classical features of gout such as podagra, tophi and rapid response to colchicine (Sivera et al., 2014). Modern imaging techniques, such as ultrasound and dual-energy computed tomography, can also be used to assist in diagnosis. Gout and septic arthritis may co-exist and to exclude septic arthritis, synovial fluid is sent for Gram staining and culture.

Course of disease

The course of gout follows a number of stages; initially, the patient may be asymptomatic with a raised SUA level (Fig. 55.2). Some patients may only ever experience one attack, but often a second attack occurs within 6–12 months. Subsequent attacks tend to be of longer duration, affect more than one joint and may spread to the upper limbs. Untreated disease can result in chronic tophaceous gout, with persistent low-grade inflammation in a number of joints resulting in joint damage and deformity. The disease is characterised by the

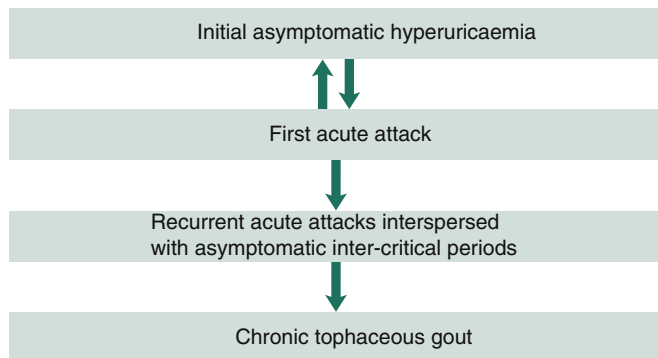

Fig. 55.2 Schematic representation of the stages of gout.

Fig. 55.3 Chronic tophaceous gout.

presence of tophi (**Fig. 55.3**), monosodium urate crystals surrounded by chronic mononuclear and giant-cell reactions. Tophi deposition can occur anywhere in the body, but they are commonly seen on the helix of the ear, within and around the toe or finger joints, on the elbow, around the knees or on the Achilles tendons. The skin overlying the tophi may ulcerate and extrude white, chalky material composed of monosodium urate crystals.

Treatment

The management of gout can be split into the rapid resolution of the initial acute attack and long-term measures to prevent future episodes (**Box 55.3**).

Gout is often associated with other medical problems including obesity, hypertension, excessive alcohol and the metabolic syndrome of insulin resistance, hyperinsulinaemia, impaired glucose intolerance and hypertriglyceridaemia. This contributes to the increased cardiovascular risk and deterioration

Box 55.3 Treatment aims in gout

Rapid alleviation of the acute attack
 Prevention of future attacks
 Lower serum uric acid levels to below saturation point
 Reduce risk of comorbidities, e.g. cardiovascular disease
 Lifestyle modification

Box 55.4 Lifestyle measures

Things to encourage	<ul style="list-style-type: none"> • Daily intake of low-fat or non-fat dairy products • Daily intake of fresh vegetables • Regular exercise • Remaining well hydrated (at least 2 L of water per day)
Items to limit	<ul style="list-style-type: none"> • Limit portion sizes and weekly consumption of beef, lamb and pork • Limit portion sizes and weekly consumption of seafood high in purines (e.g. sardines and shellfish) • Limit servings of naturally sweet fruit juices • Limit table sugar and salt • Limit alcohol consumption, particularly high-purine-type products such as beer
Things to avoid	<ul style="list-style-type: none"> • Smoking • Overweight • Organ meats high in purine content (e.g. liver, kidney and sweetbreads) • High-fructose corn-syrup-sweetened soft drinks or foods • Alcohol overconsumption (more than 2 units per day for a male and 1 unit per day for a female) • Avoid alcohol completely during an attack or if experiencing frequent attacks • Avoid becoming dehydrated

of renal function seen in patients with gout. Management is not only directed at alleviating acute attacks and preventing future attacks, but also identifying and treating other comorbid conditions such as hypertension and hyperlipidaemia. Renal function should be measured and the individual's cardiovascular risk evaluated. A recent general population study has suggested that gout may be independently associated with an increased risk of diabetes, and that the magnitude of association is significantly larger in women than men (**Rho et al., 2016**). It is important that pharmacological measures are combined with non-pharmacological approaches such as weight loss, changes in diet, increased exercise and reduced alcohol consumption (**Box 55.4**). Patients with gout should remain adequately hydrated at all times, especially those with a history of urolithiasis (kidney stones). At least 2 L of water should be consumed per day, and alkalisation of urine with potassium citrate (60 mEq/day) should be considered in recurrent stone formers.

Box 55.5 Medicines used in the management of an acute attack of gout

Initially select a single agent based on the patient's characteristics:

- Colchicine
- Oral NSAIDs (non-selective and selective)
- Intra-articular corticosteroids
- Oral corticosteroids
- Intramuscular corticosteroids
- IL-1 inhibitors

If the first agent is ineffective, consider switching to another or combining two agents (colchicine plus NSAID or colchicine and corticosteroids).

These should always be combined with non-pharmacological approaches:

- Rest the joint for 1–2 days.
- Apply ice to help alleviate pain.
- Remove contributing factors – complete a full medication review.
- Recommend lifestyle changes – diet, exercise and alcohol consumption.

NSAID, Non-steroidal anti-inflammatory drug.

Management of an acute attack

Drugs used in the management of an acute attack include colchicine, NSAIDs, corticosteroids (oral and injectable), and IL-1 inhibitors (Box 55.5). Current guidance gives no preference to a particular agent, but recommends selection based on the number plus type of joint(s) affected and individual patient characteristics (Khanna et al., 2012a; Sivera et al., 2014). In severe cases, where treatment with a single agent has been insufficient, it may be necessary to use a combination approach. Suggested combinations include colchicine with an NSAID and colchicine combined with oral or intra-articular corticosteroids (Khanna et al., 2012b). Simple analgesics such as paracetamol and weak opiates (codeine or dihydrocodeine) can also be added to the treatment regimen to provide additional pain relief. Treatment should be commenced as soon as possible and continued until the attack is terminated, usually between 1 and 2 weeks. The affected joints should also be rested for 1–2 days and initially treated with ice, which has a significant analgesic effect during an acute attack.

A complete medication review should be performed, and ideally medication that is likely to have contributed to the attack discontinued. Where loop and thiazide diuretics are being used for the management of hypertension alone, an alternative antihypertensive agent should be considered according to national guidance. Losartan, an angiotensin receptor blocker effective in hypertension, has been shown to have uricosuric properties and is a suitable agent in hypertensive patients with gout (Sica and Schoolwerth, 2002; Takahashi et al., 2003). In patients with heart failure, diuretics are often essential and cannot be discontinued. Although low-dose aspirin (≤ 325 mg/day) is known to elevate serum urate, its benefits in terms of cardiovascular disease prevention outweigh its modest effect on uric acid levels (Khanna et al., 2012a). Patients who are already taking urate-lowering medicines, such as allopurinol, should continue to take these medicines and should be counselled

on the importance of continuing urate-lowering therapies (ULTs) even during an acute attack of gout.

Colchicine

Colchicine is an alkaloid derived from the autumn crocus (*colchicum autumnale*) and has been reported to have been used in the treatment of gout since the 6th century AD. Colchicine has a slower onset of action than NSAIDs, and it should ideally be commenced within 36 hours of an acute attack. Although the mode of action of colchicine in gout is not fully understood, it is thought to arrest microtubule assembly in neutrophils and inhibit many cellular functions. It suppresses monosodium urate crystal-induced NALP3 inflammasome-driven caspase-1 activation, IL-1 β processing and release, and L-selectin expression on neutrophils. Colchicine also blocks the release of a crystal-derived chemotactic factor from neutrophil lysosomes, blocks neutrophil adhesion to endothelium by modulating the distribution of adhesion molecules on the endothelial cells, and inhibits monosodium urate crystal-induced production of superoxide anions from neutrophils (Nuki, 2008).

Although widely used, few studies have demonstrated the efficacy of colchicine. A single, randomised, controlled trial has compared the benefits of colchicine with placebo in acute gouty flare (Ahern et al., 1987). Patients were given 1 mg colchicine followed by 500 micrograms every 2 hours until the attack stopped or they felt too ill to continue taking colchicine. Colchicine was found to be superior to placebo with an absolute reduction of 34% for pain and a 30% reduction in clinical symptoms such as palpation, swelling, redness and pain. The number needed to treat (NNT) with colchicine to reduce pain was 3, and the NNT to reduce clinical symptoms was 2. All participants given colchicine experienced gastro-intestinal side effects such as diarrhoea and/or vomiting. No studies have compared colchicine with either NSAIDs or corticosteroids in an acute flare of gout.

More recent evidence has shown that low-dose colchicine (1.8 mg in 24 hours) is more effective than placebo and as effective as high-dose colchicine with an improved safety profile (Terkrta et al., 2008). EULAR guidance recommends a regimen of up to 2 mg daily (500 micrograms four times a day) for the management of an acute flare (Sivera et al., 2014). American College of Rheumatology (ACR) guidance differs in that it incorporates a 1 mg loading dose followed by 500 micrograms 1 hour later and then after 12 hours has elapsed, 500 micrograms three times a day until the acute attack resolves (Khanna et al., 2012a). If the patient has already been taking colchicine as flare prophylaxis (see later) and has received a treatment dose of colchicine in the last 14 days for an acute flare, then an alternative agent should be selected to manage the attack (Khanna et al., 2012a). It should be noted that only the oral formulation of colchicine is now available in the UK; the intravenous formulation is no longer licensed because its use has been associated with a number of fatalities (2% mortality rate).

Common side effects associated with colchicine are abdominal cramps, nausea, vomiting, and rarely bone marrow suppression, neuropathy and myopathy. Side effects are more common

in patients with hepatic or renal impairment. The dose of colchicine should be reduced in mild-to-moderate renal impairment, for example, creatinine clearance 10–50 mL/min, and it should not be used in patients with severe renal impairment, for example, creatinine clearance less than 10 mL/min. Care should also be exercised in patients with chronic heart failure because of colchicine's ability to constrict blood vessels and stimulate central vasomotor centres.

Colchicine is metabolised by CYP3A4 and excreted by P-glycoprotein; toxicity can be caused by drugs that interact with its metabolism and clearance, and this includes macrolides, disulfiram, ciclosporin and protease inhibitors. The absorption of vitamin B₁₂ may be impaired by chronic administration of high doses of colchicine. It is important to check for potential drug interactions before commencing treatment with colchicine.

Non-steroidal anti-inflammatory drugs

Both non-selective NSAIDs and selective NSAIDs (cyclooxygenase-2 inhibitors) are recommended for the management of an acute flare (Khanna et al., 2012b; Sivera et al., 2014). Non-selective NSAIDs act by direct inhibition of COX-1 and COX-2 via blockade of the COX enzyme site. The subsequent inhibition of prostaglandin production not only reduces inflammation, but also results in additional activities on platelet aggregation, renal homeostasis and gastric mucosal integrity. COX-2 inhibitors preferentially inhibit the COX-2 pathway, and their use is associated with a lower incidence of gastro-intestinal side effects. There are no high-quality trials comparing NSAIDs with placebo, and there is no evidence demonstrating superiority of one NSAID over another in the management of an acute flare (Sivera et al., 2014). Selection should be based on the individual and the presence of comorbidities. Recent studies suggest that some increased cardiovascular risk may apply to all NSAID users, irrespective of their baseline risk, and not only to chronic users (Trelle et al., 2011). The highest risk has been associated with the use of the COX-2 inhibitors, while the non-selective NSAID naproxen is proposed to have the lowest risk associated with its use. NSAIDs should be avoided in patients with heart failure, renal insufficiency and a history of gastric ulceration. Care should also be exercised in elderly patients with multiple pathologies.

The maximum recommended dose of an NSAID (selective or non-selective) should be commenced rapidly after the onset of an attack and then tapered 24 hours after the complete resolution of symptoms. The usual treatment period is 1–2 weeks. Gastric protection should be co-prescribed with both selective and non-selective NSAIDs.

Corticosteroids

Corticosteroids are usually considered where the use of an NSAID or colchicine is contraindicated or in refractory cases. They may be given intravenously, intramuscularly or direct into a joint (intra-articular) when only one or two joints are affected. In patients with a monoarthritis, an intra-articular corticosteroid injection is highly effective in treating an attack. The dose of intra-articular corticosteroids is based on the size of the affected

joint; common doses are 80 mg methylprednisolone acetate for a large joint such as a knee, and 40 mg methylprednisolone acetate or 40 mg triamcinolone acetonide for a smaller joint such as a wrist or elbow. In patients who are unable to take oral colchicine or NSAIDs and intra-articular injection is not appropriate, then intramuscular or oral corticosteroids may be considered. Intramuscular triamcinolone acetonide 60 mg has been shown to be as safe and effective as indometacin 50 mg three times daily in treating an acute attack of gout with earlier resolution of symptoms in the steroid group (Alloway et al., 1993). In patients who are nil by mouth and for whom intra-articular corticosteroids are not appropriate, then intramuscular or intravenous corticosteroids may be considered.

Studies have also demonstrated that oral corticosteroids are equally as effective as NSAIDs and have a similar safety profile (Janssens et al., 2008; Man et al., 2007). Oral prednisolone 30 mg daily for 5 days has also been shown to be equally efficacious to indometacin 50 mg three times a day for 2 days or 25 mg three times a day for 3 days plus paracetamol and has fewer adverse events (Man et al., 2007). The ACR recommends prednisolone 0.5 mg/kg for 5–10 days then stopping, or 0.5 mg/kg per day for 2–5 days and then tapering over 7–10 days (Khanna et al., 2012b). Other oral corticosteroid regimens used in practice include prednisolone 30 mg daily for 1–3 days with subsequent dose tapering over 1–2 weeks. Corticosteroids may have fewer adverse events than other acute treatments when used short-term, particularly in the elderly.

Interleukin-1 inhibitors

IL-1 β is critically associated with the inflammatory response induced by monosodium urate crystals (Rider and Jordan, 2010). Canakinumab is a fully humanised monoclonal antibody against IL-1 β . Its clinical effectiveness was demonstrated in the β -RELIEVED and β -RELIEVED II studies where it was compared with intramuscular triamcinolone 40 mg in individuals with recent gouty flares (Cavagna and Taylor, 2014). It is licensed in Europe for the symptomatic treatment of adult patients with frequent gouty arthritis attacks (at least three attacks in the previous 12 months) in whom NSAIDs and colchicine are contraindicated, are not tolerated, or do not provide an adequate response, and in whom repeated courses of corticosteroids are not appropriate. The National Institute for Health and Care Excellence (NICE) does not currently support the use of canakinumab in the management of gout (NICE, 2013).

Anakinra, an IL-1 receptor antagonist, has been shown to reduce the pain of gout and bring about complete resolution by day 3 in the majority of patients after a course of three 100-mg subcutaneous injections (McGonagle et al., 2007; So et al., 2007). Anakinra is currently not licensed for the management of gout in Europe.

Rilonacept is an Fc fusion protein that engages both IL-1 α and IL-1 β , and has demonstrated efficacy in the management of gout flares. Its market authorisation in Europe was withdrawn in 2012 at the request of the market authorisation holder because of commercial reasons.

Due to the considerable cost of the IL-1 inhibitors, compared with other agents used in the management of acute flares, their

use tends to be limited to patients with severe, refractory disease who have responded inadequately to standard therapies.

Management of chronic gout

The presence of hyperuricaemia is not an indication to commence prophylactic therapy. Some patients may only experience a single episode, and a change in lifestyle, diet or concurrent medication may be sufficient to prevent further attacks (see [Box 55.4](#)). Patients who suffer one or more acute attacks within 12 months of the first attack should normally be prescribed prophylactic ULT ([Box 55.6](#)). There are, however, some groups of patients where prophylactic therapy should be instigated after a single attack. These include individuals with uric acid stones, the presence of tophi at first presentation and young patients with a family history of renal or cardiac disease. The criteria for starting prophylactic therapy for the management of gout is detailed in [Box 55.6](#).

The aim of ULT is to maintain the serum urate level below the saturation point for monosodium urate. The British Society Rheumatology proposes a target level of 300 mmol/L or less to prevent further crystal formation and aid the dissolution of existing crystals ([Jordan et al., 2007](#)). European guidance recommends a slightly higher level of 360 mmol/L, but in the presence of tophi it suggests a lower cutoff point of 300 mmol/L ([Sivera et al., 2014](#)).

It is generally recommended that the initiation of ULT should be delayed until the acute attack has resolved; this is due to the fact that changes in SUA levels caused by ULT can prolong the acute episode or cause a repeat flare. However, the ACR suggests that ULT can be started during an acute attack provided effective anti-inflammatory management is given in conjunction with the ULT ([Khanna et al., 2012a](#)). It is important that at whatever point ULT is commenced, appropriate flare prophylaxis is given. On initiation of ULT, SUA levels should be checked regularly during dose titration (every 2–5 weeks). Once the desired SUA level is reached, it is recommended that the level is checked intermittently along with renal function.

ULTs can be classified into three groups according to their pharmacological mode of action ([Box 55.7](#)). Xanthine oxidase inhibitors (XOIs; uricostatics) act on the enzyme xanthine oxidase. Xanthine oxidase catalyses the oxidation of hypoxanthine to xanthine and subsequently xanthine to uric acid (see [Fig. 55.1](#)). Hypoxanthine comes from the catabolism of cellular

nucleoproteins and purine nucleotides. Blocking the action of this enzyme reduces the production of uric acid. Agents in this group include allopurinol and febuxostat.

Allopurinol

Allopurinol is the prophylactic agent of choice in the management of recurrent gout. To become pharmacologically active, allopurinol must be metabolised by the liver to oxypurinol. Oxypurinol has a much longer half-life than allopurinol, 14–16 hours compared with 2 hours. Both allopurinol and oxypurinol are renally excreted, with oxypurinol undergoing reabsorption from the renal tubule. In patients with reduced renal function, the half-life of oxypurinol is increased with the risk of accumulation and toxicity. It is, therefore, essential that a patient's renal function is checked before the prescribing of allopurinol, and the dose carefully titrated according to this.

Historically a treatment algorithm for allopurinol dose reduction in renal impairment was used because of concerns about toxicity and the increased risk of hypersensitivity reactions (allopurinol hypersensitivity syndrome [AHS]) in patients with poor kidney function. However, many patients do not achieve the desired SUA level with these reduced dosage regimens. A specific relationship between higher allopurinol doses in renal impairment and the risk of AHS has not been demonstrated ([Stamp et al., 2012](#)). It is proposed that the commencing dose of allopurinol is the critical factor and the rate at which the dose is then increased ([Stamp et al., 2012](#)). It has been shown that the dose can be increased above that based on creatinine clearance even in patients with renal impairment ([Stamp et al., 2011, 2012](#)).

In patients with normal renal function the starting dose should be no greater than 100 mg/day; in patients with renal impairment (glomerular filtration rate ≤ 30 mL/min) this should be reduced to 50 mg once a day. The dose should be increased every 2–5 weeks until the desired serum urate level is reached (<300 mmol/L). In patients with normal renal function the recommended dose increment is 100 mg and the maximum recommended daily dose is 900 mg/day. Where there is reduced renal function, the dose should be increased in 50 mg increments, but potentially can be increased to 300 mg/day as long as the patient is appropriately educated and is regularly monitored for signs of drug toxicity, for example, pruritus, rash and

Box 55.6 Criteria for starting prophylactic therapy for gout

The presence of one of the following factors indicates the need for a urate-lowering therapies:

- Recurring acute attacks of gout (two attacks per year)
- Identifiable tophi at presentation (palpable or imaged)
- Identifiable joint damage associated with gout
- Renal impairment at presentation (chronic kidney disease stage 2 or worse)
- History of renal stones (urolithiasis)
- First acute attack and unable to discontinue diuretic medication contributing to attack
- Primary gout starting at a young age (particularly in the presence of a family history of renal or cardiac disease)

elevated hepatic enzymes (Khanna et al., 2012a). A decrease in serum urate will occur within a couple of days of introducing allopurinol therapy, with a peak effect at 7–10 days. The dissolution of tophi may take up to 6–12 months with effective therapy.

Approximately 3–5% of patients treated with allopurinol suffer from an adverse reaction; these usually occur within the first 2–3 months of treatment. True AHS is rare, and in the USA the estimated incidence is approximately 1:1000, with a reported mortality rate of 20–25% (Khanna et al., 2012a). The spectrum of AHS includes Stevens–Johnson syndrome and toxic epidermal necrolysis, as well as systemic features such as eosinophilia, vasculitis, rash and major end organ disease. Concurrent use of thiazide diuretics, age and renal impairment has been implicated as a risk factor. Genetic studies have identified an association with HLA-B*5801 positivity and AHS in certain subpopulations. The ACR recommends the testing of HLA-B*5801 in Koreans with stage 3 or worse chronic kidney disease plus Han Chinese and Thai irrespective of renal function (Khanna et al., 2012a). If these individuals are found to be positive it is recommended that allopurinol be avoided. Before the availability of other ULTs, allopurinol desensitisation was attempted in patients with a mild hypersensitivity to allopurinol. This involved starting with a very low dose (50 micrograms daily) and gradually increasing the dose over a period of several weeks to 100 mg daily. Desensitisation is now only considered where the reaction has been mild and there is an absence of alternative treatment options.

There are a number of important drug reactions with allopurinol. Azathioprine and mercaptopurine are metabolised by xanthine oxidase; co-administration of allopurinol reduces the metabolism of these two medicines, leading to accumulation and toxicity. The dose of azathioprine or mercaptopurine should be reduced to approximately one-quarter of the normal dose when co-prescribed with allopurinol. In addition, full blood counts should be performed at regular intervals to identify potential toxicity. High-dose allopurinol (>600 mg/day) increases carbamazepine blood levels by approximately one-third; the same effect is not associated with lower doses of allopurinol (<300 mg/day).

Febuxostat

Febuxostat is a more selective and potent inhibitor of xanthine oxidase than allopurinol, and it has no effect on other enzymes involved in purine or pyrimidine metabolism (Lawrence Edwards, 2009). It is licensed for the treatment of chronic hyperuricaemia in conditions where urate deposition has already occurred, including a history, or presence of, tophus and/or gouty arthritis. It is recommended as a second-line agent in patients who are intolerant of allopurinol or for whom allopurinol is contraindicated.

Febuxostat is more effective than fixed-dose allopurinol 300 mg in lowering uric acid concentrations in trials of up to 40 months in duration (Schumacher et al., 2008, 2009). However, a reduction in the incidence of episodes of acute gout has not been demonstrated.

The recommended starting dosage for febuxostat is 80 mg once daily. If the SUA is greater than 357 mmol/L (6 mg/100 mL)

after 2–4 weeks, the dose should be increased to 120 mg once daily. The increased potency and good oral bioavailability of febuxostat leads to rapid decreases in SUA levels permitting the testing of levels 2 weeks after starting therapy or adjusting the dose. No dosage adjustment is necessary in patients with mild or moderate renal impairment; however, there are no current recommendations for use in patients with severe renal impairment, for example, creatinine clearance less than 30 mL/min. In patients with mild hepatic impairment, the dose should not exceed 80 mg daily; the use of febuxostat has not been studied in patients with severe hepatic impairment. Febuxostat should not be given to patients with ischaemic heart disease or congestive heart failure because of cardiovascular side effects. When initiating therapy with febuxostat, gout flare prophylaxis should be prescribed for at least 6 months.

The most common adverse effects include respiratory infection, diarrhoea, headache and liver function abnormalities. Rare hypersensitivity reactions have been reported, including Stevens–Johnson syndrome and toxic epidermal necrolysis; these have generally occurred in the first month of treatment. It is recommended that liver function should be tested in all patients before the initiation of therapy and periodically thereafter based on clinical judgement. The use of febuxostat is not recommended in patients concomitantly treated with mercaptopurine or azathioprine and in patients who are taking theophylline.

Selective urate reabsorption inhibitors (uricosuric agents)

Uricosuric agents increase uric acid excretion primarily by inhibiting post-secretory tubular absorption of uric acid from filtered urate in the kidney. They are indicated as second-line agents in those who are urate under-excretors and are dependent on the patient having an adequate level of renal function. These agents should be avoided in patients with urate nephropathy or those who are overproducers of uric acid due to the high risk of development of renal stones. Patients who are receiving an uricosuric agent are required to maintain an adequate fluid intake, and the need for alkalinisation of urine should be considered to prevent urate precipitation.

Benzbromarone

Benzbromarone is a potent uricosuric agent that acts via the renal transporters URAT1 and GLUT9. It has been shown to be effective in lowering serum urate levels and reducing the time to resolution of tophi (Kumar et al., 2005; Reinders et al., 2009). However, its use was associated with hepatotoxicity and it was withdrawn from the UK, although it is still possible to obtain benzbromarone on a named patient basis. The risk of hepatotoxicity has been estimated to be 1:17,000 patients. For those who are prescribed benzbromarone, regular liver function tests must be performed during the first 6 months of therapy, and the hepatotoxic risk associated with the medicine should be clearly explained to the patient at the outset.

The dosage ranges from 50 to 200 mg daily. It remains active in mild-to-moderate renal impairment, but is ineffective

Fig. 55.4 Management of chronic gout in patients who require urate-lowering therapy.

at a creatinine clearance less than 20 mL/min. It should only be used when there is a contraindication to other agents used in the management of gout such as allopurinol and febuxostat (Fig. 55.4). Diarrhoea may be troublesome in approximately 10% of patients.

Sulfinpyrazone

Sulfinpyrazone is effective in reducing the frequency of gout attacks, tophi and plasma urate levels at dosages of 200–800 mg/day. It has the same mode of action on the kidney as benzbromarone and probenecid, all of which inhibit URAT-1 transporter, resulting in reduced urate reabsorption. However, in addition to this, sulfinpyrazone inhibits prostaglandin synthesis resulting in a similar adverse effect profile to NSAIDs, for example, gastrointestinal ulceration, acute renal failure, fluid retention, elevated liver enzymes and blood disorders. The use of sulfinpyrazone is reserved for use in patients with adequate renal function who are underexcretors of uric acid and intolerant or resistant to treatment with allopurinol.

Probenecid

Probenecid monotherapy is less effective than the other agents, and it is generally reserved for those who cannot tolerate or fail to achieve the target serum urate level with XOIs. The combination of allopurinol and probenecid can provide additional urate lowering than either agent alone (Stamp and Chapman, 2014). Dosages of 0.5–2.0 g/day have been used. As with sulfinpyrazone, it is ineffective in renal impairment and is not recommended if the

creatinine clearance is less than 50 mL/min. Dyspepsia and reflux may be troublesome in some patients, and probenecid can interact with renally excreted anionic drugs. Probenecid is no longer marketed in the UK.

Lesinurad

Lesinurad is a new URAT-1 selective uric acid reabsorption inhibitor. It gained a European license in 2016 and is recommended in combination with a XOI in adults with gout who have not achieved the target SUA level with a XOI alone. The recommended dosage is 200 mg once a day, and it should be administered at the same time as the XOI. SUA levels should be measured 4 weeks after commencing treatment. The minimum allopurinol dosage to be given with lesinurad is 300 mg once a day in normal renal function and 200 mg when the glomerular filtration rate 30–59 mL/min. In clinical trials there were a number of adverse renal events, and lesinurad is contraindicated where the creatinine clearance is less than 30 mL/min, in patients undergoing dialysis and in patients with renal transplant. Renal function should be measured at baseline and at least four times a year. It is also not recommended in patients with unstable angina, New York Heart Association class III or IV heart failure, uncontrolled hypertension or with a recent event of myocardial infarction, stroke, or deep venous thrombosis within the last 12 months, due to insufficient data. Because lesinurad is metabolised by the cytochrome P450 enzymes, there are a number of important drug reactions involving substrates for CYP3A (e.g. simvastatin, amlodipine, felodipine and hormonal contraceptives) and CYP2C9 (e.g. inhibitors: fluconazole and amiodarone; inducers: carbamazepine).

Uricosytics (uricases)

In humans and the great apes, uric acid is the end product of purine degradation, but in other mammals, uric acid is further degraded by the enzyme uricase to allantoin, which is highly soluble. Biotechnology processes have been utilised to produce recombinant forms of the enzyme uricase, and current forms include rasburicase and pegloticase. The use of these recombinant products is usually restricted to severe, refractory cases of gout because of the high cost, the need for intravenous administration and the development of neutralising antibodies with subsequent hypersensitivity reactions.

Rasburicase

Rasburicase, a recombinant form of the enzyme urate oxidase (uricase), is derived from a cDNA code from a modified *Aspergillus flavus* strain expressed in a modified strain of *Saccharomyces cerevisiae*. It is licensed to treat tumour lysis syndrome and is given intravenously at a dose of 0.2 mg/kg in short courses for 5–7 days. Rasburicase has a half-life of approximately 19 hours. No dosage adjustment is required in patients with renal or hepatic impairment. Rasburicase is generally well tolerated, but adverse effects include fever, nausea,

vomiting, rash, diarrhoea, headache, allergic reactions and the development of auto-antibodies.

Pegloticase

Pegloticase is a polyethylene glycol conjugate of the recombinant enzyme uricase. Its European Market Authorisation is for severe, debilitating, chronic tophaceous gout in adults who may also have erosive joint involvement and who have failed to normalise SUA levels with an XO1 at maximum dose or in whom XO1s are contraindicated. It is given as an 8 mg intravenous infusion every 2 weeks, and pre-medication with anti-histamines and corticosteroids is required. Although phase III studies have shown it to be highly effective in lowering SUA levels and dissolving tophi, its use is limited by its immunogenicity. The generation of anti-pegloticase antibodies results in infusion reactions and a loss of clinical response. Pegloticase is currently unavailable in the UK and its use is not supported by NICE.

Preventing gout flare when initiating urate-lowering therapy

When prophylactic treatment is commenced, there is a risk of precipitating an acute gout attack, or 'mobilisation flare', for approximately 12 months. Mobilisation flares are thought to be caused by the rapid decrease in serum urate after the initiation of a ULT. When ULT therapy is commenced it is very important that additional medicines are co-prescribed to prevent precipitating an acute flare.

Colchicine

Colchicine is the agent of first choice to prevent the precipitation of a flare when commencing chronic gout treatment. Low doses of colchicine (500 micrograms orally twice a day or once a day) should be prescribed and continued for at least 6 months.

NSAIDs

If there are no contraindications to the use of NSAIDs, they may be considered second line to colchicine in patients who are intolerant to colchicine. NSAIDs should be continued for a maximum of 6 weeks, and gastric protection should be provided.

Corticosteroids

Intramuscular steroid injections (methylprednisolone acetate 80–120 mg) or low-dose oral prednisolone (<10 mg prednisolone/day) may sometimes be used to prevent the precipitation of a flare on initiation of ULT for gout.

aims of drug therapy and lifestyle advice. The need for dietary and lifestyle changes should be stressed (see Box 55.4). The UK Gout Society website can assist in providing patients with information about the condition and how it should be managed (<http://www.ukgoutsociety.org>). In overweight patients, gradual weight loss should be encouraged; very rapid weight loss should be avoided because it can cause ketosis and result in raised uric acid levels with the likelihood of precipitating an attack. Advice should include an 'action plan' for dealing with acute gout, and an emergency supply of medicine should be provided for the management of an acute attack. The patient should be clear on what dose of the medicine to take, when to initiate therapy, how long to take the medication and any possible side effects to look out for. The patient should also be advised to avoid certain over-the-counter medicines that may exacerbate an attack, for example, the use of aspirin as an analgesic.

Patients who are taking long-term prophylactic therapy need to understand the importance of continuing therapy despite being asymptomatic. Patients should be informed that gout flares will abate over time if they remain adherent to their ULT. The importance of not running out of their ULT medication should be stressed, and they should be warned that even a short gap in therapy may precipitate an attack. All patients should be advised to remain well hydrated with a water intake of at least 2 L/day; this is especially important for patients who are receiving uricosuric agents due to the risk of uric acid stone formation in the kidneys.

Case studies

Case 55.1

Mr SC is a 62-year-old man admitted to hospital with a suspected stroke. His medical history includes uncontrolled hypertension and recurrent gout. An ischaemic stroke is later confirmed after imaging. Medication on admission is amlodipine 5 mg once a day, ramipril 10 mg once a day and colchicine 500 micrograms three times a day for acute attacks of gout. The patient has no recorded drug allergies. His estimated glomerular filtration rate is 53 mL/min, he has a raised CRP of 115 mg/dL and his uric acid level is 579 mmol/L. During his recovery in hospital he experiences an acute flare of gout in his left big toe. Fluid aspirated from the joint contains monosodium urate crystals, and on examination the patient has palpable tophi on the toes. The doctor on the ward prescribes a course of colchicine (500 micrograms three times a day). After the third day the patient's symptoms improve, and the doctor stops the patient's colchicine and discusses with the patient the need to start a medicine to lower the patient's SUA level. The patient tells the doctor that he had allopurinol in the past, but it made things worse. He tells the doctor that his son takes febuxostat for his gout and has no problems. The doctor prescribes febuxostat 80 mg once a day. Three days later the patient experiences another acute episode of gout, this time affecting his elbow. The doctor stops the febuxostat during this second acute attack.

Questions

1. Are there any contraindications to use of febuxostat in this patient?
2. What might have been the cause of the second attack of gout after commencement of febuxostat?

Patient care

Patients should be provided with verbal and written information on the causes and consequences of gout, its curable nature, the

3. How could this second flare of gout be prevented?
4. What advice would you give to patients commenced on ULTs?

Answers

1. Febuxostat is recommended for the management of chronic hyperuricaemia in patients with gout who are intolerant of allopurinol or in whom allopurinol is contraindicated. Intolerance to allopurinol is defined as adverse effects that are sufficiently severe to warrant discontinuation or prevent full dose escalation for optimal effectiveness. Mr SC said that allopurinol made things worse in the past, but before excluding the use of allopurinol it is important to verify how Mr SC took his allopurinol and whether he was adherent to treatment. Intermittent use of allopurinol is likely to precipitate recurrent flares and result in non-adherence. Later discussions with Mr SC revealed that when he originally took allopurinol he did not take it regularly as he struggled to attend for blood tests and did not obtain repeat prescriptions from his primary care doctor because he was working away as a lorry driver. Fluctuations in SUA levels due to intermittent use of allopurinol by the patient caused recurrent flares and hence why he felt it made things worse.

The recommended starting dosage of allopurinol in patients with normal renal function is 100 mg once a day. This should be gradually increased in increments of 100 mg every 2–5 weeks until the desired serum urate level is reached (<300 mmol/L). The maximum recommended dosage in normal renal function is 900 mg/day. In renal impairment (glomerular filtration rate \leq 30 mL/min) the recommended starting dosage is 50 mg once a day with increased increments of 50 mg every 2–5 weeks. Failure to appropriately titrate the dose of allopurinol can result in therapeutic failure.

The patient has a history of uncontrolled hypertension and was admitted to hospital with an ischaemic stroke at the age of 62 years. In the APEX (Schumacher et al., 2008) and FACT (Becker et al., 2005) studies involving febuxostat and allopurinol, a numerically greater incidence of investigator-reported cardiovascular Anti-Platelet Trialists' Collaboration (APTC) events (defined end-points from the APTC including cardiovascular death, non-fatal myocardial infarction and non-fatal stroke) was observed in the febuxostat total group compared with the allopurinol group (1.3 versus 0.3 events per 100 patient-years). The same profile was not observed in the CONFIRMS studies (Becker et al., 2010). The incidence of investigator-reported cardiovascular APTC events in the combined phase 3 studies (APEX, FACT and CONFIRMS studies) was 0.7 versus 0.6 events per 100 patient-years. In the long-term extension studies the incidences of investigator-reported APTC events were 1.2 and 0.6 events per 100 patient-years for febuxostat and allopurinol, respectively. No statistically significant differences were found, and no causal relationship with febuxostat was established. Identified risk factors among these patients were a medical history of atherosclerotic disease and/or myocardial infarction, or of congestive heart failure. Treatment with febuxostat in patients with ischaemic heart disease or congestive heart failure is not recommended. In view of the patient's recent ischaemic stroke and history of uncontrolled hypertension, it would be preferable to use an alternative ULT.

2. Febuxostat treatment should not be started until an acute attack of gout has completely subsided. Gout flares may occur during the initiation of treatment because of changing SUA levels resulting in the mobilisation of urate from tissue deposits.
3. When initiating treatment with febuxostat, flare prophylaxis should be given for at least 6 months. Medicines recommended for the prevention of gout flares during initiation of ULT include colchicine, NSAIDs and corticosteroids. Colchicine is the agent of choice and should be given at a dose of 500 micrograms once or twice

daily for at least 6 months with the febuxostat. It is important that prophylaxis against flare is given on initiation of all ULTs. It is also important that patients stabilised on ULTs do not stop their ULT during an acute flare. The gout flare should be managed concurrently as appropriate for the individual patient.

4. Patients who are taking long-term prophylactic therapy need to understand the importance of continuing therapy despite being asymptomatic. Patients should be informed that gout flares will abate over time if they remain adherent to their ULT. The importance of not running out of their ULT medication should be stressed, and they should be warned that even a short gap in therapy may precipitate an attack. All patients should be advised to remain well hydrated with a water intake of at least 2 L/day; this is especially important for patients who are receiving uricosuric agents because of the risk of uric acid stone formation in the kidneys.

Case 55.2

Mr DW is a 77-year-old man admitted to accident and emergency with a painful swollen right knee. It woke him up in the middle of the night, and there is significant pain and swelling. He is unable to mobilise and cannot tolerate the knee being even lightly touched. He denies any trauma to the knee, and there is no fever or systemic symptoms. On examination there is palpable tophi on his fingers and his knee is swollen, hot and tender to touch. His CRP is 169 mg/dL, estimated glomerular filtration rate is 40 mL/min, urate is 713 mmol/L and he is hypertensive (185/100 mmHg). His medical history includes Charcot's arthropathy of the right foot, type 2 diabetes mellitus, stroke, chronic kidney disease, hypertension and osteoarthritis. Medication on admission is gliclazide 40 mg once a day, ramipril 2.5 mg once a day, clopidogrel 75 mg once a day, atorvastatin 40 mg once at night and lansoprazole 15 mg once a day. He drinks approximately 2 pints of beer per day, but does not smoke. He denies any history of gout. Fluid aspirated from his right knee contains monosodium urate crystals.

Questions

1. What initial therapy would you recommend to treat Mr DW's acute attack of gout?
2. What risk factors could have contributed to the acute attack?
3. Should Mr DW be placed on therapy to prevent further attacks?
4. What lifestyle and dietary advice would you give to Mr DW to assist in preventing further attacks?

Answers

1. Initial therapy should be directed at promptly and safely resolving the pain. Drugs used in the management of an acute attack include colchicine, NSAIDs and corticosteroids. Current guidance (Khanna et al., 2012b) gives no preference to a particular agent, but recommends selection based on the number plus type of joint(s) affected and individual patient characteristics. In view of Mr DW's age and multiple comorbidities including renal impairment and cardiovascular disease, the use of NSAIDs should ideally be avoided. Oral corticosteroids may have fewer adverse events than other acute treatments when used short-term, particularly in the elderly. However, Mr DW has type 2 diabetes mellitus and oral corticosteroids are likely to increase his blood sugars, leading to poor diabetic control. In patients with monoarthritis, an intra-articular corticosteroid injection is highly effective in treating an attack. The dose of intra-articular corticosteroids is based on

the size of the affected joint; common doses are 80 mg methylprednisolone acetate for a large joint such as a knee, and 40 mg methylprednisolone acetate or 40 mg triamcinolone acetonide for a smaller joint such as a wrist or elbow. Intra-articular steroids act locally with less release into the systemic circulation and are therefore not likely to significantly affect Mr DW's diabetic control. However, in addition to the acute flare in the right knee, Mr DW's smaller joints in the left foot are also affected. Intra-articular injection into the right knee (80 mg methylprednisolone acetate) combined with oral colchicine is likely to be suitable in view of the severity of the attack and Mr DW being unable to mobilise his knee. Current guidance (Khanna et al., 2012b) recommends colchicine up to 2 mg/day for the management of an acute flare in patients with normal renal function. The dose of colchicine should be reduced or the interval between doses increased in mild-to-moderate renal impairment (creatinine clearance 10–50 mL/min). The use of colchicine is contraindicated in patients with a creatinine clearance less than 10 mL/min. A preferable dosage in Mr DW would be 500 micrograms twice a day. Before commencing colchicine a review of the patient's medication should be performed to identify any potential drug interactions. Colchicine has a number of important drug interactions; a reduction in colchicine dosage or interruption of colchicine treatment is recommended in patients with normal renal and hepatic function if treatment with a P-glycoprotein (cyclosporin, verapamil or quinidine) or a strong CYP3A4 inhibitor (ritonavir, atazanavir, indinavir, clarithromycin, telithromycin, itraconazole or ketoconazole) is required. Colchicine should not be co-prescribed with these medicines in the presence of hepatic or renal impairment. The patient is taking atorvastatin, and acute myopathy has been reported in patients given colchicine with statins. Mr DW should be advised to report muscle pain or weakness, and he should also stop his colchicine if he experiences diarrhoea or vomiting. Simple analgesics such as paracetamol and weak opiates (codeine or dihydrocodeine) can also be added to the treatment regimen to provide additional pain relief. The affected joints should be rested for 1–2 days and initially treated with ice, which has a significant analgesic effect during an acute attack.

2. Mr DW has a number of risk factors that pre-dispose him to the development of gout. These include being male, increasing age, hyperuricaemia, poor renal function, hypertension, type 2 diabetes mellitus and alcohol consumption.

The prevalence of gout is much higher in men, and the risk of gout steadily increases in men as they age. Hyperuricaemia is considered the most important risk factor for the development of gout. However, it is important to note that hyperuricaemia alone is not an indicator of gout, and there are a number of contributing factors including genetics and lifestyle which may result in gout developing in an individual. Experts have emphasised the importance of screening for renal disease in individuals with gout and/or hyperuricaemia due to the strong association between the two conditions (Sivera et al., 2014). In addition, men with gout have a twofold higher risk of kidney stones than patients without gout (Jordan et al., 2007). Metabolic syndrome is a multiplex risk factor for atherosclerotic cardiovascular disease that consists of atherogenic dyslipidaemia, raised blood pressure, increased blood glucose, and both prothrombotic and pro-inflammatory states. In the USA, metabolic syndrome is present in 63% of those with gout

compared with 25% of those without gout (Choi et al., 2007a). Other studies have shown obesity, weight gain and hypertension all to be independent risk factors for the development of gout (Choi et al., 2005). Increased daily consumption of alcohol is associated with a higher risk of gout. Beer carries the greatest risk, probably because of its high purine content, followed by spirits. However, a moderate consumption of wine is not associated with an increased risk of development of gout (Jordan et al., 2007). The mechanism of action involved is thought to be the metabolism of ethanol to acetyl coenzyme A, leading to adenine nucleotide degradation, with resultant increased formation of adenosine monophosphate, a precursor of uric acid. Alcohol also raises lactic acid levels in blood, which inhibits uric acid excretion. It is recommended that males restrict their alcohol consumption to no more than 14 units/week and females to no more than 7 units/week (Khanna et al., 2012a). Beer, stout, port and fortified wines should be avoided. Alcohol should be avoided during an acute attack of gout.

Mr DW also has osteoarthritis; this has been linked to gout rather than being an actual risk factor due to the increased propensity for nucleation and growth of monosodium urate crystals in osteoarthritic cartilage.

3. Although Mr DW denies a history of gout, the severity of the attack and the presence of tophi suggest a period of prolonged hyperuricaemia. There may have been other attacks that he has self-managed. His presentation and chronic kidney disease support the initiation of a ULT.

Guidance (Khanna et al., 2012a) suggests that patients who suffer one or more acute attacks within 12 months of the first attack should normally be prescribed prophylactic ULT. However, for some groups of patients, prophylactic therapy should be instigated after a single attack. These include individuals with uric acid stones, the presence of tophi at first presentation, identifiable joint damage associated with gout, renal impairment (CKD2 or worse), history of renal stones and patients presenting at a young patient age with a family history of renal or cardiac disease.

4. It is also important to stress the importance of lifestyle modification to Mr DW because this can be helpful in preventing further attacks. Moderate physical exercise can be beneficial; however, intense muscular exercise should be avoided because it can lead to a rise in uric acid levels. In overweight patients, gradual weight loss should be encouraged. Rapid weight loss can precipitate ketosis and a subsequent rise in the urate pool. Mr DW should be given appropriate dietary advice. It is the regular consumption of foods containing purines rather than the absolute purine content of a particular food that is important. The UK Gout Society (<http://www.ukgoutsociety.org>) provides a fact sheet with dietary recommendations and the purine content of various foods for patients. Ideally, total daily purine intake should not exceed 200 mg/day, and foods such as shellfish, offal and sardines should be avoided. Dairy products have been shown to be beneficial in lowering SUA, and even the addition of yoghurt on alternate days has been shown to reduce levels. The consumption of soft drinks sweetened with fructose or sucrose (not diet drinks) should be limited. Cherries, whether sweet, tart, juice or fruit, have a urate-lowering potential. As previously mentioned, Mr DW should moderate his alcohol consumption.

Acknowledgements

The author thanks Professor Philip Conaghan, Leeds Institute of Rheumatic and Musculoskeletal Medicine, University of Leeds, for his invaluable comments regarding the structure and content of this chapter, and Amy Vigar (nee Cunningham) for her valuable contribution in the previous edition.

56 Glaucoma

Tamara Ahmed Ali and Mark D. Doherty

Key points

- Glaucoma describes a group of conditions characterised by progressive optic nerve damage and is accompanied by characteristic visual field defects.
- Primary open-angle glaucoma (POAG) is a chronic progressive disease of insidious onset.
- The aim of treatment in POAG is to reduce the intraocular pressure (IOP) to a target level, tailored individually to the patient, with the aim of preventing further damage to the nerve fibres and the development and progression of visual field defects.
- A wide range of pharmaceutical agents can be used to treat POAG. Laser treatment or surgery may be undertaken if the target pressure is not attained with medical therapy.
- POAG generally does not cause symptoms until the damage reaches an advanced stage. Adherence with therapy is therefore a critical issue.
- Acute primary angle closure (PAC) is an ophthalmological emergency that must be rapidly treated to prevent irreversible sight loss.
- The role of medical treatment in acute PAC is to reduce the IOP with a view to subsequent laser and/or surgical treatment.
- A range of drugs can provoke an attack of acute PAC in susceptible individuals.

The term ‘glaucoma’ comprises a number of distinct conditions that have differing clinical features but share a common finding: progressive optic neuropathy (nerve damage) causing characteristic visual field defects. Although glaucoma is frequently associated with raised intraocular pressure (IOP), the diagnosis is often made despite a measured IOP within the ‘normal’ range. Raised IOP therefore remains the most significant, and is the only modifiable risk factor for glaucoma, but it does not form part of the diagnostic criteria.

Normal IOP is a statistical description of the range of IOP found in the population. Mean IOP is estimated at 15–16 mmHg, and the upper limit of the normal range is calculated as 2 standard deviations above the mean, approximately 21 mmHg.

There is a circadian cycle of IOP, with maximum levels often occurring between 8 and 11 a.m. and minimum levels between midnight and 2 a.m. This may affect IOP readings taken in outpatient clinics at different times of the day. In addition, diurnal variations may be greater in patients with glaucoma. Although elevated IOP is not the only risk factor for glaucoma, it is the only parameter that can currently be modified by pharmacological

intervention and, therefore, is central to the evaluation of disease progression and clinical management.

Glaucoma management involves the setting of a target IOP, a value at which disease progression is significantly slowed. In setting the target IOP, a common strategy is to aim for a 25–30% reduction from the initial IOP at which damage occurred. In practice it is a dynamic, clinical judgement, which is frequently adjusted as appropriate to the patient’s clinical course and response to treatment. Continuous evaluation of the patient’s progress is therefore essential to achieve this objective.

Epidemiology

Glaucoma is the leading cause of irreversible blindness worldwide. In 2013 the number of people aged 40–80 years with glaucoma was estimated to be 64.3 million. This figure is due to increase to 76.0 million in 2020 and 111.8 million in 2040 (Tham et al., 2014). Affected individuals require lifelong monitoring for disease control and detection of progression, to minimise the risk of permanent visual damage.

Primary open-angle glaucoma

Primary open-angle glaucoma (POAG) is a chronic progressive disease of insidious onset, usually affecting both eyes. It is frequently an inherited condition, with a 10-fold increased lifetime risk in patients with a family history (Wolfs et al., 1998). Approximately 10% of UK blindness registrations are ascribed to glaucoma, and around 2% of people older than 40 years have POAG, a figure which rises to almost 10% in white Europeans older than 75 years (National Institute for Health and Care Excellence [NICE], 2009). The prevalence of POAG is higher in people of black African or black Caribbean descent (Sommer et al., 1991). Based on these estimates, around 500,000 people are affected by POAG in England and Wales where more than a million glaucoma-related outpatient visits are made to the hospital eye service annually (King et al., 2013).

Normal tension glaucoma

Normal tension glaucoma (NTG) shares a number of features with POAG, but by definition develops (and often progresses) at an IOP usually regarded as within the ‘normal’ range. It is unclear

Fig. 56.1 The iridocorneal angle. (A and B) Normal eye. (C) Primary angle closure. (D) After peripheral iridotomy.

whether POAG and NTG are separate conditions or similar entities occurring at opposing ends of the IOP spectrum. It has been reported that up to 24% of patients with glaucoma have NTG.

Ocular hypertension

Ocular hypertension (OHT) is a condition whereby the IOP is elevated in the absence of visual field loss or glaucomatous optic nerve damage. It is estimated that 3–5% of those older than 40 years have OHT, although the prevalence is lower in Indian and Japanese patients, and higher in African or Caribbean patients. OHT represents a risk of future development of POAG, and lowering IOP has been shown to protect against conversion to POAG.

Primary angle-closure glaucoma

Primary angle-closure glaucoma (PACG) is a condition in which closure of the iridocorneal angle results in a reduction in aqueous outflow, usually in predisposed eyes. The disease affects 0.4% of Caucasian adults older than 40 years, with higher rates in patients of Asian or East Asian descent (Day et al., 2012). It occurs in four times as many females as males. Although rarer than POAG, it carries a significantly higher risk of blindness.

Secondary glaucoma

Secondary glaucoma occurs as a result of an instigating condition or clinical circumstance. Examples include corticosteroid therapy, intraocular inflammation, pigment dispersion, pseudoexfoliation, trauma, neovascularisation and developmental abnormalities.

Congenital glaucoma

Congenital glaucoma occurs within the first year of life, typically presenting with watering, light sensitivity and blepharospasm (involuntary tight eyelid closure). The condition is due to an abnormally developed iridocorneal angle. Surgery is the mainstay of treatment. Further details of congenital glaucoma are beyond the scope of this chapter.

Aetiology

The factors that determine the level of IOP are the rate of aqueous humour production and the rate of its outflow. A fine balance between these is necessary to maintain a desirable pressure within the eye. When production exceeds outflow, IOP rises.

Production of aqueous humour occurs in the ciliary epithelium by three mechanisms:

- active secretion (independent of the level of IOP),
- ultrafiltration (influenced by the level of IOP),
- passive diffusion of ions.

Aqueous humour is produced by the ciliary body and passes anteriorly through the pupil into the anterior chamber. Outflow of aqueous humour occurs by two routes. Approximately 80–90% of total outflow is through the trabecular meshwork into the canal of Schlemm and into the venous circulation via the aqueous veins (Fig. 56.1A and B). The uveoscleral pathway, accounting for the remaining 10–20%, describes the outflow of the aqueous humour through the ciliary body, into the suprachoroidal space, finally leaving the eye through the sclera (Fig. 56.2).

Fig. 56.2 Physiological aqueous outflow pathways. (From Alm and Kaufman, *Uveoscleral Outflow: Biology and Clinical Aspects*. Mosby-Wolfe Medical Publications. Reproduced with permission of Mosby-Wolfe Medical Publications, 1998.)

Pathophysiology

The precise pathophysiology of glaucomatous damage is not entirely understood. Degeneration specifically affects the retinal ganglion cells, whose axons pass across the retina and through the lamina cribrosa to form the optic nerve head. Raised IOP causes deformation of the lamina cribrosa, with damage to retinal ganglion cell axons and subsequent cell death (Weinreb et al., 2014). Other pressure-independent mechanisms, such as impaired vascular supply and low cerebrospinal fluid pressure, may also influence glaucomatous progression. Such factors are perhaps more likely to be more significant in NTG.

In POAG, increased resistance within aqueous drainage channels causes the rise in IOP. It is thought that the main route of resistance to aqueous outflow lies in the dense juxtacanalicular trabecular meshwork and the endothelium lining the inner wall of Schlemm's canal (Stamer et al., 2015). Age-related dysfunction of these structures increases resistance to outflow and subsequent raised IOP.

In PACG, the rise in IOP is caused by a decreased outflow of aqueous humour due to closure of the iridocorneal angle. It occurs in anatomically predisposed eyes with increased lens size, shallower anterior chamber and shorter axial length (see Fig. 56.1C).

The lens continues to grow throughout life, thereby bringing its anterior surface closer to the cornea. Slackening of the zonules compounds this movement. Both factors lead to a gradual and progressive shallowing of the anterior chamber. This effect is more significant in a short hypermetropic eye with a thick and relatively anteriorly located lens. These factors in combination lead to physical obstruction of the trabecular meshwork by the iris. This is a gradual process that can ultimately lead to a sudden escalation in IOP, precipitating

an attack of acute angle closure (see Fig. 56.1C). Alternatively the condition may remain asymptomatic, with the progressive development of scarring adhesions between iris and trabecular meshwork, gradually increased IOP and subsequent glaucomatous damage.

Clinical manifestations

Table 56.1 presents the clinical features of the different glaucoma types.

Primary open-angle glaucoma

POAG is typically characterised by the following:

- IOP greater than 21 mmHg: This is most accurately measured using the Goldmann applanation tonometer attached to the slit lamp. The cornea is anaesthetised and then gently applanated with a disposable tonometer head. The IOP is then read from a scale on the side of the tonometer.
- An open angle: Gonioscopy refers to the examination of the iridocorneal angle at the slit lamp using a specialised contact lens placed onto the cornea. Observations can be made regarding the angle width, the iris features, and the presence or absence of irido-trabecular adhesions (synechiae). An estimation of the angle's likelihood of closure can thereby be made.
- Glaucomatous optic neuropathy: The hallmark sign is cupping, an increase in size of the depressed 'cup' located in the centre of the optic nerve head (optic disc). The cup becomes more prominent as the disease progresses because of ongoing retinal ganglion cell death. This may be accompanied by progressive disc pallor. Disc photography is invaluable in providing a baseline for subsequent comparison in follow-up visits.
- Retinal nerve fibre layer thinning: This can be assessed at the slit lamp and may be facilitated by the use of a green filter. Focal areas of thinning may be apparent on direct observation and may indicate early glaucomatous damage.

Chronic primary angle-closure glaucoma

Chronic PACG is usually associated with raised IOP. The anterior chamber is shallow. Gonioscopy reveals a closed iridocorneal angle, and synechiae may be evident. The disc is cupped, and nerve fibre layer defects may be evident.

Acute primary angle closure

Acute primary angle closure (PAC), an ophthalmic emergency, is caused by sudden closure of the angle and a marked elevation in IOP. The symptoms include rapidly progressive visual impairment and pain frequently with nausea and vomiting. The signs include dilation of the conjunctival blood vessels. The anterior chamber is shallow bilaterally, with the affected pupil fixed in a semi-dilated position. The IOP is elevated, frequently between 60 and 80 mmHg, causing corneal oedema. The optic disc is not usually cupped unless the IOP has been elevated for a protracted period.

Secondary glaucomas

Secondary glaucomas share features common to POAG and PACG, and may be identified by signs indicating the underlying process. Examples include iris transillumination in pigment dispersion, lens deposits in pseudoexfoliation and abnormal iris vessels in neovascularisation.

Investigations

Perimetry (visual field testing)

Visual field loss is usually asymptomatic until it reaches an advanced stage. Perimetry identifies functional deficits at an earlier stage and is a key component in the diagnosis, monitoring and management of glaucoma. The earliest clinically significant field defect is a scotoma, which is an area of depressed vision within the visual field.

Pachymetry

Measurement of central corneal thickness may influence the measured IOP, with a thick cornea causing a falsely high reading. It is considered in assessing an individual's risk of glaucomatous progression, and may also affect the efficacy of certain drug treatments (Johnson et al., 2008).

Nerve fibre analysis

Clinical findings can be augmented with the use of imaging modalities such as optical coherence tomography and laser scanning laser polarimetry. These can assist in the identification of early defects before visual field loss becomes established.

Treatment

Primary open-angle glaucoma

Medical treatment

The aim of treatment in POAG is to reduce the raised IOP to the target value, preventing further damage to the nerve fibres and the development of further visual field defects to maintain the patient's visual function and quality of life. The key to effective treatment is careful and regular follow-up, with continuous reassessment and tailoring of the target IOP in response to evidence of glaucomatous progression.

The initial treatment of POAG is usually medical in the form of topical eyedrops, with a wide range of preparations available (Table 56.2). The prostaglandin analogues (PGAs) latanoprost and travoprost and the prostamide bimatoprost are indicated for first-line use because these produce the greatest decline in IOP (Table 56.3). β -Blockers may then be added in combination with PGAs if the initial effect is inadequate, or used as monotherapy if PGAs are poorly tolerated. Carbonic anhydrase inhibitors are frequently prescribed for patients unresponsive to first-line drugs, in patients in whom the first-line agents are contraindicated or as adjunctive therapy. An α -agonist such as brimonidine may also be used in the same clinical setting. Pilocarpine is rarely used in POAG. Oral therapy with carbonic anhydrase inhibitors is reserved for use as a last resort, usually in patients awaiting surgery.

Guidance on the treatment of people with OHT or suspected POAG has been published (NICE, 2009). The treatment options (Table 56.4) take into account central corneal thickness and age, although age thresholds are appropriate only where vision is normal and the treatment is purely preventative.

Table 56.1 Clinical features of main glaucoma types

	Primary open-angle glaucoma	Normal tension glaucoma	Ocular hypertension	Primary angle closure glaucoma	Secondary glaucoma ^a
When symptoms occur	Late in disease	Late in disease	None	Pain, blurring, nausea in acute setting	Dependent on underlying condition
Mechanism	Inflow of aqueous humour exceeds outflow	Vascular and non-intraocular pressure factors likely to have a more prominent role	Inflow of aqueous humour exceeds outflow	Closed iridocorneal angle preventing adequate outflow of aqueous humour	Dependent on underlying condition
Intraocular pressure	>21 mmHg	≤21 mmHg	>21 mmHg	Any	Any
Angle	Open	Open	Open	Closed	Open or closed, depending on underlying condition
Optic nerve	Cupped	Cupped	Normal	Cupped	Cupped
Other distinguishing features	None	May have disc haemorrhages	None	May have peripheral anterior synechiae	Dependent on underlying condition

^aSecondary glaucoma is where there is an identifiable cause of increased pressure. For example it may be caused by an eye injury, inflammation, medications or diabetes.

Surgical treatment

The improved control of IOP with PGAs and prostamides has reduced the demand for surgical intervention in glaucoma (Kenigsberg, 2007). A significant number of patients will still require laser or surgical procedures to reach their target pressure.

Laser trabeculoplasty aims to improve the outflow of aqueous fluid through the trabecular meshwork and is a useful modality to reduce IOP without employing incisional surgery. This may be particularly useful for patients with mild glaucoma who require a modest IOP reduction, or in whom topical treatment is ineffective or poorly tolerated. Traditionally this was undertaken with an argon laser. More recently, selective laser trabeculoplasty has been introduced as a procedure that is easier to perform and better tolerated, with a lower complication rate.

Table 56.2 Drugs used in the treatment of primary open-angle glaucoma

Therapeutic category	Primary mechanism
Topical prostaglandins	Increase aqueous outflow
Topical prostamides	Increase aqueous outflow
Topical β -blocking agents	Decrease aqueous formation
Topical miotics	Increase aqueous outflow
Topical adrenergic agonists	Increase aqueous outflow and decrease aqueous formation
Topical carbonic anhydrase inhibitors	Decrease aqueous formation
Oral carbonic anhydrase inhibitors	Decrease aqueous formation

There is great interest in the use of minimally invasive glaucoma surgery in the management of early glaucoma. A number of different techniques and devices are available with the aim of surgically reducing IOP without the perceived complication profile of more invasive surgical solutions.

In patients with coexistent POAG and cataract, surgical removal of the latter with insertion of an intraocular lens is a useful technique that is frequently utilised to achieve a modest reduction in IOP.

The most frequently performed surgical procedure for POAG, trabeculectomy, creates a fistula between the anterior conjunctiva and subconjunctival space to act as a new route for aqueous outflow. Where trabeculectomy is undesirable or ineffective, the insertion of a glaucoma drainage device is a useful alternative. The frequency of glaucoma drainage device usage has increased markedly since the 1990s when two new designs were introduced.

Finally, where target IOP has not been achieved, or in eyes with limited visual potential, external cyclophotocoagulation can be a useful means to obtain a lower IOP by the targeted destruction of ciliary processes with a diode laser.

Acute primary angle-closure glaucoma

The medical management of acute PAC aims to relieve symptoms, reduce IOP to a safe level and prepare the eye for laser or surgical treatment. Analgesics and antiemetics are sometimes needed, dependent on symptom severity, to make the patient comfortable. The unaffected eye is usually treated prophylactically with pilocarpine, to protect against a similar attack in the fellow eye.

Paralysis of the iris sphincter usually occurs at an IOP of more than 60 mmHg as a result of ischaemia. Pilocarpine is therefore usually ineffective in the early stages, and the IOP is lowered by aqueous suppressants such as topical timolol 0.5%. An intravenous loading dose of acetazolamide is frequently used, followed by regular oral treatment. Mannitol is now a less frequently used alternative because of a greater perceived risk of

Table 56.3 Comparison of reduction in intraocular pressure with a range of ocular hypotensive drugs

Drug	Relative IOP change from baseline at trough, % (95% CI)	Relative IOP change from baseline at peak, % (95% CI)
Bimatoprost	-28 (-29 to -27)	-33 (-35 to -31)
Travoprost	-29 (-32 to -25)	-31 (-32 to -29)
Latanoprost	-28 (-30 to -26)	-31 (-33 to -29)
Timolol	-26 (-28 to -25)	-27 (-29 to -25)
Betaxolol	-20 (-23 to -17)	-23 (-25 to -22)
Dorzolamide	-17 (-19 to -15)	-22 (-24 to -20)
Brinzolamide	-17 (-19 to -15)	-17 (-19 to -15)
Brimonidine	-18 (-21 to -14)	-25 (-28 to -22)
Placebo	-5 (-9 to -1)	-5 (-10 to 0)

CI, confidence interval; IOP, intraocular pressure.

Table 56.4 Treatment of people with ocular hypertension or suspected primary open-angle glaucoma (National Institute for Health and Care Excellence, 2009)

Central corneal thickness	>590 micrometres		555–590 micrometres		<555 micrometres		
	>21–25	>25–32	>21–25	>25–32	>21–25	>25–32	>32
Untreated IOP (mmHg)	>21–25	>25–32	>21–25	>25–32	>21–25	>25–32	>32
Age (years)	Any	Any	Any	Treat until 60	Treat until 65	Treat until 80	Any
Treatment	No treatment	No treatment	No treatment	β -Blocker	Prostaglandin analogue	Prostaglandin analogue	Prostaglandin analogue

cardiopulmonary decompensation. The acetazolamide should allow the IOP to drop sufficiently to relieve iris ischaemia and allow the sphincter to respond to pilocarpine therapy.

When the IOP has been reduced medically, both eyes are treated with laser iridotomies, creating an opening in the peripheral iris to allow the flow of aqueous humour through an alternative pathway (see Fig. 56.1D). If unsuccessful, alternatives include laser iridoplasty (a succession of peripheral iris burns causing iris contraction and distraction from the angle), surgical iridectomy (removal of a peripheral section of iris tissue), cataract surgery or diode laser. Filtration surgery may be indicated later if the IOP remains uncontrolled despite these interventions.

Normal tension glaucoma

Treatment is not always required in NTG. A significant proportion of untreated patients (50% at 5 years in the Collaborative Normal-Tension Glaucoma Study Group [CNTGS] study) do not show visual field progression (CNTGS, 1998). Patients with NTG demonstrating progression despite a ‘normal’ IOP may be commenced on IOP-lowering medications. The treatment regimen employed is usually similar to that of POAG. Some clinicians avoid β -blockers because of their potential for reducing systemic blood pressure, lowering ocular perfusion pressure and increasing susceptibility to glaucomatous progression.

Secondary glaucoma

Treatment of secondary glaucoma initially involves control of the causative factor where possible. Examples include reducing or changing medication in steroid-induced glaucoma, arresting the inflammation in uveitic glaucoma, or retinal laser and anti-vascular endothelial growth factor formulations in neovascular glaucoma. If still required the IOP can then be lowered using a regimen similar to that used in other types of glaucoma.

Drug treatment

The importance of early diagnosis and treatment is essential in slowing disease progression and improving the quality of life for patients with glaucoma (McKean-Cowdin et al., 2008). Topical

glaucoma medications are the first choice of therapy; these drugs lower IOP by a variety of mechanisms (see Table 56.2).

There are five main classes of drugs:

- ocular prostanoids (PGAs and prostamides),
- β -blockers (β -adrenoceptor antagonists),
- carbonic anhydrase inhibitors and systemic drugs,
- sympathomimetic agents (α_2 -adrenergic agonists),
- miotics (parasympathomimetic).

The PGAs latanoprost, tafluprost and travoprost and the prostamide bimatoprost are indicated for first-line use because these produce the greatest decline in IOP. β -Blockers, which were traditionally the drug of choice, are now often prescribed either in combination with these or as an alternative (NICE, 2009). Carbonic anhydrase inhibitors are frequently prescribed for patients unresponsive to first-line drugs, in patients in whom the first-line agents are contraindicated or as adjunctive therapy. Sympathomimetics are less commonly prescribed in POAG, and miotics are rarely used. Contraindications and drug interactions should be considered before offering any glaucoma treatment.

Ocular prostanoids: prostaglandin analogues and prostamides

PGAs (latanoprost, tafluprost and travoprost) lower IOP by increasing uveoscleral outflow with no significant effect on other parameters of aqueous humour dynamics. The prostamide (bimatoprost) is thought to increase outflow through both trabecular and uveoscleral outflow pathways. However, there is still debate about the precise mechanisms of action of this group (Lim et al., 2008; Toris et al., 2008).

A recent systematic review and network meta-analysis comparing the effectiveness of first-line medications for POAG concluded that drugs in the prostaglandin class (bimatoprost, latanoprost and travoprost) were more efficacious than drugs in other classes in reducing IOP at 3 months. The ‘within-class’ differences were generally small (Li et al., 2016). In another meta-analysis these drugs have been shown to have a greater effect on both peak and trough readings of IOP than timolol, betaxolol, dorzolamide, brinzolamide and brimonidine, producing declines in IOP of 28–29% at trough and 31–33% at peak as shown in Table 56.3 (van der Valk et al., 2009). They are also known to reduce the IOP fluctuation during the 24-hour period with a maximum effect achieved 3–5 weeks after starting therapy (Bartlett and Jaanus, 2008).

Table 56.5 Ocular prostanoids

	Bimatoprost		Latanoprost	Tafuprost	Travoprost
Trade name	Lumigan		Xalatan	Saflutan	Travatan
Pharmacological class	Prostamide		Prostaglandin analogue	Prostaglandin analogue	Prostaglandin analogue
Strength	0.03%	0.01%	0.005%	0.0015%	0.004%
Preservative		Benzalkonium chloride 0.02%	Benzalkonium chloride 0.02%	None	Polyquaternium-1 0.001%
Storage requirements	≤25 °C	≤25 °C	2–8 °C until opened, then ≤25 °C for a period of use of 4 weeks	2–8 °C until opened, then ≤25 °C for a period of use of 4 weeks	≤25 °C

All the drugs in this class are licensed for the reduction of elevated IOP in POAG and OHT. They are administered once daily in the evening, and systemic side effects are relatively uncommon. The NICE guideline (NICE, 2009) does not differentiate between the PGAs and the prostamide (Table 56.5), but recommends one of this class for the treatment of POAG, certain patients with OHT and certain POAG suspects (see Table 56.4).

The prostanoids have some interesting local side effects (Table 56.6), most commonly increased pigmentation of the iris as a result of increased deposition of melanin in the stromal melanocytes of the iris. This mainly occurs up to 1 year of use in patients with mixed colour (green-brown, yellow-brown or blue/grey-brown) irides. Therefore, before treatment is initiated, patients should be informed of the possibility of a change in eye colour.

An increase in the length and thickness of the eyelashes and pigmentation of the palpebral skin are also known side effects. Use of these drugs may lead to disruption of the blood–aqueous barrier in patients with aphakia (no lens) and pseudophakia (implanted intraocular lens), and increase the risk of development of cystoid macular oedema; they should be used with caution in such patients and patients with known risk factors for macular oedema.

PGAs and prostamides should be used with caution in patients with active intraocular inflammation such as iritis and uveitis. They should not be used in pregnant women because there is a theoretical risk of promoting miscarriage.

Reactivation of herpes simplex infection has been reported with bimatoprost, travoprost and latanoprost; hence these drops are contraindicated in patients with a history of previous infection.

Latanoprost

Latanoprost is an isopropyl ester prodrug, which after hydrolysis is converted to its active free acid on entering the eye. The prodrug is well absorbed through the cornea, and all of the drug that enters the aqueous humour is hydrolysed during the passage through the cornea. In the UK latanoprost is the most prescribed drug in POAG (Connor and Fraser, 2014). It was the first of the prostanoids to be launched in 1996 and remains the current market leader. Like timolol among the β -blockers, latanoprost is the drug in this class against which new drugs or combinations are assessed.

Optimal effect is obtained if latanoprost is administered in the evening. The dosage should not exceed once daily because it has been shown that more frequent administration can decrease the IOP-lowering effect (Schmier et al., 2010).

Latanoprost eye drops as with other prostanoids may gradually change eye colour by increasing the amount of brown pigment in the iris. It also may gradually change eyelashes, causing increased length and thickness; eyelash changes are reversible upon discontinuation of treatment. Among prostaglandins, latanoprost has been reported to have a lower risk of conjunctival hyperaemia (redness) than travoprost and bimatoprost (Li et al., 2016).

Latanoprost is generally very well tolerated; serious adverse drug reactions were reported in only 17 of 3936 (0.43%) patients using latanoprost over a 5-year period (Goldberg et al., 2008). In practice it is well known that patient persistence with latanoprost therapy is better than that with all other frequently used monotherapies (Rahman et al., 2009).

Latanoprost is not heat stable and requires refrigeration; however, it is stable enough to be stored at room temperature for the 4-week in-use period applied in the UK.

The concentration of the preservative benzalkonium chloride in latanoprost eye drops, commonly used as a preservative in ophthalmic products, may limit its use in certain patients. The benzalkonium chloride concentration is 0.02%; this has been reported to cause punctate keratopathy and/or toxic ulcerative keratopathy and eye irritation. Contact lenses may absorb benzalkonium chloride, and these should be removed before applying the drops but may be reinserted after 15 minutes. Latanoprost in a preservative-free formulation as a single unit dose (Monopost) was launched in 2012 for the reduction of elevated IOP in patients with POAG and OHT who have proven sensitivity to benzalkonium chloride.

Travoprost

Like latanoprost, travoprost is an ester prodrug, converted to its active acid form by corneal hydrolytic enzymes as it is absorbed through the eye. It was launched in the UK in 2001, and appears to be generally well tolerated by patients and is relatively free of systemic side effects, although abdominal cramping has been reported.

It contains polyquaternium-1 as a preservative rather than benzalkonium chloride. Travoprost is licensed for the reduction in

Table 56.6 Side effects of prostanoids

Ocular	Systemic
Asthenopia	Abdominal cramp
Allergic conjunctivitis	Asthenia
Blepharitis	Asthma
Blepharospasm	Bradycardia
Browache	Dizziness
Cataract	Dyspnoea
Conjunctival follicles, papillae	Elevated liver function tests
Conjunctival hyperaemia	Headache

Visual disturbance	

IOP for both OHT and POAG in adults and children older than 2 months. Data in the age group 2 months to less than 3 years are limited. As with latanoprost, optimal effect is obtained if the dose is administered in the evening.

Patients treated with travoprost show good diurnal fluctuation control, and an ocular hypotensive effect was shown to exceed 24 hours with a single dose.

Travoprost is a stable compound throughout a range of temperatures, and the commercially available product does not require refrigeration.

Tafluprost

Tafluprost, launched in 2008, was the first of the prostanoids available in a preservative-free form. It was mainly indicated in patients allergic to, or intolerant of, benzalkonium chloride. It needs to be stored in a fridge, but can be kept up to 28 days at room temperature after opening the foil pouch on use.

Bimatoprost

Bimatoprost is a synthetic prostamide which has a potent ocular hypotensive effect. It is a fatty acid amide, which is pharmacologically similar to prostaglandin $F_{2\alpha}1$ -ethanolamide (prostamide $F_{2\alpha}$). Several mechanisms of action have been proposed, including activity of bimatoprost or its free acid, 17-phenyl prostaglandin $F_{2\alpha}$, at the prostaglandin $F_{2\alpha}$ -receptor, prostamide mimetic activity, and inhibition of PGF synthase, which leads to an increase in endogenous PGF $_{2\alpha}$. Although the free acid has been found in human eyes, its presence alone does not explain the 24-hour efficacy of bimatoprost or its hypotensive superiority over latanoprost. The pharmacology of bimatoprost itself is not explained wholly by its interaction with known prostaglandin $F_{2\alpha}$ -receptors.

Bimatoprost is administered once daily in the evening; more frequent administration may lessen the IOP-lowering effect. It lowers the IOP to a greater extent than any other topical ocular hypotensive (van der Valk et al., 2009). Some studies show it is superior to latanoprost in terms of response rate, decline in IOP and the percentage of patients reaching their target IOP (Simmons et al., 2004). Bimatoprost has also been reported to be as effective as the fixed combination of latanoprost and timolol.

Studies have shown that patients who are not achieving their target IOP while receiving latanoprost achieved lower IOPs when switched to bimatoprost by an additional 10% reduction (Sonty et al., 2008). Therefore, significant long-term IOP-lowering may be achieved by switching to bimatoprost in patients with open-angle glaucoma who are not at target IOP with latanoprost.

Generally, bimatoprost causes similar ocular side effects to latanoprost, tafluprost and travoprost. However, bimatoprost causes hyperaemia more frequently than latanoprost. This may contribute to the higher discontinuation rate seen with bimatoprost therapy (Rahman et al., 2009). To address this issue, in 2010 the manufacturers of bimatoprost introduced a lower-strength (0.01%) version containing a higher concentration of benzalkonium chloride to aid penetration of the drug. In a 12-month study, the bimatoprost 0.01% was equivalent to bimatoprost 0.03% in lowering IOP and demonstrated improved tolerability, including less frequent and severe conjunctival hyperaemia (Katz et al., 2010).

Table 56.7 Ophthalmic β -blockers

Drug	Brand name	Strength (%)	Daily dosage frequency
Betaxolol	Betoptic solution	0.5	2
	Betoptic suspension ^a	0.25	2

^aAvailable in unit dose and multidose forms.

In 2014 bimatoprost 0.03% preserved drops were discontinued. Bimatoprost 0.03% as single dose unit preservative-free is still available for patients intolerant of 0.02% benzalkonium chloride.

β -Blockers

Ocular hypotensive effects of β -blockers (β -adrenoceptor antagonists) were first evaluated in the 1970s. They reduce the IOP by a blockade of ciliary β -receptors in the ciliary epithelium inhibiting the synthesis of cyclic adenosine monophosphate, causing a reduction in aqueous humour formation as opposed to having an effect on the aqueous humour outflow.

Although there are both β_1 - and β_2 -receptors in the eye, the latter predominate, and even cardioselective β -blockers are thought to work by blockade of β_2 -receptors. Genetic factors have been shown to be important in patients' response to this group of drugs (Sidjanin et al., 2008).

Two types of topical β -blockers are available for use in reducing IOP; non-selective, which block both β_1 - and β_2 -adrenoceptors, and cardioselective, which block only β_1 -adrenoceptors. Of the β -blockers commercially available in the UK for topical

Table 56.8 Pharmacological profile of ophthalmic β -blockers

Drug	Potency ^a	Intrinsic sympathomimetic activity	Cardioselectivity	Membrane-stabilising activity
Betaxolol	3–10	–	++	+
Carteolol	30	++	–	–
Levobunolol	6	–	–	–
Timolol	5–10	–	–	+

^aPropranolol = 1.

administration, timolol, levobunolol and carteolol are non-selective; only betaxolol is cardioselective (Table 56.7).

β -Blockers have a number of important properties in addition to β -adrenoceptor blockade. These include intrinsic sympathomimetic activity (ISA), cardioselectivity and membrane-stabilising activity, which are all of importance when considering the side effects seen with these agents (Table 56.8). The property of membrane stabilisation is relevant to the incidence of ocular side effects.

Ocular β -blockers can cause systemic adverse effects after topical application to the eye; therefore, they are contraindicated in patients with bradycardia, heart block or uncontrolled heart failure (Müller et al., 2006).

All topical β -blockers have been reported to cause bronchospasm; hence 'at-risk' patients with a tendency to airway disease who require therapy for glaucoma should be treated with extreme caution. The precipitation of bronchospasm in susceptible patients can occur with the administration of as little as one drop of timolol. The β -blockers that show cardioselectivity or ISA are less likely to cause bronchoconstriction, and it has been demonstrated that respiratory function improved in patients whose treatment was changed from timolol to betaxolol or an adrenergic agonist.

Ocular β -blockers are generally not contraindicated in diabetes, although a cardioselective agent may be preferable. However, they are best avoided in patients who suffer frequent hypoglycaemic attacks because they may mask the signs and symptoms of acute hypoglycaemia.

The long-term benefits of β -blockers on visual function preservation have been shown to be less than would be expected. This may be because of adverse effects on the ocular microcirculation, whereby the β -blockers interfere with endogenous vasodilation and cause optic nerve head arteriolar vasoconstriction. The various β -blockers demonstrate marked differences in their vasoconstrictive effect, with betaxolol possibly demonstrating the least vasoconstriction.

Non-selective β -blockers are avoided by some clinicians in patients with NTG because of the perceived risk of a nocturnal decline in arterial pressure, causing a reduction in ocular perfusion and subsequent glaucomatous damage (Orgul et al., 2005).

Ophthalmic β -blockers may induce dryness of eyes, hence patients with corneal disease should be treated with caution. Ocular side effects of topically administered β -blockers are shown in Table 56.9.

Table 56.9 Ocular and systemic side effects of topical β -blockers

Ocular	Systemic
Allergic blepharoconjunctivitis	Central nervous system
Burning and itching	Anxiety
Blurred vision	Depression
Conjunctival hyperaemia	Fatigue
Corneal anaesthesia	Hallucinations
Dryness	Irritability

Macular oedema	Endocrine
Nasolacrimal duct obstruction	Hypoglycaemia (insulin induced)
Pain	Gastro-intestinal
Punctate keratitis	Nausea
Uveitis	Diarrhoea
	Vascular
	Arrhythmias
	Bradycardia
	Hypotension
	Peripheral vasoconstriction
	Reduced stroke volume
	Respiratory
	Bronchoconstriction
	Dyspnoea

Timolol

Timolol is a non-cardioselective β -blocker without ISA, which was the first to be introduced, and as such it is the agent against which all newer β -blockers have been compared. It is effective in the long-term treatment of glaucoma, often in conjunction with other antiglaucoma therapies.

Given topically to patients with an increase in IOP, timolol induces a significant and long-lasting ocular hypotensive effect. Studies have shown that IOP is lower early in the course of treatment as opposed to later stages. In addition the IOP in the fellow untreated eye may show a decrease in IOP, which suggests that a consensual effect resulting from systemic absorption can be significant.

Many patients can be placed on once-a-day therapy provided the IOP is maintained at satisfactory levels. The presentation of timolol 0.1% in a prolonged-release formulation Tiopex (a polysaccharide-based, gel-forming solution) leads to a prolonged corneal contact time and increased penetration of timolol into the eye. Therefore, this is the preferred form for once-daily administration.

Timolol eye gel 0.1% has been shown to be as effective as the 0.5% solution administered twice daily. The 0.1% gel has the advantage of a much lower drug load, giving rise to plasma levels of timolol 10 times lower than that achieved after twice-daily dosage of timolol 0.5% eye drops. The concentration of timolol achieved in the aqueous humour after administration of the 0.1% gel formulation, despite being approximately 40% of that after administration of the 0.5% solution, is sufficient to occupy 100% of β_1 - and β_2 -receptors (Volotinen et al., 2009). Timolol is also available in 0.25% strength, and there is good evidence showing

that it has similar efficacy compared with the 0.5%. Timolol is still considered the first-line choice for the treatment of POAG in third world countries due to cost (Yadav and Patel, 2013).

Levobunolol

Levobunolol is the potent L-isomer of bunolol. It is metabolised to dihydrolevobunolol in the eye, prolonging the drug's half-life and making it one of only two topical β -blockers licensed for once-daily use. It is as effective with once-daily dosing as the usual twice-daily regimen. It is a non-cardioselective drug, showing greater affinity for the β_2 -receptor, and does not possess ISA. It is reported to be as effective as timolol 0.5% in lowering IOP and more effective than betaxolol 0.5%. The incidence of allergic contact dermatitis is greater with levobunolol than timolol (Jappe et al., 2006), and a greater percentage of patients receiving levobunolol than timolol or betaxolol discontinued the drug because of adverse effects (Rahman et al., 2009).

Carteolol

It has been suggested that because of the ISA of carteolol, which is attributable to its metabolite 8-hydroxycarteolol found in the plasma, smaller changes are seen in pulmonary and cardiovascular parameters than are seen with the non-cardioselective β -blockers without ISA (timolol and levobunolol). Carteolol appears to be neutral in its effect on serum lipid levels, whereas timolol adversely affects high-density lipoprotein cholesterol and the total cholesterol/high-density lipoprotein cholesterol ratio. Carteolol is generally well tolerated and has been shown to be as effective as timolol at lowering IOP in the majority of patients. It has a greater vasodilator effect on the retinal and choroidal vasculature than timolol and levobunolol, but less than that of betaxolol. It is the least lipophilic of the topical β -blockers and consequently is likely to show a lower incidence of central nervous system side effects.

Betaxolol

In theory, because of its cardioselectivity, betaxolol should have fewer adverse effects on the pulmonary system. It should also have fewer adverse cardiovascular effects because of comparatively lower systemic β -receptor occupancy after ocular administration. Maximum occupancies for β_1 - and β_2 -receptors after ophthalmic administration were 52% and 88% for carteolol, 62% and 82% for timolol, and 44% and 3% for betaxolol, respectively (Yasuhiko et al., 2001). However, betaxolol is less effective than other β -blockers as an ocular hypotensive agent (van der Valk et al., 2009). On initiation of treatment, the decline in IOP is slower than with other topical β -blockers. The 0.25% suspension is as effective as the 0.5% solution and is better tolerated by the patient (Yalvac et al., 2007). Experimental studies showed the drug reaches the retina after topical administration and displays a voltage-dependent L-type calcium channel-blocking activity, which probably leads to improved retinal perfusion. This effect may explain the significant improvement in visual field performance seen with betaxolol in a comparison study with timolol in

open-angle glaucoma. The significant improvement with betaxolol occurred despite the more effective reductions in IOP with timolol (Araie et al., 2003).

Carbonic anhydrase inhibitors

There are many forms of the carbonic anhydrase isoenzyme in body tissues, three of which (CA-I, CA-II and CA-IV) are present in ocular tissues. Bicarbonate formation is an essential component of aqueous production. In the ciliary epithelium, the inhibition of CA-II slows the formation of bicarbonate ions and their secretion into the posterior chamber of the eye. This reduces the sodium transport into the posterior chamber and decreases aqueous humour production, resulting in lower IOP. Inhibition of other forms of the enzyme results in many side effects. Carbonic anhydrase inhibitors are sulfonamides; although there is little evidence to suggest sensitivity overlap, they are still contraindicated in patients with known hypersensitivity to sulfonamides.

Acetazolamide

Acetazolamide is the only systemic carbonic anhydrase inhibitor available in the UK. Although it is among the most potent ocular hypotensive agents available, it has limited use in the long-term management of glaucoma due to unpleasant and potentially dangerous side effects. It may be added to treatment in POAG and other chronic glaucomas in patients refractory to standard treatment. The systemic side effects are shown in [Box 56.1](#).

Acetazolamide is readily absorbed from the gastro-intestinal tract after oral administration; it attains peak plasma level within 2–4 hours. Peak levels are maintained for 4–6 hours.

Paraesthesia occurs in almost all patients on commencement of therapy, but usually disappears on continued therapy. The malaise complex can include fatigue, depression, weight loss and decreased libido. Chronic use can lead to dangerous electrolyte imbalance such that the monitoring of renal function is mandatory. In the acute setting, acetazolamide is also available in injection form and given intravenously. Plasma levels sufficient to decrease IOP occur only minutes after intravenous administration of acetazolamide. It may be useful in the preoperative treatment of POAG and in the emergency treatment of PAC.

Topical carbonic anhydrase inhibitors

The topical carbonic anhydrase inhibitors dorzolamide and brinzolamide are less effective in lowering IOP than acetazolamide but have a lower potential to produce adverse effects. They are licensed as monotherapy for patients with POAG or OHT resistant to β -blockers or those in whom use of β -blockers is contraindicated. They can also be prescribed in combination with other treatment.

Dorzolamide is also licensed for the treatment of pseudo-exfoliative glaucoma, and limited clinical data in paediatric patients are available. Both drugs are licensed as adjunctive therapy to β -blockers and brinzolamide to PGAs, although there is evidence to suggest that dorzolamide is as efficacious as brinzolamide when added to latanoprost (Nakamura et al., 2009).

Dorzolamide is used either alone three times a day or concurrently with a β -blocker or twice daily with a PGA. Although the license for brinzolamide states that the drug can be used twice a day as monotherapy, some patients may respond better to a three times daily dosage. Mean changes in IOP with brinzolamide administered twice daily and three times daily and dorzolamide administered three times daily are equivalent. However, the decline in IOP achieved with these agents is less than that seen with timolol 0.5% twice daily.

Side effects similar to those of systemic sulfonamides may occur and should be monitored. The most common side effects are shown in [Table 56.10](#). Of the two topical carbonic anhydrase inhibitors, brinzolamide appears to cause less burning and stinging on instillation because of the neutral pH (7.5) of the formulation. This is reflected in a much greater discontinuation rate with dorzolamide (31%) than with brinzolamide (14%) (Rahman et al., 2009). Owing to its form as a more viscous suspension, however, blurring is more common with brinzolamide than with dorzolamide.

Table 56.11 Examples of available ocular products containing sympathomimetic agents

Drug	Trade name	Strength	Daily dosage frequency
Apraclonidine	lopidine	1%	1h before surgery and on completion
	lopidine	0.5%	3
Brimonidine	Alphagan	0.2%	2

Sympathomimetic agents

Sympathomimetic agents (α_2 -adrenergic agonists) reduce IOP by reducing aqueous inflow via an α -mediated vasoconstriction in the ciliary body and increased outflow due to a dilation of the aqueous and episcleral veins.

The original sympathomimetic drug, adrenaline (epinephrine), and its lipophilic prodrug dipivefrine have been used in the treatment of OHT and POAG since the early 1920s. Both are classed as non-selective α - and β -adrenoreceptor agonist drugs with a relatively high potential for both ocular and systemic side effects, and are no longer used in routine clinical practice. They have been superseded by the more selective sympathomimetics: apraclonidine and brimonidine. Commercially available preparations of sympathomimetic agents are listed in Table 56.11. Ocular and systemic side effects of α_2 -agonists are listed in Table 56.12. Sympathomimetics are generally mydriatic; therefore, their use is contraindicated in untreated PAC because of the risk of precipitating acute angle closure.

Apraclonidine

Apraclonidine (a derivative of clonidine) was the first of the selective adrenergic agonists to be introduced. This drug, which acts predominantly on α_2 - but also on α_1 -receptors, reduces the rate at which aqueous humour is produced due to ciliary vasoconstriction. Eye drops containing apraclonidine 1% are used to control or prevent postsurgical elevation of IOP after anterior segment laser surgery, for example, trabeculoplasty. Eye drops containing a 0.5% solution are licensed for the short-term adjunctive treatment of patients receiving maximally tolerated medical therapy who require additional IOP reduction to delay laser treatment or glaucoma surgery, but the benefit for most patients is less than 1 month.

Apraclonidine 0.5% is as effective in lowering IOP as brimonidine 0.2%, but has less effect on blood pressure and heart rate. Although an off-license use, apraclonidine is sometimes used in children in whom brimonidine is strictly contraindicated (Wright and Freedman, 2009).

Brimonidine

More α_2 -selectivity is seen with brimonidine, which results in miosis rather than mydriasis. Vasoconstriction of microvessels is

Table 56.12 Ocular and systemic side effects of topical α_2 -agonists

Ocular	Systemic

Miosis (reported with brimonidine)	
Uveitis	

also not seen. It is thought to increase uveoscleral outflow, as well as reducing aqueous production. Brimonidine administered twice daily is almost as effective as timolol twice a day at peak. However, brimonidine is significantly less effective at trough, and some consider it to be more efficacious when administered three times a day, which is the frequency used in the USA.

A database containing details of drug use in 956 patients with glaucoma older than 18 years shows that brimonidine had the highest proportion of discontinuations because of adverse effects (Rahman et al., 2009). It has high allergenicity and may increase the likelihood of allergy to preparations subsequently used.

Brimonidine may be used as monotherapy to lower IOP in patients with POAC or OHT who are intolerant of β -blockers or in whom β -blockers are contraindicated, because there is no effect on pulmonary function and only minimal cardiovascular effect. It may also be used as an adjunctive therapy in those patients whose IOP is not adequately controlled with a single agent because its IOP-lowering activity has been shown to be additive to that of β -blockers and PGAs.

In a 4-month study, the co-administration of latanoprost and brimonidine 0.15% resulted in a greater decline in IOP than the co-administration of latanoprost and brinzolamide or dorzolamide (Bournias and Lai, 2009); this product is not available in the UK. Brimonidine is contraindicated in patients who are receiving monoamine oxidase inhibitors or antidepressants which affect noradrenergic transmission, and there is the possibility of brimonidine potentiating or causing an additive effect with central nervous system depressants.

Topical miotics

Miotics act to increase the outflow of aqueous humour by a stimulation of ciliary muscle and an opening of channels in the trabecular meshwork. Miotics are directly acting parasympathomimetic agents that act at muscarinic receptors. The only such drug

currently available commercially in the UK is pilocarpine. The onset of action of pilocarpine is 20 minutes, but its short duration of action necessitates four times daily dosing. The ocular and systemic side effects of pilocarpine are shown in [Boxes 56.2 and 56.3](#), respectively.

The use of miotics is almost exclusively confined to the treatment of PACG and some secondary glaucomas. They are no longer commonly used for the treatment of POAG and OHT mainly because of poor tolerance of side effects of these drugs and the frequency of instillation. The main side effect is miosis, which is often accompanied by frontal headache (browache), loss of accommodation and blurred vision.

New drugs in development

Inhibitors of Rho kinase have emerged as a new class of IOP-lowering medications designed to increase outflow through the trabecular meshwork and are currently being tested in clinics ([Karmel, 2013](#)).

Latanoprostene bunod, a nitric oxide-donating PGA administered once daily, is currently in development. Recent clinical trials have shown it to be more effective than latanoprost ([Weinreb et al., 2015](#)).

Combination products

Clinical practice guidelines recommend initiating treatment with one medication; however, in many patients a single medication

does not effectively reduce IOP to within the target range, and treatment with at least two medications from different classes is required ([Higginbotham, 2010](#)). Treatment with more than one eye drop has a number of disadvantages: poorer adherence with treatment, increased risk of medication washout and increased exposure to preservatives, for example, benzalkonium chloride.

The combination of two drugs in one topical ophthalmic preparation may improve adherence and result in a reduction in preservative load. For a combination of two medications to be an acceptable alternative to the prescriber, the fixed combination must be more effective than either of the components used alone and at least as effective as the drugs administered separately. In addition, adverse effects of the fixed combination should not exceed those encountered when the components are administered separately.

When compared with prescribing the individual monotherapies, fixed combination therapies offer a simple and convenient dosing regimen, and may result in some cost saving for patients who pay for their prescription. However, fixed combinations also remove the possibility of titrating the individual components both in terms of concentration and timing of administration, and may not provide the same efficacy as the individual components. Furthermore, the use of timolol in the combination at high concentration may lead to additional side effects.

In the past, fixed combination drops all contained timolol; this limited their use in patients with comorbidities that contraindicate β -blockers. In the UK a timolol-free combination product Simbrinza containing brinzolamide 10 mg/mL and brimonidine tartrate 2 mg/mL is now available.

Fixed combination of timolol and dorzolamide

A combination of timolol 0.5% and dorzolamide 2% (Cosopt) was the first topical ocular hypotensive combination to be marketed. It is indicated twice daily in the treatment of elevated IOP in patients with open-angle glaucoma or pseudoexfoliative glaucoma when topical β -blocker monotherapy is insufficient. The fixed combination of dorzolamide and timolol is more effective than either timolol or dorzolamide alone, and as effective as its two components administered separately. Fixed combination dorzolamide and timolol is also generally well tolerated. This suggests that fixed combination dorzolamide and timolol may have a beneficial role as a replacement or adjunct therapy in a clinical glaucoma practice setting when the IOP is not adequately controlled with either ([Yeh et al., 2008](#)). It has also been reported to be a useful agent when used adjunctively with latanoprost, resulting in a further decline in IOP. Although generally well tolerated, the main problem with Cosopt is burning and stinging on instillation. Although discontinuation of the combination in trials is low, Cosopt has been found to be the third most frequently discontinued eye product in practice ([Rahman et al., 2009](#)).

Fixed combination of timolol and latanoprost

A combination of timolol 0.5% and latanoprost 0.005%, marketed as Xalacom, was first launched in the UK in 2001, shortly before the launch of travoprost and bimatoprost.

Xalacom is indicated for the reduction of IOP in patients with open-angle glaucoma and OHT who are insufficiently responsive to topical β -blockers or PGAs alone. It is administered once a day and has been shown to be more effective when administered in the evening than in the morning (Takmaz et al., 2008).

Fixed combination of timolol and travoprost

A fixed combination of travoprost 0.004% and timolol 0.5% (DuoTrav) has been shown to be more effective than either of its components and is as efficacious as the components administered concomitantly, whereas fewer side effects are reported with the combination product (Gross et al., 2007). The fixed combination of travoprost and timolol is indicated to decrease IOP in patients with open-angle glaucoma or OHT who are insufficiently responsive to topical β -blockers or PGAs. Although the Summary of Product Characteristics states that the dose is one drop in the affected eye(s) once daily, in the morning or evening, it has been shown that an evening dose demonstrates better 24-hour pressure control (Konstas et al., 2009).

Fixed combination of timolol and bimatoprost

A fixed combination of bimatoprost 0.03% and timolol 0.5% (Ganfort) is available for the reduction of IOP in patients with open-angle glaucoma or OHT who are insufficiently responsive to topical β -blockers or PGAs. The fixed combination has been shown to be more effective than either of its components used alone and as effective as the components used in their usual dosing regimen (bimatoprost once daily in the evening and timolol twice daily, used concomitantly). Conjunctival hyperaemia has been reported more frequently by patients receiving bimatoprost (39%) than the bimatoprost/timolol fixed combination (23%), with the lowest incidence in those receiving timolol (7%) (Brandt et al., 2008).

Fixed combination of timolol and brimonidine

A combination of timolol 0.5% with brimonidine 0.2% is marketed as Combigan and is indicated for the reduction of IOP in patients with POAG or OHT who are insufficiently responsive to topical β -blockers.

The fixed combination has been shown to be superior in reducing IOP than either brimonidine or timolol alone and is as safe and effective as concomitant treatment with the individual components. Use of the combination product has been shown to result in a 24% decrease in IOP (Papaconstantinou et al., 2009). Use of the brimonidine and timolol combination results in a greater number of side effects than timolol alone, but has fewer side effects than brimonidine alone (Sherwood et al., 2006) and fewer cases of allergy than brimonidine used alone (Motolko, 2008).

Fixed combination of timolol and brinzolamide

A fixed combination of brinzolamide 1% and timolol 0.5% (Azarga) is a topical ocular hypotensive presentation launched in 2009. The combination is indicated to reduce IOP in adult patients with open-angle glaucoma or OHT for whom monotherapy has produced insufficient IOP reduction. It has greater IOP-lowering efficacy than brinzolamide or timolol alone (Kaback et al., 2008).

Brinzolamide/timolol administration leads to a 30–33% decline in IOP at trough and 34–35% at peak and is better tolerated than, and preferred to, the dorzolamide/timolol combination, probably because of the neutral pH (7.2) of the suspension (Manni et al., 2009).

Fixed combination of timolol and tafluprost

A new preservative-free fixed-dose combination product consisting of 0.0015% tafluprost, a PGA, and 0.5% timolol, a β -blocker (Taptiqom), has recently been developed.

Although studies have shown the IOP reduction in POAG and OHT is similar to other prostaglandin-timolol fixed-combination products, this product causes less superficial ocular side effects and less conjunctival hyperaemia. In conclusion, a review of the double-masked, controlled, phase III clinical trials with the fixed-combination products of prostaglandin and timolol revealed that the products yielded a similar reduction in IOP of approximately 32–36% from an untreated baseline IOP of around 24–29 mmHg (Hollo et al., 2014).

Fixed combination of brinzolamide and brimonidine

Formerly fixed combination drops all contained timolol; this limited their use in patients with comorbidities that contraindicate β -blocker therapy. In 2014, a timolol-free combination product was launched, containing brinzolamide 1% and brimonidine 0.2% ophthalmic suspension. Referred to as Simbrinza it is a fixed combination of carbonic anhydrase inhibitor and an α_2 -adrenergic receptor agonist. It is indicated for the reduction of elevated IOP in patients with POAG and OT in the UK, European Union, and USA.

Hyperosmotic agents

Hyperosmotic agents can be considered for use in the emergency treatment of acute angle closure because of their speed of action and effectiveness. The most commonly used agents are oral glycerol and intravenous mannitol. The mechanism of action is the creation of osmotic shifts of water from the aqueous circulation, thus lowering IOP. The maximal effect of glycerol is seen within 1 hour and lasts for about 3 hours, whereas mannitol acts within 30 minutes with effects lasting for 4–6 hours.

Glycerol

Glycerol is given orally, usually as a 50% solution in water, the dose being 1–1.5 g/kg body weight given as a single dose. It is not a strong diuretic but may cause headaches, nausea and vomiting. Although it is metabolised to glucose in the body, it may be given to individuals with diabetes that is well controlled. All practitioners should be aware of the difference in dose in millilitres required for a 50% solution of glycerol formulated as a 50% w/v solution and one formulated as a 50% v/v solution (Table 56.13).

Mannitol

Mannitol is given as a 20% solution in water for intravenous administration. The dose is 1–2 g/kg body weight up to a maximum of 500 mL given over 30–40 minutes at a rate not exceeding 60 drops/min (see Table 56.13). It is a strong diuretic and as large volumes are required, it may cause problems because of

Table 56.13 Doses of hyperosmotic agents used in the treatment of acute angle-closure glaucoma

cardiovascular overload, pulmonary oedema and stroke. Cerebral dehydration leads to headache, and the patient may experience chills and chest pain. It should therefore be used with great caution.

Patient care

Primary open-angle glaucoma

When the condition is first diagnosed, patients should be told that the disorder cannot be cured but only controlled by the regular use of the prescribed treatment. Because patients are usually unaware of progression of the disease, the result of non-adherence with treatment should be made clear and the importance of regular attendance at clinics stressed.

The existence of a patient self-help group, the International Glaucoma Association (<http://www.glaucoma-association.com>), should be brought to the patient's attention. They will be able to put the patient in contact with their nearest local support group.

The patient's technique for installing eye drops should be checked and corrected if necessary. Emphasis should be on the dose (one drop), the position of instillation (into the temporal side of the lower conjunctival sac) and the importance of punctal occlusion to minimise systemic side effects.

The preferred times for administration of topical medication should be discussed with the patient. Prostaglandins and prostamides are best administered at bedtime; a 12-hourly regimen should be used for twice-daily drugs, 8-hourly for drugs given

three times a day, and as near a 6-hourly regimen as practical for the aqueous formulation of pilocarpine.

β-Blockers given once daily should be administered in the morning. The importance of allowing a reasonable interval between drops should be emphasised. Sometimes the order of instillation of different types of eye drop is important for pharmacological or practical reasons. For example, the instillation of pilocarpine should always precede that of a sympathomimetic to prevent pain in the eye resulting from a strong miosis after a weak mydriasis.

The instillation of aqueous eye drops, which remain in the conjunctival sac for a maximum of 10 minutes, should precede that of viscous eye drops (e.g. hypromellose eye drops) or suspensions (e.g. dexamethasone 0.1% eye drops) where the contact time is prolonged.

Eye drops containing benzalkonium chloride should not be instilled if soft contact lenses are in situ. The patient should be instructed to remove the lens immediately before instillation and replace it approximately 15 minutes later.

Because there is a hereditary component to POAG, patients should be told to advise first-degree relatives to be screened. Such people older than 40 years are entitled to free eye tests by their optometrist.

Primary angle-closure glaucoma

Patients found to have shallow anterior chambers and narrow angles normally undergo laser peripheral iridotomies. In the interim they should be advised of the symptoms of an attack of acute PAC so that medical attention can be sought if necessary.

If peripheral iridotomies are not performed, the patient should be advised that a number of prescription and non-prescription drugs should be avoided (Lachkar and Bouassida, 2007). When visiting the doctor and purchasing medicines from a pharmacy, the patient should always remember to mention their condition, and the prescriber should ensure that the drug is appropriate for a patient prone to angle closure. Examples of drugs contraindicated in this condition are listed in Table 56.14. Note that the absence of a drug from this list does not imply safety.

After an attack of acute angle closure and surgical treatment of the disorder, the patient should be told that the drugs previously contraindicated can be safely taken provided that iridectomy/iridotomy remains patent.

Patient adherence

The patient is more likely to comply with the prescribed treatment if the drug or drugs can be administered according to a

simple, infrequent dosage regimen with minimal, local or systemic side effects.

Thus, a patient treated with a once-daily PGA or prostamide or once- or twice-daily β -blocker would be expected to adhere to the regimen better than someone treated with pilocarpine, with its unfortunate side effects and inconvenient four-times-a-day dosage regimen. Common side effects of topical and systemic medication should be fully discussed with the patient so that the hyperaemia encountered with the prostanoids and the paraesthesia with acetazolamide are not unexpected, leading to premature discontinuation of therapy.

Because glaucoma is predominantly a disease of elderly people, physical disability may prevent successful treatment, however conscientious the patient. For example, rheumatoid arthritis may reduce the patient's ability to squeeze the bottle of eye drops, while the tremor of Parkinson's disease can make correct positioning of instillation difficult. Various aids have been introduced to help with correct positioning and squeezing of eye drops, and these should be made available to patients who require such support.

Table 56.14 Drugs contraindicated in primary angle-closure glaucoma

Therapeutic class	Examples
Antimuscarinics	Topical Atropine, cyclopentolate, homatropine, tropicamide
Antispasmodic	Atropine, dicycloverine, hyoscine, propantheline
Motion sickness	Hyoscine, promethazine, cyclizine
Bronchodilator	Ipratropium, tiotropium
Urinary retention	Darifenacin, fesoterodine, flavoxate, oxybutynin, propiverine, solifenacin, tolterodine, trospium
Drugs used in anaesthesia	Glycopyrronium, ketamine, suxamethonium
Antidepressants	Amitriptyline, amoxapine, citalopram, clomipramine, dosulepin, doxepin, duloxetine, fluvoxamine, imipramine, lofepramine, maprotiline, mirtazapine, nortriptyline, paroxetine, phenelzine, reboxetine, sertraline, trazodone, trimipramine, venlafaxine
Antipsychotics	Chlorpromazine, clozapine, flupentixol, fluphenazine, olanzapine, pericyazine, perphenazine, promazine, risperidone, sulphiride, thioridazine, trifluoperazine, zuclopenthixol
Antihistamines	Alimemazine, antazoline, cetirizine, chlorphenamine, clemastine, cyproheptadine, diphenhydramine, hydroxyzine, loratadine, pizotifen
Antiarrhythmics	Disopyramide
Antiepileptics	Carbamazepine, topiramate
Sympathomimetics	Adrenaline, cocaine, dipivefrine, ephedrine, isometheptene, naphazoline, phenylephrine, pseudoephedrine, salbutamol, xylometazoline
Drugs used in the treatment of attention deficit hyperactivity disorder	Atomoxetine, dexamphetamine, methylphenidate, ritodrine
Drugs used in the treatment of parkinsonism	Benserazide, carbidopa, entacapone, levodopa, orphenadrine, procyclidine, selegiline, trihexyphenidyl
Non-steroidal anti-inflammatory drugs	Mefenamic acid
Sulfonamide-derived drugs	Acetazolamide, co-trimoxazole, hydrochlorothiazide, sulfasalazine
Miscellaneous	Botulinum toxin, carboprost, paricalcitol, pilocarpine

Table 56.15 Common therapeutic problems in glaucoma

Problem	Comments
Lack of adherence	Treatment perceived to be worse than disease Complex multiple-drug regimens Frequency of dosing Inability to differentiate between different types of medication Inability to instil medication
Contraindication to therapy	Pilocarpine in uveitis β -Blockers in asthma, bradycardia, heart block, uncontrolled heart failure Prostaglandin analogues and prostamides in aphakia Wide range of topical and systemic drugs in shallow anterior chamber α_2 -Agonists in depression Carbonic anhydrase inhibitors in renal failure
Intolerance to drug	Miosis and ciliary spasm with pilocarpine Red eye with prostaglandin analogues, bimatoprost Bronchospasm with β -blockers Paraesthesia with acetazolamide
Use outside of licensed indications	Paediatric patients Pregnant women Nursing mothers
Hypersensitivity	To active drug To preservative in multidose formulation

Patients with poor visual acuity can be helped by the colour coding of eye drop labels and supplying bottles labelled with large print. Some manufacturers have endeavoured to enhance adherence by including dose-reminder caps and facilitating instillation by supplying aids to open or position the bottle.

Other manufacturers have made their eye drop containers easier to squeeze or supply aids to squeeze the bottle. A list of such devices, some of which are available on prescription and others free of charge from manufacturers of drugs used in the treatment of glaucoma, is available on the International Glaucoma Association's website (<http://www.glaucoma-association.com>).

Where self-medication is impossible, a simple infrequent dosage regimen is more likely to be achieved when a relative, a neighbour or the district nursing service can assist with administration of the medication. In these cases, a drug administered once daily, such as a long-acting timolol preparation or a PGA or bimatoprost, has an obvious advantage over one that should be administered at 12-hourly intervals.

Common therapeutic problems in glaucoma are listed in [Table 56.15](#).

Case studies

Case 56.1

A 64-year-old Asian woman, Mrs GV, attended the emergency department suffering from a severe headache, nausea and vomiting. Her right eye was red, and she reported blurred vision. The only new medication she had used recently was some antimitotic tablets recommended by her local pharmacist. Her medical history includes type 2 diabetes.

Question

What is the most likely cause of Mrs GV's symptoms, and what investigations and treatment would you expect Mrs GV to have?

Answer

Headache, painful red eye and blurred vision are all signs of an acute PAC attack. PAC is more common in elderly female patients, especially of Asian ethnicity such as Mrs GV. The lens grows with aging and can push the iris forwards, narrowing the angle between the iris and cornea; this will affect the drainage of aqueous humour. Medication with antimuscarinic side effects (antimitotic tablets) can precipitate an attack. A previous history of acute PAC is infrequent and this attack is usually the first indication of having this condition. The attack is usually unilateral; however, long-term management will be for both eyes. Acute PAC is an emergency; prompt diagnosis and treatment are essential to prevent damage to the optic nerve and irreversible blindness.

On examination, Mrs GV feels very unwell; her IOP is substantially elevated, greater than 50 mmHg. Slit-lamp findings include shallow anterior chambers in both eyes, closed iridocorneal angle and corneal epithelial oedema. The pupil is fixed and mid-dilated. Mrs GV's initial treatment involves acetazolamide given intravenously with topical glaucoma medications, for example, timolol if not contraindicated. In addition, steroids drops are used to reduce inflammation, as well as pilocarpine, a miotic that causes the pupil to constrict, opening drainage channels and allowing the aqueous humour to leave and the IOP to reduce.

Case 56.2

A 44-year-old man, Mr JT, has been treated for POAG for more than a year. He visited his primary care physician last week having noticed that both of his eyes were markedly red, sore and dry.

Mr JT is currently using:

latanoprost at night to both eyes,
timolol 0.5% twice a day to both eyes,
dorzolamide twice a day to both eyes.

Question

What are the contributing factors for Mr JT's symptoms?

Answer

Red, sore, dry eyes are associated with a number of underlying conditions. For Mr JT the use of three different eye drops increases his exposure to the preservative benzalkonium chloride that can cause eye irritation and, rarely, ulcerative keratopathy. The concentration

of benzalkonium chloride in latanoprost eye drops is generally high (0.02%). Changing to a preservative-free formulation for all the above drops can be an option, as can the prescribing of combination products. It might be worthwhile considering travoprost as an

alternative to latanoprost because it contains a different preservative and would reduce the cost associated with preservative-free preparations.

57 Drug-induced Skin Disorders

Sarah Walsh and Daniel Creamer

Key points

- Drug-induced skin reactions are common, accounting for 30% of all reported adverse drug reactions.
- Diagnosis requires a comprehensive drug history and knowledge of likely causative drugs.
- Treatment involves drug withdrawal and general supportive measures.
- All skin eruptions will cause morbidity, but the severe reactions, such as Stevens–Johnson syndrome/toxic epidermal necrolysis, are associated with appreciable mortality.
- Certain individuals are at higher risk of drug eruptions, for example, patients with HIV infection.
- Some types of drug reaction can cause systemic as well as skin involvement, affecting the hepatic, haematological and lymphatic systems.

Adverse drug reactions (ADRs) are an inevitable consequence of modern drug therapy. They are an important cause of iatrogenic illness in terms of morbidity and mortality. ADRs can cause serious harm to the patient, as well as carrying medico-legal and economic consequences. Fortunately, only about 2% of all drug-induced skin reactions are severe, and very few are fatal. However, all drug-induced skin eruptions can cause morbidity and affect the patient's confidence in the prescriber and future adherence with medication. Therefore, it is important that all drug-associated rashes are carefully evaluated and documented. It is essential that the patient is made aware of his or her sensitivity because subsequent exposure to the drug may cause a more severe eruption. At the population level, both reporting of adverse events via the Medicines and Healthcare Products Regulatory Agency (MHRA) 'yellow card scheme' and post-marketing surveillance of new drugs have a role in identifying patterns of drug eruption.

It is important to remember that the potential of an individual drug to cause a skin eruption is variable. Any drug can potentially cause any reaction pattern in the skin. Some drugs, such as ferrous sulphate, seldom produce a rash, whereas others, for example, carbamazepine, penicillin antibiotics and sulfasalazine, are far more likely to precipitate a skin eruption.

Diagnosis

It is often difficult to determine the cause of a drug-induced eruption for the following reasons:

- Almost any drug can affect the skin.
- Unrelated drugs can produce similar reactions.
- The same drug may produce different reaction patterns in different patients.
- Some drug reactions are difficult to distinguish from specific skin diseases such as acne, eczema and psoriasis.

In most cases, diagnosis of a drug-induced skin eruption is based on the history and the temporal association of the onset of the rash to the commencement of the medication. Particular difficulties are presented by the patient taking combined preparations, for example, co-tenidone, which contains both a diuretic and a β -blocker. Excipients contained in medication, such as preservatives, stabilisers or colours, may be the culprit rather than the drug itself. Changes in the brand of medication may, for this reason, provoke a skin reaction in someone who appears to have been established on a drug for some time and suddenly develops a rash. Patients may be taking preparations acquired over the counter (OTC), or from an alternative practitioner, which they may not immediately volunteer when asked about current medication. If a patient presents with a rash and is currently taking, or has recently finished, medication, the following are important steps:

- Take an accurate drug history, including OTC medicines, herbal and homeopathic preparations and any injections. Record both generic and brand names of medicines.
- Ask if the patient has any history of drug sensitivity.
- Ascertain when the eruption started in relation to drug use (the latency of onset of the eruption).

Definitive diagnosis of a drug-induced dermatosis would require drug re-challenge; however, this is not recommended due to the possibility of provoking a more severe reaction on second exposure (Po and Kendall, 2001).

Drug-induced skin disorders

In this chapter, drug reactions are considered under the following headings: drug reactions causing changes in skin function, mild drug-induced skin disorders and severe drug-induced skin disorders.

Box 57.1 Drugs causing light-induced eruptions

Topical preparations

- Topical NSAIDs
- Components of sunscreen, such as para-aminobenzoic acid, benzophenone

Systemic drugs

Phototoxic reactions

- Amiodarone
- Nalidixic acid
- NSAIDs
- Chlorpromazine
- Tetracyclines

Photoallergic reactions

- Griseofulvin
- NSAIDs
- Sulfonamides
- Sulfonyleureas
- Thiazide diuretics

NSAIDs, Non-steroidal anti-inflammatory drugs.

Drug reactions causing changes in skin function

Some drugs alter the ability of the skin and associated structures (hair and nails) to perform their functions normally.

Abnormal photosensitivity

Drugs may induce an excessive sensitivity to sunlight. Ultraviolet wavelengths of sunlight (290–400 nm) are able to interact with certain drugs in the skin to provoke abnormal photosensitivity. An eruption occurring on all uncovered skin implicates exposure to a systemic photosensitising agent, for example, a patient who commences bendroflumethiazide and subsequently develops sunburn on a cloudy day. A localised eruption indicates a reaction to a locally applied topical photosensitiser and subsequent exposure to light. This may be seen in individuals who are sensitive to a component of sunscreens such as benzophenone, a chemical sunblock.

Drug-induced photosensitivity can be either phototoxic or photoallergic (Box 57.1). Phototoxic reactions, which are more common, resemble severe sunburn and can progress to blistering. They are dose dependent for both the drug and sunlight; they occur within 5–15 hours of taking the drug and subside quickly on drug withdrawal. Photoallergic rashes are usually eczematous but may be lichenoid, urticarial, bullous or purpuric. They are not dose dependent and occur after exposure to normal amounts of sunlight exposure. The onset can be delayed by weeks or months, and recovery is often slow after drug withdrawal. Rarely, a photoallergic state can persist for years after the drug responsible has been discontinued.

Patients receiving known photosensitising drugs should be advised to avoid strong sunlight. They should also be advised to use a broad-spectrum topical sunscreen, providing both UVA protection (indicated by the ‘star rating’ on the bottle) and UVB cover (indicated by the sun protection factor, SPF).

Fig. 57.1 Minocycline pigmentation: this female patient was taking minocycline for 2 years for treatment of rosacea and developed unsightly grey pigmentation around the mouth. This did not respond to stopping the medication.

Pigmentary changes

The skin's colour can be altered by drugs; hyper-pigmentation, hypo-pigmentation and discoloration can all potentially be induced by a variety of medicines (see Fig. 57.1 and Table 57.1). Pigmentary changes can be widespread or localised. The most common examples of localised pigmentation are the facial blue–black pigmentation in individuals on amiodarone or minocycline and melasma facial pigmentation occurring in some women taking the combined oral contraceptive pill. Generalised pigmentary change induced by drugs is rare but can occur with chemotherapeutic agents such as bleomycin. This may have the appearance of generalised hyper-melanosis or may take on a more flagellate appearance with multiple linear areas of hyper-pigmentation.

The mechanism of drug pigmentation is not always known; however, proposed pathogenetic mechanisms are as follows:

- Drug or drug metabolite deposition in the dermis and epidermis. An example of this would be agyria, in which systemic absorption of silver from, for example, topical silver sulfadiazine, causes a slate-grey discoloration of the skin.
- Enhanced melanin production with or without an increase in the number of active melanocytes. This appears to be the pathogenetic mechanism in melasma and also bleomycin-induced pigmentation (Moncada et al., 2009).

Nail changes

The growth and colour of the fingernails and toenails can be modified by drugs. Abnormalities of the texture and architecture of the nail unit can also be drug induced. Blue discoloration of the nails can result from therapy with mepacrine, whereas a blue–black pigmentation may accompany treatment with minocycline and certain cytotoxic drugs such as hydroxyurea. Potassium permanganate solutions will dye nails brown. White nails (leukonychia) can result from treatment with chemotherapy agents, especially cyclophosphamide, doxorubicin and vincristine. Beau's lines, transverse depressions of the nail, represent interruption of the

Table 57.1 Drugs causing skin pigmentation

Drug	Pigmentation
Amiodarone	Blue–grey
Anticonvulsants	Brown
Antimalarials	Blue–grey
β-Blockers	Brown
Imatinib	Hypo-/hyperpigmentation
Imipramine	Blue/grey
Mepacrine	Blue/black
Methyldopa	Brown
Oral contraceptives	Brown spots/patches
Phenothiazines	Brown/blue–grey
Psoralens	Brown
Tetracyclines	Blue–black

normal growth of the nail matrix and are caused by systemic infection, metabolic upset or, occasionally, drugs. In the drug-induced form, the most common cause is again chemotherapy agents, similar to those which cause leukonychia.

Onycholysis is characterised by separation of the nail plate from the underlying nail bed. Any cytotoxic agent may induce onycholysis by direct toxicity to the matrix. Photo-onycholysis describes lifting of the nail plate and is caused by the combination of a photosensitising drug, for example, minocycline or oxytetracycline, and by UVA exposure.

Hair changes

Drugs may exert an effect on the hair follicle itself or on the growth cycle of hair. The cycle of hair growth involves anagen (the growth phase of the hair), catagen (the resting phase) and telogen (the shedding phase). Either loss of hair or excessive growth of hair may result.

Loss of hair. Drug-induced alopecia (Box 57.2) may be partial or complete. The temporal relationship between the introduction of the drug and the subsequent loss of hair depends on the part of the hair cycle with which the drug interferes. Cytotoxic drugs interfere with the ‘anagen’ or growth phase of the hair cycle, and so loss is rapid and complete; it begins shortly after administration of the drug, and the effect is dose dependent and fortunately reversible, but a delay of several weeks is common before regrowth begins.

Delayed hair loss after the introduction of a drug is a more insidious process and may not be noticed immediately by the patient. In this scenario, the drug is often interfering with the ‘telogen’ or shedding part of the hair cycle, moving follicles through this phase more quickly. Hair is shed at a rate that exceeds that at

Box 57.2 Drugs causing hair disorders

Alopecia

- Acitretin
- Anticoagulants
- Anticonvulsants
- Antithyroid drugs
- β-Blockers
- Cimetidine
- Cytotoxic drugs
- Gold salts
- Interferons
- Isotretinoin
- Leflunomide
- Lithium
- Sodium valproate
- Statins
- Tacrolimus
- Vismodegib

Hirsutism/hypertrichosis

- Acetazolamide
- Anabolic steroids
- Androgens
- Corticosteroids (topical and systemic)
- Ciclosporin
- Danazol
- Minoxidil
- Oral contraceptives
- Penicillamine
- Phenytoin
- Tamoxifen
- Verapamil

which the follicles can produce new hair, resulting in a thinning effect. Given the length of the hair cycle, this type of hair loss can occur 2–4 months after a drug is initiated. Retinoid therapy, including isotretinoin prescribed for acne, or acitretin for psoriasis, may induce a telogen alopecia.

Androgens promote the shrinking of hair follicles and shorten the duration of the growth stage of the hair-follicle cycle (anagen stage). Drugs with androgen activity can induce male-pattern baldness, for example, exogenously administered testosterone, which may be prescribed for hypogonadism in men and occasionally in post-menopausal women as an adjunct to hormone replacement therapy. Oestrogens are known to prolong the anagen stage and counteract androgenetic alopecia. Oestrogenic stimuli may cause the hair follicle to shift into the anagen phase and vice versa. The use of the oestrogen receptor antagonist tamoxifen in women with breast cancer can exacerbate female-pattern hair loss. Tamoxifen competes for the oestrogen receptor and produces an environment with relative hyperandrogenism, which may augment the androgen action on follicles.

Excessive hair. Hirsutism is excessive hairiness, especially in women, in the male pattern of hair growth, whereas hypertrichosis is the growth of hair at sites not normally hairy. Both conditions can be drug induced, and in some cases, the same drug can produce both patterns of hair growth (see Box 57.2). The capacity of minoxidil to produce hypertrichosis was noted during early trials of this drug as an antihypertensive. It is infrequently used for its originally intended purpose because it produces profound

Fig. 57.2 Drug exanthem: maculopapular, itchy eruption appeared 4 days after the introduction of a course of co-amoxiclav for a respiratory tract infection. Note the linear marks indicating excoriation (scratching) on the left posterior shoulder.

postural hypotension, but its most noticeable side effect has been exploited as a topical preparation for the treatment of male-pattern baldness.

Changes to the skin's immune system and skin malignancy

The skin's innate immune surveillance system detects and repairs UV-induced DNA damage, thus limiting the tendency to cutaneous carcinogenesis. Drug-induced immunosuppression places an individual at an increased risk of skin cancer, notably squamous cell and basal cell carcinomas. As well as a reduction in immune surveillance, immunosuppression increases susceptibility to the human papilloma virus, some strains of which may predispose to the development of squamous malignancy. Patients taking drugs such as azathioprine, ciclosporin, tacrolimus, mycophenolate mofetil and chemotherapeutic agents should be counselled about the importance of sun protection to minimise the risk of the development of malignant and pre-malignant skin cancers. Certain high-risk patients on immunosuppressant drugs, particularly renal transplant recipients, should undergo formal follow-up with skin monitoring by a dermatologist on a yearly basis.

Mild drug-induced skin disorders

Mild drug reaction patterns in the skin are numerous; some of the more commonly seen morphologies are discussed in this section.

Drug-induced exanthems

A drug-induced exanthem (widespread rash) is the most common type of drug reaction in the skin. Exanthems are characterised by erythema (redness) and may be morbilliform (resembling measles) or maculopapular (a mixture of flat and raised areas) (see Fig. 57.2). Less frequently there may be blisters, which may be small (vesicles) or larger (>5 mm, bullae), and the skin may feel hot, burning or itchy.

Fig. 57.3 Urticaria: patient developed the classic raised red itchy wheals of urticaria after the commencement of ibuprofen for musculoskeletal pain.

The proportion of the body surface area (BSA) involved varies from case to case, but when it is severe, involving more than 90% of the BSA, the presentation is referred to as 'erythroderma', which is discussed later. In theory, any drug is capable of producing a drug-induced exanthem in the skin, but in practice, common causes include antibiotics (e.g. sulfonamides, ampicillin, isoniazid), anticonvulsants (e.g. phenytoin, carbamazepine) and antimalarials (chloroquine).

Most drug-induced exanthems begin within 7 days of commencing a drug, the mechanism being a delayed (type IV) hypersensitivity (Griffiths et al., 2016; Hausmann et al., 2012). If the drug can be identified, it should be stopped, and appropriate symptomatic relief should be instituted with antihistamines and topical steroids. A clear record of the reaction should be made in the patient's notes. Both the patient and the primary care doctor should be made aware of the reaction for the purposes of future avoidance.

An exanthematous reaction commonly occurs after administration of ampicillin (or its derivatives, including amoxicillin) to patients suffering from glandular fever (infectious mononucleosis). It does not usually represent a true penicillin allergy but a complex interplay between viral factors (infectious mononucleosis being caused by Epstein–Barr virus) and drug epitopes (Hausmann et al., 2012). This reaction to the drug would not be expected to be seen in the same patient in the absence of the virus.

Urticaria and angioedema

Urticaria, also known as hives, describes the appearance of red, itchy wheals on the skin (Fig. 57.3). Angioedema is a more serious, related condition in which the patient develops deep soft-tissue swellings, most notably on the face. Urticaria and angioedema can be either allergic, a reaction between an antigen and specific mast cell-bound IgE, or non-allergic. Drugs are recognised triggers of urticaria and angioedema (Box 57.3) and can also exacerbate pre-existing urticaria. The most important culprits are the NSAIDs and opiates, both of which lower the threshold for mast cell degranulation. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), for example, candesartan, can provoke angioedema in a susceptible individual.

Box 57.3 Drugs causing urticaria/angioedema

- Antibiotics (particularly penicillins, and especially when given by the parenteral route)
- Barbiturates
- Angiotensin-converting enzyme inhibitors
- Angiotensin receptor blockers
- Levamisole
- Non-steroidal anti-inflammatory drugs
- Opiate analgesics
- Phenolphthalein
- Quinine
- Rifampicin
- Sulfonamides
- Thiopental
- Vancomycin

Drug-induced urticaria/angioedema can be a cutaneous manifestation of anaphylaxis, and in this situation, urgent medical attention is needed with the administration of adrenaline, antihistamine and intravenous corticosteroid.

Pruritus

Pruritus (itching) can accompany a drug rash or may be an isolated symptom provoked by a medication. The most common trigger of drug-induced pruritus is the administration of opiate analgesics and their related synthetic derivatives such as tramadol. Opiate-induced pruritus is centrally mediated, rather than by peripheral nerves; therefore, antihistamines do not, in general, ameliorate the itch. This can pose a particular problem in the palliative care setting where opiate analgesics are required regularly.

Fixed drug eruptions

Fixed drug eruption is characterised by one or more inflammatory patches that recur at the same cutaneous or mucosal site(s) each time the patient is exposed to the offending drug (Fig. 57.4). The eruption usually involves the torso, hands, feet, face or genitalia, and is characterised by a deep-red, circular, well-demarcated patch. They take between 2 and 24 hours to develop after drug ingestion. On the first drug exposure, there is usually only one lesion, but subsequent exposure can result in multiple lesions.

The group of drugs with the potential to cause a fixed drug eruption is virtually limitless, but some of the drugs more commonly responsible are listed in Box 57.4.

Once the drug has been stopped, the lesions resolve and may leave an area of post-inflammatory hyperpigmentation. This may be the only physical sign at the time the patient presents. Topical steroids may ameliorate the symptoms.

Acneiform eruptions

Acne may be drug induced or drug exacerbated. One of the most commonly prescribed drugs to produce an acneiform eruption is a corticosteroid, in either topical or oral form. Illicit use of

Fig. 57.4 Fixed drug eruption: female patient developed persistent macular inflamed areas on her upper chest wall 2 months after starting a new combined oral contraceptive pill. A fixed drug eruption was suspected, and the lesions resolved after stopping the medicine.

Box 57.4 Drugs causing fixed drug eruptions

- Ampicillin
- Aspirin
- Barbiturates
- Dapsone
- Metronidazole
- Non-steroidal anti-inflammatory drugs
- Oral contraceptives
- Phenytoin
- Quinine
- Sulfonamides
- Tetracyclines

anabolic steroids by athletes can also produce this effect, occasionally in its most severe form, acne fulminans. Other drugs which may worsen or provoke acne include ciclosporin, lithium and progesterone-only oral contraceptives.

The anticancer drugs classified as endothelial growth factor receptor (EGFR) antagonists, for example, cetuximab, commonly produce an acneiform eruption. The papules and pustules which occur are more monomorphic than those seen in idiopathic acne. Interestingly, studies have shown that there is a positive correlation between the severity of the acneiform eruption and the response of the cancer to the treatment (Susman, 2004). Most drug-induced or drug-exacerbated acne can be managed with the same treatments as used in idiopathic acne, such as topical agents, oral tetracycline antibiotics, erythromycin or, in severe cases, oral retinoids. Examples of drugs which may cause an acneiform eruption are given in Box 57.5.

Psoriasisiform eruptions

Drugs can either exacerbate psoriasis in predisposed patients or induce psoriasisiform rashes in previously unaffected patients (see Box 57.6). The psoriasisiform eruptions mimic psoriasis and are

Box 57.5 Drugs causing acne

- Androgens (in women)
- Corticosteroids (oral and topical) and adrenocorticotrophic hormone (including inhaled preparations)
- Ciclosporin
- Epidermal growth factor receptor antagonists (cetuximab)
- Ethambutol
- Haloperidol
- Isoniazid
- Lithium
- Oral contraceptives
- Phenobarbital
- Phenytoin
- Propylthiouracil

Box 57.6 Drugs that exacerbate psoriasis

- Angiotensin-converting enzyme inhibitors
- Antimalarials – chloroquine, mepacrine
- Biological therapy targeting tumour necrosis factor alpha (occasionally – slightly paradoxical given that such drugs are also given to treat psoriasis)
- β -Blockers (most frequently atenolol, oxprenolol and propranolol)
- Corticosteroids, e.g. prednisolone
- Granulocyte-colony stimulating factor
- Lithium
- Non-steroidal anti-inflammatory drug

characterised by itchy, scaly, red patches on the elbows, forearms, knees, legs and scalp. Drugs that have a well-established effect of worsening pre-existing psoriasis include β -blockers, lithium, antimalarials and ACE inhibitors.

Lichenoid eruptions

Drug-induced lichenoid eruptions (see [Box 57.7](#)) resemble lichen planus, and occur as flat, mauve lesions. However, they may be atypical, showing scaling and confluence. The lesions can be seen at any site but are found mainly on the forearms, neck and the inner surface of the thighs. The eruption resolves with drug withdrawal, with or without topical steroids, but post-inflammatory hyperpigmentation is often long lasting.

Xerosis, eczematous eruptions and contact dermatitis

Retinoid drugs (such as isotretinoin, acitretin and alitretinoin), EGFR inhibitors (cetuximab, erlotinib, lapatinib) and statins have a drying effect on the skin, termed xerosis. This can exacerbate pre-existing eczema, or precipitate eczema in a susceptible individual. Irritant contact dermatitis may be seen in preparations with an alcohol base, such as topical antibiotics, or with the application of topical preparations, which are inherently irritant such as benzoyl peroxide, tar or dithranol.

Box 57.7 Drugs causing lichenoid eruptions

- Antimalarials – chloroquine, mepacrine
- Aspirin
- Angiotensin-converting enzyme inhibitors
- β -Blockers
- Calcium channel blockers, e.g. amlodipine, nifedipine
- Carbamazepine
- Ethambutol
- Gold salts
- Imatinib
- Interferon- α
- Lithium
- Methyl dopa
- Non-steroidal anti-inflammatory drugs
- Penicillamine
- Phenothiazines
- Quinine
- Sulfonyleureas

Allergic contact dermatitis is a delayed (type IV) hypersensitivity reaction, which can develop to any topical preparation, for example, eye drops in a sensitised individual. Most commonly, this will be a reaction to excipients contained in the preparation, such as preservatives, for example, sodium metabisulfite, fragrances or stabilisers, but may be to the drug itself. In all cases of irritant or allergic contact dermatitis, the patient should be counselled to stop the preparation. Patch testing carried out by a dermatologist is a useful way of investigating patients in whom a diagnosis of allergic contact dermatitis is suspected.

Erythema nodosum

Erythema nodosum is an acute inflammatory reaction with painful subcutaneous nodules, usually but not exclusively found on the shins. Erythema nodosum is usually a complication of infection with, for example, streptococcus or tuberculosis, or is a cutaneous manifestation of an inflammatory condition such as sarcoidosis. In its drug-induced form, it may be caused by oral contraceptives, sulfonamide antibiotics, salicylates, penicillins and gold salts.

Hand–foot reactions

Painful, burning erythema of the hands and feet is a common side effect of some chemotherapeutic agents. This may be termed ‘hand–foot syndrome’. It is most frequently caused by 5-fluorouracil, doxorubicin, the EGFR/protein kinase inhibitors (e.g. cetuximab, erlotinib) and BRAF inhibitors (e.g. vemurafenib). The redness may sometimes be accompanied by painful hyperkeratosis (thickening) of the skin of the hands and feet, and in these cases, an emollient containing urea may provide symptomatic relief.

Severe drug-induced skin disorders

Erythema multiforme (EM), Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are all idiosyncratic, immunologically mediated severe drug eruptions. For our purposes,

Box 57.8 Drugs causing erythema multiforme

- Allopurinol
- Antiretrovirals, e.g. nevirapine
- Barbiturates
- Carbamazepine
- Cimetidine
- Dapsone
- Gold salts
- Isoniazid
- Lamotrigine
- Leflunomide
- Macrolide antibiotics
- Mefloquine
- Non-steroidal anti-inflammatory drugs
- Penicillins
- Phenytoin
- Rifampicin
- Sulfonamides

these diseases may be considered to be on a spectrum, from the mild and self-limiting at one end (EM) to the fulminating severe at the other (TEN).

Erythema multiforme

EM is an eruption of target-like lesions which are characterised by concentric red and pale rings with, in severe cases, central blistering. EM typically occurs on the limbs rather than the trunk, but mucous membrane surfaces, such as the eye, the mouth and the genital tract, may also become involved. A significant proportion of EM cases are caused by infection, particularly herpes simplex virus reactivation; however, in some patients, EM is triggered by a drug (see [Box 57.8](#)). Drug-induced EM will usually present within 2 weeks of starting a new medication. Once the responsible drug has been stopped, treatment is symptomatic with paracetamol, topical steroids and appropriate topical therapy for the mouth and other involved mucosal surfaces.

Stevens–Johnson syndrome and toxic epidermal necrolysis

SJS and TEN are terms used to describe a life-threatening, mucocutaneous drug hypersensitivity syndrome characterised by blistering and epidermal sloughing ([Fig. 57.5](#)). In SJS, there is epidermal detachment of less than 10% BSA; in TEN, there is detachment of greater than 30% of the BSA, and cases with 10–30% involvement are labelled SJS/TEN overlap. The systemic problems that accompany widespread epidermal loss, such as high losses of heat and fluid, and the heightened risk of infection due to diminished barrier function can cause serious morbidity, similar to extensive burns. TEN carries a mortality rate of approximately 30%, but this can rise to 90% mortality in the presence of co-morbidities. HIV-infected patients and patients with systemic lupus erythematosus (SLE) have an enhanced risk of developing SJS/TEN. Drugs causing SJS/TEN are listed in [Box 57.9](#).

Clinical features. A prodrome of fever, malaise, and upper respiratory tract symptoms may precede the eruption by a few

days. Involvement of the mucous membranes of the eyes, mouth, and nose is a prominent early feature. Eye involvement results in blepharitis, haemorrhagic conjunctivitis, mucus secretion, and pseudomembranes. Ophthalmological input is required early if long-term sequelae, such as blindness from corneal opacities and synechiae, are not to occur. Urethral involvement must also be anticipated and the patient catheterised if strictures are not to complicate the disease course. Mouth involvement causes an erosive and haemorrhagic mucositis. On the skin, dusky red macules 1–3 cm in diameter appear at any site and evolve to become confluent. The skin lesions pass through vesicular and bullous phases before epidermal detachment occurs. Shearing pressure to the skin causes detachment of involved epidermis (positive Nikolsky's sign). In TEN, there is widespread epidermal loss and sloughing of the necrotic epidermis, which peels back to leave large areas of exposed dermis. Denuded dermis exudes serum, becomes secondarily infected and readily bleeds. The patient is in severe pain and is usually extremely ill. The visceral manifestations that result from widespread epithelial loss include pneumonia, pancreatitis, thromboembolic disease and renal and hepatic impairment.

The patient with SJS/TEN will require full supportive care, preferably in an intensive care unit. Patients with SJS with less extensive involvement may be managed in a lower-dependency environment but should be monitored closely for signs of progression in the first 48 hours of admission. A multidisciplinary approach, including dermatologists, ophthalmologists and intensive care physicians, is critical to a successful outcome. After drug withdrawal, the management is supportive, including prompt treatment of infection; careful attention to thermoregulation, fluid balance and skin care; and the introduction of appropriate eye and lid care. The literature has failed to identify one treatment which definitively improves outcomes, but agents which have been used include systemic steroids, ciclosporin and intravenous immunoglobulin.

Drug reaction with eosinophilia and systemic symptoms

Drug reaction with eosinophilia and systemic symptoms (DRESS) is sometimes known as drug-induced hypersensitivity syndrome (DIHS) and is a distinct, severe and potentially fatal drug-induced skin disorder. The drugs commonly associated with this syndrome are listed in [Box 57.10](#).

Typically, the dermatosis of DRESS is an extensive, inflammatory, maculopapular exanthem. Other skin signs may also be present, including pustules, purpura, blisters, target-like lesions and facial oedema ([Fig. 57.6](#)). To meet the diagnostic criteria, there will also be a haematological abnormality, either a raised eosinophil count ($>1.5 \times 10^9/L$) or the presence of atypical lymphocytes on the blood film. There is prominent systemic involvement in DRESS, most commonly fever, lymph node enlargement and liver function abnormalities. Less typically, there is renal, pulmonary or cardiac involvement.

DRESS is characterised by its long latency of onset, with the syndrome usually presenting between 2 and 8 weeks after commencement of the causative drug. This is an important point to

Fig. 57.5 Stevens–Johnson syndrome is a serious, idiosyncratic reaction of the skin (B) and mucous membranes (A) to a drug. It results in blistering and subsequently widespread epidermal loss and can have a high mortality rate.

Box 57.9 Drugs causing Stevens–Johnson syndrome and toxic epidermal necrolysis

- Allopurinol
- Antiretrovirals, e.g. nevirapine
- Carbamazepine
- Co-trimoxazole
- Dapsone
- Gold salts
- Lamotrigine
- Leflunomide
- Non-steroidal anti-inflammatory drugs, e.g. meloxicam, diclofenac
- Penicillins, e.g. amoxicillin, ampicillin
- Phenobarbitone
- Phenolphthalein
- Phenylbutazone
- Phenytoin
- Sulfadiazine
- Sulfasalazine
- Tetracyclines, e.g. doxycycline

Box 57.10 Common causes of Drug Reaction with Eosinophilia and Systemic Symptoms

- Allopurinol
- Antiretrovirals, e.g. efavirenz
- Carbamazepine
- Cotrimoxazole
- Lamotrigine
- Minocycline
- Phenobarbitone
- Phenytoin
- Sulfadiazine
- Sulfasalazine
- Vancomycin

note in the medication history because the drug responsible may often be overlooked if it is considered to have been started ‘too long ago’.

DRESS is accompanied by significant morbidity, and the mortality has been estimated at 10%. Systemic steroids are usually administered and may be beneficial, but there are no randomised controlled trials to support their use. Management involves stopping the suspected drug and supportive care dictated by the extent of involvement.

Acute generalised exanthematous pustulosis

Acute generalised exanthematous pustulosis (AGEP) describes a reaction pattern to a drug consisting of widespread sterile, monomorphic pustules studding the skin in a generalised fashion. Such

patients are generally systemically unwell with a fever and the complications of generalised skin inflammation, including excessive heat and fluid loss. The differential diagnosis would include pustular psoriasis. Although the condition is self-limiting, potent topical steroids may accelerate resolution. The drugs which can cause AGEP are summarised in [Box 57.11](#).

Erythroderma and exfoliative dermatitis

Erythroderma is the term used to describe any pattern of drug reaction in the skin where more than 90% of the BSA is involved. This is usually an extension of a severe drug-induced exanthem. The erythrodermic patient often feels shivery and may have lymphadenopathy and fever. The large surface area involved in erythroderma leads to substantial losses of heat and fluid from the body. This puts the patient at risk of electrolyte imbalances, hypothermia and, with the loss of skin barrier function, infection. Admission to hospital is indicated in cases of erythroderma, and management is supportive, with intravenous fluids, warming measures and treatment of infection. Topical corticosteroids are often prescribed but must be used with caution because significant amounts will

Fig. 57.6 Drug reaction with eosinophilia and systemic symptoms: female patient developed a severe systemic reaction after commencement of phenytoin for seizure prophylaxis after brain surgery. She had an erythematous urticated eruption as seen here accompanied by lymphadenopathy, derangement of liver function and a circulating eosinophilia as seen here (A and B).

Box 57.11 Drugs causing acute generalised exanthematous pustulosis

- Allopurinol
- Amoxicillin
- Carbamazepine
- Cefuroxime
- Co-trimoxazole
- Doxycycline
- Macrolide antibiotics, e.g. erythromycin, pristinamycin
- Metronidazole
- Lamotrigine
- Phenytoin
- Sulfasalazine
- Vancomycin

be systemically absorbed across the erythrodermic skin. During recovery, the patient will desquamate, referred to as the exfoliative phase. Drugs commonly provoking this pattern of reaction are similar to those that cause a drug-induced exanthem (**Box 57.12**).

Lupus erythematosus

Syndromes indistinguishable from lupus erythematosus (LE) may occur after drug administration (see **Box 57.13**) and can be accompanied by seroconversion to antinuclear antibody (ANA) positivity. Serological clearance of ANA may occur after drug withdrawal, but this may take months or years.

The cutaneous manifestations of drug-induced LE include the characteristic butterfly-shaped rash on the face, photosensitive erythema on dorsal hands and neck and annular lesions on limbs.

Box 57.12 Drugs causing exanthematous eruptions

- Amoxicillin
- Ampicillin^a
- Bleomycin
- Captopril
- Carbamazepine
- Chlorpromazine
- Co-trimoxazole
- Gold salts
- Nalidixic acid
- Non-steroidal anti-inflammatory drug
- Phenytoin
- Penicillamine

^aAmpicillin rashes do not necessarily indicate penicillin hypersensitivity but may be seen when administered to a patient with glandular fever (see text).

Biological therapy targeting tumour necrosis factor alpha (TNF- α), such as infliximab and etanercept, has been found to provoke lupus both in its systemic and limited cutaneous forms.

Vasculitis

Vasculitis is characterised pathologically by inflammation in vessel walls and clinically as palpable purpuric lesions most commonly found on the lower limbs. Cutaneous vasculitis without other organ involvement is the rule, but systemic involvement, such as renal, can occasionally occur. The purpuric areas on the legs may become ulcerated and require specialist dermatology input.

Box 57.13 Drugs causing lupus erythematosus

- Anticonvulsants: phenytoin
- β -Blockers
- Chlorpromazine
- Griseofulvin
- Hydralazine
- Isoniazid
- Lithium
- Methyl dopa
- Oral contraceptives
- Penicillamine
- Phenytoin
- Procainamide
- Propylthiouracil
- Sulfasalazine
- Terbinafine
- Biological therapy targeting tumour necrosis factor alpha, e.g. infliximab

Box 57.14 Drugs that may cause cutaneous vasculitic reactions

- Angiotensin-converting enzyme inhibitors
- Allopurinol
- Amiodarone
- Aspirin
- Carbamazepine
- Carbimazole
- Diltiazem
- Erythromycin
- Furosemide
- Gold
- Haematopoietic growth factors (granulocyte-colony stimulating factor and granulocyte-macrophage colony-stimulating factor)
- Hydralazine
- Interferons
- Methotrexate
- Minocycline
- Non-steroidal anti-inflammatory drugs
- Penicillamine
- Propylthiouracil
- Sulfasalazine
- Sulfonamides
- Thiazides
- Thrombolytic agents

Drugs are the cause of approximately 10% of cutaneous vasculitis cases and should be considered in any patient with small vessel vasculitis (**Box 57.14**). Withdrawal of the causative drug is often sufficient to resolve the clinical manifestations without the need for treatment with systemic corticosteroids or more powerful immunosuppressants.

Skin necrosis

The term *widespread cutaneous necrosis* describes extensive skin infarction, which often heralds a severe systemic coagulopathy. Widespread cutaneous necrosis can be triggered by a reaction to

warfarin or, less commonly, to heparin. In warfarin or coumarin skin necrosis, the buttocks and breasts are the most commonly involved sites. Discontinuation of the anticoagulant responsible is essential; however, ongoing management of the coagulopathy is critical, and patients need to be assessed by a haematologist.

Patient care

Withdrawal of the likely offending drug should be the first intervention in cases of suspected drug eruption. This should be done in consultation with the prescribing physician because an alternative drug may be required to control the patient's condition. General methods which will provide symptomatic relief in a mild, limited drug eruption include emollients, soap substitutes and oral antihistamines. A mild topical corticosteroid may also be appropriate. In cases where the eruption is more extensive, or if a mucosal surface is involved, specialist care provided by a dermatologist will be necessary.

Case studies

Case 57.1

A 36-year-old female patient, Ms FG, with a long history of chronic idiopathic urticaria attends her local pharmacy for some advice. Her skin disease is usually well controlled with an occasional dose of cetirizine which she buys OTC. Ms FG has recently begun taking ibuprofen for muscular pain associated with her marathon training, but she has found, to her dismay, that her urticaria has become much worse and is flaring on a daily basis.

Questions

1. What is the likely cause of the deterioration in the control of Ms FG's urticaria?
2. What management should be advised?
3. What other group of drugs is likely to produce this effect?

Answers

1. NSAIDs are known to increase the frequency of attacks of urticaria in susceptible individuals. It is likely that the self-medicating with ibuprofen has lessened Ms FG's control of her urticaria.
2. In the first instance, the ibuprofen should be stopped. An alternative such as paracetamol could be advised for the musculoskeletal symptoms. An enquiry should be made as to whether or not any symptoms suggestive of angioedema, such as lip/tongue swelling, or difficulty breathing, have accompanied the urticaria, as this would imply a need for medical attention. In the acute phase, regular administration of an antihistamine such as chlorphenamine should help rapidly relieve the symptoms. Ms FG should be warned that the ability of NSAIDs to worsen urticaria is a 'class effect' and that similar symptoms may be produced with drugs such as aspirin, meloxicam and naproxen.
3. Opiate analgesics lower the threshold for mast cell degranulation, which is the most important pathophysiological mechanism in the production of urticaria. Thus, morphine and related products such as codeine should be avoided.

Case 57.2

A 69-year-old male patient, Mr PH, with a history of psoriasis attends the pharmacy looking for advice. In the past, his skin disease has always been well controlled with topical preparations. Mr PH was recently admitted to hospital with a myocardial infarction and has noticed a marked deterioration in his psoriasis control since discharge. During his admission, he was commenced on:

- aspirin 75 mg daily,
- alopodogrel 75 mg daily,
- atorvastatin 80 mg daily,
- bisoprolol 2.5 mg daily,
- ramipril 2.5 mg daily.

Questions

1. What is the likely reason for the exacerbation of Mr PH's psoriasis?
2. How should this be treated?

Answers

1. Mr PH's psoriasis could have worsened due to the stress of his recent illness, but it is probably secondary to the introduction of bisoprolol or ramipril. Both β -blockers and ACE inhibitors have been associated with the worsening of psoriasis.
2. Given the recent myocardial infarct, any interruptions or substitutions to treatment must be made in conjunction with the patient's primary care doctor or cardiologist. The worsening of psoriasis with β -blockers is likely to be a class effect, and therefore substituting a different β -blocker is unlikely to resolve the problem. The treating physician may wish to prescribe a calcium channel blocker. If this does not ameliorate the situation, then the ACE inhibitor may be suspected, and trial stoppage may be considered. An ARB such as candesartan may be acceptable as an alternative.

Case 57.3

A 37-year-old man, Mr AG, presents with swelling of his upper lip. He asks if this could be stress induced because he has had several previous episodes of localised swelling of the face over the last 6–12 months.

Mr AG has been taking bendroflumethiazide and enalapril for hypertension for the last 3 years but has not taken any other medications recently.

Questions

1. What condition does Mr AG's symptoms suggest?
2. Could this be drug induced?
3. How should the condition be treated?

Answers

1. This pattern of localised swelling of the face is characteristic of angioedema.
2. Angioedema is a known adverse effect of ACE inhibitors with an overall incidence of 0.5–1%. Although this commonly occurs in the first week of treatment, delayed-onset angioedema can occur even after many years of treatment.
3. Because angioedema can be life-threatening, any suspect drug should be stopped. There is a very low incidence of this occurring with an ARB, and this may be a suitable alternative for this

patient. The acute presentation of angioedema is treated with anti-histamine and corticosteroids. If the patient presents with respiratory symptoms, subcutaneous epinephrine (adrenaline) is indicated.

Case 57.4

Miss AF is a 15-year-old renal transplant patient who attends the pharmacy 6 weeks after transplant. She is very distressed about the growth of facial hair and the worsening of acne.

Questions

1. What are the possible causes of Miss AF's skin complaints?
2. What other side effects should be enquired about?
3. How might these conditions be treated?

Answers

1. It is likely that Miss AF is receiving transplant immunosuppression that includes ciclosporin and prednisolone. The ciclosporin is most likely to have caused the growth of facial hair. Both the oral corticosteroid and the ciclosporin may have aggravated pre-existing acne or precipitated new-onset acne.
2. Ciclosporin may cause gingival hyperplasia, tremor, paraesthesia and nausea. Corticosteroids can cause increased appetite/weight gain, alterations of mood (euphoria, depression), sleep disturbance, gastritis and numerous other side effects.
3. Hirsutism is a side effect of ciclosporin that many young transplant patients have to cope with, and depilatory creams are commonly used. Tacrolimus is an alternative long-term immunosuppressant which is less likely to cause acne and hirsutism and which may be used in place of ciclosporin.

Case 57.5

An 85-year-old gentleman with rheumatoid arthritis, Mr DC, attends the local pharmacy with a persistent lesion on his anterior scalp (Fig. 57.7), which has recently been bleeding. For the last 18 years, his rheumatoid arthritis has been treated with methotrexate. You know Mr DC is a retired naval officer, and his skin is severely sun damaged. He tells you he has had a number of skin cancers in the past and is concerned that this may be another.

Questions

1. What is the likely diagnosis?
2. What risk factors does Mr DC have for this diagnosis?
3. How should he be advised?

Answers

1. This is likely to be a squamous cell carcinoma (SCC). Squamous cell carcinomas usually occur on sun-exposed sites and are related to high cumulative levels of sun exposure. They can have a number of different appearances but are generally hyperkeratotic nodules or nodules with a central keratin plug, as in this case.
2. Mr DC has a number of risk factors for developing an SCC:
 - Age: These lesions tend to occur in the older age group, presumably because of their high level of actinic damage accrued over many years. In addition, sunscreen was not as widely used in the mid- to late 20th century as it is today.

Fig. 57.7 A patient with squamous cell carcinoma.

- Immunosuppressed state: Mr. DC has been on an immunosuppressant for 18 years, resulting in his tumour surveillance mechanisms being attenuated.
 - Occupation: It is likely that Mr DC will have served in some very sunny climates. A history of active service with the Armed Forces should always prompt healthcare professionals to ask about the patient's history of sun exposure.
3. Firstly, Mr DC should be asked to consult his primary care doctor or dermatologist because the lesion will require treatment. If left unattended, squamous cell carcinomas continue to grow and can become locally invasive or can metastasise. Secondly, Mr. DC should be advised of the importance of sun protection, using a high-factor (30 or greater) sunscreen with good UVA protection (as indicated by the star rating system on the back of the bottle). A hat provides excellent cover for the scalp and face. The sun should be avoided completely between the hours of midday and 2 p.m., when the levels of ultraviolet light are at their highest.

Case 57.6

A 56-year-old man, Mr SW, presents to the pharmacy in an alarmed state. In recent months, he has had several episodes of gout and was recently prescribed allopurinol. He has now taken four doses of the drug. Last night, Mr SW developed an unusual rash on his palms and soles, which this morning has developed blisters. The rash has now extended to involve his arms and legs. He also complains of 'mouth ulcers', a gritty feeling in the eyes, and pain on passing urine. Mr SW is not feverish now but had a raised temperature overnight.

Questions

1. What is the likely diagnosis?
2. How should Mr SW be managed?

Answers

1. This patient is developing SJS. He has a blistering eruption which commenced peripherally, which is classical for this disorder. Mr SW now has evidence of mucosal site involvement, including the oral mucosa and conjunctivae, with urethral involvement suggested by his history of dysuria. Allopurinol is a common culprit for this condition.

2. Patients with suspected SJS need urgent dermatological assessment and often require in-patient care. The suspected drug should be withheld. After admission to hospital, a full blood count, urinalysis, blood culture, and a chest X-ray should be performed to screen for infection. An ophthalmological opinion should be sought to ensure that no synechiae (scarring) of the eyes forms because this can occasionally arise with the degree of inflammation seen in this patient. Catheterisation is required if urethral mucosal involvement is suspected, to prevent strictures forming due to scarring. Mr SW should not be exposed to allopurinol or related drugs again because recurrence is likely.

Case 57.7

A 24-year-old female, Ms AM, was commenced on the combined oral contraceptive pill last month. Ms AM is concerned because she has noticed the appearance of raised red nodules on both shins, which are tender to touch and have been becoming more numerous over the last 3 days. She has never had any such eruption before. There is no recent travel history, and Ms AM has no rashes elsewhere, nor does she have any arthralgia.

Questions

1. What is your diagnosis?
2. What is the likely cause of Ms AM's eruption, and what are the other possible causes?
3. What is the prognosis?

Answers

1. Ms AM has developed erythema nodosum, an inflammatory condition seen on the anterior legs, usually bilaterally. *Erythema nodosum* is a Latin term meaning 'red lumps', it represents a pathological process in which subcutaneous fat becomes inflamed.
2. The combined oral contraceptive pill is the most likely precipitant in this case. However, a full drug and medical history should be taken because other medicines may cause erythema nodosum, for example, antibiotics or NSAIDs. A very common cause of erythema nodosum in young people is streptococcal throat infection. A travel history is important because the same clinical reaction pattern may be brought about by tuberculosis. Finally, a number of other medical problems, such as ulcerative colitis and Crohn's disease or sarcoidosis, may also produce erythema nodosum.
3. Ms AM should see a dermatologist to have the other causes of erythema nodosum excluded. The management of erythema nodosum is supportive, with regular NSAIDs or paracetamol given for pain. The combined oral contraceptive pill should be stopped, and Ms AM should be switched to a different form of contraception.

Case 57.8

A 17-year-old girl, Miss AW, asks for some advice regarding a widespread itchy rash which has appeared suddenly over the last 24 hours. Miss AW visited her primary care doctor 4 days ago complaining of a sore throat and a productive cough. Having auscultated the chest, the primary care doctor suspected a respiratory tract infection and prescribed amoxicillin. Five days later, Miss AW developed a widespread maculopapular rash. She attends the pharmacy for advice, and you suspect the rash to be drug-induced.

Questions

1. What is the cause of the eruption?
2. How should Miss AW be managed?
3. Should Miss AW be advised to avoid penicillin antibiotics in the future?

Answers

1. This is likely to be an amoxicillin-induced drug eruption.

2. The antibiotic should be stopped, and the clinical indication for an alternative preparation should be assessed by the primary care doctor. An antihistamine and a mild-/moderate-potency topical corticosteroid should provide symptomatic relief. If the patient does not obtain relief with such treatment, if the rash is becoming widespread or if there are any features of a systemic illness such as fever or enlarged lymph nodes, the patient should see the primary care doctor.
3. The reaction may be provoked by any antibiotic in the penicillin group, so the patient needs to be informed of the need to avoid all such antibiotics in the future.

58 Eczema and Psoriasis

Richard Woolf and Nemesha Desai

Key points

- Eczema and psoriasis are chronic inflammatory skin diseases that are commonly encountered in clinical practice.
- Eczema and psoriasis manifest as erythematous and pruritic rashes; however, their aetiology, morphology and long-term treatment options differ significantly.
- Emollient therapy is a mainstay of treatment for most types of eczema, with active inflammation commonly treated using topical anti-inflammatory therapies, such as corticosteroids or calcineurin inhibitors.
- Eczematous skin can become secondarily infected, and appropriate recognition of secondary bacterial and viral infections is important.
- Mild-to-moderate psoriasis is often managed with topical therapies alone, such as steroids and vitamin D analogues, in combination with topical emollients.
- Severe psoriasis and severe atopic eczema may require treatment with a systemic agent. This will often be an immunosuppressive medication, such as methotrexate. In psoriasis, additional biologic agents have been developed that target specific inflammatory cytokine pathways. Acute eczema is often treated with systemic corticosteroids, but these should be avoided in patients with psoriasis. Therefore, when choosing a systemic therapy, both careful patient selection and regular monitoring are important.
- These conditions are chronic and have a significant impact on the individual's quality of life. Therefore, patient education and support are extremely important.

Eczema

Eczema refers to a group of conditions that are loosely defined by the development of ill-defined erythematous (red), scaly and pruritic (itchy) patches of skin inflammation. The terms 'eczema' and 'dermatitis' may be used interchangeably and describe the same clinical and histological entity. Although the morphological and histological findings in different eczemas may be similar, their pathologies can be quite different.

Pathology and clinical features

Acute eczema is an inflammatory process that leads to the accumulation of fluid (oedema) in the epidermis. This is seen histologically as epidermal 'spongiosis' and is associated with a predominantly lymphocytic infiltrate in the dermis. Clinically this

manifests as a patch of inflamed scaly skin. The epidermal oedema can accumulate and evolve into tiny blisters (histologically intra-epidermal vesicles) that may then coalesce. These may appear as fragile ruptured vesicles at sites of inflammation, or as 'pompholyx' blisters on thicker palmar/plantar skin. Tightly packed keratinocyte cells in the epidermis usually provide a physical barrier that prevents transepidermal fluid loss and the entry of pathogens. This becomes impaired in eczema. A schematic diagram demonstrating the normal skin epidermis and the effects on the barrier function during an acute eczema flare is shown in Fig. 58.1. The main symptom that develops as a result of these pathological processes is itch, which can cause considerable distress to the patient.

In chronic eczema, prolonged scratching and rubbing results in thickening of the epidermis, with an increase in the upper horny cell layer of keratinocytes, which is termed hyperkeratosis. Clinically the skin appears thickened, leathery and 'lichenified', with exaggerated skin markings (Fig. 58.2).

Clinical types

Atopic eczema

The lifetime prevalence rate of atopic eczema is 10–20%, and the majority of cases develop in childhood, making it the commonest skin disorder of children (Deckers et al., 2012). The term 'atopy' describes an increased propensity to form IgE to common allergens. In atopic dermatitis, up to two-thirds of patients will have either elevated serum IgE levels or develop another associated atopic disorder, such as asthma or allergic rhinoconjunctivitis (hay fever). The molecular pathology of atopic eczema is complex and involves a combination of genetic, environmental and immunological factors. Genome-wide association studies (GWASs) have identified more than 30 susceptibility loci, with the strongest known genetic risk factor being a mutation in the gene that encodes the epidermal protein filaggrin, with other loci implicating additional epidermal barrier and immune-mediated mechanisms (Weidinger and Novak, 2016). It is hypothesised that disruption of the epidermal barrier leads to pathological inflammation in the skin, through the activation of keratinocytes, which in turn mediate innate immune responses, Langerhans cell activation, and T-helper type 2 (T_H2) lymphocyte activation. There is increasing evidence that the interaction between the impaired epidermis and this immune environment also facilitates percutaneous allergic sensitisation.

Despite this understanding of the molecular pathology of atopic eczema, it remains a clinical diagnosis. Diagnostic criteria have

Fig. 58.1 Schematic diagram demonstrating the normal skin epidermis (left) and the effects on the barrier function (right) during an acute eczema flare.

Fig. 58.2 Dry, excoriated, lichenified chronic eczema. (Courtesy of M. Carr.)

been developed that define key features, such as a chronic relapsing eczema/dermatitis, pruritus, dry skin (xerosis) and a personal or family history of atopy (Brenninkmeijer et al., 2008). The clinical course and typical sites affected change through puberty and adulthood. In infants, common areas involved are the face, neck and limbs. Through childhood, flexural sites, such as folds of the elbows and backs of the knees, are classically affected (Fig. 58.3). In adults, this may go on to involve the hands and neck. Symptoms usually improve with age, and in approximately 60% of individuals atopic eczema resolves by the age of 16 years.

Exacerbating factors

A number of factors can aggravate atopic eczema:

- infection: bacterial or viral;
- irritants: soap, detergents, shower gels, bubble baths and water;
- allergens: contact, food, inhaled and airborne;

Fig. 58.3 Flexural eczema in childhood. (Courtesy of M. Carr.)

Fig. 58.4 Impetigo complicating atopic eczema. (Courtesy of M. Carr.)

- dry environments;
- extremes of temperature;
- stress.

The commonest trigger of exacerbations of atopic eczema in the paediatric population is secondary infection. In atopic eczema there is reduced diversity in the normal skin microbiome, with the skin becoming colonised primarily by the bacterium *Staphylococcus aureus*. This is possibly due to the impaired barrier and aberrant innate and adaptive immune function of the skin of these individuals. *Staphylococcus aureus* can in turn contribute to flares and the chronification of atopic eczema (Fig. 58.4) through their production of proteases, the stimulation of innate immune pathways and the release of enterotoxins that act as T-cell superantigens. In addition, *Staphylococcus aureus* can cause pathological infection of the skin that will require antibiotic therapy. Viral infections, such as herpes simplex, may also complicate atopic eczema. In some cases this may lead to disseminated cutaneous herpes infection, known as eczema herpeticum or Kaposi's varicelliform eruption (Fig. 58.5). This can be a dermatological emergency and requires urgent assessment and treatment with a systemic antiviral agent, such as aciclovir.

In some cases of severe atopic eczema, especially in children, patients are also sensitised to certain foods. This may lead to either

Fig. 58.5 Eczema herpeticum in an infant. (Courtesy of M. Carr.)

immediate immunoglobulin E (IgE)-mediated non-eczematous skin reactions, such as urticaria or angioedema, or delayed non-IgE-mediated flares of their eczema. If food allergy is suspected, these cases should be referred to an allergy specialist. Dietary restriction may be required, which should only be done under the supervision of a trained dietician. Although most paediatric food allergies that are associated with atopic eczema tend to resolve with time, allergies to nuts and fish often persist into adulthood.

Contact dermatitis

Contact dermatitis refers to the development of a chemical-induced eczematous rash that is usually limited to the site of cutaneous exposure to that chemical, and can be classified as either an allergic contact dermatitis (ACD) or irritant contact dermatitis (ICD).

Allergic contact dermatitis

ACD describes a delayed-type antigen-specific hypersensitivity reaction that develops upon re-exposure to an allergen to which the host immune system has been previously sensitised. Therefore, symptoms rarely develop on early exposure to the allergen, with the allergic reaction often manifesting months or years after the primary exposure. However, this will depend on when sensitisation or re-exposure occurs.

Many common compounds can lead to ACD:

- metals (e.g. nickel and cobalt),
- medications (e.g. neomycin, a topical antibiotic),
- fragrances (e.g. Balsam of Peru),
- rubber compounds,
- hair dyes (e.g. *p*-phenylenediamine),
- preservatives (e.g. formaldehyde and formaldehyde-releasing compounds),
- plants (e.g. poison ivy).

The diagnosis of ACD relies heavily on a detailed patient history, as well as recognising the pattern and distribution of the eczematous rash. Although the signs are usually localised to the area exposed to the allergen, a secondary generalised eczema may develop ('autoeczematisation'). When ACD is considered, the standard diagnostic investigation is patch testing, which can differentiate between allergic and irritant causes of contact

Table 58.1 Common locations for allergic contact dermatitis and possible sensitisers

Location	Possible sensitising agents
Periorbital	Airborne allergens, cosmetics, contact lens solution
Umbilicus	Nickel hypersensitivity to belt buckle or trouser button
Neck	Antiseptic in soap, cosmetics
Hairline/scalp	<i>p</i> -Phenylenediamine in hair dye, hair perming solution
Hands	Latex or rubber accelerators in gloves, nickel, fragrances, protein contact dermatitis in food preparation, irritant contact dermatitis due to water

dermatitis. This involves the application of a panel of compounds to the patient's back for 48 hours (day 2). A standard panel of potential allergens is tested with and without additional specialised panels for certain allergens (e.g. fragrances), depending on the clinical presentation. This is followed by clinical examination for a cutaneous reaction at days 2 and 4. Identification of the relevant compound allows the patient to avoid the substance in the future, which should reduce symptoms. Common areas of the body affected by ACD, with corresponding potential sensitisers, are listed in [Table 58.1](#).

Irritant contact dermatitis

ICD is the most common form of occupational dermatitis and hand eczema. ICD is not the result of an adaptive immune response to a sensitising agent, but is due to the direct cytotoxic effects of the agent on the skin. This leads to disruption of the epidermal barrier and cutaneous inflammation, which manifests as an acute eczema. Patients with pre-existing epidermal barrier dysfunction, such as atopic eczema, are at higher risk of ICD. Common irritants include detergents, oils, water, inorganic acids, alkalis, alcohols and plastics. Therefore, the occupation of the individual may also be a risk factor, especially those working as builders, hairdressers, gardeners, healthcare workers and chefs. Patch testing may be required to exclude ACD. Management of ICD is primarily with preventative skin care, which includes the use of barriers, such as emollients or cotton gloves, in addition to avoiding suspected irritants.

Discoid eczema

Discoid eczema is a type of disseminated chronic eczema that is also known as nummular dermatitis. It presents with coin-shaped eczematous lesions that are typically intensely pruritic and often on the limbs. Lesions can be very inflamed with vesicles, weep serous fluid and have evidence of secondary bacterial infection. Management is primarily with regular emollients and moderate- to potent-strength topical corticosteroids. Secondary infection

should be treated with appropriate topical/systemic antibiotics. If poorly controlled with topical therapy, patients with discoid eczema may require treatment with a systemic agent as in severe atopic eczema.

Dyshidrotic eczema

Dyshidrotic eczema is also known as pompholyx or vesicular palmoplantar dermatitis. It is an eczema that affects the palms and/or soles and is characterised by the development of small and intensely pruritic vesicles, often along the edge of the palms, fingers or soles. These can coalesce to form larger blisters. There is also often thickening of the epidermis, which can become cracked and painful. Management is primarily with regular ointment emollients and moderate- to potent-strength topical corticosteroids.

Stasis eczema

Stasis eczema is also known as stasis dermatitis, gravitational dermatitis or varicose eczema. Clinical features include scaly eczematous plaques confined to the lower legs. Stasis eczema is one component of several clinical changes seen in chronic venous insufficiency, which include varicose veins, peripheral oedema, skin discolouration, subcutaneous fibrotic changes (lipodermatosclerosis) and chronic ulceration. Often multiple topical medications and dressings have been used in this setting, which may also lead to contact dermatitis. Management of the underlying venous stasis should improve the stasis eczema, which can also be symptomatically controlled with regular emollients, soap substitutes and moderate-strength topical corticosteroids.

Asteatotic eczema

Asteatotic eczema usually affects the legs and presents as dry, cracked skin that is likened to ‘crazy paving’ and is also described as eczema craquelé. Asteatotic eczema can be inflamed and intensely pruritic. It is associated with older age, low humidity and frequent bathing. Management is primarily with regular emollients, soap substitutes and moderate-strength topical corticosteroids.

Seborrhoeic dermatitis

Seborrhoeic dermatitis (syn. Seborrhoeic eczema) is a common disorder that is usually confined to areas with high sebum production. The aetiology is not known but thought to involve an overgrowth of the commensal yeast *Malassezia furfur* (*Pityrosporum ovale*) at these sites. In adults the clinical features are pink-yellow greasy patches of dermatitis with overlying ‘greasy’ scale, typically in the sebaceous-rich scalp, nasal folds, medial eyebrow, pre-sternal region and flexural sites. In babies, seborrhoeic dermatitis can manifest in the first few months of life as coherent scaling of the scalp with dermatitis and ooze, known as ‘cradle cap’. In adults, the symptoms are usually mild with a chronic, relapsing course. More severe seborrhoeic dermatitis is seen in patients with human immunodeficiency virus (HIV) infection or Parkinson’s disease. Management usually includes topical antifungals, such as imidazoles (shampoo or cream preparations), and topical anti-inflammatory agents, such as corticosteroids or calcineurin inhibitors.

Treatment

The management of eczema is targeted at improving symptoms and long-term disease control. This involves avoiding exacerbants (which is particularly relevant in contact dermatitis), supporting the barrier function of the skin with regular emollients and soap substitutes, and immunosuppressive medications to limit cutaneous inflammation. Immunosuppressant agents are most commonly used as topical preparations, such as corticosteroids or calcineurin inhibitors; however, severe disease, such as in atopic or discoid eczema, may require a systemic agent. Systemic agents used in atopic eczema include oral prednisolone, methotrexate, ciclosporin, azathioprine or mycophenolate mofetil. Phototherapy may also be of benefit in these patients.

Secondary bacterial infection should be treated with topical/systemic antibiotics; however, these patients have often been exposed to multiple antibiotics, hence bacterial resistance is common. The decision to treat with antibiotics should therefore be carefully considered, and if possible, the choice of agent guided by in vitro bacterial sensitivities as determined by skin swab and culture results. If there is an associated viral infection, this should be confirmed with viral skin swab and polymerase chain reaction assay, and the patient initiated on a systemic antiviral agent, such as aciclovir.

Emollients

Emollients are topical hydrating agents that form a lipid barrier on the surface of the skin, which prevents trans-epidermal water loss and therefore improves hydration of the epidermis. Emollients can be ointment preparations that only contain lipid(s), or lotions and creams that also contain water and emulsifying agents. Emollients are the mainstay of eczema management because a defective skin barrier is central to the pathogenesis and so they are an effective first-line treatment. Regular, liberal use of emollients will reduce physical irritation from dry, scaly skin and can reduce topical corticosteroid requirements. Greasier products that have a higher lipid content have a greater emollient effect; however, they may be less well tolerated by patients and may be impractical for regular use throughout the day. Dry and inflamed skin is often aggravated by soaps and bathing products. Therefore, patients with chronic inflammatory skin conditions, such as eczema, should be advised to use an emollient as a soap substitute for washing.

Emollients are often underused. It is important that patients are educated to use appropriate quantities of emollient and have ongoing access to sufficient amounts. Restoring the barrier function of the skin is important in atopic eczema, and it has been reported that the use of liberal full-body emollients can in fact reduce the risk of development of atopic eczema by up to 50% in high-risk infants (Horimukai et al., 2014; Simpson et al., 2014).

Bandaging

In chronic atopic eczema, occlusion with bandages is useful to prevent scratching and to potentiate the action of ointments and creams on the skin. ‘Wet wrapping’ involves the application of

Table 58.2 Comparative potencies of topical corticosteroid preparations

UK steroid group	Trade name	Strength	Relative strength compared with hydrocortisone
Hydrocortisone 0.5–2.5%	Hydrocortisone	Mild	1
Fluocinolone acetonide 0.0025%	Synalar 1:10 dilution		
Betamethasone valerate 0.025%	Betnovate RD	Moderately potent	2.5× stronger
Clobetasone butyrate 0.05%	Eumovate		
Fluocinolone acetonide 0.00625%	Synalar 1 in 4 dilution		
Fludrocortisone 0.0125%	Haelan		
Betamethasone valerate 0.1%	Betnovate	Potent	10× stronger
Mometasone furoate 0.1%	Elocon		
Clobetasol propionate 0.05%	Dermovate	Very potent	50× stronger

emollients, with or without topical corticosteroids steroids, under double-layer cotton bandaging to keep the inner layer moist. This approach is more commonly used in children, and parents can be trained to apply these bandages at home. ‘Wet wrapping’ should not be done if there is concern that the eczema may be secondarily infected because the occlusion may spread the infection.

Topical corticosteroids

Topical corticosteroids are an important agent in the management of acute eczema and form first-line anti-inflammatory treatment. Topical corticosteroids are classified into four main groups according to their strength of action: mild, moderate, potent and very potent (Table 58.2). The choice of topical corticosteroid is dependent on the severity of skin disease and body site where they will be used. Potent and very potent corticosteroids are an effective treatment for the trunk and limbs, but should be avoided on delicate sites such as the face, genitals and flexures, unless under specialist supervision. The periorbital region should be treated with caution because of the thin skin, increasing the likelihood of absorption and risk of cataracts or glaucoma with chronic exposure.

In acute active eczema, patients should be advised to use an appropriate strength topical corticosteroid for that body site once or twice daily. Treatment should be reviewed regularly and tailored accordingly (Hoare et al., 2000). The recommended amount used can be quantified using a fingertip unit (Fig. 58.6), which is the quantity required to cover an area the size of two adult palms. Table 58.3 details the quantities for application to different sites required for twice-daily treatment for 1 week. Under specialist supervision, topical corticosteroids can also be used under occlusion with a dressing or bandage, which will increase absorption and potentiate their actions. There is some evidence in atopic eczema that long-term intermittent application of topical steroid, such as on 2 days of the week, can limit disease relapses (Hoare et al., 2000).

Fig. 58.6 Recommended amount of a topical corticosteroid corresponding to one fingertip unit. The fingertip unit (FTU) is equivalent to approximately 0.5 grams of cream/ointment and should cover a skin area of about two palms (20 cm²).

Table 58.3 Minimum quantity (grams) of topical application required for twice-daily treatment for 1 week

Age	Whole body	Trunk	Both arms and legs
6 Months	35	15	20
4 Years	60	20	35
8 Years	90	35	50
12 Years	120	45	65
Adult (70 kg)	170	60	90

Courtesy of M. Carr.

Topical corticosteroids are available in a range of preparations that include ointments (oil based), creams (water based) and aqueous/alcohol solutions. In general, ointment preparations are preferable to creams in eczema management because they are absorbed better and have fewer additional preservatives. Alcoholic solutions may lead to irritation and should not be applied to acutely inflamed or broken skin. Foam and shampoo formulations are available for hair-bearing sites, such as the scalp.

Adverse effects of chronic topical corticosteroid use are mainly limited to the sites where the steroid is applied and include hypopigmentation (temporary), epidermal thinning, telangiectasia (visible dilated small blood vessels), bruising, striae (stretch marks) and acneiform rashes. Less common side effects may include poor wound healing, spread or worsening of untreated infections and hypertrichosis. Rarely chronic widespread use of potent or very potent topical corticosteroids can lead to systemic absorption, adrenal suppression and Cushing's syndrome. In addition, patients can become sensitised to topical corticosteroid preparations. Such reactions may be directly to the steroid medication, with some cross-reactivity between different steroids, or a component of the vehicle/base. In patients with chronic eczema that is poorly responsive or possibly exacerbated by topical steroids, patch testing should be considered.

Patients and non-specialists often have high levels of anxiety regarding the potential adverse effects of topical corticosteroids. This commonly leads to undertreatment in adults and children. Local and systemic side effects are rare following the appropriate use and duration of topical corticosteroid treatment. Eczema education programmes are a crucial part of eczema management and should include advice about the safe and effective use of topical corticosteroids.

Antibiotics and corticosteroid combinations

Combination preparations can be useful in treating mild bacterial infection of eczematous skin. Long-term use should be limited because of the risks for sensitisation and antibiotic resistance. In general, invasive bacterial infections are best managed with systemic antibiotics.

Calcineurin inhibitors

Topical calcineurin inhibitors are an anti-inflammatory class of medication that act by blocking the intracellular phosphatase enzyme calcineurin, which is important in lymphocyte activation during inflammatory responses. They offer an alternative to topical corticosteroids and are primarily used as second-line agents, with the aim of avoiding or reducing topical corticosteroid use. Topical pimecrolimus 1% cream is licensed in the UK for mild-to-moderate atopic eczema and is often used to treat the face and neck in children aged 2 years or older. Topical tacrolimus ointment is more effective than pimecrolimus (Paller et al., 2005), is licensed in the UK for moderate-to-severe atopic eczema and is often used in adults (0.03% and 0.1%) and children older than 2 years (0.03%). Topical calcineurin inhibitors also have a role in the long-term prevention of eczema exacerbations with

application to troublesome sites on 2 consecutive days a week reducing flares.

The main side effect of topical calcineurin inhibitors is a burning or stinging sensation after initial application, but this usually improves after a few days, and patients should be advised of this. Rare cases of malignancy (e.g. skin cancer and lymphoma) have been reported in patients treated with these agents. However, a causal relationship has not been established, and although large case-control studies have demonstrated an increased risk of lymphoma associated with increased atopic eczema severity, this was not associated with topical calcineurin inhibitor use (Eichenfield et al., 2014). Therefore, patients should use these agents within licensed indications and be monitored if they use prolonged regimens. Calcineurin inhibitors should be avoided in infected eczema and are generally not as effective as corticosteroids in acutely inflamed eczema. Therefore, their greatest value is in maintenance therapy regimens.

Antihistamines

Pruritus is a prominent and distressing feature of eczema. Oral antihistamines have little direct effect on pruritus in atopic eczema, but may lead to some relief because of their sedating effect, especially overnight. Sedating antihistamines may cause daytime drowsiness, and so caution should be taken if patients are driving or operating machinery or if prescribed to school-aged children.

Coal tar preparations

Tar creams and ointments can be used in the management of hyperkeratotic, lichenified eczema. These are less cosmetically acceptable than other topical preparations, but coal tar is also an effective antipruritic.

Systemic therapies

Corticosteroids

Systemic corticosteroids (e.g. oral prednisolone 0.5 mg/kg) are an effective first-line short-term treatment in the management of severe acute eczema that needs rapid control. Long-term treatment with systemic corticosteroids is now rarely used because of the risk of long-term side effects, including infections, hypertension, diabetes mellitus, osteoporosis and adrenal suppression.

Ciclosporin

Ciclosporin is a calcineurin inhibitor that blocks lymphocyte activation and is used as an oral preparation in the treatment of atopic eczema. It is effective as a short-term bridging therapy in severe chronic adult eczema and is licensed for its treatment. It has a rapid onset of action with an approximate 50% improvement seen by 6–8 weeks of treatment (Schmitt et al., 2007; Roekevisch et al., 2014). Intermittent courses for 3 months at doses of 2.5–5 mg/kg per day are useful in controlling eczema, but dose-related (cumulative) renal nephrotoxicity limits treatment to a maximum duration of 12 months. Other side effects include hypertension and increased risk of malignancy, and a detailed patient history should identify previous skin or cervical malignancy. During

treatment with ciclosporin, patients require close monitoring, notably of renal function and blood pressure.

Azathioprine

Azathioprine is a purine analogue that inhibits DNA synthesis. It is used as an unlicensed oral preparation in the treatment of atopic eczema and is effective with a mean 50% improvement seen after 12–24 weeks (Roekevisch et al., 2014). Bone marrow suppression is a major concern. Before azathioprine initiation, patients should have their thiopurine methyltransferase (TPMT) activity determined, because reduced/absent levels are associated with an increased risk of toxicity. Azathioprine should be avoided in individuals with absent TPMT activity, and the dose reduced in those with low TPMT activity. During treatment with azathioprine, patients require close monitoring, notably of full blood count and liver function.

Methotrexate

Methotrexate is an antimetabolite that in its active form inhibits purine and pyrimidine synthesis, required for DNA synthesis, and leads to the accumulation of extracellular adenosine, which has anti-inflammatory effects. It is used as an unlicensed oral or subcutaneous preparation in the treatment of atopic eczema, with some evidence that subcutaneous delivery leads to greater bioavailability. Methotrexate, given once a week, has a similar efficacy to azathioprine at 12–24 weeks of treatment (Roekevisch et al., 2014). The main side effect that patients report with methotrexate therapy is nausea. Concomitant folic acid is often given to reduce toxicity. During treatment with methotrexate, patients require close monitoring, notably of full blood count and liver function. Conception should be avoided during and for at least 3 months after methotrexate treatment in either men or women because of teratogenic risk.

Mycophenolate mofetil

Mycophenolate mofetil prevents T- and B-cell proliferation and is used as an unlicensed oral agent in the treatment of atopic eczema. Although it has a favourable side-effect profile, it is often used as a third-line agent because there is little clinical trial evidence supporting its use in atopic eczema. During treatment with mycophenolate mofetil, patients require close monitoring, notably of full blood count. Conception should be avoided during and for up to 6 weeks (women) or 12 weeks (men) after mycophenolate mofetil treatment because of teratogenic risk.

Phototherapy

Phototherapy can be effective in some patients with atopic eczema, and narrow-band ultraviolet B (UVB) is the therapy of choice (Gambichler et al., 2005; Meduri et al., 2007). Potential adverse events associated with all types of phototherapy include burning, premature ageing and an increased risk of skin cancer that increases with cumulative treatment. A small proportion of patients may have photosensitive eczema, which should be screened for before phototherapy (either a history of photo-aggravated eczema or by formal photo-testing). A treatment course requires a patient to attend two or three times a week for at least 6 weeks.

Patient care

Treatment failure is often due to poor adherence, which can be due to poor information about treatments or inconvenient/impractical regimens. In addition, it is important to recognise that eczema affects many aspects of a patient's life, including social interactions and schooling/work, and can have considerable effects on the family. Additional quality-of-life factors affected in eczema include body image, irritability and loss of sleep due to profound itch (Fig. 58.7). A multidisciplinary approach is often needed in overcoming these issues, and healthcare workers including primary care doctors, dermatologists, specialist nurses and pharmacists may be involved. Treatment regimens should be kept as simple as possible and be tailored to the individual patient, with time taken to clearly explain both the disease process and the treatment goals. Patient and parental education is important because treatments are designed to control and manage the disease. Although atopic eczema is likely to improve throughout childhood, expectations of an immediate cure need to be addressed. Trained nurses or clinical psychologists can provide additional support, and nurse-led clinics improve disease severity and quality-of-life outcomes (Ersser et al., 2014). Patients with eczema should aim to lead as normal a life as possible, and school staff and employers can play an important part in achieving this goal. Advice and support through contact with other patients and their families can be obtained from the National Eczema Society (<http://www.eczema.org>).

An algorithm for the management of eczema is shown in Fig. 58.8.

Psoriasis

Psoriasis is a chronic inflammatory disorder of the skin that affects approximately 2% of the population in Europe and North America. The usual presentation is with well-demarcated erythematous

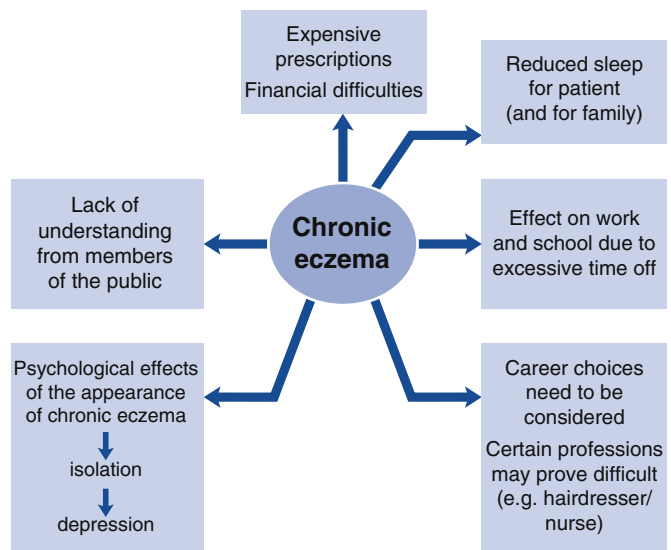

Fig. 58.7 The social and psychological effects of chronic eczema.

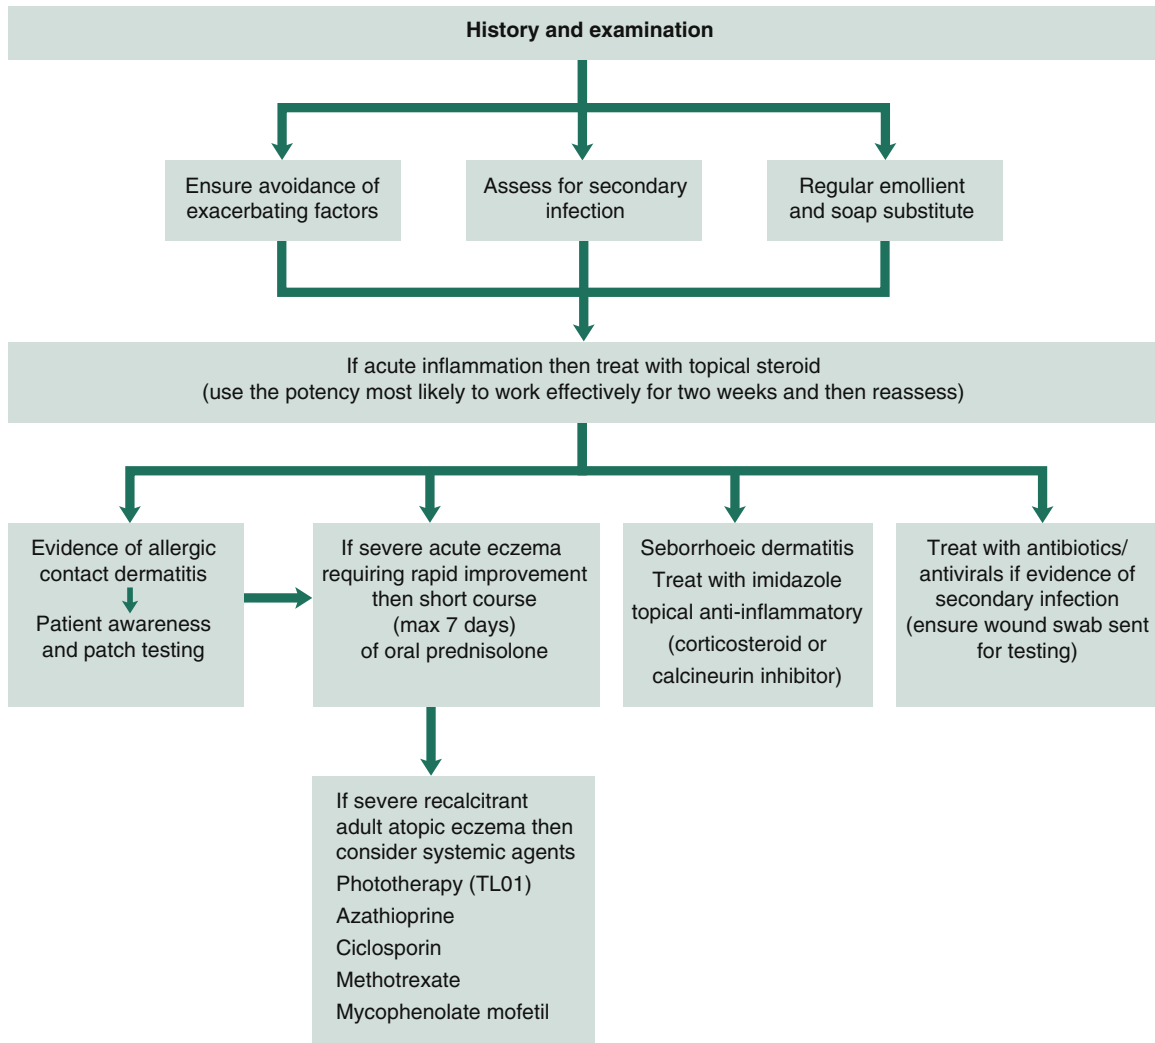

Fig. 58.8 Algorithm for the management of eczema.

plaques with an overlying scale (Fig. 58.9). Common sites affected include the scalp, buttocks, elbows, knees and nails. Although psoriasis is often thought of as limited to the skin, up to 25% of patients also have an associated psoriatic arthropathy (Zachariae, 2003), and moderate-to-severe psoriasis is associated with an increased risk of cardiovascular disease and death (Mehta et al., 2010). In addition, psoriasis causes significant psychosocial morbidity to those affected, resulting in an impaired quality of life.

Pathology and clinical features

The aetiology of psoriasis, as with atopic eczema, is complex and involves a combination of genetic, environmental and immunological factors. Genetic predisposition is important, with a high degree of heritability demonstrated in both linkage and twin studies, and up to 70% of patients report a family history of psoriasis. More recently, GWASs have identified more than 40 susceptibility loci that implicate skin barrier function, innate immunity and adaptive immunity in the disease pathogenesis (Mahil et al., 2015).

Fig. 58.9 Chronic scaly plaque psoriasis on an elbow. (Courtesy of M. Carr.)

Immune cell activation is central to the pathogenesis of psoriasis, with genetic variation within the major histocompatibility class I region giving the strongest association signal in all GWASs, primarily because of variation in the HLA-Cw6 allele (Mahil et al., 2015). It is hypothesised that, in a predisposed individual, after exposure to uncertain triggers (such as microbial products) there is a complex interaction between cells of both innate and adaptive immunity, including certain dendritic and T-cell subsets (Nestle et al., 2009). These interactions lead to the development of T_H1- and T_H17-mediated immune responses within the skin. As a result, keratinocytes are inappropriately activated, resulting in their hyper-proliferation and the development of a psoriatic plaque. The importance of key inflammatory pathways, such as the cytokines tumour necrosis factor- α (TNF- α), interleukin (IL)-23 and IL-17, has been demonstrated in genetic and immunological studies. This has been confirmed by the response of patients with psoriasis to treatments that either target T cells or specifically block these pro-inflammatory cytokine pathways (Nestle et al., 2009).

Psoriatic plaques are histologically characterised by epidermal hyperplasia (acanthosis), with a thickened upper horny layer (hyperkeratosis), which is reflected by the clinical features of thick, scaly skin. The buildup of scale is due to increased epidermal turnover. The differentiation of cells through the epidermis normally takes approximately 40 days, but in psoriatic skin may be as rapid as 7 days. In the dermis, superficial capillaries proliferate and are dilated, which explains why psoriatic plaques appear erythematous and bleed after minimal trauma/scraping off scale (Auspitz sign). There is a dense dermal lymphocytic infiltrate, with inflammatory cells also migrating up into the epidermis, where granulocytes form microabscesses.

Precipitating factors

Extrinsic factors also have a role in triggering or exacerbating psoriasis in predisposed individuals. These are described as follows.

Infections

It has been hypothesised that bacterial antigens have a role in triggering psoriasis. Streptococcal infections, particularly pharyngitis, frequently precede the onset of guttate psoriasis. In addition, psoriasis in individuals with HIV infection is often more severe.

Drugs

Certain drugs can exacerbate or induce psoriasis in predisposed individuals. The most common agents implicated are lithium, β -blockers, certain antimalarial medications, non-steroidal anti-inflammatory drugs (NSAIDs), tetracyclines and the rapid withdrawal of systemic corticosteroids.

Koebner phenomenon

The Koebner phenomenon refers to the development of psoriatic lesions at sites of skin injury, such as surgical scars, burns and trauma. Certain other inflammatory skin conditions also show koebnerisation.

Alcohol and smoking

Excess alcohol consumption may exacerbate established psoriasis. In addition, psoriasis is associated with high rates of alcoholism, which is thought to be due to the psychological burden of having the condition.

Smoking is strongly associated with palmoplantar psoriasis, with up to 95% of individuals who develop this variant being smokers at its onset. Smoking cessation should be actively discussed with patients because it may improve the psoriasis severity and help reduce the risk of cardiovascular and/or respiratory disease.

Emotional stress

Anecdotal observations and frequent patient reports identify stress as an important trigger factor for psoriasis, with some evidence demonstrating that the onset and severity of psoriasis can correlate with prior stress (Kirby et al., 2008). Furthermore, psoriasis can cause considerable psychological distress and depression.

Clinical types

Psoriasis vulgaris

Psoriasis vulgaris is also known as chronic plaque psoriasis and is the most common subtype of psoriasis, affecting 85–90% of patients. Psoriasis vulgaris most commonly develops in young adults and has a chronic relapsing course. It can, however, develop in individuals of any age, with childhood and late-onset adult variants described. The typical psoriatic lesion is an erythematous well-demarcated plaque with overlying scale. Classically there are multiple lesions that are distributed symmetrically to involve extensor sites, such as the elbows, knees and buttocks. Other sites commonly affected are the sacrum, umbilicus and ears. Involvement of the scalp may be the only manifestation of psoriasis in some patients, which typically affects the anterior hairline or post-auricular scalp but can also be more extensive. Associated hair loss is rare. Psoriatic plaques may itch but not usually to the same extent as eczematous lesions.

Guttate psoriasis

Guttate psoriasis is more commonly seen in children and young adults, and is characterised by a widespread eruption of small (<1 cm) scaly plaques on the trunk and limbs (Fig. 58.10). The presentation is often acute and can appear 10–14 days after a streptococcal upper respiratory tract infection. Topical treatments or UVB phototherapy are usually effective. Guttate psoriasis often resolves; however, it may be the first presentation of psoriasis vulgaris in some individuals.

Generalised pustular psoriasis

Generalised pustular psoriasis is an acute, unstable form of psoriasis that manifests as widespread annular erythematous patches with 'sheets' of tiny sterile pustules, which typically develop towards the edge of the patches. This rare but severe subtype

Fig. 58.10 Guttate psoriasis showing Koebner phenomenon in scratch mark. (Courtesy of M. Carr.)

of psoriasis has been shown in genetic studies to have a distinct pathogenesis to psoriasis vulgaris, with the IL-1 pathway and mutations in the *IL36RN* gene implicated (Onoufriadis et al., 2011). Patients with generalised pustular psoriasis can be systemically unwell with fever and general malaise, and their presentation may be a dermatological emergency. Flares of pustular psoriasis can also be precipitated by the withdrawal of systemic or potent topical corticosteroids in patients with known pustular psoriasis or psoriasis vulgaris. Systemic corticosteroids should therefore be avoided in patients with known psoriasis.

Palmoplantar psoriasis

Palmoplantar psoriasis describes psoriasis limited to the palms and soles, where there is sharp demarcation of the involved areas. It can take two forms: either inflamed hyperkeratotic fissured skin, which can be very painful or sterile pustules on an erythematous base which dry to leave small brown macules (palmoplantar pustulosis) (Fig. 58.11). Pustular palmoplantar psoriasis is more common in smokers.

Flexural psoriasis

Psoriasis can occur at flexural sites, such as the axillae, submammary areas, groin, perineum and genitalia. Psoriasis at these sites can differ in appearance from classical psoriasis and although well-demarcated, they tend to be red and shiny, rather than scaly. Secondary infection, particularly with *Candida*, is common. Potent corticosteroids are not advised at these sites because of the risk of skin atrophy. Management is primarily with combined preparations that include mild- to moderate-strength corticosteroids and antifungals, with or without antibiotics.

Erythrodermic psoriasis

Erythroderma, or exfoliative dermatitis, is a severe, potentially life-threatening condition in which greater than 90% of the body surface is erythematous (Fig. 58.12). Erythroderma can occur as a consequence of several different skin conditions, which include psoriasis, as well as eczema, drug eruptions and cutaneous T-cell lymphoma. When large areas of skin are inflamed, its function

Fig. 58.11 Pustular psoriasis of sole. (Courtesy of M. Carr.)

is significantly impaired and patients suffer dehydration, electrolyte imbalance, temperature dysregulation, and potential serious secondary infection. This is a dermatological emergency, and acutely unwell patients need urgent hospital admission, supportive medical care and topical treatment. Initially, bland emollients (e.g. white soft paraffin) and mild-to-moderate topical corticosteroids should be used. Once a diagnosis is established, often after a skin biopsy, the underlying condition, such as psoriasis, can be treated with appropriate systemic agents.

Psoriatic arthropathy

Up to 25% of patients with psoriasis will also be affected by an associated psoriatic arthropathy (Zachariae, 2003). There are several distinct patterns of psoriatic arthritis that include asymmetrical mono-/oligo-arthritis, symmetrical polyarthritis, distal small joint arthritis, sacroiliitis and arthritis mutilans. Psoriatic arthritis is also associated with enthesitis and tendonitis, and can present as an acutely swollen finger/toe (dactylitis). These patients are rheumatoid factor negative (seronegative), and the arthritis may precede skin findings. Concomitant psoriatic arthritis may indicate the need for systemic treatment and determine the choice of agent, such as methotrexate or biologics that block TNF- α or IL-17. These patients should be jointly managed with a rheumatologist.

Psoriatic nail disease

The nails are frequently affected in psoriasis, and changes seen include nail pitting, nail ridging, onycholysis (separation of the nail from the nail bed), hyperkeratosis under the nail and complete nail destruction. It is thought that some of these changes may represent underlying enthesitis. In a small proportion of patients only the nails are affected with no other skin signs.

Fig. 58.12 Erythrodermic psoriasis. (Courtesy of St John's Institute of Dermatology, London.)

Psoriatic nail disease can be cosmetically disfiguring, and topical treatments are rarely effective. Systemic treatments such as methotrexate, when prescribed for generalised psoriasis, may improve nail disease.

Treatment

Many patients with psoriasis have only mild localised disease, for example limited to the elbows. This may only require emollient therapy to prevent drying and fissuring of the areas involved. However, a wide range of additional active treatments for psoriasis exists, which range from topical preparations to phototherapy and systemic agents. Psoriasis is a chronic inflammatory condition for which there is no cure, and so treatment decisions should take into account the type and severity of the psoriasis and the impact that it has on the patient's life. Managing the patients' expectation and agreeing on treatment goals will improve patient adherence and treatment outcomes. Other things to consider are patient comorbidities and lifestyle factors, such as their occupation and ability to attend frequent appointments.

Topical therapy

Topical therapies are first-line treatments for mild-to-moderate psoriasis, and can often be used in combination with systemic treatments in more severe psoriasis. In addition to topical active therapies, patients with psoriasis should use regular emollients to hydrate the skin, remove scale and prevent fissuring. When deciding on a topical agent, the prescriber should take into account patient preference, cosmetic acceptability and practical aspects of application such as the extent of psoriasis to be treated. Different formulations should also be discussed with the patient, such as ointment, creams and gels, and the formulation prescribed should be guided by the patient's preference. Some topical treatments are used only in a specialist setting, and some patients benefit from periods of intensive therapy administered by trained staff, such as specialist nurses, in a daycare facility.

Corticosteroids

Topical corticosteroids have an anti-inflammatory effect, and mild-to-moderate strength preparations, when used once or twice daily, are an effective treatment for chronic stable plaque psoriasis. A wide range of corticosteroid preparations are available for psoriasis that are cosmetically acceptable and easy to apply. These include gels, lotions and shampoos for the scalp. Topical corticosteroids are also of great value in acutely inflamed psoriasis. Reducing acute inflammation may also allow subsequent treatment with other agents that would otherwise irritate acutely inflamed plaques, such as vitamin D analogues or coal tar.

Chronic topical corticosteroid use can be limited by irreversible side effects, such as skin atrophy and striae. The use of potent corticosteroids in psoriasis is limited by the risk of systemic absorption and rebound effect (rapid disease relapse) on withdrawal. Potent steroids should only be used on the limbs or trunk under specialist supervision. They are often reserved for localised disease, such as thicker acral sites, and often in combination with salicylic acid if there is hyperkeratosis. Very potent corticosteroids should generally be avoided in psoriasis.

Vitamin D analogues

Vitamin D analogues inhibit keratinocyte differentiation and production, and the most commonly used agent is calcipotriol. Topical calcipotriol applied once or twice daily is an effective treatment for mild localised psoriasis and is commonly used in a primary care setting. Vitamin D analogues can cause some local irritation, and so should not be used, or with caution, on delicate skin sites such as the face and flexures. Hypercalcaemia has been described due to systemic absorption if the maximum weekly dose exceeds 100 g. Efficacy may be enhanced when used in combination with a topical corticosteroid, and some combined corticosteroid and calcipotriol formulations are available.

Coal tar

Coal tar is one of the oldest topical treatments for psoriasis and has anti-inflammatory, antibacterial, antipruritic and antimitotic effects. A variety of preparations are available including bath preparations, shampoos, creams and ointment. Coal tar

concentrations of 1–10% can be used; however, higher concentrations should occur in a supervised setting because they can cause local irritation. Coal tar can be used in combination with other products, such as topical corticosteroids or UVB phototherapy (Goeckerman regimen). In addition to being an irritant, coal tar treatment can be limited by its odour and temporary staining of skin and clothing. Although coal tars contain polycyclic aromatic hydrocarbons, epidemiological studies have not demonstrated any association with carcinogenic risk and their topical use.

Dithranol

Dithranol (anthralin in the USA) is a synthetic anthracene derivative that has antiproliferative and anti-inflammatory effects on the skin. It is an effective treatment for psoriasis and, with coal tars, is one of the oldest treatments used. Dithranol can irritate normal skin and stain clothing, with treatment starting at lower concentrations that can be titrated up depending on how well it is tolerated. In current practice it is used in a dermatology daycare setting over several weeks, where it is often used for ‘short contact’ treatment and washed off after a defined period of time.

Salicylic acid

Salicylic acid is a keratolytic that breaks down the hyperkeratotic component of psoriatic plaques, thereby reducing scale and enabling better penetrance of other topical preparations. Salicylic acid can be used alone or in combination with other topical medications, such as corticosteroids. Higher concentration preparations may be required for particularly hyperkeratotic sites, such as acral sites in palmoplantar psoriasis.

Topical treatment of psoriasis at special sites

Scalp

Scalp psoriasis should first be treated with a potent topical corticosteroid, using an appropriate formulation (shampoo, gel, lotion or foam). Patients should be shown how to effectively use scalp preparations because this can be challenging and lead to poor adherence. If the scalp is scaly, topical corticosteroids should be used in combination with a descaling agent, such as an emollient (e.g. coconut oil or ointment) or a salicylic acid-containing product. Vitamin D analogues, alone or in combination with corticosteroid, are also effective for scalp psoriasis. Coal tar preparations, such as shampoos, are effective in mild disease, but should be used in combination with other treatments for moderate-to-severe scalp psoriasis.

Flexures/Genitals

Flexural and genital regions are prone to irritation and steroid atrophy. These areas should be treated with short courses (1–2 weeks) of mild- to moderate-potency topical corticosteroids. Areas unresponsive to topical corticosteroid can be treated with twice-daily application of a calcineurin inhibitor for up to 4 weeks, which should only be initiated by a specialist.

Nails

Topical treatments are not effective in treating psoriatic nail disease, which may show some response to systemic therapies. When assessing dystrophic nails in a patient with psoriasis, it is also important to exclude fungal infection.

Phototherapy

Many patients with psoriasis will report an improvement in their skin after sunny holidays, with only 10% of patients reporting deterioration in symptoms on sun exposure. Phototherapy with either UVB or photochemotherapy with UVA after psoralen exposure (PUVA) has an immunosuppressive effect on the skin and has been used to treat psoriasis for more than 80 years.

UVB

Narrow-band UVB or TL-01 (311–313 nm) is the most commonly used phototherapy modality for moderate-to-severe psoriasis and is preferable to older broadband UVB (290–320 nm) lamps, due to increased safety and reduced risk of burning. Narrow-band UVB is an effective treatment for getting rapid control of widespread disease, with approximately 75% of patients being clear or nearly clear of psoriasis after a course of treatment (usually two to three treatments a week for approximately 6 weeks) (Dawe et al., 1998).

Photochemotherapy with UVA after psoralen exposure

PUVA also has a role in the treatment of stable moderate-to-severe psoriasis. Psoralens are drugs that are activated by long-wave UV light (320–400 nm), which then act by interfering with DNA synthesis and reducing epidermal turnover. Two psoralens are available in the UK: 8-MOP (methoxypsoralen) and 5-MOP. Usually psoralens are taken orally 2 hours before exposure to UVA to the whole body; however, PUVA can also be given locally for limited disease after topical psoralen application to the affected site, such as the hands or feet. The treatment is usually given twice a week for a 6-week period. The commonest adverse effect is nausea due to systemic psoralens, and the eyes must be photo-protected for at least 12 hours after treatment to reduce the risk of cataracts.

The most serious adverse effect of excessive UV exposure is an increased long-term risk of skin cancer. Therefore, the total number of treatments and cumulative exposure doses need to be carefully monitored. Fair skin types and systemic immunosuppression (past/present) are at greatest risk of skin malignancy after PUVA, and because of these considerations PUVA is generally reserved for patients unresponsive to UVB therapy. Safe exposure limits are considered to be up to 350 treatments for narrow-band UVB therapy and 150–200 treatments for PUVA.

Systemic therapy

Systemic therapy can be used for all types of psoriasis. It is indicated when the psoriasis cannot be controlled with topical therapy alone, is not responsive or rapidly relapses after phototherapy, and the psoriasis is either extensive or localised but associated with

significant functional impairment/distress. Objective measures have been developed to measure disease severity; the Psoriasis Area and Severity Index (PASI) is used to measure disease severity based on clinical features of individual lesions and the extent of disease (range 0–72); the Dermatology Quality of Life Index (DLQI) uses a range of questions to grade the impact of the skin condition on daily living (range 0–30). For both indices, scores greater than 10 are considered a marker of severe disease. These measures have been incorporated into national guidelines for certain psoriasis treatments and should be used to assess disease

severity before starting a systemic medication, but also at intervals throughout treatment to monitor the patient's response.

When considering initiation of a systemic medication it is important to take into account the psoriasis subtype, treatment history, relevant comorbidities (such as psoriatic arthritis), conceptions plans and the views/goals of the patient. Systemic non-biologic treatments commonly used in psoriasis include methotrexate, ciclosporin, acitretin and hydroxyurea. Drug interactions are important, and a detailed patient drug history is important (Table 58.4). In addition, these treatments require monitoring

Table 58.4 Examples of interactions with drugs used in the treatment of eczema and psoriasis

Interacting drug		Outcome
Methotrexate	Aspirin	Increased plasma concentration and toxicity of methotrexate
	NSAIDs	Increased plasma concentration and toxicity of methotrexate
	Probenecid	Increased plasma concentration and toxicity of methotrexate
	Phenytoin	Increased bone marrow toxicity
	Sulfonamides	Increased toxicity
	Trimethoprim	Increased antifolate effect of methotrexate
	Acitretin	Increased plasma concentration of methotrexate
Azathioprine	Allopurinol	Enhanced effect and toxicity of azathioprine
	Warfarin	Inhibition of anticoagulant effect
	Cimetidine	Enhanced myelosuppression
	Indometacin	Increased risk of leucopenia
Ciclosporin	Non-steroidal anti-inflammatory drugs	Increased risk of nephrotoxicity
	Aminoglycosides	Increased risk of nephrotoxicity
	Co-trimoxazole	Increased risk of nephrotoxicity
	Ciprofloxacin	Increased risk of nephrotoxicity
	Ketoconazole	Increased plasma concentration of ciclosporin
	Itraconazole	Increased plasma concentration of ciclosporin
	Erythromycin	Increased plasma concentration of ciclosporin
	Oral contraceptives	Increased plasma concentration of ciclosporin
	Calcium channel blockers	Increased plasma concentration of ciclosporin
Acitretin	Phenytoin	Decreased plasma concentration of ciclosporin
	Carbamazepine	Decreased plasma concentration of ciclosporin
	Rifampicin	Decreased plasma concentration of ciclosporin
	Methotrexate	Increased plasma concentration of methotrexate

Always check latest British National Formulary or other reference source for specific drug interaction information.

Table 58.5 Common adverse effects and monitoring requirements for systemic treatments of eczema and psoriasis

Therapy	Adverse effects	Monitoring requirements
Methotrexate	Hepatic fibrosis; myelosuppression; nausea; pulmonary fibrosis; teratogenic (contraindicated in both males and females for 4 weeks before and 3 months after treatment)	FBC U&E LFTs Pro-collagen III peptide (P3NP) ± liver biopsy Chest X-ray (screening)
Hydroxyurea/hydroxycarbamide	Myelosuppression; skin reaction; teratogenic; liver toxicity (narrow therapeutic window)	FBC U&Es LFTs
Ciclosporin	Renal nephrotoxicity Hypertension Gingival hypertrophy	FBC U&E LFTs Lipid profile Blood pressure Urinalysis
Acitretin	Teratogenic (including up to 3 years post-treatment) Dryness of mucous membranes and skin Hyperostoses, increased serum triglyceride Occasional hepatotoxic reaction	FBC U&E LFTs Lipid profile
Fumaric acid esters	Gastro-intestinal side effects Flushing Lymphopenia Proteinuria Renal failure	FBC U&E LFTs Urinalysis
Azathioprine	Myelosuppression Deranged liver function Gastro-intestinal effects	TPMT pre-treatment FBC U&E LFTs

FBC, Full blood count; LFT, liver function test; TPMT, thiopurine methyl transferase genetic polymorphism screening; U&E, urea and electrolytes.

for adverse events, with responsibility for treatment being with a specialist centre (Table 58.5). Certain biologic agents, which block specific inflammatory cytokine pathways, are also licensed for the treatment of psoriasis that is unresponsive to standard non-biologic systemic therapy.

Methotrexate

As previously discussed, methotrexate inhibits purine and pyrimidine synthesis, which is required for DNA synthesis, and leads to the accumulation of extracellular anti-inflammatory metabolites. Methotrexate is administered as a weekly oral or subcutaneous dose of usually 15–25 mg, and it is considered the gold standard, first-line systemic agent for moderate-to-severe psoriasis. It is an effective agent with approximately two-thirds of patients treated seeing at least a 50% improvement in psoriasis after 16 weeks of treatment (Heydendael et al., 2003; Saurat et al., 2008). The main side effect that patients report with methotrexate therapy is nausea. Concomitant folic acid is often given to reduce toxicity. Conception should be avoided during and for at least 3 months after methotrexate treatment, in either men or women, because of teratogenic risk.

Patients require close monitoring during treatment with methotrexate, notably of full blood count and liver function, because treatment is associated with myelosuppression and the development of hepatic fibrosis (see Table 58.5). Liver function tests do not reliably predict hepatic fibrosis, and so additional investigations are required. Liver biopsy is the gold standard test to diagnose hepatic fibrosis but is associated with pain, bleeding and a small risk of fatality (0.01–0.1%). Serial blood pro-collagen III peptide measurement has been shown to be an effective screening test to replace/guide routine liver biopsy (Chalmers et al., 2005). Additional non-invasive investigations for hepatic fibrosis, such as liver fibroelastography (FibroScan), are also under investigation for methotrexate-monitoring purposes.

Ciclosporin

Ciclosporin is a calcineurin inhibitor that blocks lymphocyte activation and is used as an oral preparation in the treatment of psoriasis. It is an effective treatment for all clinical subtypes of psoriasis. Ciclosporin is dosed daily, ranging from 2 to 5 mg/kg, and has a similar efficacy to methotrexate at 16 weeks of treatment; however, ciclosporin has a more rapid onset of action that

may favour its use in a more acute setting (Heydendael et al., 2003). As with atopic eczema management, ciclosporin treatment is often limited at 12 months because of the increased risk of renal nephrotoxicity with long-term therapy. Adverse events reported include hypertension, hypertrichosis, paraesthesia, tremor and increased risk of infections. There is also a significantly increased risk of skin cancer in patients who have also received multiple courses of phototherapy.

Acitretin

Acitretin is a vitamin A derivative that inhibits epidermal proliferation and is an effective oral agent for disorders of keratinisation, which includes psoriasis, and offers an alternative to immunosuppressive agents. Acitretin is usually initiated at a low dose of 25–30 mg daily for 2–4 weeks, which is subsequently increased as guided by clinical response. In chronic plaque psoriasis it is reported that at higher doses, up to 85% of patients will see at least a 50% improvement in their skin (Ormerod et al., 2010). Common side effects are dry skin/mucous membranes, hair loss and lethargy, and long-term therapy is associated with hyperlipidaemia. Therefore, patients should be monitored whilst on treatment. Conception should be avoided during and for up to 3 years after acitretin treatment because of teratogenic risk (Ormerod et al., 2010).

Hydroxyurea/hydroxycarbamide

Hydroxyurea/hydroxycarbamide is a cytotoxic immunosuppressant drug that inhibits DNA synthesis. It has a similar mode of action to methotrexate, including bone marrow suppression, but it is less hepatotoxic. Hydroxyurea/hydroxycarbamide has been used historically as an unlicensed oral treatment for psoriasis (500–1500 mg/day) and is effective after 6–8 weeks; however, it is now less commonly prescribed. Conception should be avoided during and for up to 12 months after treatment because of teratogenic risk.

Fumaric acid esters

Fumaric acid esters have been used since the early 1960s to treat psoriasis and target both keratinocyte and T-cell activity. Although fumaric acid esters are licensed in Europe for severe chronic plaque psoriasis, they are not licensed in the UK. The main side effects are gastro-intestinal upset and flushing, and rare adverse events include renal impairment and lymphopenia.

Biologic therapy

Biologic therapies or ‘biologics’ in psoriasis refer to a group of engineered monoclonal antibodies that specifically block pro-inflammatory cytokines, including TNF- α , IL-23 and IL-17, which are central to the disease pathogenesis. Biologics are effective therapies for moderate-to-severe chronic plaque psoriasis, with 50–80% of patients seeing at least a 75% improvement in their disease after 12–16 weeks of treatment and with some patients having very striking responses (Menter et al., 2007; Saurat et al., 2008; Griffiths et al., 2010; Langley et al., 2014). These treatments, however, are expensive, and national registries have also been developed to collect prospective safety data regarding the

use of these relatively newer agents. In the UK, biologics are recommended for patients with moderate-to-severe chronic plaque psoriasis (as defined by PASI \geq 10 and DLQI $>$ 10) who have not responded successfully to at least two standard systemic agents that includes methotrexate (Smith et al., 2009). Before initiating a biologic agent, patients should be screened for infections, including viral hepatitis, HIV and active/latent tuberculosis, with certain additional cautions or contraindications for each agent. Biologics are generally well tolerated, with injection-site reactions sometimes reported. Clinical response should be assessed after 12–16 weeks of treatment, at which point a decision should be made whether to continue the treatment (NICE, 2012).

The following are the licensed dosing regimens for these agents (UK).

TNF- α antagonists

The pro-inflammatory cytokine TNF- α plays a central role in the pathogenesis of psoriasis, and several biologics that block its function have been developed for the treatment of chronic plaque psoriasis. These include adalimumab, infliximab and etanercept, which all have a potent targeted immunosuppressant action. Serious adverse events associated with anti-TNF- α agents include serious infections requiring hospitalisation, in particular reactivation of tuberculosis, exacerbation of severe cardiac failure, demyelinating disease and a potential risk of malignancy, including solid organ tumours and lymphoma. Therefore, careful selection of suitable patients and regular monitoring are important.

Adalimumab. Adalimumab is humanised anti-TNF- α monoclonal antibody. It is administered by subcutaneous injection, initially at a dose of 80 mg, followed by a fortnightly maintenance dose of 40 mg.

Infliximab. Infliximab is a chimeric anti-TNF- α monoclonal antibody. It is administered by intravenous infusion at a dose of 5 mg/kg at weeks 0, 2 and 6 and then a maintenance dose every 8 weeks. Infliximab has been associated with acute infusion-related reactions and delayed hypersensitivity reactions, especially if there has been a break in treatment, and should therefore be administered in a setting with access to appropriate resuscitation equipment and facilities.

Etanercept. Etanercept is an engineered receptor fusion protein that binds to soluble TNF- α with high affinity and blocks its actions. It is administered as a subcutaneous injection at a dose of 25 mg twice weekly.

IL-12/IL-23 antagonists

Ustekinumab. Ustekinumab is a fully human monoclonal antibody licensed in the treatment of moderate-to-severe psoriasis, which acts by binding to and blocking a common subunit of the cytokines IL-12 and IL-23. It is administered as a subcutaneous injection at a dose of 45 mg (or 90 mg if $>$ 100 kg) at baseline, week 4, and then every 12 weeks.

IL-17 antagonists

Secukinumab. Secukinumab is a fully human anti-IL-17A monoclonal antibody. It is administered as a subcutaneous

Fig. 58.13 Treatment algorithm for psoriasis. PUVA, psoralen with ultraviolet A; UVB, ultraviolet B.

injection at a weekly dose of 300 mg for 4 weeks, followed by a 300 mg monthly maintenance dose.

A treatment algorithm for psoriasis is shown in Fig. 58.13.

Patient care

Psoriasis is a chronic disease, and many of the psoriasis treatments are not straightforward. Topical regimens can be time consuming and messy, and systemic treatments require regular blood tests and outpatient consultations. Patients often experience ‘treatment fatigue’ and frustration with the chronicity of the condition. Psoriasis can also affect many other aspects of patients’ lives. Co-existent psoriatic arthritis may cause physical disability that impacts on individuals’ ability to perform daily activities, which may also impact on their work or education. Psoriasis is also associated with significant psychosocial morbidity, such as depression, alcohol misuse, negative body image and difficulty with intimate relationships. This is overall associated with a reduced quality of life. Therefore, in the holistic approach to caring for such patients, all of these factors must be considered. It is important that patients are educated about their condition, and that realistic treatment goals are set out with agreement of both the clinical team and patient. Engaging with patients’ broader needs and providing support for these can further help to improve their adherence to treatment. Organisations such as The Psoriasis Association (<http://www.psoriasis-association.org.uk>) provide excellent additional support services for patients, together with practical advice for managing their condition from day to day.

Fig. 58.14 A young child with moderate-to-severe atopic eczema. (Courtesy of St John’s Institute of Dermatology, London.)

Case studies

Case 58.1

A 3-year-old child with known atopic eczema is seen in clinic with a widespread, excoriated, dry rash (Fig. 58.14). Her eczema symptoms started at the age of 6 weeks. Her sleep has always been poor because of the marked itch symptoms at night. She has had two recent courses of oral antibiotics for presumed bacterial skin infection. Her normal skin treatment involves hydrocortisone 1% ointment to affected areas twice daily. Her parents are concerned regarding the possible triggers of her eczema flares and are keen to pursue possible allergy testing.

Question

What advice could be given to the child’s parents?

Answer

Fig. 58.14 shows a young child with moderate-to-severe atopic eczema. Ill-defined, dry, erythematous patches of eczema are visible. A few of the patches around her ankles appear crusty and eroded. This may represent secondary infection.

Management should include regular topical emollient therapy, and the correct quantities should be emphasised. A regular soap substitute should be prescribed. The skin is excoriated and crusted, and so there may be secondary infection, most likely with *Staphylococcus aureus*. Therefore, when infection is present, wet wrap dressings are not appropriate because they may exacerbate this. Wound swabs should always be taken before prescribing an oral antibiotic for presumed infected eczema.

A moderately potent or potent topical corticosteroid ointment should be administered daily. When a moderately potent or potent topical corticosteroid is prescribed for a child, medical follow-up must be arranged to avoid potential local side effects such as skin atrophy. If the treatment is ineffective, a short admission to hospital or regular dermatology day care should be arranged for further intensive topical treatments or dressings. Time should be spent explaining to the parents the aetiology of atopic eczema. Although atopic eczema is considered a chronic disease with no 'cure', it should also be explained that approximately 60% of children will have minimal or no symptoms after the age of 16 years. Carers of children with atopic eczema commonly request allergy testing. Although allergies are more common in children with eczema, it is not always appropriate. Allergy testing may be indicated if there is a clear history of the hives (urticarial) or swelling (angioedema) after exposure to possible triggers or exacerbations of the eczema. However, triggers to eczema flares are often not allergens and may be environmental irritants, such as soaps, or other factors such as psychological stress. Allergy testing may involve blood tests (RAST tests), skin prick tests and patch testing. Such testing should be done in a specialist paediatric allergy centre because a positive result does not always directly correlate with the effect of allergen avoidance on the course of atopic eczema.

Case 58.2

A 22-year-old male nurse attends outpatients reporting dry, painful eczema affecting his hands. He had previously suffered with childhood eczema and asthma. Since starting his new job, his symptoms have developed, causing severe pain, fissures, itch and dry skin. His finger pulps are particularly affected. He attended occupational health and was then advised to see a dermatologist.

Question

What is the likely cause of his symptoms, and what advice should be given?

Answer

The aetiology of hand dermatitis is often complex and multifactorial. This man has an atopic predisposition, but this also puts him at greater risk of an ICD and/or ACD than the general population. The need for him to regularly wash his hands with soaps and/or antiseptic hand wash is likely to be a major factor.

This man should be advised to use an emollient soap substitute when washing his hands, and some products exist that also contain antiseptic agents, for example, Dermol 500. In addition, to treat the active dermatitis, a potent topical corticosteroid and emollient with a good barrier effect should be prescribed. For fissured areas, overnight application of adhesive tape that is impregnated with corticosteroid (Haelan tape) may also be beneficial for local therapy. Patch testing would also be appropriate to ascertain whether there is an allergic contact component to his symptoms.

Atopic eczema predisposes to contact dermatitis. Therefore, young adults with moderate or severe eczema should be made aware of this risk when they are considering certain occupations that are also associated with a higher risk of contact dermatitis, especially ICD. Such careers include hairdressing, domestic cleaning or working in a healthcare environment that requires regular hand washing.

Case 58.3

A 28-year-old male management executive with lifelong atopic eczema has attended clinic with worsening severity of his eczema.

Fig. 58.15 A young patient with eczema herpeticum. (Courtesy of St John's Institute of Dermatology, London.)

He has been using emollients and moderately potent topical corticosteroids for many years and feels that these are no longer effective. Over the past year, he has required two short courses of oral corticosteroids. His sleep is affected and he is concerned at how much time he is taking off work.

Question

What are the treatment options for this patient?

Answer

This patient needs a more effective treatment regimen. Although systemic corticosteroids are an effective short-term treatment for severe flares of eczema, they are not a long-term option. His topical regimen should be explored to ensure that it is optimal. His use of emollients and soap substitutes should be discussed, as well as the quantity and frequency of topical corticosteroids for regular eczema management. In addition, his aims, expectations and other medical issues should be explored with a view to possible systemic treatment.

Ciclosporin would be an appropriate first-line systemic agent, and pre-treatment screening should include blood pressure measurement, urinalysis and blood tests to assess renal function. Although ciclosporin has a more rapid effect than other systemic agents, treatment should be limited to less than 12 months because of the risk of the development of treatment-associated side effects. If longer-term systemic management is anticipated, or second-line agent required after ciclosporin, azathioprine or methotrexate would be potential options, but efficacy would only be evident after approximately 8 weeks of treatment.

Case 58.4

A 12-year-old boy with known atopic eczema presented with a vesicular, blistering eruption over his face and trunk (Fig. 58.15). His mother noticed the blisters 2 days ago and brought him to hospital as he has become systemically unwell and feverish. He has chronic atopic eczema that is usually well controlled with regular emollients and twice-weekly application of calcineurin inhibitors to troublesome sites. His sister has recently been suffering with cold sores.

Question

Fig. 58.15 shows the young patient with eczema herpeticum. What advice would you give this patient and his mother?

Answer

Eczema herpeticum, or Kaposi's varicelliform eruption, is an important and potentially serious complication in patients with atopic eczema and certain other chronic inflammatory skin conditions. This eruption occurs after inoculation of herpes simplex virus to skin damaged by eczema and can spread rapidly to affect the eyes and lungs. Typically, the tiny blisters (vesicles) have an umbilicated appearance and may also develop into 'punched-out' erosions that commonly have a golden crust, which is indicative of secondary staphylococcal infection ('impetiginisation').

Eczema herpeticum can progress rapidly, and therefore should be treated aggressively with systemic antiviral medications, such as aciclovir, and antibiotics, if there is concern of secondary bacterial infection. If the skin is dry or inflamed, aerosolised emollients, such as Emollin spray, can be used which also limit cutaneous spread of infection. Skin swabs should be done to confirm viral infection and test for bacterial antibiotic sensitivities. If systemically unwell, patients may require hospitalisation. If there is a concern that there may be eye involvement, urgent ophthalmological review is required to assess for herpetic corneal ulceration, which can lead to long-term visual complications.

Children with atopic eczema and their parents should be educated to recognise the signs and symptoms of eczema herpeticum.

Case 58.5

A 33-year-old electrician presents to clinic with a 5-month history of a mildly itchy eruption occurring around the nasal area and eyebrows (Fig. 58.16). He describes it as occasionally scaly and is very concerned regarding the cosmetic appearance. On examination, he also has mild scale and erythema affecting the scalp. The dandruff shampoos he usually purchases from his local community pharmacy have been ineffective.

Question

What would you offer as a topical treatment for facial seborrhoeic dermatitis?

Fig. 58.16 Man with seborrhoeic dermatitis. (Courtesy of St John's Institute of Dermatology, London.)

Answer

Ketoconazole shampoo and ketoconazole 2% cream will reduce the population of *Pityrosporum ovale* on the skin, which may improve the rash. If there is marked dermatitis and the area is symptomatic (itchy), a mild topical corticosteroid with or without an antifungal or a topical calcineurin inhibitor would be appropriate. In addition, patients should be counselled that seborrhoeic dermatitis is a common condition that is often chronic, so periodic exacerbations may occur.

Case 58.6

A 55-year-old woman presents with a history of long-standing chronic plaque psoriasis. Since the age of 16 she has used multiple topical treatments with repeated course of UVB phototherapy; however, more recently these have not managed her skin adequately. In addition, for the past 18 months she has developed painful swelling and stiffness over the proximal joints of both hands, which is much worse in the morning. NSAIDs have not alleviated her symptoms, and her function at work is now affected. On examination, she has moderate-to-severe psoriasis and evidence of proximal interphalangeal joint swelling (synovitis) with subtle deformity.

Question

What management options should be offered for this patient?

Answer

This woman has moderate-to-severe psoriasis with evidence of psoriatic arthropathy. Psoriatic arthropathy affects up to 30% of patients with psoriasis, which can manifest as a destructive arthritis leading to significant functional disability. In addition to regular NSAIDs and analgesics to improve symptomatic control, a systemic treatment should be considered, and this woman would optimally be jointly managed by a dermatologist and rheumatologist. Methotrexate is the gold standard systemic medication for both chronic plaque psoriasis and psoriatic arthritis. If methotrexate fails, there should be a low threshold for a biologic medication that would treat both the skin and joint disease, such as an anti-TNF- α agent (e.g. adalimumab) or anti-IL-17 agent (e.g. secukinumab). Systemic corticosteroids should be avoided as an arthritis treatment because there is a significant risk that upon their withdrawal the psoriasis flares and/or develops into a generalised pustular psoriasis.

Case 58.7

A 45-year-old man with psoriasis has been reporting an itchy, scaly scalp for the last 8 months. He has seen his primary care doctor who has prescribed a moderate-strength topical corticosteroid preparation, but this treatment has had little effect. He is troubled by thick scale and severe itch at night.

Question

What treatment options could be considered?

Answer

Treatment of scalp psoriasis often can be challenging and differs from other forms of psoriasis because of the presence of thick hair.

Topical treatments can be difficult and messy to apply, and phototherapy is not usually effective. Topical preparations should be used in conjunction with a method to reduce the scale, which will increase their efficacy. Oil-based emollients, such as coconut oil or Arachis oil (avoid if peanut allergic), or preparations that contain salicylic acid are effective at softening/lifting scale. These preparations should be left on for approximately 1 hour and then washed off. In addition to descaling the scalp, an anti-inflammatory agent is often required, such as coal tar-containing preparations or potent topical corticosteroids. Most topical preparations used to treat psoriasis on the body have equivalent scalp preparations, but these are often in a lotion or gel formulation to improve the ease with which they can be applied to the scalp. As with other body sites, intermittent rather than prolonged use of topical corticosteroids is advised. Education and support from specialist nurses are often invaluable in treating severe scalp psoriasis because many patients find treatment regimens complicated and time consuming.

Case 58.8

A 45-year-old man has become increasingly limited by his palmoplantar pustular psoriasis. He has had frequent crops of inflamed pustules on the palms and soles which dry up to form crusts and scaling followed by painful fissuring of the skin. He works as a joiner, and is finding this increasingly difficult, leading to prolonged periods off work. He has tried both regular emollients and intermittent topical corticosteroids, but with only temporary relief.

Question

What are the best options for the treatment of this patient?

Answer

This patient should be encouraged to continue using regular emollient therapy to the hands and feet, and soap substitutes to wash the affected areas. Topical corticosteroid therapy could be optimised by either using a very potent preparation (e.g. clobetasol propionate 0.05%) in an ointment vehicle, such as propylene glycol, or with salicylic acid. In addition, occluding the sites with either cotton garments or cling film can improve corticosteroid penetration into the skin, but this should be done under specialist supervision. Alternatively, a systemic therapy may be appropriate, of which either oral acitretin or ciclosporin is an effective therapy for palmopustular psoriasis. Both agents require blood test monitoring during the treatment period. If acitretin or ciclosporin cannot be used, localised hand and foot PUVA is an alternative, but this would require frequent attendance at a specialist centre. Smoking exacerbates palmoplantar psoriasis, and so patients should be advised to either avoid or stop smoking, with some evidence demonstrating that smoking cessation improves disease severity (Michaëlsson et al., 2006).

Case 58.9

A 24-year-old man presents at the clinic with a 10-year history of plaque psoriasis affecting his elbows, knees and sacral area,

with a few small plaques elsewhere. He is otherwise fit and well. He regularly plays football and is embarrassed by the appearance of his skin. He has tried Betnovate RD ointment (0.025%), which smoothed the plaques a little, and calcipotriol ointment, which removed the scale from the plaques but did not clear them.

Question

What treatment could this patient try next?

Answer

Because the patient has only a few localised plaques, topical therapy could be optimised. One option would be to use a more potent topical corticosteroid *in combination* with topical calcipotriol, for which some combined formulations exist (e.g. Dovobet). These are applied once daily to the affected areas until the plaques clear. Alternatively, if the patient is willing to attend his local dermatology department he could either have a course of short contact dithranol or tar therapy or narrow-band UVB phototherapy. Although effective skin-targeted therapy should induce a remission in mild-to-moderate disease, this may not be long lasting, and the patient should be counselled about potential future systemic medications.

Case 58.10

A 35-year-old male patient with chronic plaque psoriasis is being reviewed in the dermatology department. He has used multiple previous treatments, including topicals, UVB phototherapy, and ciclosporin. Most recently he has been established on methotrexate – initially orally for the first 4 months and then subcutaneous injections for the last 6 months. Despite this his psoriasis remains poorly controlled and his work and psychological well-being are suffering. He is otherwise well with no significant comorbidities. On examination he has severe plaque psoriasis affecting more than 40% of his body surface area. This is consistent with a PASI of 25 and DLQI of 13.

Question

What treatment options could now be offered?

Answer

This man fulfils the eligibility criteria for biologic therapy in the UK (Smith et al., 2009). He has 'severe disease', which is defined as having both a PASI and DLQI greater than 10. In addition, he has been unresponsive to standard systemic therapy, which includes methotrexate, the gold standard systemic therapy for chronic plaque psoriasis. Before initiating a biologic agent, pre-treatment screening for infection (including active or latent tuberculosis), heart failure, demyelinating disease and malignancy is required. Several different classes of biologic therapy are licensed to treat psoriasis in the UK, and agents that target either TNF- α (e.g. adalimumab) or IL-12/23 (e.g. ustekinumab) are used first line.

59 Wounds

Samantha Holloway and Keith Harding

Key points

- Acute wound healing should progress through an orderly sequence of events to re-establish tissue integrity.
- A functional blood vessel network is fundamental for wound healing.
- Changes occur in the repaired tissue for a year or more, with the scar tissue becoming stronger with time.
- A number of intrinsic and extrinsic factors can affect the healing process and include age, diabetes, infection, nutrition, smoking and drugs.
- Wounds are costly to treat, and therefore accurate assessment of a patient and his or her wound is important.
- Assessment should be part of an ongoing process, with opportunity for regular re-assessment.
- Acute wounds such as surgical incisions heal quickly with minimal complications; chronic (non-healing) wounds such as diabetic foot ulcers, leg ulcers and pressure ulcers take longer to heal.
- The management of patients with diabetic foot ulcers needs to include treatment of their diabetes, as well as local wound management and off-loading techniques to reduce foot pressures.
- Venous leg ulcers are the most common cause of ulceration in the population and require the external application of compression therapy (bandages and hosiery) to aid healing. These ulcers can be complicated by gravitational eczema; therefore, treatment of the surrounding skin is of equal importance.
- The majority of pressure ulcers are preventable. Management of patients requires a multidisciplinary approach with the use of pressure redistribution, support surfaces and repositioning as adjunctive measures to ensure appropriate care.

A wound can be thought of as any break in the integrity of the skin (Enoch and Leaper, 2005), although when this is due to minor trauma, it might be termed a cut or an abrasion. Such wounds tend to heal fairly quickly by the process of regeneration of tissue and cells and generally do not pose any long-term problems. However, the time it takes for a wound to heal will depend on a number of factors related to the nature of the wound, the individual and the environment. Many of these factors will be dealt with at different points throughout this chapter.

Structure of the skin

The skin is made up of the epidermis and dermis, below which is the sub-cutis, muscle and bone. Within the epidermis, there are four layers:

- stratum corneum,
- stratum granulosum,
- stratum spinosum,
- stratum basale.

Within the very thin structure of the epidermis, some of the key cells required for healing are present, in particular, keratinocytes, dendritic cells and melanocytes.

The dermis is separated into the papillary and reticular dermis and is thicker than the epidermis. It is joined to the epidermis by structures known as rete ridges or 'pegs'. In uninjured tissue, this arrangement helps the skin maintain its normal function, something which can be affected when a wound occurs or as an individual's skin changes with age. Like the epidermis, the dermis also contains many of the key cells/structures that are required for the normal healing response to occur; these include:

- fibroblasts for the production of collagen;
- endothelial cells to stimulate blood vessel growth;
- leucocytes such as lymphocytes, neutrophils and macrophages;
- smooth muscle cells;
- extracellular matrix.

The functions of the skin and the factors that affect skin condition are listed in [Table 59.1](#). How these roles link to wounds and wound healing will be explored in more detail later.

Wound healing

In adults, a scar is the normal end product of most injuries, with occasionally excessive scarring that is hypertrophic or keloid, complicating matters. However, wound healing can also be scarless, such as in fetal skin or the oral mucosa (Desai, 1997a; Wysocki, 2007). This type of healing presents an interesting concept and may offer some significant developments in the future. There are also many individuals for whom healing is delayed; such wounds are often referred to as 'chronic' or 'non-healing'. Other terminology is used in clinical practice to describe how wounds heal and includes:

- primary intention,
- delayed primary closure,
- secondary intention.

Table 59.1 Functions of the skin and factors affecting skin condition

Functions of the skin	Factors affecting skin condition
Protective covering	Dryness
Moisture retention	Age
Sensation	Environment
Regulation of body temperature	Nutrition
Release of waste	Hydration
Absorption of nutrients, i.e. vitamin D	

Essentially, healing by primary intention (Fig. 59.1) describes where the wound edges are apposed, that is, brought together by sutures, staples or glue, and wound healing occurs mainly by connective tissue formation. Delayed primary closure is used where there may be a risk of contamination or infection, such as if the patient has undergone emergency abdominal surgery. In this instance, some of the layers of tissue are stitched, and the sutures are placed in readiness for the remainder of the wound to be closed after 48 hours when the risk of infection is less. In contrast, healing by secondary intention (Fig. 59.2) describes a situation in which the wound is left open to heal by the laying down of granulation tissue and wound contraction. This type of healing is relevant to many of the types of wounds that will be discussed later.

Any injury to the skin will result in a sequence of events aimed at repairing the defect. Fig. 59.3 shows the process of wound healing, which is divided into four phases:

- haemostasis,
- inflammation,
- proliferation,
- remodelling or maturation.

An insult to the tissues causes a number of systemic processes to occur simultaneously. Platelets aggregate and adhere to the sub-endothelium; coagulation factors and growth factors are also released. Through changes in the platelet structure and function, thrombin and fibrin are released to aid clot formation and reduce excess blood loss. Once this has occurred, haemostasis is said to have been established. The initial fibrin matrix provides the scaffold for the subsequent structure. This process relies on the individual having a normal clotting response and may be affected by drugs or systemic disease.

After haemostasis, the inflammatory phase extends from day 0 through to about day 10 in normal healing and involves neutrophils (early inflammation) and macrophages (late inflammation). Neutrophils phagocytose bacteria and kill foreign bodies by producing oxygen metabolites such as hydroxyl radicals, hydrogen peroxide and superoxide ion. In normal healing, the numbers of neutrophils decrease in number over time leading to an increase in the number of macrophages present. The key function of macrophages is to digest bacteria, dead tissue and old neutrophils. There is some evidence to suggest that in wounds which are not healing, it may be the inflammatory phase and its related

**Fig. 59.1** Example of wound healing by primary intention.**Fig. 59.2** Example of wound healing by secondary intention. Wound bed shows healthy granulation tissue, and epithelial tissue can be seen at the wound edges.

cells that are at fault. The classic signs of inflammation are well reported and include:

- redness,
- swelling,
- heat,
- pain.

These signs are normal and should not be considered as indicating the presence of infection.

The proliferative phase begins approximately 1 day post-injury and should be resolving by about day 30. There are three main activities that occur during this time:

- granulation tissue formation, which requires new blood vessel formation (known as angiogenesis) and formation of collagen;
- contraction of the wound;
- epithelialisation.

The presence of a functional blood vessel network is fundamental for wound healing to progress. Angiogenesis, the formation of blood vessels, is required to supply oxygen to the wound environment, and it is through the migration of capillaries through the provisional matrix that the vasculature is re-established. Endothelial cells migrate and proliferate to eventually join the existing blood supply to the injured area. Once this has

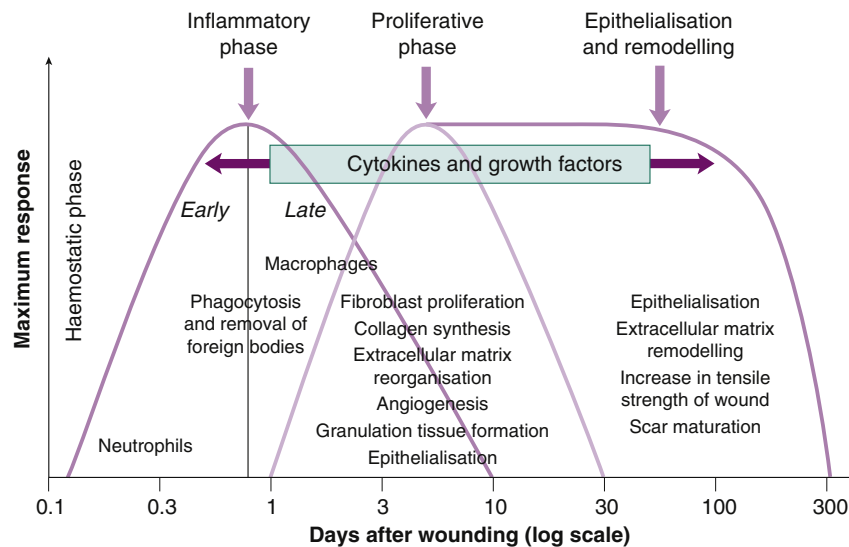

Fig. 59.3 Phases of wound healing. (From Enoch et al., 2008.)

occurred, granulation tissue can form to begin to repair the defect. The provisional tissue laid down (see Fig. 59.2) is made up of fibrin, fibronectin, collagen and glycosaminoglycans. Through the action of fibroblasts, collagen is produced, and the continued presence of macrophages ensures the wound is kept 'clean'. Collagen production is essential for healing to progress, and in particular, types I, III and IV are required.

In conjunction with the laying down of granulation tissue, the wound edges begin to contract at around day 8, and this process assists wound closure. The key cell involved is the myofibroblast, which applies tension to the surrounding matrix to induce contraction. The normal process of contraction should not be confused with contracture, which is an abnormal feature of scarring.

Around the same time, it may also be possible to see signs of epithelialisation occurring (see Fig. 59.2). Keratinocytes, the cell associated with this process, are initiated hours after injury; they migrate from the edge of a wound over the provisional matrix laid down, or they dissect through it. Hair follicles can act as islands of regenerating epithelium in some areas. During the proliferative phase the wound bed can be easily damaged by simple things, such as incorrect dressing choice, causing significant damage. Current clinical practice still reflects the original principles of moist wound healing proposed by Winter (1962) to support the normal physiological process of healing.

The final phase of the healing process is termed remodelling or maturation. During this time, the initial collagen that has been laid down is synthesised by enzymes, ultimately leading to a more ordered network that increases in structure and strength over time. However, this repaired area is never as strong as normal tissue and is always at risk of breakdown. These final changes can take place for up to a year or more after the initial injury.

Factors affecting wound healing

Generally, wound healing should progress as described previously; however, numerous factors that affect healing have been

Table 59.2 Intrinsic and extrinsic factors affecting wound healing

Intrinsic (systemic) factors	Local factors	Extrinsic factors
Age	Blood supply	Nutrition
Uraemia	Changes in oxygen tension	Smoking
Jaundice	Vessel trauma	Radiotherapy
Diabetes	Abnormal scarring	Infection
Anaemia	Haematoma	Drugs
Hormones	Local infection	Iatrogenic influences
Malignant disease		Wound dressings

identified (Grey and Harding, 2008). A summary of these is provided in Table 59.2, some of which include:

- age,
- diabetes,
- infection,
- nutrition,
- smoking,
- drugs.

Age

Younger patients appear to have an increased rate of healing, and there are differences in fetal healing that make the regeneration process superior, with little or no inflammation or scarring (Desai, 1997b). In comparison, wound repair in the elderly is slower (Ashcroft et al., 2002), and management may be more challenging because of concurrent disease processes. This is a particular problem in the proliferative

Fig. 59.4 Skin changes that occur with age.

Table 59.3 Complications of diabetes

Peripheral neuropathy	Causes damage to nerves that leads to a lack of the protective pain sensation, but the blood supply remains good. Very common and can lead to foot deformities and abnormal walking patterns. Neuropathy should be considered in terms of sensory, autonomic and motor changes. The foot is usually warm, numb and dry, with palpable foot pulses.
Peripheral arterial disease	Often develops as a result of atherosclerosis but develops at a faster rate in diabetic patients. Can affect the large (macro) and small (micro) vessels, leading to decreased blood flow to the legs and feet, which can ultimately lead to minor or major amputations. The foot is often cool and clammy, with absent or reduced foot pulses.
Neuro-ischaemia	A combination of peripheral neuropathy and peripheral arterial disease.
Infection	More common in diabetic patients, probably because they have an associated defective immunity. The neutrophil and lymphocyte response is slow (partly due to vascular problems); therefore, the inflammatory and subsequent phases are impaired. Hence, these patients have an increased tendency to develop infections.

and remodelling phases, where tissue appears to be more friable and fragile. The overall effects of age on wound healing appear to be:

- decreased inflammatory response,
- delayed angiogenesis,
- decreased collagen synthesis and degradation,
- slower epithelialisation.

There are also changes that affect the skin as we age, for example, the normal epidermal turnover rate is 28 days. This increases by 30–50% by the age of 80. Also, changes in the stratum corneum and reduced lipid content alter the barrier function, as does the slower turnover rate. Decreased amino acids also lead to a decrease in natural moisturising factors, meaning the skin is much more at risk of being dry. The collagen content of the skin decreases by 1% per year and becomes less soluble, and the process of new collagen formation is slowed. Furthermore, delayed angiogenesis leads to changes in the microvasculature and nerve function, leading to atrophic skin (Marcos-Garcés et al., 2014) (Fig. 59.4).

Diabetes

In individuals with diabetes, wound healing can be delayed, and management is often challenging because of concurrent peripheral diabetic neuropathy (PDN), peripheral arterial disease (PAD), neuro-ischaemia and infection (Table 59.3).

Infection

Bacterial invasion of wounds is very common. In fact, any break in the skin integrity places the wound at risk of local contamination or infection and if untreated can lead to systemic infection. The spectrum of infection from colonisation through to infection is demonstrated in Fig. 59.5. The difficulty may be in recognising when such circumstances are present. The normal inflammatory signs were discussed earlier, and these should be borne in mind when examining a patient's wound. However, there are additional local signs that may be present in wounds healing by primary or secondary intention (Fig. 59.6) that suggest an infective process. These include:

- increased pain;
- delayed wound healing;
- wound that bleeds easily;
- friable, fragile tissue;
- pocketing/bridging of tissue;
- wound breakdown (dehiscence).

Infection in a wound can often be diagnosed by clinical signs and symptoms alone, and unless a systemic infection is suspected, that is, the patient complains of flu-like symptoms, it can be treated locally with topical antimicrobial dressings rather than oral antibiotics.

Fig. 59.5 Schematic representation for the outcome of bacterial invasion.

Fig. 59.6 Infection in a granulating wound.

In recent years, there has been increased recognition that bacteria have the ability to build up colonies that present a challenge in terms of the management of bacterial load. Known as biofilms, they have the ability to resist removal and have been implicated in delayed healing of a number of wound types. The removal of dead tissue from the wound bed seems to have some effect in preventing the growth of biofilms (Wolcott and Rhoads, 2008); however, this method is not suitable for all wounds, so other approaches are being sought.

The choice of topical treatment for the management of local wound infection is dealt with in a later section.

Nutrition

The nutritional requirements for wound healing have been the subject of debate, with limited evidence as to the exact dietary components for individual wound types. In general, if the patient has a balanced diet, this should be sufficient for the normal processes to take place. However, a diet that is lacking in vital nutrients can lead to delayed wound healing and wound breakdown. In the extreme, the patient can become malnourished, with surgical patients most at risk of protein-energy malnutrition (PEM). Box 59.1 outlines the nutritional factors that should be considered in the assessment of individuals, many of which have been incorporated in nutritional risk assessment tools. Individuals who are most at risk of nutritional deficiencies are those affected by:

- ill health in old age,
- cancer,
- chronic neurological disease,

Box 59.1 Nutritional assessment and treatment options

General nutritional assessment to include
 Current appetite
 Food intake
 Patient's ability to eat/chew/swallow
 Presence of dentures

Specialist nutritional assessment
 Anthropometric measurements such as:
 Body mass index, % weight loss, haemoglobin, skinfold thickness, grip strength, serum albumin
 Gut function
 Total energy requirements

Nutrients required for healing
 Protein
 Zinc
 Copper
 Iron

Vitamins required for healing
 A
 B complex
 C
 E

Treatment options
 Modified normal diet: increase high-energy/high-protein foods
 Modified normal diet plus nutritional supplementation
 Total enteral support
 Naso-gastric feeding
 Total parenteral nutrition
 Percutaneous endoscopic gastrostomy

- chronic inflammatory bowel disease,
- surgery (pre- and postoperatively),
- stroke,
- acute and chronic pain,
- immunodeficiency disease such as HIV and AIDS.

One of the most commonly used tools to assess nutritional status in clinical practice is the Malnutrition Universal Screening Tool (MUST; British Association for Parenteral and Enteral Nutrition, 2015).

Smoking

Smoking is known to be detrimental to health generally, and in addition, the effect of nicotine and carbon monoxide on skin and muscles is well documented (Ortiz and Grando, 2012). These substances reduce the oxygen levels in the tissues and can lead to

Fig. 59.7 Perianal ulceration associated with administration of nicorandil.

the formation of thrombi. A good blood supply and adequate vascularisation are important for normal wound healing. There has been debate about the period of time patients should abstain from smoking to reduce relevant potential complications. This has been suggested to vary from 4 (Sorensen et al., 2003) to 8 weeks (Møller et al., 2002). There is emerging evidence to suggest that offering nicotine replacement to reduce the risk of postoperative complications along with smoking cessation counselling can be helpful (Thomsen et al., 2014).

Drugs

There are certain drugs that are suggested to have an effect on the healing process. These include non-steroidal anti-inflammatory drugs (NSAIDs), corticosteroids and immunosuppressive agents (Grey and Harding, 2008), which affect the inflammatory response, collagen synthesis and mitosis, respectively. Whilst drugs do not generally cause wounds, there have been recent reports that nicorandil (used for the treatment of angina) may cause peri-anal wounds (Fig. 59.7) that resolve on cessation of the medication (Ferner, 2016).

Wound assessment

Wounds are costly to treat (Phillips et al., 2016); therefore, it is important to appreciate the various considerations that need to be taken into account when assessing a patient. Assessment should not be viewed as a one-off occurrence but instead should be undertaken as part of an ongoing process with the emphasis on the patient, not just his or her wound.

A structured approach to the assessment of a patient with a wound is required. The six key elements of the original wound healing matrix are as follows, and the key concepts are depicted in Fig. 59.8:

- Phase of wound healing
- Aetiology:
 - acute, for example, surgical, trauma, burn injuries;
 - chronic, for example, leg ulcers, diabetic foot ulcers, pressure ulcers.

Fig. 59.8 Assessment of a patient with a wound.

- Clinical manifestation:
 - size;
 - shape;
 - characteristics, that is, exudate, odour, tissue type.
- Environment and care:
 - primary care;
 - secondary care.
- Healthcare system and resources
- Site of the wound

Diabetic foot ulcers

Epidemiology

According to estimated figures, in 2014 the number of individuals diagnosed with diabetes in the UK increased to more than 3.2 million (Diabetes UK, 2014). The cost of treating individuals with diabetes accounts for at least 9% of the acute healthcare costs in the UK. These costs, however, do not take into account the personal cost to the individual, such as a reduction in the ability to work and the time he or she may need to take off work (Waters and Holloway, 2009). Diabetic foot problems are the most common cause for admission, and patients admitted to hospital for in-patient care are often hospitalised for 4–6 weeks, which obviously increases the financial costs considerably.

One of the major risks to patients with diabetic foot disease is that of amputation, which could be minor, that is mid-foot to toe, or major, that is mid-foot and above (Holman et al., 2012). The National Service Frameworks for diabetes introduced by the Department of Health (DH) in 2001 and 2007 sought to address this (DH, 2001, 2007a, 2007b). Of concern is that up to 85% of amputations are preceded by foot ulcers. Therefore, if the incidence of foot ulcers can be reduced, this might lead to a reduction in amputations.

Aetiology

Individuals with diabetes are at risk of a number of systemic complications (see Chapter 45).

Table 59.4 Clinical features of a diabetic foot with neuropathy or arterial disease

Characteristic	Peripheral neuropathy	Peripheral arterial disease
Temperature	Warm	Cool
Foot pulse	Present/'bounding'	Absent/reduced
Pain	Commonly no pain ^a	Pain on walking (intermittent claudication) Depends on degree of neuropathy
Site of ulcers	Toes and metatarsal heads	Lateral (outer) border of foot
Callus (hard skin)	Present	Absent

^aPainful peripheral neuropathy is a rare but potential feature.

There are two main causes of foot ulceration in patients with diabetes:

- peripheral diabetic neuropathy (PDN),
- peripheral arterial disease (PAD).

PDN causes damage to the nerves that leads to a lack of the protective pain sensation and is present in 75% of patients with diabetes. In this group of individuals, the blood supply to the extremities remains good, but the foot becomes insensate and can subsequently become deformed. This leads to an abnormal walking pattern and potentially tissue breakdown from abnormal pressures placed upon the foot. The characteristics of the diabetic foot are set out in [Table 59.4](#). Unfortunately, the early systemic changes associated with the onset of diabetes may be present for up to 12 years before a diagnosis is made, by which time damage has already begun to occur and is often irreversible.

Neuropathy can be related to lack of sensation (sensory neuropathy) and may also cause atrophy and weakness of muscles in the foot (motor neuropathy). In addition, there are effects on the autonomic nervous system which can cause changes in blood flow and sweat secretion (autonomic neuropathy). Each of these elements needs to be considered as each has significant effects on the lower limb in individuals with diabetes.

PAD usually occurs as a result of atherosclerosis. This often results in a reduction in blood flow to the lower limbs and pain on walking (claudication), pain at rest with possible progression to gangrene and amputation. PAD is common in the elderly and is not just a complication of diabetes, although people who have diabetes are at an increased risk of developing it. Foot ulceration due to PAD is less common, accounting for approximately 5% of cases.

Clinical signs

The clinical features of a diabetic foot with PDN and PAD are summarised in [Table 59.4](#), and their typical presentations are shown in [Figs. 59.9 and 59.10](#), respectively. There are a number of factors that place patients at increased risk of ulceration,

Fig. 59.9 Diabetic foot ulcer caused by peripheral neuropathy.

Fig. 59.10 Peripheral arterial disease in a patient with diabetes.

including foot deformity; ill-fitting footwear; mechanical injury, for example, treading on a sharp object; thermal injury, for example, heat from a fire, or stepping into a hot bath; and chemical trauma, typically caused by an over-the-counter preparation purchased to remove hard skin. National guidelines outline the processes that should be in place to ensure the monitoring of patients deemed at risk ([National Institute of Health and Care Excellence \[NICE\], 2015a, 2015b](#)). One of the key issues to consider is that the feet of patients with diabetes do not ulcerate spontaneously; instead, any one, or a combination, of the factors discussed could be the cause.

Diagnosis

Initial assessment should include a clinical examination of the foot and may also require objective testing, for example, an

Table 59.5 Examination of the diabetic foot

Clinical examination		Objective test
Shape and deformities	Toe deformities Foot deformities Callus	X-ray
Sensory function	Vibration Protective sensation	Biothesiometry Semmes–Weinstein filament
Motor function	Wasting Weakness Ankle reflexes	Electrophysiological tests
Autonomic function	Reduced sweating Callus Warmth Appearance of veins on the foot	Quantitative sweat test
Vascular status	Foot pulses Temperature Swelling	Non-invasive Doppler studies, ankle brachial pressure index and/or toe pressure indices

X-ray. The key features of this examination are set out in [Table 59.5](#). In addition, further tests such as a full blood count, examination of urine, alternate imaging methods, magnetic resonance imaging, colour duplex scans and angiograms, may be indicated.

Infection in the diabetic foot is a real risk and a common complication. It has been estimated that 20–50% of diabetic ulcers are infected. The severity of the infection will depend on the nature of the bacteria, but commonly cellulitis and osteomyelitis occur in patients with neuropathic ulcers with gangrene being more associated with PAD. Bacterial cultures from ulcers are usually polymicrobial with both Gram-positive and Gram-negative organisms, as well as anaerobic bacteria. There should be concern if any of the following features occur:

- difficulty walking and/or applying shoes;
- swelling in part or all of the foot;
- redness or other discolouration;
- foot becomes hotter than normal;
- discharge or unusual odour;
- open sores or blisters;
- nausea, vomiting or high temperature;
- difficulty maintaining blood glucose control.

Treatment

Infection

The signs of infection are often delayed or insidious in patients with diabetes. Virtually all diabetic foot infections require antimicrobial therapy, but this alone is rarely sufficient. If soft-tissue infection is superficial, then oral, relatively narrow-spectrum

antibiotics for 1–2 weeks are indicated for mild infections and 2–3 weeks for moderate to severe infections ([Lipsky et al., 2012](#)); however, if there is cellulitis and spreading infection, parenteral antibiotic therapy may be required for up to 4 weeks. In addition to antibiotics, the patient may require hospitalisation if removal of dead tissue (debridement) is required. An X-ray of the foot may also be advisable if the tissue loss is over the bone, and referral to a vascular or orthopaedic specialist may be necessary for surgery.

Other considerations

Treatment of a diabetic foot ulcer should also include:

- podiatry,
- skin and wound care,
- provision of footwear to remove/redistribute weight,
- offloading options to include orthoses/custom-made insoles,
- patient education,
- pain relief,
- control of diabetes,
- multidisciplinary team approach.

The range of treatment options will be determined by whether there is neuropathy and/or PAD present, as well as the presence of ulcers and/or infection. The debridement of callus and dead tissue is essential because it enables the true dimensions of the ulcer to be established ([Edmonds and Foster, 2000](#)). Dressings are important but should not be viewed in isolation from the other essential aspects of treatment listed previously. Key aspects in the choice of dressing for diabetic foot ulcers are how it will perform in a shoe, whether it will withstand pressure and shear forces, how well it will absorb any fluid from the wound, how often the dressing needs to be changed and the cost effectiveness of the dressing.

Prevention of recurrence

Many of the considerations discussed previously are also important in terms of preventing a recurrence of ulceration and should be borne in mind when planning the management of individuals with diabetes. Ideally, ulceration should be prevented via intensive screening programmes, although unfortunately, this is not always achievable. In addition, the maintenance of tight control over blood glucose and blood pressure is required. Guidelines ([NICE, 2015a, 2015b](#)) recommend the following:

- blood pressure $\leq 140/80$ mmHg or $\leq 130/80$ mmHg if there is kidney, eye or cerebrovascular damage;
- blood glucose 48 mmol/mol (6.5%) or 53 mmol/mol (7%) for adults on a drug associated with hypoglycaemia.

Leg ulcers

Epidemiology

The prevalence of leg ulcers in the Western world is 0.11–0.18% ([Briggs and Closs, 2003](#)). There is a preponderance of 2.8:1 female to male ratio, with venous disease being the main cause of ulceration. The risk of leg ulceration increases with age.

The estimated cost in the UK of all leg ulcers is between £200 million and £600 million, with the costs of individual ulcer treatment between £557 and £1366 over a year (Tennvall and Hjelmgren, 2005). Between 60% and 90% of patients are managed in the community.

Aetiology

Leg ulcers can be classified as follows:

- venous;
- arterial;
- mixed, that is ulcers that have a venous and arterial component;
- diabetic, typically on the foot, rather than the leg;
- autoimmune, for example, rheumatoid arthritis.

Venous ulcers

Ulcers of venous origin account for the majority of all leg ulcers. There are a number of reasons why they occur, including failure of the calf muscle pump to work effectively, which leads to pooling of fluid in the lower limb and oedema. This can lead to high pressures in the lower limb on walking, known as venous hypertension. This swelling can lead to poor oxygenation of the tissues and trapping of harmful substances such as growth factors and enzymes. Ultimately, this can lead to tissue breakdown precipitated by simple trauma such as knocking the leg.

The calf muscle pump relies on an adequate level of mobility; therefore, anything that might affect this, such as increasing age, obesity and trauma, predisposes the individual to a sequence of events if the individual also has poor venous return.

Risk factors associated with the development of venous ulcers include deep vein thrombosis (DVT), varicose veins, and surgery/trauma to the leg.

Clinical signs

Venous disease. As a result of venous hypertension and leakage of fluid, red blood cells are deposited in the tissues, causing discolouration known as haemosiderin. This can often be seen on the lower limb and may be red or brown in colour. Varicose veins may also be visible as will oedema (swelling) and a characteristic change known as lipodermatosclerosis (LDS). Over time, the limb may develop a typical inverted 'champagne bottle' appearance. Venous ulcers are typically shallow and develop in the gaiter area (Fig. 59.11). Patients may also have associated gravitational eczema.

Diagnosis

The key element is the accuracy of the assessment, which should include:

- clinical history,
- clinical investigation,
- assessment of the limb,
- assessment of the ulcer.

Table 59.6 summarises the key aspects of the assessment of an individual with a leg ulcer.

Fig. 59.11 Venous leg ulceration.

Assessment of ankle brachial pressure index (ABPI). The use of a hand-held Doppler device is used to assess the arterial blood flow. Ideally, this test should be undertaken on any patient presenting with a leg ulcer. Furthermore, it should be carried out on first presentation and at subsequent intervals depending on whether the ulcer is improving or not. Essentially, the ABPI compares the patient's brachial (arm) and ankle systolic pressures:

$$\text{ABPI} = \frac{\text{highest ankle systolic pressure}}{\text{highest brachial systolic pressure}}$$

The patient should rest for 20 minutes before the assessment, and the pressures should be measured supine (lying down). Two measurements should be taken from the foot and the highest value used in the calculation.

The ABPI is not a definitive measure of arterial status but merely serves as an indicator of blood flow. Other clinical signs and symptoms such as the colour and temperature of the limb, the presence/absence of pulses and pain also need to be taken into account.

As a general principle, the ABPI or ratio should be ≥ 1.0 in individuals with no arterial disease (Al-Qaisi et al., 2009) (Table 59.7). However, this should not be relied upon in the presence of diabetes because calcification of arteries can occur and lead to falsely high ABPI readings. In this instance, a Duplex scan would be a more reliable indicator of vascular status. Furthermore, both hypo- and hypertension can affect the readings.

Treatment

The mainstay of treatment for confirmed venous ulceration is compression therapy (bandages and hosiery). Known as graduated compression, specific bandage systems are used to apply external pressure to aid venous return. The ABPI must be ≥ 0.9 for this treatment to be used. Although there is much debate about which bandage system is preferable, the choice should be based on an individual patient assessment and may include (Wounds International, 2013):

- bandage components or layers wrapped around the leg (either full leg or below knee),
- compression hosiery (e.g. compression stockings).

Table 59.6 Factors to be taken into account in the assessment of an individual with a leg ulcer

Clinical history	Clinical investigations	Assessment of both limbs	Assessment of the ulcer
Family history	Blood pressure	Oedema	Year first ulcer occurred
Varicose veins	Ankle brachial pressure index	Site of ulcer	Site of ulcer/previous ulcers
Deep vein thrombosis/pulmonary embolus	Full blood count	Depth of wound	Size of ulcer(s)
Phlebitis		Appearance of wound bed	Number of previous episodes
Surgery or fracture of the leg		Surrounding skin	Time free of ulcers
Heart disease/stroke		Perfusion of feet	Past treatment (successful or not)
Diabetes		Presence of pulses	Previous/current uses of compression bandaging
Peripheral arterial disease		Ankle brachial pressure index	
Chest pain/angina			
Smoker			
Rheumatoid arthritis			
Medication			
Allergies			

Table 59.7 Ankle brachial pressure index or ratio (Andriessen et al., 2017)

ABPI ^a	Arterial status	Compression therapy
>1.3	Is usually indicative of non-compressible blood vessels	
>1.00–1.3	Considered to be normal	Indicated
= 0.8–1.0	Mild peripheral disease	Use with caution
≤0.8–0.6	Significant arterial disease	Modified compression may be used with caution – specialist referral required
<0.5	Critical ischaemia may be associated with rest pain, ischaemic ulceration or gangrene	Compression contraindicated. Urgent referral to a vascular specialist required

^aABPI, Ankle brachial pressure index – should be used in conjunction with a comprehensive clinical assessment.

The aim of most systems is to create pressures of 40 mmHg at the ankle decreasing up to the knee to assist in venous return. In addition to bandaging, the patient should be encouraged to keep mobile, which could be as simple as undertaking ankle exercises to improve blood flow. Leg elevation and rest should also form part of overall management.

Even where arterial disease has been excluded as a complication, the patient should be monitored carefully for signs of compromised blood flow because serious injury, such as skin necrosis, can occur. This is a potentially serious complication that in the extreme can lead to significant circulatory compromise and amputation.

Other treatment options may include antibiotics if systemic infection is suspected or topical antimicrobial dressings for local infection, which include iodine- or silver-based products.

Intermittent pneumatic compression, surgery, skin grafting, bioengineered skin and pharmacological treatments such as oxpentifylline have all been suggested as adjuvant therapies to compression therapy (Scottish Intercollegiate Guideline Network, 2010).

General wound care should include cleansing of the ulcerated area with saline or tap water to maintain cleanliness and hygiene, as well as debridement of any dead tissue. Dressings should be simple and as low adherent as possible because they have to perform well under the compression system chosen. There is a need to be aware of the potential of contact sensitivity to the dressings, bandages or skin treatments used.

Gravitational eczema is commonplace in patients with venous disease and is related to the changes caused by venous hypertension (Fig. 59.12). The patient may complain of intense itching, and scratch marks may be visible on examination. It is important to distinguish eczema from contact sensitivity and cellulitis because each of these requires a different treatment. Treatment of eczema will include a combination of a topical corticosteroid

Fig. 59.12 Venous leg ulceration and gravitational eczema.

such as clobetasone butyrate (Eumovate) or mometasone furoate (Elocon) ointments and emollients such as Epaderm or similar mixtures of soft white paraffin and liquid paraffin to manage this inflammatory condition.

Prevention of recurrence

Once a venous ulcer is healed, compression hosiery (in the form of stockings) is required. This hosiery is classed as 1, 2 or 3 depending on the level of pressure applied. Class 3 stockings and tights provide strong support (25–35 mmHg at the ankle) and are the preferred choice to prevent recurrence of venous ulcers. [Table 59.8](#) provides the compression values for hosiery. Ideally, they will need to be worn for life or at least a minimum of 5 years. Unfortunately, recurrence is common, often because of the inconvenience associated with the wearing of stockings. Patient education and follow-up are essential. Community leg ulcer clinics have been established in many areas of the UK and have shown to be effective in supporting patients ([Lindsay, 2013](#)).

Arterial ulcers

Arterial ulceration is commonly associated with atherosclerosis and peripheral arterial occlusive disease (PAOD), much of which has been discussed previously in relation to diabetic foot disease. Both macro-disease (large vessel) and micro-disease (small vessel) may be present.

Clinical signs

The classic clinical features of arterial insufficiency are:

- intermittent claudication/rest pain;
- colour changes, for example, pallor;
- muscle atrophy/weakness;
- poor perfusion, for example, cool limb;
- loss of skin hair;
- thickening/hardening of the nails;
- ulceration;
- gangrene.

Arterial ulcers often appear ‘punched out’ ([Fig. 59.13](#)) and have a pale wound bed. The significant feature is pain, with many patients reporting pain on walking known as intermittent

Table 59.8 British National Formulary compression values for hosiery

Compression class	Level of support	Compression hosiery (British Standard)
Class 1	Light	14–17 mmHg ^a
Class 2	Medium	18–24 mmHg ^a
Class 3	Strong	25–35 mmHg ^a

^aCompression provided at the ankle.

Fig. 59.13 Arterial leg ulceration.

claudication. As the disease progresses, patients may also report that their pain is worse at rest, particularly when their legs are elevated. This feature affects their ability to sleep, eat and keep mobile, which can ultimately mean they are unable to leave the house.

Diagnosis

A simple test known as Buerger’s test (see Glossary) is normally used to look for positive signs of disease. If it is possible, a Doppler test should also be undertaken to calculate the patient’s ABPI. Typically, an ABPI of 0.5–0.8 indicates a moderate degree of arterial disease, whereas a value of ≤ 0.5 is considered to be indicative of severe disease ([Al-Qaisi et al., 2009](#)). In addition, a colour Duplex scan is usually required to ascertain the extent of the disease. If treatment is required, angiography will usually be undertaken to examine the affected vessels.

Treatment

An angioplasty may be carried out to improve the blood supply. Where this is not possible, vascular reconstruction may be advised to try and prevent further progression. Treatment should also include pain relief, prevention of infection and nutritional support. In addition, smoking cessation advice may be needed as might pharmaceutical intervention for cholesterol or lipid-lowering purposes.

Table 59.9 Incidence of pressure ulcers in UK (Clark et al., 2004)

	Grade ^a distribution	Annual incidence
Grade I	34.9%	140,000
Grade II	41.2%	170,000
Grade III	12.9%	50,000
Grade IV	11.0%	50,000

^aGrade is the same as category/stage in the new NPUAP et al. (2014) guidelines.

Prevention of recurrence

The main risk of individuals with arterial disease is amputation (minor or major). The patient plays a key role in prevention because many of the predisposing factors are lifestyle issues such as giving up smoking, eating a healthy diet and exercise.

Mixed ulcers

Although the term ‘mixed ulceration’ is used in clinical practice to describe ulcers with an element of venous and arterial disease, technically, it is not a diagnosis. Patients present with symptoms of venous and arterial disease, for example, skin discoloration and skin changes, as well as intermittent claudication. The ABPI is likely to be between 0.6 and 0.8. Treatment is directed at the symptoms causing the most concern, with compression therapy only used under very close supervision. The management options are as discussed previously for venous and arterial ulcers, with the degree of arterial compromise being the most significant factor determining management.

Pressure ulcers

Epidemiology

Previously referred to as ‘bed sores’ or ‘pressure sores’, this wound type is now generally referred to as a pressure ulcer (National Pressure Ulcer Advisory Panel [NPUAP] et al., 2014) and defined as follows:

A pressure ulcer is localized injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear. A number of contributing or confounding factors are also associated with pressure ulcers; the significance of these factors is yet to be elucidated.

(NPUAP et al., 2014, p. 12)

The prevalence of pressure ulcers across five European countries was previously estimated at 18.1% (Clark et al., 2004). There is no national method for collecting data on the occurrence of pressure ulcers; however, Table 59.9 provides a summary of the most recent data on incidence (Clark et al., 2004).

Fig. 59.14 Effect of external pressure on the capillaries.

Common sites of pressure ulcers

Pressure ulcer damage can occur anywhere on the body but is most common over bony prominences, including:

- sacrum,
- heels,
- buttock,
- trochanter.

Sacral damage often occurs from the patient slipping down the bed or whilst sitting in a chair, with shear forces causing the most damage. Injury to other areas is more likely to be due to direct pressure over a bony prominence. In acutely ill patients, medical devices and equipment such as nasal cannula can even cause pressure damage to the nose.

Aetiology

As the name implies, this sort of wound is caused by external pressure on the tissues, which, if sustained, leads to decreased capillary flow, ischaemia and capillary thrombosis. In turn, fluid escapes from the vasculature into the surrounding tissues causing oedema, accumulation of metabolic waste and cell death (Fig. 59.14).

There are different types of pressure that may be implicated in the onset of damage, and it is both the type and duration of pressure that is of importance. The types of pressure are listed as follows:

- capillary closing pressure,
- vertical pressure,
- tissue interface pressure,
- shear and friction forces.

In addition to pressure, other factors that may influence the development of the damage include:

- reactive hyperaemia,
- reperfusion injury,
- patient age: extremes of age most at risk,
- nutritional status: extremes of weight most at risk,
- mobility status,
- condition of peripheral circulation,
- continence status.

Clinical signs

Early signs of damage may present as a red area on the skin that remains even after the pressure has been relieved (referred to as

non-blanching erythema), or damage may present as broken skin or an abrasion. Pressure ulcers are now classified using six categories or stages based on the *NPUAP et al. (2014)* guidelines, as described in the following sections.

Category/stage I: non-blanchable erythema

These pressure ulcers have intact skin with non-blanchable redness of a localised area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area.

The area may be painful, firm, soft and warmer or cooler compared with adjacent tissue. Category/stage I may be difficult to detect in individuals with dark skin tones. This may indicate ‘at-risk’ individuals (a heralding sign of risk).

Category/stage II: partial skin loss

These pressure ulcers have partial-thickness loss of dermis presenting as a shallow open ulcer with a red–pink wound bed, without slough. This may also present as an intact or open/ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising. Bruising indicates suspected deep tissue injury. This category/stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration or excoriation.

Category/stage III: full-thickness skin loss

These pressure ulcers have full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. This may include undermining and tunnelling. The depth of a category/stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have subcutaneous tissue, and category/stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep category/stage III pressure ulcers. Bone/tendon is not visible or directly palpable.

Category/stage IV: full-thickness tissue loss

These pressure ulcers have full-thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present on some parts of the wound bed. The wound often includes undermining and tunnelling. The depth of a category/stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have subcutaneous tissue, and these ulcers can be shallow. Category/stage IV ulcers can extend into muscle and/or supporting structures (e.g. fascia, tendon or joint capsule), making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.

Unstageable: depth unknown

These pressure ulcers have full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green or brown) and/or eschar (tan, brown or black) in the wound bed. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore category/stage, cannot be determined. Stable (dry, adherent, intact without erythema

Fig. 59.15 Category III pressure ulcer showing presence of undermining.

or fluctuance) eschar on the heels serves as ‘the body’s natural (biological) cover’ and should not be removed.

Suspected deep tissue injury: depth unknown

These pressure ulcers have a purple or maroon localised area of discoloured intact skin or blood-filled blister due to damage of the underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy and warmer or cooler compared with adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid exposing additional layers of tissue even with optimal treatment.

Diagnosis

Pressure ulcers are usually diagnosed on clinical appearance and presenting history. Using the classification system outlined previously, it is also possible to determine the severity of the ulcer.

X-rays of the ulcer may be required, especially if it is over a bony area, to exclude any underlying infection in the bone (osteomyelitis). In addition, blood tests to examine inflammatory markers, such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), may also be useful in determining the presence of infection.

If undermining or tunnelling is present (**Fig. 59.15**), further ultrasound scans may be required to examine the full extent of the wound and to identify any collection of fluid.

Treatment

The care of patients with pressure ulcers will depend on the severity of the damage, but there are interventions common to all patients, and these include (*NPUAP et al., 2014*):

- nutrition,
- repositioning and early mobilisation,
- support surfaces,
- classification of pressure ulcers,
- assessment of pressure ulcers and monitoring of healing,
- pain assessment and treatment,
- wound care: cleansing,

- wound care: debridement,
- assessment and treatment of infection and biofilms,
- wound dressings,
- growth factors,
- biophysical agents,
- surgery.

Prevention of pressure ulcers

The majority of pressure ulcers are preventable. Important considerations in terms of prevention include:

- patient repositioning,
- use of equipment,
- skin care,
- nutritional support.

An individual's potential risk of developing damage should be assessed with a view to identifying those that are vulnerable. Once an individual is deemed to be at risk of skin breakdown, the aim should be to improve tissue tolerance, which can be achieved using the elements described previously.

Assessment of the tissue type should include examination of the following:

- dead tissue, that is, slough (yellow or grey), necrosis (black);
- infected tissue (bright red, bleeds easily, green discoloration);
- granulating, that is, presence of pink tissue in the wound bed;
- epithelial tissue, that is, pink, silvery tissue at the edges of a wound.

Once this information has been established, the selection of a dressing will depend on:

- treatment objective,
- stage of healing,
- tissue type,
- site and size of the wound,
- frequency of the dressing change,
- comfort/cosmetic appearance,
- where/by whom the dressing is to be changed,
- if the dressing is available.

Box 59.2 lists the main types of dressings available. Dressings alone will not heal a wound, and other aspects of care may need to be taken into account, including:

Principles of wound management

There are a number of principles to wound management, including:

- knowledge of wound healing physiology,
- assessment of the patient,
- assessment of the wound/ulcer,
- assessment of the tissue type,
- recognition of factors affecting healing,
- knowledge of dressings available,
- availability of resources.

The healthcare professional needs to be clear about the aim of management, and the expected outcome before the most appropriate treatment can be selected. Table 59.10 outlines the main considerations to be taken into account. Whilst wound healing is often viewed as the eventual outcome, in some instances this may not be feasible; therefore, alternative aims should be identified to demonstrate success.

Table 59.10 Criteria to consider in choosing appropriate wound management

Aim	Criteria
Protect from	Drying out Infection Further damage
Debride using	Autolytic methods Mechanically Sharp/surgical
Control	Larvae Bleeding Exudate Pain Odour

Box 59.2 Wound management products

Basic wound contact dressings, that is, knitted viscose/polymer dressings

Low-adherence dressings – indicated for clean granulating wounds with a light amount of exudate. Note: Dressing may stick, so be cautious of trauma on removal

Absorbent dressings – are also low adherence and suitable for mild and moderate (but not viscous) exudate

Advanced wound dressings

Hydrogel – generally donates liquid to aid autolytic debridement of sloughy, necrotic wounds. Available in amorphous or sheet form depending on the size and shape of the wound. Choice will depend on the amount of exudate present.

Vapour permeable films and membranes – also allow the passage of water vapour and oxygen but remain impermeable to water and bacteria. They allow viewing of the wound and are flexible and conform to awkward wound shapes. Mainly suitable for partial-thickness wounds and formulated with and without an absorbent pad for exudate management. Use would be avoided in infected and highly exuding wounds.

Soft polymer – often with added silicone. Designed to be non-adherent and are useful if the skin/wound is fragile and where further damage is to be avoided. They can be used on wounds that have light to moderate exudate but may require a secondary absorbent dressing if large amounts of exudate are present.

Hydrocolloids – semi-permeable to water vapour and oxygen and to gel in the presence of exudate. Promote autolytic debridement and are also useful on granulating wounds because they can be left in place for a number of days. Generally, these dressings are indicated for moderate to heavy exudate; careful monitoring for maceration of the wound edges and surrounding skin would be important.

Foam – suitable for most types of wounds but requires a moist wound interface. Can absorb various levels of exudate, with some having better fluid-handling capacity than others. Presented in adhesive and non-adhesive forms, the choice of which is often based on the integrity of the patient's surrounding skin.

Box 59.2 Wound management products—cont'd

Alginate – usually fibrous dressings, made from seaweed; some have haemostatic properties. Require moisture so are not suitable for dry wounds. They are suitable for exuding wounds and can aid autolytic debridement. Available as packing material (ropes) or flat sheets, the choice of which depends on the size and shape of the wound. May require a secondary dressing to hold in place.

Capillary action – contraindicated in bleeding wounds but useful for exuding wounds, particularly when slough is present. Absorbent core absorbs and contains the exudate, which minimises the risk of maceration. A secondary dressing is also required.

Odour absorbent – utilise activated charcoal to absorb odour from wounds. Some require a suitable primary contact layer, whereas others are layered and provide a non-adherent wound contact interface. The cause of the odour should always be established because underlying infection may require additional treatment.

Antimicrobial – used to treat local rather than spreading or systemic infection. Can be used to reduce the levels of bacteria in the wound. The amount of exudate should be a consideration when choosing an antimicrobial dressing.

Honey – medical honey is anti-inflammatory as well as antimicrobial and can aid with debridement of the wound and combating odour. Caution should be exercised in diabetic patients and its use should be avoided if a patient is allergic to bees/bee stings.

Iodine – available as povidone-iodine or cadexomer-iodine, preparations are useful in clinically infected wounds. Iodine is effective against a wide range of bacteria, but its effect can be diluted if large amounts of exudate are present. Cadexomer-iodine is effective at debriding wounds. Iodine can cause sensitivity, and systemic absorption can occur, especially from large wounds or prolonged use.

Silver – used when infection is suspected. Available in different presentations and can be used on all wound types that have clinical signs of infection and where exudate is present. Skin discoloration and systemic absorption can occur; therefore, use is contraindicated in pregnancy and neonates.

Other antimicrobials – including preparations such as chlorohexidine, Flaminal and Prontosan.

Specialised dressings

Protease-modulating matrix – acts on the proteolytic enzymes in chronic wounds and re-establishes normal enzymatic activity. Can be used on non-healing wounds that do not seem to be progressing.

Silicone keloid dressings – used to reduce hypertrophic and keloid scarring and therefore are not appropriate for open wounds. A staged approach to application is advised, with increasing wear time being indicated. Dressings can be washed and re-used.

Adjunct dressings and appliances

Surgical absorbents – useful as secondary layer over a primary wound contact layer. Absorb exudate but allow leakage of exudate ('strike-through'). Can adhere to the wound bed, and fibres may be shed; therefore, should be used cautiously.

Wound drainage pouches – use when other exudate-absorbing dressings are not sufficient to manage the fluid levels; wound drainage bags may be useful as a means of containing the leakage.

Physical debridement pads – used for the debridement of superficial wounds containing loose slough or debris. Can also be used to remove hyperkeratosis.

Complex adjunct therapies

Topical negative pressure therapy – useful for acute and chronic cavity wounds and shallower wounds healing by secondary intention; topical negative pressure or vacuum-assisted closure aims to stimulate angiogenesis, remove excess exudate, reduce the bacterial burden and stimulate the production of granulation tissue.

Bandages

Compression (multi-layer) – provide compression for treatment of venous ulcers. Correct application of bandage is essential because the incorrect application technique can be hazardous. A Doppler assessment to establish the patient's ankle brachial pressure index (ABPI) is essential before application. Systems include high compression, short stretch and multi-layer (four layers and two layers). Choice is often dependent on patient preference.

Compression hosiery – prevents recurrence of venous ulcers but also now used in the treatment of active ulceration. ABPI should be established prior to application. Class III is preferred.

Compression garments – for management of lymphoedema. Used in conjunction with intermittent pneumatic compression systems.

Skin care

Skin barriers that protect the peri-wound area are important because wound exudate contains enzymes that can cause damage to tissues. Simple silicone-based creams or petroleum-based ointments can be useful in providing a protective layer for fragile skin.

Refer to the British National Formulary for more detailed information (<http://www.evidence.nhs.uk/formulary/bnf/current/a5-wound-management-products-and-elasticated-garments>).

- compression therapy for patients with venous ulcers,
- pressure-relieving equipment for individuals with or at risk of pressure ulcers,
- footwear and off-loading devices for patients with diabetic foot disease,
- devices such as negative pressure wound therapy (NPWT) for wounds healing by secondary intention,
- nutritional supplementation,
- drugs to influence healing,
- surgical interventions.

Case studies**Case 59.1**

A 75-year-old man, Mr DL, was admitted to hospital after a stroke. Over the proceeding few days, Mr DL developed a sore area between his buttocks (Fig. 59.16). The area is very moist and there is loss of the epidermis, but the ulcer is shallow.

Fig. 59.16 A shallow wound between the buttocks of a patient.

Questions

1. What is the most likely cause of the ulceration?
2. How should the wound be managed?
3. How can this damage be prevented?

Answers

1. Whilst from the position and appearance of the wound it looks like a category II pressure ulcer, it is in fact a 'moisture lesion'. A moisture lesion is defined as being caused by urine and/or faeces and perspiration which is in continuous contact with intact skin of the perineum, buttocks, groins, inner thighs, natal cleft or skin folds and where skin is in contact with skin. Moisture lesions cause superficial loss of epidermis and/or dermis, which may be preceded by areas of erythema on intact skin (*All Wales Tissue Viability Nurse Forum and All Wales Continence Forum, 2014*).
2. If Mr DL is incontinent the skin should be cleansed carefully. However, care must be taken to avoid damaging the skin further with harsh cleansers; therefore, a pH-balanced skin cleanser should be used. Skin barrier products can also be used to protect the skin from excessive moisture. These are topical preparations that are available as a cream, spray, foam applicator or wipes. Creams can be applied to dry, intact skin, whereas sprays, wipes or applicators can be applied to broken and/or intact skin.
3. Assessment and management of continence issues is the main way to prevent moisture lesions from occurring. In addition, there are other areas that need attention, such as the following: skin monitoring and good skin care; ensuring the patient has a good nutritional status; maintaining an optimal microclimate; repositioning immobile patients; providing adequate pressure relief.

Case 59.2

A 78-year-old man, Mr AT, presents with ulceration to his lower limb (**Fig. 59.17**). He has signs of venous disease, for example, haemosiderin staining and lipodermatosclerosis, and has been treated with compression therapy previously. Mr AT now reports having increased pain in his lower leg, particularly when walking. The primary care nurse has undertaken a Doppler, and his ABPI is 0.8.

Fig. 59.17 A wound on the medial malleolus area.

Questions

1. What is the likely cause of Mr AT's ulcers?
2. How should Mr AT be managed?
3. What treatment should be avoided, and why?

Answers

1. Mr AT has signs and symptoms of venous disease but also reports pain on walking. This is known as intermittent claudication because the pain is relieved by rest. Mr AT's ABPI result suggests the presence of arterial disease; that is, 0.8 suggests only 80% blood flow in the lower limb. Given the presenting symptoms, Mr AT would be deemed to have 'mixed ulcers'.
2. Mr AT should be referred to a vascular surgeon, where he is likely to have a Duplex scan and may then require angiography and/or surgery to improve the blood supply to the lower limb.
3. Mr AT should not have compression therapy. The blood flow to his lower limb is reduced, and application of compression could reduce that further. The risk to the patient is the loss of a limb if the circulation is compromised further.

Case 59.3

A 58-year-old woman, Mrs SG, presents with a raised scar to her sternum (**Fig. 59.18**). She underwent cardiac surgery 12 months previously. Mrs SG is worried about the appearance as the scar is raised and itchy.

Questions

1. Is this the normal appearance of a scar at 1 year post-surgery?
2. What name is given to this sort of scarring?
3. What treatment is required?

Answers

1. The remodelling phase of wound healing takes place up to 1 year after injury. The initial collagen that is laid down is changed, so the scar should be thinner, flatter and also paler.

Fig. 59.18 Scar tissue 12 months post cardiac surgery.

2. This type of scarring is known as hypertrophic scarring. A hypertrophic scar is a red, raised scar that forms along a wound and can have the following characteristics for around 2–5 years:
 - It can restrict movement because scar tissue is not as flexible as the original skin.
 - It heals within the size of the original wound.
 - The healing tissue is thicker than usual.
 - It is red and raised initially, becoming flatter and paler with time.
3. Treatment might include the use of silicone gel sheets such as CICA-CARE (Smith & Nephew), which is thought to occlude the skin to hydrate the scar area. This results in increased moisture around the scar, reducing the blood supply and deposit of collagen. The patient may require referral to a dermatologist or plastic surgeon if the scarring does not resolve. Further treatment might include the use of pressure garments, intra-lesional corticosteroid injections or surgery.

AUC	area under the curve	C₁, C₂, ...	cervical vertebrae 1, 2, ...
AUR	acute urinary retention	CA	cancer
AV	aortic valve		carcinoma
	atrioventricular		cardiac arrest
A-V	arteriovenous	Ca	coronary artery
AVNRT	atrioventricular nodal re-entry tachycardia		carcinoma
AVR	aortic valve replacement	CABG	coronary artery bypass graft
	augmented V lead, right arm (ECG)	CAD	coronary artery disease
AVRT	atrioventricular re-entry tachycardia	CAH	chronic active hepatitis
AVS	arteriovenous shunt	CAP	community-acquired pneumonia
AXR	abdominal X-ray	CAPD	continuous ambulatory peritoneal dialysis
B Bx.	breast biopsy	cART	combination antiretroviral therapy
BACUP	British Association of Cancer United Patients	CAT	computed axial tomography
BA-MDI	breath-actuated metered-dose inhalers	CAVH	continuous arteriovenous haemofiltration
BAPEN	British Association of Parenteral and Enteral Nutrition	CBA	cost–benefit analysis
BBB	bundle branch block	CBP	chronic bacterial prostatitis
BBBB	bilateral bundle branch block (ECG)	CBT	cognitive behaviour therapy
BCAA	branched-chain amino acid	CC	chief complaint
BCC	basal cell carcinoma		current complaint
BCG	bacille Calmette–Guérin	CCB	calcium channel blockers
BDA	British Diabetic Association	CCF	congestive cardiac failure
bDMARDs	biologic disease modifying anti-rheumatic drugs	CCU	coronary care unit
BE	base excess	CDAI	Crohn's Disease Activity Index
BEACOPP	bleomycin, etoposide, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), procarbazine, prednisolone	CEA	cost-effectiveness analysis
	carmustine, etoposide, cytarabine, melphalan	CF	cardiac failure
BEAM			complement fixation
BG	blood glucose		cystic fibrosis
BHS	beta-haemolytic streptococci	CFT	complement fixation test
BIA	bioelectrical impedance analysis	CGL	chronic granulocytic leukaemia
BJ protein	Bence-Jones protein	CGN	chronic glomerulonephritis
BKA	below knee amputation	CHAD	cold haemagglutinin disease
		CHB	complete heart block
		CHD	coronary heart disease
		CHF	congestive heart failure

CHM	Commission on Human Medicines	CSAP	cryosurgical ablation of prostate
CHO	carbohydrate	csDMARD	conventional synthetic disease modifying anti-rheumatic drug
CHOP	cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone	CSF	cerebrospinal fluid
CHOP-R	cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone, rituximab	CSH	colony stimulating factor
CI	cardiac index	CSM	chronic subdural haematoma
	cerebral infarction	CSP	carotid sinus massage
	confidence interval	CSR	cerebrospinal meningitis
CINV	chemotherapy-induced nausea and vomiting	CSS	carotid sinus pressure
CIVA	centralised intravenous additive	CSU	Cheyne–Stokes respiration
CK	creatinine kinase (same as CPK)	CT	correct sedimentation rate
CKD	chronic kidney disease		carotid sinus stimulation
CL	clubbing		central sterile supply
Cl_{Cr}	creatinine clearance		catheter specimen of urine
CLD	chronic liver disease		circulation time
	chronic lung disease		clotting time
CLL	chronic lymphocytic leukaemia		computed tomography
CMA	cost minimisation analysis	cTnI	Coombs' test
CML	chronic myelocytic leukaemia	cTnT	coronary thrombosis
CMV	cytomegalovirus	CTPA	cardiac troponin I
CNS	central nervous system	CTZ	cardiac troponin T
	coagulase-negative staphylococci	CUA	computed tomography pulmonary angiogram
CO	cardiac output	CUG	chemoreceptor trigger zone
CoA	coenzyme A	CV	cost–utility analysis
COC	combined oral contraceptive		cystourethrogram
COD	cause of death		cardiovascular
COG	closed-angle glaucoma		central venous
COMT	catechol- <i>o</i> -methyl transferase	CVA	cerebrovascular
COP	capillary osmotic pressure		contingent valuation
COPD	chronic obstructive pulmonary disease		cerebrovascular accident (stroke)
COX	cyclo-oxygenase	CVD	costovertebral angle
CP	chronic prostatitis	CVP	cardiovascular disease
	cor pulmonale	CVVH	central venous pressure
	creatine phosphate	Cx	continuous venovenous haemofiltration
CPA	cardiopulmonary arrest		cervical
	cerebellar pontine angle	CXR	cervix
CPAP	continuous positive airway pressure	Cys-C	chest X-ray
CPD	continuous peritoneal dialysis	d	cystatin C
CPK	creatine phosphokinase		dead
CPM	central pontine myelinolysis	D & C	deceased
CPN	chronic pyelonephritis	D & V	dilation and curettage
CPPS	chronic pelvic pain syndrome	D/C	diarrhoea and vomiting
CPPV	continuous positive pressure ventilation	D/S	discontinue
CPR	cardiopulmonary resuscitation	D₅W	dextrose and saline
CPSI	chronic prostatitis symptom index	DAD	dextrose 5%
CPZ	chlorpromazine	DAFNE	delayed after depolarisation
CR	cardiorespiratory	DALY	(insulin) dose adjustment for normal eating
	clot retraction	DAS	disability-adjusted life-year
	colon resection	DBP	disease activity score
	complete remission	DD	disease activity score
	conditional reflex	DDx.	diastolic blood pressure
	crown-rump	DES	dyssynergic defecation
CRD	chronic renal disease	DEXA	differential diagnosis
CRF	chronic renal failure	DH	diethylstilboestrol
	corticotrophin-releasing factor	DIC	dual energy X-ray absorptiometry
CRP	C-reactive protein	DILD	drug history
		DILI	disseminated intravascular coagulation
			drug-induced liver disease
			drug-induced liver injury

DIP	drug-induced parkinsonism	ELISA	enzyme-linked immunosorbent assay
DIT	di-iodotyrosine	EM	ejection murmur
DKA	diabetic ketoacidosis		erythema multiforme
DLBCL	diffuse large B-cell lymphoma	EMEA	European Medicines Evaluation Agency
DLE	discoid lupus erythematosus	EMG	electromyogram
	disseminated lupus erythematosus	EN	erythema nodosum
DLQI	Dermatology Quality of Life Index	ENDR	endoscopy negative reflux disease
DM	diabetes mellitus	ENT	ears, nose and throat
	diastolic murmur	EP	ectopic pregnancy
DMARD	disease-modifying antirheumatic drug	EPSE	extra pyramidal side effects
DNA	did not attend (outpatients)	ER	oestrogen receptor
DOA	dead on arrival	ERCP	endoscopic retrograde cholangiopancreatography
DOAC	direct oral anticoagulant	ERP	effective refractory period
DOB	date of birth	ESA	erythropoietin-stimulating agent
DOD	date of death	ESBL	extended spectrum beta-lactamase
DOE	dyspnoea on exertion	ESHAP	etoposide, methylprednisolone, cytarabine, cis-platin
DOTS	Directly Observed Treatment		ejection systolic murmur
DPI	dry powder inhalers	ESM	educationally subnormal
DPP-4	inhibitors dipeptidyl peptidase inhibitors	ESN	end-systolic pressure
DRE	digital rectal examination	ESP	erythrocyte sedimentation rate
DRESS	drug rash with eosinophilia and systemic symptoms	ESR	end-stage renal failure
		ESRF	endotracheal tube
DROP	dyslipidaemia, insulin resistance, obesity and high blood pressure	ET	essential tremor
		ETT	exercise tolerance test
DSM	<i>Diagnostic and Statistical Manual of Mental Disorders</i>	FAS	fetal alcohol syndrome
DTI	direct thrombus imaging	FB	finger breadths
DTP	diphtheria, tetanus, pertussis (vaccine)	FBC	full blood count
DTs	delirium tremens	FBS	fasting blood sugar
DU	diagnosis undetermined	FCE	finished consultant episode
	duodenal ulcer	FDA	US Food and Drug Administration
DUB	dysfunctional uterine bleeding	FeNa	fractional excretion of sodium
DUE	drug use evaluation	FEV	forced expiratory volume
DUP	drug use process	FEV₁	forced expiratory volume in 1 second
DVT	deep vein thrombosis	FFA	free fatty acid
Dx.	diagnosis	FFP	fresh frozen plasma
DXT	deep X-ray therapy	FH	familial hypercholesterolaemia
E/I	expiration–inspiration ratio		family history
EAD	early after depolarisation	FHH	familial hypocalcaemic hypercalcaemia
EBV	Epstein–Barr virus	FMD	fludarabine, mitoxantrone, dexamethasone
ECBV	effective circulating blood volume	FOB	faecal occult blood
ECF	extracellular fluid	FP	frozen plasma
ECFV	extracellular fluid volume	FRC	functional reserve capacity
ECG	electrocardiogram		functional residual capacity
ECHO	echocardiogram	FSH	follicle-stimulating hormone
	echoencephalogram	FSNGN	focal segmental necrotising glomerulonephritis
ECMO	extracorporeal membrane oxygenation	FT₄	free thyroxine
ECP	extra-corporeal photopheresis	FTI	free thyroxine index
ECT	electroconvulsive therapy	FUO	fever of unknown origin
EDD	expected date of delivery	FVC	forced vital capacity
EDTA	ethylenediaminetetra-acetic acid	Fx.	fracture
EDV	end-diastolic volume	G6PD	glucose-6-phosphate dehydrogenase
EEG	electroencephalogram	GA	general anaesthesia
EENT	eyes, ears, nose and throat		general appearance
EF	ejection fraction	GABA	γ-aminobutyric acid
eGFR	estimated glomerular filtration rate	GABA_A	γ-aminobutyric acid A
EGFR	epidermal growth factor receptor	GAD	glutamic acid decarboxylase
ELBW	extremely low birth weight		generalised anxiety disorder

gamma-GT	γ -glutamyl transferase	HER2	human epidermal growth factor receptor type 2
GB	gallbladder	HF	heart failure
	Guillain–Barré (syndrome)	HHV	human herpes virus
GBM	glomerular basement membrane	Hib	<i>Haemophilus influenzae</i> type b
GBS	Glasgow–Blatchford score	HIE	hypoxic-ischaemic encephalopathy
G-CSF	granulocyte-colony-stimulating factor	HIFU	high-intensity focused ultrasound
GDM	gastro-intestinal diabetes mellitus	HIT	heparin-induced thrombocytopenia
GF	glomerular filtration	HIV	human immunodeficiency virus
	gluten-free	HLA	human lymphocyte antibody
GFR	glomerular filtration rate	HMD	hyaline membrane disease
GGT	γ -glutamyl transpeptidase (transferase)	HMMA	4-hydroxy-3-methoxymandelic acid
GI	gastro-intestinal	hMPV	human metapneumovirus
GIK	glucose, insulin and potassium	HONK	hyperosmolar non-ketotic hyperglycaemia
GLA	γ -linolenic acid	HPEN	home parenteral and enteral nutrition
GM seizure	grand mal seizure	HPI	history of present illness
GM-CSF	granulocyte macrophage-colony-stimulating factor	HPN	home parenteral nutrition
GN	glomerulonephritis	HPRT	hypoxanthine-guanine phosphoribosyl transferase deficiency
GNDC	Gram-negative diplococci		
GnRH	gonadotrophin-releasing hormone	HPV	human papillomavirus
GORD	gastro-oesophageal reflux disease	HR	heart rate
grav.	gravid (pregnant)	HRS	hepatorenal syndrome
GRE	glycopeptide-resistant enterococci		Hodgkin and Reed-Sternberg
GS	general surgery	HRT	hormone replacement therapy
	genital system	HS	half strength
GTN	glyceryl trinitrate		Hartmann's solution
GTT	glucose tolerance test		heart sounds
GU	gastric ulcer	HSA	human serum albumin
	genitourinary	HSCT	haematopoietic stem cell transplantation
	gonococcal urethritis	HSV	herpes simplex virus
GUS	genitourinary system	HT, HTN	hypertension
GVHD	graft-versus-host disease	HUS	haemolytic uraemic syndrome
GWAS	genome wide association studies	HVA	homovanillic acid
H & L	heart and lungs	HVD	hypertensive vascular disease
h/o	history of	Hx.	history
HAA	hepatitis-associated antigen	IADHS	inappropriate antidiuretic hormone syndrome
HACAs	human anti-chimeric antibodies	IBC	iron binding capacity
HAP	hospital-acquired pneumonia	IBD	inflammatory bowel disease
HAS	human albumin solution	IBS	irritable bowel syndrome
HAV	hepatitis A virus	IC	intercostal intracerebral intracranial
HB	heart block	ICA	islet cell antibody
Hb (Hgb)	haemoglobin	ICD	<i>International Classification of Diseases</i>
HbA_{1c}	glycated haemoglobin		implantable cardioverter-defibrillator
HbA₂	haemoglobin found in β -thalassaemia carriers		impulse control disorder
HBAg	hepatitis B antigen		irritant contact dermatitis
HBD, HBDH	hydroxybutyrate dehydrogenase	ICE	ifosfamide, carboplatin, etoposide
HBGM	home blood glucose monitoring	ICF	intracellular fluid
HBI	Harvey–Bradshaw Index	ICH	intracerebral haemorrhage
HbS	sickle haemoglobin in sickle cell disease	ICM	intracostal margin
HBsAg	hepatitis B surface antigen	ICS	intercostal space
HBV	hepatitis B virus		inhaled corticosteroids
HCAI	healthcare-associated infections	ICU	intensive care unit
Hct. (hct.)	haematocrit	ID	intra-dermal
HCV	hepatitis C virus	IDA	iron deficiency anaemia
HDL	high-density lipoprotein	IDL	intermediate-density lipoprotein
HDL-C	high-density lipoprotein cholesterol	IDL-C	intermediate-density lipoprotein cholesterol
HDT	high-dose therapy	IDP	intradialytic parenteral nutrition
HEPEF	heart failure with preserved ejection fraction	IEP	immunoelectrophoresis
HER1	human epidermal growth factor receptor type 1	IFRT	involved field radiotherapy

Ig	immunoglobulin	LBW	low birth weight
iGAS	invasive group A streptococcal infection	LCAT	lecithin-cholesterol acyltransferase
IGT	impaired glucose tolerance	LCT	long-chain triglyceride
IHC	immunohistochemistry	LD, LDH	lactate dehydrogenase
IHD	ischaemic heart disease	LDL	low-density lipoprotein
IHR	intrinsic heart rate	LDL-C	low-density lipoprotein cholesterol
IID	infectious intestinal disease	LDS	lipodermatosclerosis
IMP	impression	LE	lupus erythematosus
INI	integrase inhibitors	LFT	liver function test
INR	international normalised ratio	LH	luteinising hormone
IOP	intraocular pressure	LHRH	luteinising hormone-releasing hormone
IPCN	International Prostatitis Collaborative Network	LIF	left iliac fossa
IPF	idiopathic pulmonary fibrosis	LK	left kidney
IPI	International Prognostic Index	LKKS, LKS	liver, kidneys, spleen
IPP	intermittent positive-pressure inflation with oxygen	LL	left leg
IPPB	intermittent positive-pressure breathing		left lower
IPPV	intermittent positive-pressure ventilation		lower lobe
IPS	International Prognostic Score	LLL	left lower lobe
IRDS	idiopathic respiratory distress syndrome		left lower lid
ISA	intrinsic sympathomimetic activity	LLQ	left lower quadrant
ISDN	isosorbide dinitrate	LMN	lower motor neurone
ISI	International Sensitivity Index	LMP	last menstrual period
ISMN	isosorbide mononitrate	LMWH	low molecular weight heparin
IT	intrathecal(ly)	LN	lymph node
ITT	insulin tolerance test	LNG-IUS	levonorgestrel intrauterine system
IUCD	intrauterine contraceptive device	LNMP	last normal menstrual period
IUD	intrauterine death	LOM	limitation of movement
	intrauterine device	LP	lumbar puncture
i.v.	intravenous	Lp(a)	lipoprotein a
IVD	intervertebral disc	LPA	left pulmonary artery
IVH	intraventricular haemorrhage	LS	left side
IVP	intravenous push		liver and spleen
	intravenous pyelography		lumbosacral
IVSD	interventricular septal defect	LSD	lymphosarcoma
IVU	intravenous urography	LSK	lysergic acid diethylamide
J	jaundice	LSM	liver, spleen, kidneys
JVD	jugular venous distension	LT	late systolic murmur
JVP	jugular venous pressure	LTBI	leukotriene
KA	ketoacidosis	LTC	latent tuberculosis infection
KCCT	kaolin-cephalin clotting time	LTOT	long-term care
KLS	kidney, liver, spleen	LUL	long-term oxygen therapy
KS	Kaposi's sarcoma	LV	left upper lobe
KUB	kidneys, ureters, bladder	LUQ	left upper quadrant
L	left	LV	left ventricle
	lower	LVDP	left ventricular diastolic pressure
	lumber	LVE	left ventricular enlargement
L & A	light and accommodation	LVEDP	left ventricular end-diastolic pressure
L & U	lower and upper	LVEDV	left ventricular end-diastolic volume
L & W	living and well	LVET	left ventricular ejection time
L₁, L₂, ...	lumbar vertebrae 1, 2, ...	LVF	left ventricular failure
LA	left arm	LVH	left ventricular hypertrophy
	left atrium	LVP	left ventricular pressure
	local anaesthesia	M	male
LABA	long-acting β_2 -adrenoceptor agonist		married
LAD	left anterior descending		metre
LADA	latent autoimmune diabetes in adults		mother
LAMA	long-acting antimuscarinic		molar
LBBB	left bundle branch block		murmur
LBM	lean body mass		

M:P	milk-to-plasma ratio	MRA	magnetic resonance angiography
MA	marketing authorisation	MRCPC	magnetic resonance cholangiopancreatography
MABP	mean arterial blood pressure	MRD	minimal residual disease
MAC	<i>Mycobacterium avium</i> complex	MRDM	malnutrition-related diabetes mellitus
MAI	<i>Mycobacterium avium-intracellulare</i>	MRI	magnetic resonance imaging
MALT	mucosal-associated lymphoid tissue	MRP	medication-related problem
MAMC	mid-arm muscle circumference	MRSA	meticillin-resistant <i>Staphylococcus aureus</i>
MAO-A	monoamine oxidase A	MS	mitral stenosis
MAO-B	monoamine oxidase B		multiple sclerosis
MAOI	monoamine oxidase inhibitor		musculoskeletal
MAP	mean arterial pressure	MSL	midsternal line
MARS	molecular adsorbent recycling system	MSM	men who have sex with men
MBC	minimum bactericidal concentration	MSSA	meticillin-sensitive <i>Staphylococcus aureus</i>
MBP	mean blood pressure	MSU	midstream urine specimen
MCH	mean corpuscular cell haemoglobin	MTB	<i>Mycobacterium tuberculosis</i>
MCHC	mean corpuscular cell haemoglobin concentration	MTI	minimum time interval
		MTP	metatarsophalangeal
MCI	mild cognitive impairment	MUD	matched unrelated donor
MCP	metacarpophalangeal (joint)	MV	minute volume
MCT	medium-chain triglycerides		mitral valve
MCV	mean corpuscular cell volume	MVP	mitral valve prolapse
MD	mitral disease	MVPP	mustine, vinblastine, procarbazine, prednisolone
	muscular dystrophy	MVR	mitral valve replacement
MDI	metered-dose inhaler	MWH	moist wound healing
MDM	mid-diastolic murmur	N	normal
MDMA	methylenedioxymethamphetamine, ecstasy	N & T	nose and throat
MDRD	modification of diet in renal disease formula for GFR estimation	N & V	nausea and vomiting
		NAAT	nucleic acid amplification techniques
MDRST	multidrug-resistant <i>Salmonella enterica</i> serovar typhi	NAD	no appreciable disease
			normal axis deviation
MDR-TB	multidrug-resistant tuberculosis	NADPH	nothing abnormal detected
MDS	myelodysplastic syndrome		nicotinamide adenine dinucleotide phosphate hydrogen
MEN	multiple endocrine neoplasia	NAFLD	non-alcoholic fatty liver disease
MERS	Middle East respiratory syndrome	NAG	narrow-angle glaucoma
MERS-CoV	Middle East respiratory syndrome coronavirus	NAI	neuraminidase inhibitor
met.	metastatic (metastasis)	NAPQI	<i>N</i> -acetyl- <i>p</i> -benzoquinoneimine
MGN	membranous glomerulonephritis	NARI	noradrenergic reuptake inhibitor
MH	medical history	NARTI	nucleoside analogue reverse transcriptase inhibitor
	menstrual history	NASH	non-alcoholic steatohepatitis
MHPG	methoxyhydroxyphenylglycerol	NaSSA	noradrenergic and specific serotonergic antidepressant
MHRA	Medicines and Healthcare products Regulatory Agency		nil by mouth
MI	myocardial infarction	NBM	necrotising enterocolitis
	mitral incompetence	NEC	nasogastric
MIC	minimum inhibitory concentration	NG	non-Hodgkin's lymphoma
MID	multi-infarct dementia	NHL	non-invasive ventilation
MIRU	mycobacterial interspersed repetitive unit typing	NIV	non-ketotic hyperosmolar acidosis
MIT	monoiodotyrosine	NKHA	nodular lymphocyte-predominant Hodgkin's lymphoma
ML	middle lobe midline	NLPHL	
MMR	measles, mumps, rubella		nuclear magnetic resonance
MMSE	mini-mental state examination	NMR	neuroleptic malignant syndrome
MODY	maturity-onset diabetes of the young	NMS	non-nucleoside reverse transcriptase inhibitor
MOPP	mustine, Oncovin (vincristine), procarbazine, prednisolone	NNRTI	non-warfarin oral anticoagulants
		NOAC	novel oral anticoagulants
MOTT	mycobacteria other than tuberculosis		non-vitamin K antagonists oral anticoagulant
MPJ	metacarpophalangeal joint	NOF	neck of femur
MR	mitral regurgitation		
MRCF	medication-related consultation framework		

NS	nephrotic syndrome nervous system normal saline no specimen	PC	presenting complaint prostate cancer
NSAID	non-steroidal anti-inflammatory drug	PCA	patient-controlled analgesia
NSFTD	normal spontaneous full-term delivery	PCAS	patient-controlled analgesia system
NSR	normal sinus rhythm	PCC	prothrombin complex concentrate
NSTEMI	non-ST-elevated myocardial infarction	PCI	percutaneous coronary intervention
NSU	non-specific urethritis	PCO₂	partial pressure of carbon dioxide
NT	nasotracheal (tube)	PCR	polymerase chain reaction protein creatinine ratio
NTS	nucleus tractus solitarius	PCS	portocaval shunt
NVD	nausea, vomiting, diarrhoea	PCV	packed cell volume
NYHA	New York Heart Association	PD	Parkinson's disease peritoneal dialysis
O	oedema	PDA	patent ductus arteriosus
O & A	observation and assessment	PE	physical examination pleural effusion pulmonary embolism
O & E	observation and examination	PEARLA	pupils equal and react to light and accommodation
O/A	on admission	PEF	peak expiratory flow
O/E	on examination	PEFR	peak expiratory flow rate
OA	osteoarthritis	PEG	percutaneous endoscopic gastrostomy
OAB	overactive bladder	PEJ	percutaneous endoscopic jejunostomy
OAG	open-angle glaucoma	PEM	prescription event monitoring protein energy malnutrition
OB	occult blood	PEP	post-exposure prophylaxis
OCD	obsessive compulsive disorder	PERLA	pupils equal, react to light and accommodation
OD	overdose	PERRLA	pupils equal, round, react to light and accommodation
OGTT	oral glucose tolerance test	PET	position emission tomography
OH	occupational history	PF	peak flow
OHT	ocular hypertension	PF4	platelet factor 4
OI	opportunistic infection	PFR	peak flow rate
OKGA	ornithine salt of α -ketoglutaric acid	PFT	pulmonary function test
OLT	orthoptic liver transplantation	PG	prostaglandin
OPA	outpatient appointment	P-gp	P-glycoprotein
OPD	outpatient department	PH	past history patient history personal history prostatic hypertrophy pulmonary hypertension primary HIV infection present illness protease inhibitor peripherally inserted central catheter pelvic inflammatory disease patient information leaflet prostatic intra-epithelial neoplasia proximal interphalangeal joint protruded intervertebral disc premature junctional beat premature junctional contraction <i>Pneumocystis jiroveci</i> pneumonia phenylketonuria product licence prolymphocytic leukaemia premenstrual dysphoric disorder
ORS	oral rehydration solution	PHI	
OSAHS	obstructive sleep apnoea hypopnoea syndrome	PI	
OT	occupational therapy	PICC	
P & A	percussion and auscultation	PID	
P & V	pyloroplasty and vagotomy	PIL	
PA	pernicious anaemia pulmonary artery	PIN	
PAAP	personal asthma action plan	PIP	
PACG	primary angle-closure glaucoma	PIVD	
PaCO₂	arterial carbon dioxide tension	PJB	
PAD	peripheral arterial disease	PJC	
PAF	platelet-activating factor	PJP	
PAH	pulmonary artery hypertension	PKU	
pANCA	perinuclear anti-neutrophil cytoplasmic antibody	PL	
PaO₂	arterial oxygen tension	PLL	
PAPS	primary antiphospholipid syndrome	PMDD	
PAS	<i>p</i> -aminosalicylic acid pulmonary artery stenosis		
PASI	Psoriasis Area and Severity Index		
PAT	paroxysmal atrial tachycardia		
PAWP	pulmonary artery wedge pressure		
PB	premature beat		
PBC	primary biliary cirrhosis		
PBI	protein-bound iodine		
PBSCT	peripheral blood stem cell transplantation		

pMDI	pressurised metered-dose inhaler	PV	vaginal examination (per vagina)
PMH	past medical history	PVB	premature ventricular beat
PMI	past medical illness	PVC	premature ventricular contraction
PMN	polymorphonucleocyte	PVD	peripheral vascular disease
PMR	polymyalgia rheumatica	PVP	pulmonary venous pressure
PMS	premenstrual syndrome	PVR	post-void residual
	postmenopausal syndrome	PVT	paroxysmal ventricular tachycardia
PMT	premenstrual tension	Px.	past prognosis
PMV	prolapsed mitral valve	QALY	quality-adjusted life-year
PN	parenteral nutrition	R	respiration
	percussion note	RA	renal artery
	peripheral nerve		rheumatoid arthritis
	peripheral neuropathy		right arm
PND	paroxysmal nocturnal dyspnoea		right atrial (atrium)
	postnasal drip	RANKL	receptor activator of nuclear factor- κ B ligand
PO₂	partial pressure of oxygen	RARS	refractory anaemia with ring sideroblasts
POAG	primary open-angle glaucoma	RAST	radio-allergosorbent test
POMR	problem-oriented medical record	RAT	rapid antigen test
PONV	postoperative nausea and vomiting	RBBB	right bundle branch block
PPAR-γ	proliferative-activated receptor- γ	RBC	red blood cell
PPD	purified protein derivative		red blood (cell) count
PPH	postpartum haemorrhage	RBS	random blood sugar
PPHN	persistent pulmonary hypertension of the neonate	R-CVP	rituximab, cyclophosphamide, vincristine, prednisolone
PPI	proton pump inhibitor		respiratory distress syndrome
PPNG	penicillinase-producing <i>Neisseria gonorrhoeae</i>	RDS	rapid eye movement sleep
PPV	positive-pressure ventilation	Re-PUVA	PUVA treatment with retinoids
PR	per rectum	RF	renal failure
	progesterone receptor		rheumatic fever
PRCA	pure red cell aplasia		rheumatoid factor
PREP	pre-exposure prophylaxis	RFT	respiratory function tests
PROM	premature rupture of membranes	Rh factor	rhesus factor
PS	pulmonary stenosis	RHF	right heart failure
	pyloric stenosis	RHL	right hepatic lobe
PSA	prostate-specific antigen	rhuEPO	recombinant human erythropoietin
PSC	primary sclerosing cholangitis	rhuGM-CSF	recombinant human granulocyte-macrophage colony-stimulating factor
PSG	presystolic gallop		right iliac fossa
PSGN	poststreptococcal glomerulonephritis	RIF	reversible inhibitor of monoamine oxidase type A
PSVT	paroxysmal supraventricular tachycardia	RIMA	radiofrequency interstitial tumour ablation
PT	parathyroid		right kidney
	paroxysmal tachycardia	RITA	right leg
	physical therapy	RK	right lung
	physical training	RLC	residual lung capacity
	posterior tibial	RLD	related living donor
	prothrombin time	RLL	right lower lobe (lung)
PTC	percutaneous cholangiogram	RLQ	right lower quadrant (abdomen)
PTH	parathyroid hormone	RP	radial pulse
PTLD	post-transplant lymphoproliferative disorder	RPGN	rapidly progressive glomerulonephritis
PTSD	post-traumatic stress disorder	RPI	resting pressure index
PTT	partial thromboplastin time	RQ	respiratory quotient
PTTK	partial thromboplastin time kaolin	RR	respiratory rate
PTU	propylthiouracil	RR & E	round, regular and equal (pupils)
PU	pass urine	RRT	renal replacement therapy
	per urethra	RS	respiratory system
	peptic ulcer	RSF	rheumatoid serum factor
PUCAI	Paediatric Ulcerative Colitis Activity Index	RSV	respiratory syncytial virus
PUD	peptic ulcer disease		
PUO	pyrexia (fever) of unknown origin		
PUVA	psoralen and ultraviolet A radiation		

RTA	road traffic accident	SV	stroke volume
rt-PA	recombinant tissue plasminogen activator	SVI	stroke volume index
RUL	right upper lobe	SVT	supraventricular tachycardia
RUQ	right upper quadrant	SWS	slow-wave sleep
RV	residual volume	Sx.	symptoms
	right ventricle	T	temperature
RVH	right ventricular hypertrophy	T & C, T & X	type and cross-match
RVOT	right ventricular outflow tract	T₃	tri-iodothyronine
SA	sinoatrial (node)	T₄	thyroxine
	Stokes–Adams (attacks)	TAGvHD	transfusion-assisted graft-versus-host disease
	surface area	TB	tuberculosis
SAH	subarachnoid haemorrhage	TBA	to be administered
SARS	severe acute respiratory syndrome		to be arranged
SARS CoV	severe acute respiratory syndrome-associated coronavirus	TBG	thyroid-binding globulin
	seen by	TBI	total body irradiation
SB	shortness of breath	TBM	tuberculous meningitis
	shortness of breath on exertion	TBW	total body weight
SBE	subacute bacterial endocarditis	TC	total capacity
	shortness of breath on exertion		total cholesterol
SBO	small-bowel obstruction		tricarboxylic acid cycle
SBP	spontaneous bacterial peritonitis	TCA	tricyclic antidepressant
SCCAI	simple clinical colitis activity index	TD	tardive dyskinesia
SCID	severe combined immunodeficiency syndrome	TDM	therapeutic drug monitoring
sCr	serum creatinine	TEN	toxic epidermal necrolysis (Lyell's syndrome)
sCT	spiral computed tomography	TENS	transcutaneous electrical nerve stimulation
SCU, SCUF	slow continuous ultrafiltration	TF	tissue factor
SDD	selective decontamination of the digestive tract	TFT	thyroid function test
SEM	systolic ejection murmur	TGF	tubuloglomerular feedback
SERM	selective oestrogen receptor modulator	TG	triglyceride
SGLT2s	sodium-glucose co-transporter-2 inhibitors	TH	thyroid hormone (thyroxine)
SGOT	serum glutamate-oxaloacetate transaminase	THA	tetrahydroaminoacridine
SGPT	serum glutamate-pyruvate transaminase	THC	tetrahydrocannabinol
SH	social history	TIA	transient ischaemic attack
SIADH	syndrome of inappropriate antidiuretic hormone	TIBC	total iron-binding capacity
SIDS	sudden infant death syndrome	TIMP	tissue inhibitor of metalloproteinases
SJS	Stevens–Johnson syndrome	TIPSS	transjugular intrahepatic portosystemic shunting
SLE	systemic lupus erythematosus	TKI	tyrosine kinase inhibitor
SMI	soft mist inhalers	TLC	total lung capacity
SNRI	serotonin-noradrenaline reuptake inhibitor		tender loving care
SOA	swelling of ankle(s)	TLCO	transfer factor of the lung for carbon monoxide
SOAP	subjective, objective, assessment, plan	TLS	tumour lysis syndrome
SOB	short of breath	TNF	tumour necrosis factor
SOBOE	short of breath on exertion	TNF-α	tumour necrosis factor alpha
SOL	space-occupying lesion	TNM	tumour node metastasis
SP	systolic pressure	TP & P	time, place and person
SPA	suprapubic aspiration	t-PA	tissue plasminogen factor
SPC, SmPC	Summary of Product Characteristics	TPMT	thiopurine methyltransferasethiopurine methyltransferase testing
SR	sinus rhythm		total parenteral nutrition
	sustained release	TPN	temperature, pulse, respiration
SS	serotonin syndrome	TPR	total prostate-specific antigen
SSI	surgical site infection	tPSA	thyroid receptor antibody
SSRI	selective serotonin reuptake inhibitor	TRAB	thyrotrophin-releasing hormone
ST	sinus tachycardia	TRH	transrectal ultrasonography
stat.	immediately (Latin: <i>statim</i>)	TRUS	targeted synthetic disease modifying anti-rheumatic drugs
STEMI	ST elevated myocardial infarction	tsDMARDs	triceps skinfold thickness
STD	sexually transmitted disease		thyroid-stimulating hormone
STS	sodium tetradecyl sulphate	TSF	
	serological tests for syphilis	TSH	

TTA	transtracheal aspiration	VF	ventricular fibrillation
TTO	to take out (to take home)	VHD	valvular heart disease
TUIP	transurethral incision of the prostate	VKA	vitamin K antagonist
TUMT	transurethral microwave heat treatment	VLBW	very low birth weight
TUR	transurethral resection	VLDL	very low-density lipoprotein
TURB	transurethral resection of the bladder	VMA	vanillylmandelic acid
TURP	transurethral resection of the prostate	VNTR	variable number of tandem repeats typing
TV	tidal volume	VP	venous pressure
TVN	tissue viability nurse	VPC	ventricular premature contraction
TWOC	trial without catheter	V/Q	ventilation/perfusion ratio
Tx.	transfusion treatment	VS	vital signs
UA	unstable angina	VT	ventricular tachycardia
U & E	urea and electrolytes	VTE	venous thromboembolism
UBIC	unsaturated iron-binding capacity	VTEC	verotoxin-producing <i>Escherichia coli</i>
UC	ulcerative colitis	VUR	vesicoureteric reflux
UCEIS	ulcerative colitis endoscopic index of severity	VVC	vulvovaginal candidiasis
UFH	unfractionated heparin	VZV	varicella zoster virus
UPCR	urine protein creatinine ratio	WAIHA	warm autoimmune haemolytic anaemia
URTI	upper respiratory tract infection	WBC	white blood cell
US	ultrasound		white blood count
UTI	urinary tract infection	WCC	white cell count
UVA	ultraviolet A	WHO	World Health Organization
UVB	ultraviolet B	WPW	Wolff–Parkinson–White (syndrome)
VaD	vascular dementia	WR	Wassermann reaction
VAP	ventilator associated pneumonia	WTA	willingness to accept
VAS	visual analogue score	WTP	willingness to pay
VC	vital capacity	XDR-TB	extensively drug-resistant tuberculosis
	vulvovaginal candidiasis	ZE	Zollinger–Ellison (syndrome)
VD	venereal disease	ZIG	zoster immune globulin
VDRL	Venereal Disease Research Laboratory (test for syphilis)	ZPP	zinc protoporphyrin
VEGF	vascular endothelial growth factor		

Glossary

Acanthosis nigricans: Diffuse, velvety acanthosis with grey, brown or black pigmentation, chiefly in axilla and other body folds, occurring in an adult form, often associated with an internal carcinoma and in a benign, nevoid form, more or less generalised.

Achlorhydria: Absence of hydrochloric acid from maximally stimulated gastric secretion.

Acral: Pertaining to or affecting a limb or other extremity.

Acropachy: Clubbing of the fingers and toes with distal periosteal bone changes and swelling of the overlying soft tissues.

Addisonian crisis: The symptoms that accompany an acute onset or worsening of Addison's disease, including fatigue, nausea and vomiting, loss of weight, hypotension, fever and collapse.

Adenomyosis: Penetration of endometrial tissue into the myometrium.

Agensis: Absence of an organ.

Agryria: Congenital malformation or absence of the convolutions of the cerebral cortex.

Alloimmunity: Immunity to an alloantigen.

Alport's syndrome: Hereditary disease of the kidneys that primarily affects men. Heterogeneous group of conditions may manifest, including glomerulonephritis, haematuria, proteinuria, hypertension, nephrotic syndrome, end-stage renal disease, and variably accompanied by sensorineural deafness, coloured urine, swelling, cough and poor vision. Eventually, kidney dialysis or transplant may be necessary.

Amphipathic: Molecules containing groups with characteristically different properties, for example, both hydrophilic and hydrophobic properties.

Amphoteric: Having opposite characters, that is, capable of acting as an acid and a base.

Anoxaemia: Reduction of blood oxygen content below physiological levels.

Anthropometry: The science which deals with the measurement of the size, weight and proportions of the human body.

Anuria: Non passage of urine.

Aphakia: No lens.

Aphasia: Language disorder where people have problems speaking.

Aplasia cutis: Localised failure of development of skin.

Apnoea: Cessation of breathing.

Apoptosis: Programmed destruction of cells; mechanism that keeps cell numbers in check by eliminating senescent cells or those without useful cell function.

Arachnoiditis: Inflammation of the arachnoidea, a delicate membrane interposed between the dura mater and the pia mater.

Ataxia telangiectasia: Hereditary disorder with severe progressive cerebellar ataxia, associated with oculocutaneous telangiectasia, sinopulmonary disease with frequent respiratory infections and abnormal eye movements.

Atelectasis: Incomplete expansion of a lung.

Atretic: Without an opening; characterised by atresia.

Auspitz's sign: Removal of a yellow-white, sharply demarcated plaque of psoriasis, results in pinpoint haemorrhage.

Azoospermia: Absence of spermatozoa in the semen, or failure of formation of spermatozoa.

Bacteriuria: The presence of bacteria in the urine.

Barrett's oesophagus: A precancerous condition in which normal cells lining the oesophagus are replaced with abnormal cells that may develop into an adenocarcinoma.

Basal nucleus of Meynert: Formed in the brain by a group of cells in the substantia innominata.

Beau's lines: Transverse depression of the nail that represents interruption to the normal growth of the nail matrix.

BK virus: A human polyomavirus that causes widespread infection in childhood and remains latent in the host; believed to cause haemorrhagic cystitis and nephritis in immunocompromised patients.

Bronchiectasis: Characterised by dilation of the small bronchi and bronchioles, associated with the presence of chronic pulmonary sepsis. It presents as a chronic cough, often with the production of large amounts of purulent, foul-smelling sputum, and may eventually lead to repeated episodes of pneumonia and respiratory failure.

Bronchoalveolar lavage: A procedure performed during bronchoscopy in which the bronchial tree is literally washed (lavaged) with a small volume of sterile saline. The saline is then collected and sent for microbiological or cytological examination.

Bronchoscopy: The procedure in which a flexible fiberoptic endoscope is inserted into the bronchial tree to allow direct visualisation of the bronchi and, if required, the collection of specimens for microbiology or histology.

Brugada syndrome: A genetic disease characterised by an abnormal electrocardiogram and an increased risk of sudden cardiac death. More prevalent in those from South East Asia.

Bruxism: Tooth grinding.

Budd–Chiari syndrome: Symptomatic obstruction or occlusion of the hepatic veins, usually of unknown origin but probably caused by neoplasms, strictures, liver disease, trauma, systemic infections or haematological disorders.

Buerger's test: Two-part test to assess adequacy of the arterial supply to the leg.

Bullae: A bulla (plural bullae) is a fluid filled blister of more than 5 mm in diameter with thin walls.

Cachectic: A profound and marked state of general ill health and malnutrition.

Cardiogenic emboli: Emboli originating from the heart; caused by abnormal function of the heart.

Carpal tunnel syndrome: A complex of symptoms resulting from compression of the median nerve in the carpal tunnel, with pain and burning or tingling paraesthesias in the fingers and hand, sometimes extending to the elbow.

Catamenia: Term used to designate age at onset of menses.

Cataract: An opacity of the crystalline lens of the eye.

Cavitation: Formation of cavities – for example, in the lungs when the liquefied centre of a tuberculous lesion drains (usually into a bronchus).

Charcot's arthropathy: A destructive arthropathy (disease of any joint) with impaired pain perception or position sense.

Cholelithiasis: The presence or formation of gallstones.

Chondrocyte: A mature cartilage cell embedded in a lacuna (a small pit or hollow cavity) within the cartilage matrix.

Christmas disease: Haemophilia B.

Churg–Strauss syndrome: Allergic granulomatosis.

Chvostek's sign: Spasm of the facial muscles elicited by tapping the facial nerve in the region of the parotid gland, seen in tetany.

Coarctation of the aorta: A localised malformation characterised by deformity of the aortic media, causing narrowing (usually severe) of the lumen of the vessel.

Cognitive: Pertaining to cognition; that operation of the mind by which we become aware of objects of thought or perception; it includes all aspects of perceiving, thinking and remembering.

Corneal arcus: Crescentic deposition of lipids in the cornea.

Cor pulmonale: Persistent lung damage, eventually leads to increased blood pressure in the pulmonary arteries (pulmonary hypertension), which in turn leads to stress on the right ventricle, right ventricular hypertrophy and heart failure. This process is known as cor pulmonale.

Cryptogenic: Obscure, doubtful or unascertainable origin.

Cytotoxin: A toxin or antibody that has a specific toxic action upon cells of special organs.

Denudation: Removal of the epithelial covering from any surface.

Diarthrodial joint: A joint characterised by mobility in a rotary direction.

D-Dimer: D-dimer is a product formed in the body when blood is broken down.

Dimorphic: Occurring in two distinct forms.

Disseminated intravascular coagulation (DIC): In this condition vigorous activation of the clotting cascade causes widespread intravascular deposition of fibrin and consumption of clotting factors and platelets. There are numerous potential triggers for this process, including severe sepsis, burns, massive transfusion and placental abruption.

Diverticulosis: The presence of circumscribed pouches or sacs of variable size called diverticula that occur normally or are created by herniation of the lining mucous membrane through a defect in the muscular coat of a tubular organ such as the gastrointestinal tract.

Ductopenia: Absence/shortage of ducts; typically absence of interlobular bile ducts.

Dubin–Johnson syndrome: Familial chronic form of non-haemolytic jaundice due to a defect in the excretion of conjugated bilirubin and other organic anions.

Dupuytren's contracture: Shortening, thickening and fibrosis of the palmar fascia, producing a flexion deformity of a finger. The term also applies to a flexion deformity of a toe.

Dyschezia: Difficult or painful evacuation of faeces from the rectum.

Dyskinesia: Impairment of the power of voluntary movement, resulting in fragmentary or incomplete movements.

Dyspareunia: Difficult or painful intercourse.

Dyspnoea: Difficult or laboured breathing.

Dystonia: Disordered tonicity of muscle.

Dysuria: Painful or difficult urination.

Eclampsia: Convulsions and coma occurring in a pregnant or puerperal woman, associated with hypertension, oedema and/or proteinuria.

Electrodiathermy: Heating of the body tissues due to their resistance to the passage of an electric current.

Elliptocytosis: A hereditary disorder in which the majority of erythrocytes are elliptical in shape and characterised by varying degrees of increased red cell destruction and anaemia.

Emphysema: A state in which the alveoli of the lung become dilated, possibly with destruction of the alveolar walls, leading to large, empty air spaces which are useless for gas exchange. It is often seen accompanying chronic bronchitis but may be caused by inherited disorders such as α_1 -antitrypsin deficiency.

Encephalopathy: Any degenerative disease of the brain.

Endophthalmitis: Inflammation involving the ocular cavities and their adjacent structures.

Enterostomy: The formation of a permanent opening into the intestine through the abdominal wall.

Enterotoxin: A toxin arising in the intestine.

Enthesitis: Inflammation of the entheses, the sites where tendons or ligaments insert into the bone.

Episcleritis: Inflammation of the loose connective tissue forming the external surface of the sclera.

Epstein–Barr virus: A herpes virus originally isolated from Burkitt lymphomas and believed to be the aetiological agent in infectious mononucleosis or closely related to it.

Euthymic: Normal state of thymus.

Exanthema: Widespread rash usually occurring in children caused by toxins, drugs, micro-organisms or autoimmune disease.

Faecal: Occult blood in the stools. Called 'occult' because it is partly digested and therefore no longer red in colour. Usually detected by means of a chemical test.

Faecal microbiota transplantation: Administration of a solution of faecal matter from a donor into the intestinal tract of a recipient in order to directly change the recipient's gut microbial composition and confer a health benefit.

Fanconi's anaemia: A rare hereditary disorder, transmitted in a recessive manner and having a poor prognosis, characterised by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin due to the deposition of melanin, and associated with multiple congenital anomalies of the musculo-skeletal and genitourinary systems.

Fastidious organism: An organism that will only grow with specialist culture media or under certain physiological conditions.

Feculent: Having dregs or a sediment.

Felty's syndrome: Combination of chronic rheumatoid arthritis, splenomegaly, leucopenia and pigmented spots on the skin of the lower extremities.

Fibroadenoma: Benign tumour that is made of glandular and fibrous tissue and typically occurs in breast tissue.

Fibromuscular: Composed of fibrous and muscular tissue.

Fistula: An abnormal passage or communication, usually between two internal organs or from an internal organ to the surface of the body.

Foreign body giant cells: Giant cells resembling Langhans giant cells, having clusters of nuclei scattered in an irregular pattern throughout the cytoplasm, characteristic of granulomatous inflammation due to invasion of the tissue by a foreign body.

FRAX score: Diagnostic tool used to assess the 10-year risk of a hip or osteoporotic fracture.

Gastroschisis: Congenital fissure of the abdominal wall not involving the site of insertion of the umbilical cord, and usually accompanied by protrusion of the small and part of the large intestine.

Gaucher's disease: A group of hereditary disorders of glucocerebrosidase metabolism characterised by accumulation of glucocerebrosidase in the spleen, liver, lungs, bone marrow and sometimes the brain leading to splenomegaly, hepatomegaly, erosion of the cortices of the long bones and pelvis, and central nervous system impairment.

Glasgow–Blatchford score: Screening tool to assess likelihood that a patient with an acute upper gastro-intestinal bleed will require medical intervention.

Glomerulonephritis: Nephritis characterised by inflammation of the capillary loops in the glomeruli of the kidney.

Glossitis: Inflammation of the tongue.

Goeckerman regimen: Combination of coal tar and ultraviolet B light to bombard the skin with anti-psoriasis treatment.

Gonioscopy: Estimate of the width of the eye chamber angle, measured using a slit lamp.

Goodpasture's disease: Autoimmune disease characterised by glomerulonephritis and haemorrhaging from the lung.

Granuloma: A tumour-like mass or nodule of granulation tissue, with actively growing fibroblasts and capillary buds; it is due to a chronic inflammatory process associated with infectious disease or with invasion by a foreign body.

Guillain–Barré syndrome: Acute febrile polyneuritis.

Haematuria: Blood in the urine.

Haem(at)opoiesis: The formation and development of blood cells.

Harris Benedict equation: Equation first developed in 1919 to predict basal energy expenditure.

Hasenclever score: Prognostic score for Hodgkin's disease.

Haustral: Pertaining to the haustra of the colon, denoting sacculations in the wall of the colon produced by adaptation of its length.

Heberden's nodes: Gelatinous cysts or bony outgrowths on the dorsal aspects of the distal interphalangeal joints.

Heinz bodies: Inclusion bodies in red blood cells resulting from oxidative injury to and precipitation of haemoglobin, seen in the presence of certain abnormal haemoglobins and erythrocytes with enzyme deficiencies.

Henoch–Schönlein purpura: An acute or chronic vasculitis primarily affecting skin, joints and the gastro-intestinal and renal systems.

Hepatorenal syndrome: Development of renal failure secondary to liver disease.

Hirschsprung's disease: Congenital megacolon.

Horner's syndrome: Sinking in of the eyeball, ptosis of the upper eyelid, slight elevation of the lower lid, constriction of the pupil, narrowing of the palpebral fissure, anhidrosis and flushing of the affected side of the face; caused by paralysis of the cervical sympathetic nerves.

Horton's syndrome: Migrainous neuralgia; also called paroxysmal nocturnal cephalalgia.

Huntington's chorea: A rare hereditary disease characterised by chronic progressive chorea and mental deterioration terminating in dementia. The age of onset is variable but usually occurs in the fourth decade of life.

Hyaline membrane: A layer of eosinophilic hyaline material lining the alveoli, alveolar ducts and bronchioles, found at autopsy in infants who have died of respiratory distress syndrome of the newborn.

Hypermelanosis: Excessive deposition of melanin.

Hypersplenism: A condition characterised by exaggeration of the inhibitory or destructive functions of the spleen, resulting in deficiency of the peripheral blood elements, singly or in combination, hypercellularity of the bone marrow and usually splenomegaly.

Hypertrichosis: Growth of hair at sites not normally hairy.

Hypophonic: Reduced volume of speech.

Hypovolaemia: Abnormally reduced volume of circulating fluid in the body/plasma.

Ileus: Obstruction or lack of smooth muscle tone in the intestines.

Immunoblastic: Pertaining to or involving the stem cells (immunoblasts) of lymphoid tissue.

Index case: The first detected case in a particular series that prompts investigation into other patients.

Interstitial nephritis: Inflammation of the renal interstitial tissue resulting from arterial, arteriolar, glomerular or tubular disease which destroys individual nephrons.

Intussusception: The prolapse of one part of the intestine into the lumen of an immediately adjoining part.

Involved-site radiation therapy: Radiation therapy aimed only at the lymph nodes which originally contained lymphoma.

Jod–Basedow syndrome: Thyrotoxicosis produced in a patient with goitre, when given a bolus of iodine.

Kayser–Fleischer ring: A grey-green to red-gold pigmented ring at the outer margin of the cornea, seen in progressive lenticular degeneration and pseudosclerosis.

Koebner phenomenon: Induction of new psoriasis skin lesions following local trauma or injury to the skin.

Koilonychia: Dystrophy of the fingernails, in which they are thin and concave, with edges raised.

Kussmaul's respiration: Air hunger.

Kwashiorkor: Insufficient protein provision.

Kyphosis: Abnormally increased convex curvature of the spinal column.

Labyrinthitis: Inflammation of the labyrinth; otitis interna.

Lacunar syndrome: Small infarct or small cavity in brain tissue that develops after the necrotic tissue of a deep infarct is resorbed.

Laminectomy: Excision of the posterior arch of a vertebra.

Laparoscopy: Examination of the interior of the abdomen by means of a laparoscope.

Lesch–Nyhan syndrome: Rare disorder of purine metabolism due to deficiency of the enzyme hypoxanthine-guanine phosphoribosyl-transferase and characterised by physical and mental retardation, self-mutilation of fingers and lips by biting, choreo-athetosis, spastic cerebral palsy and impaired renal function.

Leucocytosis: Total white cell count in excess of $11 \times 10^9/L$.

Leuconychia: White nails.

Lewy bodies: Abnormal protein aggregates which develop inside neurons.

Lichenoid: Resembling the skin lesions designated as ‘lichen’ – the name applied to many different kinds of papular skin.

Liddle’s syndrome: Autosomal dominant disorder in which the kidneys excrete potassium but retain too much sodium and water, leading to high blood pressure diseases in which the lesions are typically small, firm papules that are usually set very close together.

Lipæmia retinalis: Retinal deposition of lipid.

Lipohypertrophy: Thickening of subcutaneous tissues at injection sites because of recurrent injections in the same area.

Livedo reticularis: A peripheral vascular condition characterised by a reddish blue net-like mottling of the skin and extremities.

Lyme disease: A multisystem tick-borne disorder caused by the spirochaete *Borrelia burgdorferi*. Clinical manifestation includes an erythematous macule followed by systemic disorders, such as arthralgias, myalgias and headache, followed by neurological manifestations, cardiac involvement and a migratory polyarthritis.

Lymphadenopathy: Disease of the lymph nodes.

Lymphoblastic: Pertaining to a lymphoblast.

Maculopapular: An eruption consisting of both macules (areas distinguishable by colour from their surroundings, e.g. spots) and papules (small circumscribed, superficial, solid elevations of the skin).

Malleolus medialis: The rounded protuberance on the medial surface of the ankle joint.

Mallory-Weiss tear: Occurs in the mucus membrane at the junction of the lower part of the oesophagus and the upper part of the stomach.

Malrotation: Abnormal or pathological rotation.

Marasmus: Insufficient energy provision.

Melaena: The passage of dark stools stained with blood pigments or with altered blood.

Menorrhagia: Excessive and prolonged uterine bleeding occurring at the regular intervals of menstruation.

Microalbuminuria: Small amounts of albumin present in the urine.

Miliary: Literally, resembling small, round millet seeds. Miliary tuberculosis is so called because the chest radiograph usually shows miliary speckling.

Morbilloform: Resembling the eruption of measles.

Mucositis: Inflammation of a mucous membrane.

Mycosis fungoides: A rare, chronic, malignant, lymphoreticular neoplasm of the skin and, in the late stages, the lymph nodes and viscera, marked by the development of firm, reddish, painful tumours that ulcerate.

Myelofibrosis: Replacement of the bone marrow by fibrous tissue occurring in association with a myeloproliferative disorder or secondary to another disorder.

Myoclonus: Shock-like contractions of a group of muscles.

Myoglobulinuria: Presence of myoglobin in the urine.

Myomas: Fibroids, common benign tumours of the myometrium.

Myometrium: The muscular layers of the uterus that contract spontaneously throughout the menstrual cycle.

Myopathy: Unexplained muscle soreness or weakness.

Myositis: Inflammation of a voluntary muscle.

Necrobiosis lipoidica: A dermatosis usually occurring in individuals with diabetes characterised by necrobiosis (swelling and distortion of collagen bundles in the dermis) of the elastic and connective tissue of the skin, with degenerated collagen occurring in irregular patches, especially in the upper dermis.

Nephrolithiasis: Formation of uric acid calculi in the kidneys.

Nikolsky’s sign: Easy separation of the outer portion of the epidermis from the basal layer on exertion of firm sliding pressure by the finger or thumb.

Nocturia: Waking at night to pass urine.

Nosocomial: Originally taking place in a hospital, or acquired in a hospital, used particularly in reference to an infection.

Nystagmus: Involuntary rapid movement of the eyeball, which may be horizontal, vertical, rotatory or mixed.

Obligate intracellular pathogen: An organism that cannot be cultured using artificial media because it requires living cells for growth.

Oligohydramnios: Presence of less than 300 mL of amniotic fluid at term.

Oliguria: Diminished urine output.

Onycholysis: Separation of the nail from its bed.

Oophorectomy: Removal of an ovary or ovaries.

Ophthalmopathy: Any disease of the eye.

Opsionisation: The rendering of bacteria and other cells subject to phagocytosis.

Orchiectomy: Excision of one or both testes.

Orosomucoid: α_1 -Acid glycoprotein, a glycoprotein occurring in blood plasma.

Orthopnoea: Difficult breathing except in an upright position.

Orthoptic: Correcting obliquity of one or more visual axes.

Osler’s nodes: Small, raised, swollen tender areas, about the size of a pea and often bluish, but sometimes pink or red, occurring most commonly in the pads of the fingers or toes, in the palm or the soles of the feet.

Osteomalacia: Reduced mineralisation.

Osteophyte: A bony or osseous outgrowth.

Pallidotomy: A stereotaxic surgical technique for producing lesions in the globus pallidus or extirpation of it by other means.

Palmar striae: Yellow raised streaks across the palms of the hands.

Pancytopenia: Deficiency of all cell elements of the blood.

Panmyelopathy: A pathological condition of all the elements of the bone marrow.

Paroxysmal nocturnal dyspnoea: Difficult or laboured breathing at night that recurs in paroxysms.

Pericarditis: Inflammation of the fibrous sac (pericardium) that surrounds the heart and the roots of the great vessels.

Petechial: Characterised by pinpoint, non-raised, round, purplish red spots caused by intradermal or submucous haemorrhage.

Phaeochromocytoma: A tumour of chromaffin tissue of the adrenal medulla or sympathetic paraganglia. The cardinal symptom that represents the increased secretion of adrenaline and noradrenaline is hypertension, which may be persistent or intermittent.

Phagocytosis: The engulfing of micro-organisms, cells and foreign particles by phagocytes.

Phlebitis: Inflammation of a vein.

Pica: A craving for unnatural articles of food.

Pneumaturia: Passage of urine charged with air.

Polyangiitis: Previously known as Churg–Strauss syndrome is a type of systemic necrotising vasculitis.

Polycythaemia rubra vera: A myeloproliferative disorder in which the abnormal bone marrow overproduces red blood cells (white cells and platelets may also be raised).

Polymorphic: Occurring in several or many forms.

Polyp: A protruding growth from a mucous membrane.

Pompholyx: A skin eruption on the sides of the fingers, toes, palms or soles, consisting of discrete round intraepidermal vesicles 1 or 2 mm in diameter, accompanied by intense itching and occurring in repeated self-limited attacks lasting 1 or 2 weeks.

Porphyria: Any of a group of disturbances of porphyrin metabolism, characterised by a marked increase in formation and excretion of porphyrins or their precursors.

Pouchitis: Inflammation of the ileal pouch which will have been surgically formed from ileal tissue.

Pretibial myxoedema: Localised myxoedema associated with preceding hyperthyroidism and exophthalmus, occurring typically on the anterior (pretibial) surface of the legs where mucin deposits as plaques and papules.

Priapism: Persistent, abnormal erection of the penis, usually without sexual desire, and accompanied by pain and discomfort.

Prinzmetal's angina: A variant of angina pectoris in which the attacks occur during rest.

Proptosis: A forward displacement or bulging, especially of the eye.

Pseudophakia: False lens.

Pyruvate kinase deficiency: A deficiency in the glycolytic (metabolic) pathway of red blood cells that results in haemolysis.

Pyuria: Presence of pus in the urine.

Raeder's syndrome: A syndrome consisting of Horner syndrome but without loss of sweating on the affected side of the face.

Reed–Sternberg cells: Giant histiocytic cells, typically multinucleate, most often binucleate; the nuclei are enclosed in abundant amphophilic cytoplasm and contain prominent nucleoli.

Retinopathy: Any non-inflammatory disease of the retina.

Retroperitoneal fibrosis: Deposition of fibrous tissue in the retroperitoneal space, producing vague abdominal discomfort, and often causing blockage of the ureters with resultant hydronephrosis and impaired renal function.

Retrosternal: Situated or occurring behind the sternum.

Reiter's syndrome: Triad of non-gonococcal urethritis, conjunctivitis, and arthritis frequently with mucocutaneous lesions.

Reye's syndrome: An acute and often fatal childhood syndrome of encephalopathy and fatty degeneration of the liver, marked by rapid development of brain swelling and hepatomegaly, and by disturbed consciousness and seizures.

Rhabdomyolysis: Dissolution of muscle associated with excretion of myoglobin in the urine.

Rockall score: Scoring system to identify patients at risk of adverse outcome following acute upper gastro-intestinal bleed.

Roth's spots: Round or oval white spots sometimes seen in the retina early in the course of subacute bacterial endocarditis.

Rotor's syndrome: Chronic familial non-haemolytic jaundice differing from Dubin–Johnson syndrome in the lack of liver pigmentation.

Sarcoidosis: A chronic, progressive, generalised granulomatous reticulosis of unknown aetiology, involving almost any organ or tissue.

Schofield equation: An equation to predict basal metabolic rate; may be used to estimate the total calorie intake required to maintain current body weight.

Scleral icterus: A yellowing of the white of the eye.

Sclerotherapy: The injection of sclerosing solutions in the treatment of haemorrhoids or varicose veins.

Scotoma: An area of depressed vision within the visual field, surrounded by an area of less depressed or of normal vision.

Sézary syndrome: Generalised exfoliative erythroderma produced by cutaneous infiltration of reticular lymphocytes and associated with intense pruritus, alopecia, oedema, hyperkeratosis, pigment and nail changes.

Shy–Drager syndrome: Orthostatic hypotension, urinary and rectal incontinence, anhidrosis, atrophy of the iris, external ophthalmoplegia, rigidity, tremor, loss of associated movements, impotence, atonic bladder, generalised weakness, fasciculations and neuropathic muscle wasting.

Sickle cell anaemia: A hereditary haemolytic anaemia occurring almost exclusively in black people, characterised by arthralgia, acute attacks of abdominal pain, ulcerations of the lower extremities and sickle-shaped erythrocytes in the blood.

Sjögren's syndrome: A symptom complex of unknown aetiology, usually occurring in middle-aged or older women, in which keratoconjunctivitis is associated with pharyngitis sicca, enlargement of the parotid glands, chronic polyarthritis and xerostomia.

Sloughing material: Soft, gel-like material often found in ulcer bases. Composed of tissue exudate and cellular debris.

Spherocytosis: The presence of spherocytes (thick, almost spherical red blood cells) characterised by abnormal fragility of erythrocytes, jaundice and splenomegaly.

Splinter haemorrhages: Linear haemorrhages beneath the nail.

Steatosis: Fatty degeneration.

Stenosis: Narrowing or stricture of a duct or canal.

Stevens–Johnson syndrome: A severe form of erythema multiforme in which the lesions may involve the oral and anogenital mucous membranes in association with constitutional symptoms, including malaise, prostration, headache, fever, arthralgia and conjunctivitis.

Stromal keratitis: Immune-mediated non-suppurative stromal inflammation with an intact epithelium usually linked to a causative disorder such as Epstein–Barr virus, herpes zoster and simplex, mumps, measles, Lyme disease and tuberculosis.

Subchondral: Beneath a cartilage.

Subluxation: An incomplete or partial dislocation.

Substantia nigra: Basal ganglia structure located in the midbrain.

Supranuclear palsy: Pseudobulbar paralysis.

Sweet's syndrome: Acute febrile neutrophilic dermatosis.

Sympathetic ileus: Failure of gastro-intestinal motility secondary to acute non-gastro-intestinal illness, for example, hyaline membrane disease or septicaemia.

Tamponade: Surgical use of the tampon; also pathological compression of a part, as compression of the heart by pericardial fluid.

Tau neurofibrillary tangles: These insoluble proteins are a primary marker of Alzheimer's.

Telangiectasia: Prominent surface blood vessels.

Tendon xanthomas: Yellow papules or nodules or lipids deposited in tendons.

Tenesmus: Straining, especially ineffectual and painful straining at stool or in urination.

Tenosynovitis: Inflammation of a tendon sheath.

Thalassaemia: A heterogeneous group of hereditary haemolytic anaemias that have in common a decreased rate of synthesis of one or more haemoglobin polypeptide chains, which are classified according to the chain involved (a, b, g). The homozygous form (thalassaemia major) is incompatible with life. The heterozygous form (thalassaemia minor) may be asymptomatic or marked by mild anaemia.

Thrombocytopenia: Decrease in the number of blood platelets.

Thrombocytosis: Increased number of platelets in blood.

Thrombophilia: A tendency to the occurrence of thrombosis.

Thromboplastin: Phospholipid-protein extract of tissue that promotes the activation of factor X by factor VIII.

Tonometry: Measurement of intraocular pressure.

Tophi: Deposits of monosodium urate crystals, typically in subcutaneous and periarticular areas.

Trephine: Biopsy examination of an intact core of tissue (e.g. liver, bone marrow) obtained through a wide-bore needle.

Tropical sprue: A malabsorption syndrome occurring in the tropics and subtropics. Protein malnutrition is usually precipitated by the malabsorption, and anaemia due to folic acid deficiency is particularly common.

Trousseau's sign: Spasmodic contractions of muscles provoked by pressure upon the nerves which go to them; seen in tetany.

Tuberoeruptive xanthomas: Groups of flat or yellowish raised nodules on the skin over joints, especially the elbows and knees.

Tuberous sclerosis: Congenital familial disease characterised by tumours on the surfaces of the lateral ventricles and sclerotic patches on the surface of the brain and marked clinically by progressive mental deterioration and epileptic convulsions.

Tubular cast: A cast formed from gelled protein precipitated in the renal tubules and moulded to the tubular lumen; pieces of these casts break off and are washed out with the urine.

Uraemic frost: Crystalline area deposited on the skin.

Urethral: Pertaining to the urethra, the membranous canal conveying urine from the bladder to the exterior of the body.

Variant angina: *See* Prinzmetal's angina.

Volvulus: Intestinal obstruction due to a knotting and twisting of the bowel.

Von Willebrand's disease: A lack of or a defective plasma protein (von Willebrand factor) necessary for the adhesion of platelets to vascular elements when a blood vessel is damaged.

Wernicke-Korsakoff syndrome: The co-existence of Wernicke's disease (acute onset of mental confusion, nystagmus, ophthalmoplegia and gait ataxia, due to thiamine deficiency) with Korsakoff's syndrome (a gross disturbance in recent memory, sometimes compensated for by confabulation).

West's syndrome: A form of myoclonus epilepsy with onset in infancy or early childhood and characterised by seizures involving the muscles of the neck, trunk and limbs, with nodding of the head and flexion and abduction of the arms. Mental retardation is common.

Wilson's disease: Characterised by progressive accumulation of copper within body tissues, particularly erythrocytes, kidney, liver and brain, and associated with liver and lenticular degeneration.

Xanthelasma: Yellow plaques or nodules of lipids deposited on eyelids.

Xenotransplantation: Transplantation of tissue from another species.

Xerosis: Dry skin.

in chronic kidney disease, 305–306
in diabetes, 772
with diabetes, 327–328
in elderly, 327
and lipoprotein levels, 423t
potential problems with, 374
in pre-renal acute kidney injury, 279
for stable angina, 340
for ST-elevation myocardial infarction, 349, 349t
teratogenicity of, 821, 822t
- Angiotensinogen, 295
- Anglo Scandinavian Cardiac Outcomes Trial
(ASCOT) study, 324, 326
- Anidulafungin, 712t–713t, 730t, 735t, 737t, 739
- Anion exchange resins, pruritus in liver disease, 265
- Anisocytosis, 84t
- Ankle brachial pressure index, 1025, 1026t
- Ann Arbor classification system, Cotswolds
modification of, 892, 892t

- Anoro (umeclidinium/vilanterol), for chronic obstructive pulmonary disease, 462
- Antacids
absorption of, 55
constipation from, 233t
diarrhoea from, 236t
for dyspepsia, 190
- Antagonistic interactions, 60–61
- Anthracyclines
for acute lymphoblastic leukaemia, 875
for acute myeloblastic leukaemia, 875–877
for acute promyelocytic leukaemia, 878
- Anti-androgens, for prostate cancer, 847
- Antiarrhythmic drugs, 394
class I, 394–397
class Ia, 396
class Ib, 396
class Ic, 396–397
class II, 397, 397f
class III, 398
class IV, 399
pharmacokinetics of, 395t–396t
- Antibacterials
for chronic heart failure, 372t–373t
diarrhoea from, 236t
- Antibiotics
for asthma, 449
for bronchitis, 611
for chronic obstructive pulmonary disease, 464–465, 613
for cystic fibrosis, 618
for diarrhoea, 235, 238
elimination of, 60
for gastro-intestinal infections, 635–636, 640–643
for hepatic encephalopathy, 269
hepatotoxicity of, 249
for hospital-acquired pneumonia, 616
for infection
in acute kidney injury, 287
in neutropenia, 883
for inflammatory bowel disease, 219, 222t–223t
intrathecal and intraventricular administration of, 656, 656t
for neonates
with infection, 135
monitoring of, 137
with necrotizing enterocolitis, 136
for otitis media, 610
for pain, 587t
prophylaxis
for leukaemia, 882
for urinary tract infections, 632
for prostatitis, 851
resistance, in urinary tract infections, 629
for sore throat, 609
for urinary tract infections, 630t
- Anti-CD3 monoclonal antibodies, 764
- Anti-CD33 monoclonal antibody, for acute myeloblastic leukaemia, 877
- Anticholinergics
absorption of, 55
in elderly, 160
for schizophrenia, 516–517
- Anticholinesterases, 161
- Anti-citrullinated peptide antibodies (ACPAs), 925
- Anticoagulants
metabolism of, 58, 59t
for NSTEMI, 351–352, 351f–352f
for ST-elevation myocardial infarction, 347, 350
for stroke, 163
for venous thromboembolism, 409–413
- Anticonvulsants
for bipolar disorders, 508
for chronic heart failure, 372t–373t
hepatotoxicity of, 245
mood disorders and, 499b
- Anticytokine monoclonal antibodies, for graft-versus-host disease, 881
- Antidepressants, 503
adverse effects of, 501
for anxiety disorders, 490–491
constipation from, 233t
for COPD, 468
diarrhoea from, 236t
for insomnia, 479
mood disorders and, 499b
for pain, 587, 587t
clinical use of, 587
in premenstrual syndrome, 796
for ST-elevation myocardial infarction, 349–350
- Antidiabetic agent, diarrhoea from, 236t
- Antidiarrhoeals, for inflammatory bowel disease, 219
- Antidiuretic hormone (ADH), 87–88, 295
- Antidopaminergics, 600
- Antidotes, for drug-induced liver injury, 250–252
- Antiemetics, 598–601
constipation from, 233t
diarrhoea from, 236t
for ST-elevation myocardial infarction, 344–345
- Antiepileptic drugs
action of, 532, 532f
adverse reaction to, 70–71
altering drug regimens, 530
constipation from, 233t
development of, 532
diarrhoea from, 236t
for different seizure types, 529t
dose changes of, 531
drug interactions involving, 535t
follow-up of, 531
hepatotoxicity of, 249
initiation of therapy, 529
maintenance dosage of, 529–530, 533t
metabolism of, 56–57
monitoring of, 531
newer, 530t, 531
for pain, 587–588, 587t
practice points on, 537t
profiles, 532–539
side-effect profile of, 536t
starting doses of, 533t
withdrawal of, 530–531
- Antifibrinolytic drugs, in heavy menstrual bleeding, 801
- Antifibrotic agents, for primary biliary cholangitis, 274
- Antifungal agents, 729
administration difficulties, 740t–741t
for chronic heart failure, 372t–373t
diarrhoea from, 236t
for infection in neutropenia, 883
pharmacokinetics of, 737t
resistance to, 740t–741t
side effects of, 730t
spectrum of activity in, 735t
toxicity of, 740t–741t
- Antiglutamic acid decarboxylase (GAD) antibodies, 763
- Antihistamines
absorption of, 55
antiemesis, 598–600, 603
for eczema, 1002
for insomnia, 478t, 479–480
for pain, 588
- Antihistamines (*Continued*)
for pruritus
in chronic kidney disease, 307
in liver disease, 265
- Antihypertensive drugs, 165
dyslipidaemia and, 424–425
hepatotoxicity and, 249
for hypertension
in chronic kidney disease, 305
classes of, 322–324
clinical trial evidence of, 325–326
recommendations for drug sequencing in, 326
selection of, 325, 325t
timing of dosing in, 326
- Anti-IL-6 antibodies, for graft-versus-host disease, 881
- Anti-ischaemic drugs, for NSTEMI, 352
- Antilymphocyte globulin, in renal transplantation, 313
- Antimalarials
diarrhoea from, 236t
mood disorders and, 499b
psoriasis and, 1005
- Antimicrobial catheters, 631
- Antimicrobials
for diarrhoea, 238
inappropriate prescribing of, 15
for meningitis, 650–656
pharmacokinetics of, 650, 650t
prophylaxis, in surgical site infection, 664–669
cephalosporin-free, 667t
choice of antimicrobial in, 664
commonly isolated microorganism in, 666t–667t
 β -lactam allergy in, 669, 670t
number needed to treat for, 666t
recommendations for, 665t
repeat doses in, 668–669, 668f, 669t
susceptibility of common pathogens in, 666t
timing and duration of, 664–668, 668f
topical or local, 669–670
recommended regimens of, 650–656
- Antimotility agents, for diarrhoea, 238
- Antimuscarinic receptor antagonists, for benign prostatic hyperplasia, 841
- Antimuscarinics, 600
constipation from, 233t
for detrusor instability, 167
long-acting, 461
for Parkinson's disease, 551
short-acting, 461
- Anti-nerve growth factor (anti-NGF) monoclonal antibodies, for osteoarthritis, 944
- Anti-neutrophil cytoplasmic antibody (ANCA)-associated AVV, 280–281
- Antinuclear antibodies (ANAs), 925–926
lupus erythematosus and, 992
- Antioxidants
for coronary heart disease, 338
and dyslipidaemia, 427–428
nitrates and, 342
- Antiplatelet therapy
for NSTEMI, 350–352, 351f–352f
for ST-elevation myocardial infarction, 345, 345t, 347, 350
for stroke, 163
- Antiprotozoals, diarrhoea from, 236t
- Antipsychotics, 515
'atypical,' 515–516
classification of, 515f
constipation from, 233t
depot, 518, 519f, 520t
diarrhoea from, 236t
dose of, 516–517

- Antipsychotics (*Continued*)
 drug-induced parkinsonism and, 546t
 individuals response to, 515
 interactions and, 508t–509t, 518–519
 long-acting formulations, 518, 519f
 longer-term prescribing of, 572
 for mania, 506
 maximum and equivalent doses of, 518
 mode of action of, 515
 movement disorders associated with, 517b
 onset of effect of, 518
 selecting of, 516–517
 side effects of, 516–517
 ‘typical,’ 515–516
 use, 517–518
- Antiretroviral therapy
 choosing and monitoring, 693–694, 694b
 commonly used, 695t–702t
 highly active, 693
 in HIV infection, 693–707
 post-exposure prophylaxis in, 694–703
 pre-exposure prophylaxis in, 703
 for primary biliary cholangitis, 274
 starting, 693
 studies, 693
 toxicity of, 705–706
 treatment interruptions in, 694
- Antispasmodics
 for dysmenorrhoea, 798
 for pain, 587t
- Antithrombin drugs, for NSTEMI, 350
- Antithrombin III deficiency, 405
- Antithymocyte globulin, in renal transplantation, 313
- Antithyroid drugs, 751–752
 adverse effects of, 752, 752t
 patient counselling, 752, 753b
 regimen, 752
- Anti-TNF- α antagonists, for inflammatory bowel disease, 217
- α 1-Antitrypsin deficiency, 262
- Anti-tumour necrosis factor (anti-TNF), for graft-versus-host disease, 881
- Antivirals
 constipation from, 233t
 diarrhoea from, 236t
 for hepatitis C, 272
- Antral gastritis, 175
- Anxiety disorders, 484–494
 acute heart failure with, drug therapy for, 361t
 aetiology of, 486–487
 case studies on, 492–493
 clinical manifestations of, 486–487
 definitions of, 484–485
 differential diagnosis of, 487
 division of, 484–485, 485t
 epidemiology of, 484–485, 484f, 485b
 investigations of, 487
 neurotransmitters and, 486
 pathophysiology of, 485–486, 486f
 symptoms of, 484–485, 484f
 treatment of, 487–491, 492t
 antidepressant drugs for, 490–491
 benzodiazepines for, 487–490, 488t, 490b
 pharmacotherapy for, 487–491, 492t
 psychological interventions for, 487
- Anxiolytics, for pain, 588
- Apixaban
 for atrial fibrillation, 391t
 pharmacokinetics of, 390t
 for venous thromboembolism, 411–412
- Apnoea, neonatal, 136
- Apolipoprotein C-II deficiency, familial, 422–423
- Apomorphine, for Parkinson’s disease, 549
- Apoproteins (apo), 419
- Appendectomy, 197
- APPT. *see* Activated partial thromboplastin time
- Apraclonidine, for glaucoma, 976, 976t
- Apreritant, 918
 diarrhoea from, 236t
- Aptivus, 704
- Aqueous humour, 966
- Arachidonic acid
 in heavy menstrual bleeding, 800
 pathway, 176f
- Arachnoid mater, 647
- Arachnoid villi, 647
- ARBD. *see* Alcohol-related brain damage
- Area postrema, 598
- Area under the concentration time curve (AUC), 37, 37f
- Arginine vasopressin, in chronic heart failure, 359
- Aripiprazole, 520t
 diarrhoea from, 236t
- Aromatase inhibitor, for chemoprevention, 911
- Aromatherapy, for dementia, 575
- Arousal system, 485–486, 486f
- Arrhythmias, 380–403
 abnormal impulse formation in, 382–384
 abnormal automaticity in, 382–383, 383f
 triggered activity in, 383–384, 383f
 abnormal impulse propagation, re-entry, 384, 384f
 acute heart failure with, drug therapy for, 361t
 cardiac action potential in, 380–381, 381f
 case studies on, 401–402
 clinical problems, 384
 depolarisation in, 381
 diagnosis, 385
 from digoxin, 374
 drug therapy for, 394–400
 management of, 385–394, 401t
 mechanisms, 382–384
 normal cardiac conduction, 381–382, 382f
 normal cardiac electrophysiology, 380–382
 patient care, 400–401
 refractoriness, 381
 repolarisation in, 381
 in ST-elevation myocardial infarction, 348–349
 Vaughan-Williams classification of, 394–400
- Arsenic salts, for inflammatory bowel disease, 222t–223t
- Arsenic trioxide (ATO), for acute promyelocytic leukaemia, 878
- Arterial blood gases, 101–102, 102t
 interpretation of, 102, 102t
- Arterial leg ulcers, 1027–1028
 clinical signs of, 1027, 1027f
 diagnosis of, 1027
 prevention of recurrence of, 1028
 treatment of, 1027
- Arterial thromboembolism, 413–415
 aetiology of, 413–414
 case studies on, 415–416
 patient care for, 415
 treatment and prevention of, 414–415
 aspirin for, 414
 clopidogrel for, 414
 dipyridamole for, 414–415
 glycoprotein IIb/IIIa inhibitors for, 415
 prasugrel for, 414
 ticagrelor for, 414
- Arteriosclerosis, in chronic kidney disease, 297
- Arthritis, 165
 in chronic heart failure, 369

- Betahistine, antiemesis, 603
- Betamethasone, 132, 134
- Betaxolol
 adverse effects of, 974–975
 for glaucoma, 973t, 974–975
 properties and pharmacokinetics of, 341t
- Bevacizumab, for solid tumours, 916
- Bicalutamide, prostate cancer and, 847
- Bicarbonate, 102
 in extracellular fluid osmolality, 88
 in haemodialysis, 288
 in oral rehydration solution, 237–238
- Bifidobacteria*, 197
- Biguanides
 adverse effects of, 780–782
 in diabetes mellitus, 780–782, 781t
 mode of action, 780
- Bilateral renal artery stenosis, in ACE inhibitors, 363–364
- Bile acid binding agents
 adverse effects of, 433
 for dyslipidaemia, 432–433, 432t
 patient counselling on, 433
- Bile salt sequestrants, for inflammatory bowel disease, 219
- Biliary drainage system, 258, 259f
- Biliary excretion, 60
- Biliary fistula, 112t
- Bilirubin
 in liver disease, 264
 in liver function tests, 93–94
 unconjugated, 93

- Bimatoprost
for glaucoma, 970, 971t, 972–973
side effects of, 972–973
timolol and, 978
- Bioavailability, 37
- Biochemical liver function tests, in liver disease, 264
- Biochemical tests, in drug-induced liver injury, 249
- Biofilms, 1021
- Biologic agents, for inflammatory bowel disease, 214–219, 216t–217t
with immunomodulators, 218–219
medication optimisation of, 219
- Biologic disease-modifying anti-rheumatic drugs
response to, 938
for rheumatoid arthritis, 931–937
- Biopsy urease test, for *Helicobacter pylori*
detection, 178
- Biosimilars, for rheumatoid arthritis, 931
- Bipolar disorder, 495–496, 496f
case studies on, 510–512
clinical manifestations of, 498, 499b
incidence of, 496
- Bisacodyl, for constipation, 167, 234
- Bismuth chelate, for peptic ulcer disease, 189–190
- Bismuth salts, for inflammatory bowel disease, 222t–223t
- Bisoprolol
for chronic heart failure, 364t–365t, 365
for coronary heart disease, 12t
diarrhoea from, 236t
properties and pharmacokinetics of, 341t
for stable angina, 340–341
- Bisphosphonates
absorption of, 55
as alternative to HRT, 816
constipation from, 233t
diarrhoea from, 236t
for hypercalcaemia, 757t
for osteoporosis, 164
for pain, 587t
for prostate cancer, 847–848
- Bivalirudin, 347–348
for NSTEMI, 351–352
- Black cohosh, as alternative to HRT, 816
- Bladder, menopausal changes in, 807
- Blatchford score, 177, 178t
- Bleeding, in acute liver failure, 271
- Bleomycin, for Hodgkin's lymphoma, 893–894, 894t
- α -Blockers
constipation from, 233t
for hypertension, 325t, 330t
- β -Blockers, 423t
adverse effects of, 395t, 973, 974t
for anxiety disorders, 491
for arrhythmias, 386, 391, 394, 397, 397f
in ST-elevation myocardial infarction, 348
for chronic heart failure, 360, 364t–365t, 365, 368–371, 370t, 372t–373t
constipation from, 233t
for coronary heart disease, 11t
diarrhoea from, 236t
dyslipidaemia and, 424–425
fibrinolysis and, 348
for glaucoma, 970, 973–975, 973t
for hypertension, 323, 325t, 326, 330t
with diabetes, 327–328
in elderly, 327
for hypertension, in chronic kidney disease, 306
lipid solubility of, 397
mood disorders and, 499b
for NSTEMI, 352
potential problems with, 374
- β -Blockers (*Continued*)
properties and pharmacokinetics of, 341t
psoriasis and, 1005
for stable angina, 340–341
for ST-elevation myocardial infarction, 349
teratogenicity of, 822t
in thyroid disease, 747t
- Blood
cultures, for gastro-intestinal infections, 640
glucose, in ST-elevation myocardial infarction, 349
test, in chronic heart failure, 360t
- Blood pressure
lifestyle modifications on, 321t
measuring, 319
regulation of, 318
target, 322, 322t
threshold, for intervention, 321t
- Blue bloater, 459
- Body mass index (BMI)
dyslipidaemia and, 425
hormone replacement therapy and, 809
parenteral nutrition and, 105, 105t
- Body surface area (BSA), 146
- Body weight, 144, 144t
ageing and, 808
and dyslipidaemia, 426–427
- Bone disease, in chronic kidney disease, 301, 301f–302f
- Bone marrow
leukaemia and, 874
sideroblastic anaemia and, 861
suppression of
chemotherapy and, 919, 903t, 904
transplantation of, 877
- Bones
complications of, in ulcerative colitis, 202
menopausal changes in, 807–808, 813, 813f
metastatic pain, 590–591, 590t
- Borage, 62
- Borago officinalis*, 62
- Bortezomib, for Hodgkin's lymphoma, 898
- Bosutinib, for chronic myelocytic leukaemia, 879
- Botulinum toxin, 588
- Botulism, 639
- Bouchard's nodes, 941
- Bowel cancer, 909
- Bradycardia, 393–394
AV block, 393
from digoxin, 367, 374
first degree, 393–394
management of, 394
second degree, 394
sinus, 394
third degree, 394
- Bradykinesia, 545
- Brain-type natriuretic peptide (BNP) and N-terminal (NT) proBNP (BNP/NT-proBNP) level, in chronic heart failure, 359–360
- Breast cancer, 909
adjuvant chemotherapy for, 915
hormone replacement therapy and, 814t–815t, 815
- Breastfeeding, tuberculosis in, 685
- Breath-actuated metered dose inhaler, 452
- Breathlessness, acute heart failure with, drug therapy for, 361t
- Brentuximab vedotin, for Hodgkin's lymphoma, 895–896
- Bretylium
adverse effects of, 395t
pharmacokinetics of, 396t
- Brimonidine
brinzolamide and, 978
contraindications to, 976
for glaucoma, 976, 976t
timolol and, 978
- Brinzolamide, timolol and, 978
- British Asians, hypertension in, 326
- Brivaracetam, 529t–530t
adverse effects of, 536t
for epilepsy, 532
- Bromelain, 62
- Bromocriptine, in premenstrual syndrome (PMS), 796–797
- Bronchial hyper-reactivity, 441
- Bronchiectasis, 458
- Bronchiolitis, 612–613
- Bronchitis
acute, 611
causative organisms of, 611
chronic, 457–458
clinical features of, 611
definition of, 611
diagnosis of, 611
treatment for, 611
- Bronchoconstriction, 441
- Bronchodilators
for asthma, 448–449
for chronic obstructive pulmonary disease, 461–462, 464
long-acting, 461–462
- Bronchopneumonia, 612
- Bronchopulmonary dysplasia, 134–135
- Bronchospasm, 973
- Bruton kinase inhibitor, for chronic lymphocytic leukaemia, 879
- Buccal route of administration
absorption, paediatric, 144
in children, 146
in neonates, 132
- Budd-Chiari syndrome, 248
in liver disease, 261
- Budesonide
for asthma, 443–444, 445t
for autoimmune hepatitis, 273
for inflammatory bowel disease, 208, 208t, 222t–223t
- Buerger's test, 1027
- Bulimia, 597
- Bulk-forming agents, 234
- Bumetanide, for chronic heart failure, 361, 363t
- Bundle of His, 382
- Bupivacaine
local anaesthesia, 586
for postherpetic neuralgia, 591
- Buprenorphine, 584–585
- Bupropion, smoking cessation and, 466
- Burkholderia cepacia* complex, 618
- Burkitt's lymphoma, 896, 900
- Burn pain, 592
- Buserelin, prostate cancer and, 846–847
- Buspiron, for anxiety disorders, 491
- Butyrophenones, 600

C

- Cabergoline, for Parkinson's disease, 549
- Caesarian section, antimicrobial prophylaxis in, 665

- Caffeine
for apnoea, 136
transfer of, into breast milk, 831
- Calamine lotion, pruritus in liver disease, 265
- Calcineurin inhibitors
for eczema, 1002
for inflammatory bowel disease, 213–214
in liver transplantation, 271
in renal transplantation, 311–312
topical, 1002
- Calcipotriol, for psoriasis, 1007
- Calcitonin
diarrhoea from, 236t
for hypercalcaemia, 757t
for osteoporosis, 165
- Calcitriol, 301, 309
absorption of, 55
for osteoporosis, 164
pruritus in liver disease, 265
- Calcium, 95–97
distribution, 95–96, 95t, 96f
in haemodialysis, 288
for osteoporosis, 163
parathyroid hormone and, 754–757
in premenstrual syndrome, 795–796
regulation, 95t, 96
- Calcium acetate, for hyperphosphataemia, 309
in acute kidney injury, 287
- Calcium antagonists, for hypertension, 330t
- Calcium-blocking antianginal vasodilators, potential problems with, 375
- Calcium carbonate
in acute kidney injury, 287
for hyperphosphataemia, 309
in thyroid function, 747t
- Calcium-channel antagonist, 447t
- Calcium channel blockers (CCBs), 936
for arrhythmias, 399
constipation from, 233t
for hypertension, 166, 323, 325t, 326
in chronic kidney disease, 305
with diabetes, 327–328
in elderly, 327
during pregnancy, 329
on lipoprotein levels, 423t
for stable angina, 341–342
- Calcium gluconate, in acute kidney injury, 287
- Calcium leucovorin, 916
- Calcium phosphate precipitation, 114, 114t
- Calcium tablets, in hypocalcaemia, in acute kidney injury, 287
- Calf muscle pump, 1025
- Calgary Cambridge framework, 22, 22f
- Calicheamicin, for acute myeloblastic leukaemia, 877
- Calorie, for acute kidney injury, 288
- Campath-1H, for chronic lymphocytic leukaemia, 879
- Campylobacter*, 234–235, 635
gastro-intestinal infections caused by, 636t, 638t
transmission of, 635
treatment for, 641, 644t
- Canagliflozin. *see* Sodium-glucose co-transporter-2 inhibitors
- Canakinumab, for gout, 956
- Cancer
cell, 911, 912f
in HIV, 722
hormone replacement therapy and, 814–815, 814t
parenteral nutrition in, 119
risk of, tumour necrosis factor inhibitor and, 934
- Cancer pain, 589–590
adjuvant drugs and treatments for, 590
case study on, 593–594
- Cancer pain (*Continued*)
opioid use in, 589–590
specific syndromes, 590
- Candesartan, for chronic heart failure, 364t–365t
- Candida* sp.
in ear infection, 732
fungal meningitis caused by, 649
- Candidiasis, 730–731, 734t
balanitis, 731
clinical presentation of, 730
in ear infection, 732
epidemiology of, 730
neonatal, 135
oesophageal
clinical presentation of, 730
treatment of, 739
oral
clinical presentation of, 730
treatment of, 730–731
oropharyngeal/oesophageal, 709, 712t–713t
skin, 730–731
systemic, 733t
treatment of, 730–731
vaginal
clinical presentation of, 730
treatment of, 730–731
- Cangrelor, in ST-elevation myocardial infarction, 345
- Cannabinoids
antiemesis, 601
for pain, 588
- Capacity limited clearance, 38–39, 38f
- Capecitabine, 917
- Capreomycin
adverse reactions to, 682t–684t
for tuberculosis, 679t–680t
- Capsaicin, for osteoarthritis, 943
- Capsicum, 62
- Captopril
for chronic heart failure, 364t–365t, 369–370
for hypertension, 325
potential problems with, 374
- Carbamazepine, 447t
absorption of, 45
adverse effects of, 70–71, 533, 536t
for bipolar disorders, 508
for chronic heart failure, 372t–373t
diarrhoea from, 236t
distribution of, 44–45
drug interactions involving, 535t
elimination of, 45
for epilepsy, 533
metabolism of, 56–57, 59t
pharmacokinetics of, 44–45, 48t, 534t
plasma concentration-response relationship when used in treatment of epilepsy, 44
for postherpetic neuralgia, 591
practical implications of, 45
rectal administration of, 147
in thyroid function, 747t
for trigeminal neuralgia, 591
- Carbapenems
for cystic fibrosis, 619t
for gastro-intestinal infections, 642
- Carbidopa, for Parkinson's disease, 547
- Carbimazole, for thyrotoxicosis, 751–752, 751t
- Carbocysteine, for chronic obstructive pulmonary disease, 464
- Carbohydrates, in diabetes mellitus, 774
- Carbon dioxide, 102
- Carbonic anhydrase inhibitors
for glaucoma, 970, 975, 975b
side effects of, 975t, 975b
topical, 975, 975t
- Carboplatin
hypomagnesaemia caused by, 93
for non-Hodgkin's lymphoma, 895t, 900
- Cardiac action potential in, 380–381, 381f
- Cardiac biomarkers, for acute myocardial infarction, 344
- Cardiac failure, in elderly, 166
- Cardiac function, improvement of, for ST-elevation myocardial infarction, 344–345
- Cardiac glycosides, for chronic heart failure, 367t, 370t
- Cardiac markers, 99
- Cardiac rehabilitation classes, for coronary heart disease, 338
- Cardiomyopathy, chemotherapy-induced, 903t
- Cardioselective β -blockers, 365
for hypertension, 324
- Cardiovascular disease (CVD)
antiretroviral toxicity, 706
in chronic kidney disease, 297
in diabetes mellitus, 771
and lipid profile, 418–419
risk of, COX-2 inhibitors and, 930–931
- Cardiovascular drugs, potential problems with, 375, 375t
- Cardiovascular system, menopausal changes in, 808, 813–814
- Caribbean family origin, hypertension in, 318, 326
- Carmustine, for non-Hodgkin's lymphoma, 900, 902t
- Carteolol
adverse effects of, 974
for glaucoma, 973t, 974
properties and pharmacokinetics of, 341t
- Carvedilol
for chronic heart failure, 364t–365t, 365
diarrhoea from, 236t
properties and pharmacokinetics of, 341t
- Case-control studies, 75
- Case reports, 74
- Caspofungin
clinical use of, 739
diarrhoea from, 236t
for fungal infections in compromised host, 734
for infection in neutropenia, 883
for oropharyngeal/oesophageal candidiasis, 712t–713t
pharmacokinetics of, 737–738
side effects of, 730t
spectrum of activity of, 735t
- Castration
medical, 846–847
surgical, 847
- Catechol-O-methyl transferase (COMT) inhibitors, for Parkinson's disease, 549–550
- Cates plot, 77, 77f
- Catheter ablation, of arrhythmias, 390–391
- Catheter-associated urinary tract infections, 631
- Catheters, antimicrobial, 631
- CCR5 inhibitors, 704–705
- CD4 count, in HIV infection, 691, 692f
- CD20, 898
- Cefalexin
for bacteriuria of pregnancy, 631–632
for urinary tract infections, 630t
- Cefotaxime
for meningitis, 651, 652t, 654
for spontaneous bacterial peritonitis, 268
- Ceftazidime
for acute pyelonephritis, 630
for cystic fibrosis, 619t
for urinary tract infections, 631t

- Ceftriaxone
for gastro-intestinal infections, 642
for meningitis, 651, 652t, 654
- Cefuroxime
for acute pyelonephritis, 630
for urinary tract infections, 631t
- Celcentri, 705
- Celecoxib, 66
for rheumatoid arthritis, 930–931
- Celiprolol, properties and pharmacokinetics of, 341t
- Central corneal thickness, 968
- Central nervous system
leukaemia and, 873–874
menopause and, 816
prophylaxis of, for aggressive non-Hodgkin's lymphoma, 898
stimulant, constipation from, 233t
- Central venous pressure (CVP), in acute kidney injury, 284
- Centralised intravenous additive services (CIVAS), 148
- Centrally acting drugs, for hypertension, 323
in chronic kidney disease, 307
- Centrally acting vasodilator, for hypertension, 325t, 330t
- Cephalosporins
for acute pyelonephritis, 630
for cystic fibrosis, 619t
for epiglottitis, 610
for gastro-intestinal infections, 635–636, 642
for meningitis, 651–652
for sore throat, 610
surgical site infection prophylaxis and, 664
for urinary tract infections, 629
- Cerebrospinal fluid (CSF), 647, 648f
- Cerivastatin, for dyslipidaemia, 429
- Certolizumab
for inflammatory bowel disease, 218, 222t–223t
for rheumatoid arthritis, 932, 932t
- Certolizumab pegol, for inflammatory bowel disease, 216t–217t
- Cervical cancer, 909
- Cetirizine, pruritus in liver disease, 265, 266t
- Cetuximab
adverse effects of, 988
for solid tumours, 916
- CHA₂DS₂-VASc score, 388–389, 388t, 389f
- Chamomile, 62, 64
- Chan Su, 62
- Channelopathies, 380, 393, 393b
- Charcot arthropathy, in diabetes mellitus, 774
- Chelation, 55
- Chemical poisons, in acute tubular necrosis, 281t
- Chemicals, exposure to, leukaemia and, 871–872
- Chemoprevention, for solid tumours, 911
- Chemoreceptor trigger zone (CTZ), 597
- Chemotherapy
adverse effects of, 903t
cytotoxic, 914–916
adjuvant, 915
adverse effects of, 916
chemotherapy-specific adjunctive treatments, 916
neo-adjuvant, 915
patient management, 917–920
cumulative dosing in, 917–918
domiciliary treatment in, 919
dose modification or delay in, 918
drug interactions in, 918
in-patient or outpatient treatment in, 919
monitoring anticancer therapy in, 919–920
patient information and counselling in, 918
prescription verification in, 917, 917b
symptom control in, 918–919
- Chemotherapy (*Continued*)
regimen for, 914–915, 915t
dose in, 915
scheduling in, 914–915, 915f
response to, 919–920
synchronous chemoradiation in, 916
toxicity of, 919
for prostate cancer, 848
- Chemotherapy-induced nausea and vomiting, 602–603, 602t, 603b
- Chest radiography
for chronic heart failure, 360t
for chronic obstructive pulmonary disease, 459
for tuberculosis, 675
- Child health clinics, 143
- Children
adverse drug reactions in, 69, 152–153
bacteriuria in, 628
consent for, 17
constipation in, 230
diarrhoea in, 234–235
drug absorption of, 143–144
drug distribution of, 144, 144t
drug metabolism of, 145
drug therapy in, 145–149
buccal route of, 146
choice of preparation for, 146–149
dosage of, 145–146, 146t
dose regimen selection for, 149, 149t
nasogastric, gastrostomy and jejunostomy administration of, 147
oral route of, 146–147
parenteral route of, 147–148
pulmonary route of, 148–149
rectal route of, 147
suitable formulations for, 148
fluid requirements of, 148t
gastroenteritis in, 237
licensing medicines for, 153–154
medication errors in, 152–153
medicines optimisation for, 149–150
with meningitis, 651–653, 651t
monitoring parameters in, 150–152
assessment of renal function, 150–152
normal, 142–143
parenteral nutrition for, 120–122
formulation and stability issues in, 120
heparin for, 120
nutritional requirements of, 120, 121t
routes of administration in, 120–122
stages of development of, 143f
tuberculosis in, 685–686
urinary tract infection prophylaxis in, 632
urinary tract infections in, 624–625, 630
- Chimeric anti-CD25, in renal transplantation, 311t
- Chinese ginseng, 62
- Chlamydia trachomatis*, 625, 798
- Chloral hydrate, 147
- Chlorambucil
for chronic lymphocytic leukaemia, 879
for Hodgkin lymphoma, 894t, 895
for nausea and vomiting, 902
- Chloramphenicol
adverse reaction to, 69
for gastro-intestinal infections, 642
for meningitis, 651–652, 652t
sideroblastic anaemia and, 861
- Chlordiazepoxide, 488t
- Chloride
in extracellular fluid osmolality, 88
in oral rehydration solution, 237–238
- Chloroquine, for rheumatoid arthritis, 930
- Chlorphenamine, for pruritus
in chronic kidney disease, 307
in liver disease, 265, 266t
- Chlorpromazine
drug-induced parkinsonism, 545
hepatotoxicity of, 244
- Chlortalidone, for hypertension, 165, 323, 325
- ChlVPP (chlorambucil, vinblastine, procarbazine, prednisolone), for Hodgkin lymphoma, 894t, 895
- Cholecalciferol, 301
- Cholera, 642
- Cholestasis, 246–247
aetiology of, 246
clinical manifestation of, 247
drugs associated with, 246t
with hepatitis, drugs associated with, 246t
pathophysiology of, 246
- Cholesterol, reduction of, for myocardial infarction, 349t
- Cholesterol absorption inhibitors, for dyslipidaemia, 431
- Cholesterol ester transfer protein inhibitors, 434
- Cholestyramine, for inflammatory bowel disease, 222t–223t
- Cholestyramine/colestipol, in thyroid function, 747t
- Choline acetyltransferase, 160
- Cholinergic system, age-related changes in, 160
- Chondrodysplasia punctata, 410–411
- Chondroitin, for osteoarthritis, 943
- Chromium, reference nutritional intake for, 111t
- Chronic active hepatitis, 247
drugs associated with, 246t
- Chronic glomerulonephritis, in chronic kidney disease, 298–299
- Chronic heart failure, 357–379
aetiology of, 357–358
case studies in, 375–378
classification of, 357, 358t
clinical manifestations of, 359, 359t
epidemiology of, 357
investigations of, 359–360, 360t
pathophysiology of, 358–359
patient care for, 368–375
patient education and self-monitoring for, 369, 370t
treatment of, 360–368, 361f, 361t–365t, 367t
guidelines for, 368
monitoring effectiveness of, 369–371, 371b, 372t

- Enalapril
 for chronic heart failure, 364t–365t
 with hydrochlorothiazide, for hypertension, 325
- Enbrel. *see* Etanercept
- ENCORE, 6, 6b
- Endocrine/autonomic arousal system, 485
- Endocrine factors, affective disorders and, 497
- Endometrial ablation, in heavy menstrual bleeding, 801–802
- Endometrial cancer, 799–800
 hormone replacement therapy and, 815
- Endometriosis, 802–803
- Endorphins, 580
- Endoscopy
 for dyspepsia, 177
 for inflammatory bowel disease, 203
 for oesophageal varices, 269
- Endothelial dysfunction, in coronary heart disease, 336–337
- Endothelins
 in blood pressure, 318
 in dysmenorrhoea, 797
- End-stage renal disease (ESRD), 294–316
 causes of, 297–298
 clinical manifestations of, 299–303
 prognosis of, 304–305
 renal transplantation for, 309–313
- Energy
 dual, 108, 108b
 from glucose, 108–109, 108b, 109t
 from lipid emulsions, 109, 109f–110f, 109t
 in parenteral nutrition, 108–109, 108t
- Enfuvirtide, in HIV infection, 707t, 718t–719t
- Enkephalinase inhibitors, for diarrhoea, 238
- Enlarged liver, in liver disease, 263
- Enlarged spleen, in liver disease, 263
- Enoxaparin, for NSTEMI, 351
- Enoximone, for chronic heart failure, 367t
- Enpagliflozin. *see* Sodium-glucose co-transporter-2 inhibitors
- Entacapone
 diarrhoea from, 236t
 for Parkinson's disease, 549–550
- Entamoeba histolytica*, 636t, 637, 638t
- Entecavir, in hepatitis B, 271–272
- Enteric fever, 638
 investigations of, 640
 treatment for, 642, 644t
- Enteric microflora, 197
- Enterobacter* sp., urinary tract infections caused by, 624
- Enterobacteriaceae (coliforms), 654
 surgical site infection and, 663
- Enterohepatic shunt, 60
- Enterotoxins, 235, 637
- Enteroviruses, 648–649
- Entry inhibitor, for HIV infection, 704–705, 707t, 718t–719t
- Environmental factors
 affective disorders and, 497
 in inflammatory bowel disease, 197
 in schizophrenia, 514
 in solid tumours, 909–910, 910t
- Enzalutamide, for prostate cancer, 848
- Enzyme, 94–95
 induction, 56–58, 58t
 in drug-induced liver injury, 244–245
 inhibition, 58–59, 58b, 59t
- Eosinophils, 85
- Epidermal growth factor receptor (EGFR), 916
- Epidermis, 1017

 aetiology of, 525
 case studies on, 540–541
 chronic, 531
 clinical manifestations of, 526–527
 cryptogenic, 525
 diagnosis of, 527–528
 epidemiology of, 524–525
 evidence for antiepileptic drugs, 539–540
 febrile convulsions, 528–529
 incidence of, 525
 intractable, 531
 mortality of, 525
 pathophysiology of, 526
 prevalence of, 525
 prognosis of, 525
 seizures. *see* Seizures
 severe myoclonic epilepsy of infancy, 539
 spasms, 527
 status epilepticus, 528
 treatment for, 528–539, 528b
 general principles of, 529–531
 long-term, 529
 monitoring, 531–532
 during seizures, 528–529
- Epirubicin, for non-Hodgkin's lymphoma, 895t
- Episcleritis, in inflammatory bowel disease, 202
- Epirivir, 704
- Eplerenone
 for chronic heart failure, 363t, 366
 diarrhoea from, 236t
 for hypertension, in chronic kidney disease, 306
 for ST-elevation myocardial infarction, 349
- Epoetin alfa and beta, for anaemia, in chronic kidney disease, 308
- Epstein-Barr virus (EBV)
 lymphomas and, 896
 pharyngitis (sore throat) caused by, 609
- Eptifibatid, 351
 for arterial thromboembolism, 415
- Erectile dysfunction, in Parkinson's disease, 553t
- Erlotinib, for solid tumours, 916
- Erythema multiforme, drug-induced, 990, 990b
- Erythema nodosum
 drug-induced, 989, 995
 inflammatory bowel disease and, 202
- Erythrocyte glucose-6-phosphatase dehydrogenase deficiency. *see* Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Erythrocyte sedimentation rate, 97
- Erythroderma, 987
 drug-induced, 991–993, 992b
- Erythrodermic psoriasis, 1006, 1007f
- Erythromycin
 adverse reaction to, 70
 in breast fed infants, 827t
 for cholera, 642
 for community-acquired pneumonia, 615
 for gastro-intestinal infections, 641
 hepatotoxicity of, 244
 for Legionnaire's disease, 615
 metabolism of, 56
 for otitis media, 611
- Erythromycin-induced cholestatic hepatitis, 253
- Erythropoiesis, 855–856, 856f
- Erythropoietin, 81–82, 856
 analogues, 860
 for sickle cell anaemia, 866
- Escherichia coli*, 135
 antibiotic resistance, 629
 in diarrhoea, 235
 gastro-intestinal infections caused by, 636t, 638t
 transmission of, 635
 treatment for, 640–641
- Escherichia coli* (Continued)
 urinary tract infections caused by, 624
 verotoxin-producing, 636t, 638t
- Escitalopram, for depression, 504
- ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin), for non-Hodgkin's lymphoma, 895t, 900
- Eslicarbazepine, 529t
 adverse effects of, 536t
 for epilepsy, 530t, 534
- Esmolol
 for arrhythmias, 397
 properties and pharmacokinetics of, 341t
- Esomeprazole, for peptic ulcer disease, 183t, 186t
- Estradiol
 hormone replacement therapy and, 810, 813–814
 menopause and, 807, 810
 in premenstrual syndrome, 794
- Estrone, 807
- Eszopiclone, for insomnia, 478
- Etanercept
 guidance on the use of, 938
 for psoriasis, 1011
 for rheumatoid arthritis, 932, 932t
- Ethambutol
 adverse reactions to, 681, 682t–684t
 for *Mycobacterium intracellulare* infection, 717–719
 for tuberculosis, 676, 677t–678t
- Ethanol, distribution of, in elderly, 159
- Ethics, prescribing (of drugs), 17–18
 autonomy, 17, 18b
 beneficence, 18
 justice and veracity, 18
 non-maleficence, 17–18
- Ethinylestradiol, 796
- Ethnicity/race
 adverse drug reactions and, 70
 chronic kidney disease and, 294
 inflammatory bowel disease and, 198
 prostate cancer and, 843
- Ethosuximide, 529t
 adverse effects of, 534, 536t
 drug interactions involving, 535t
 for epilepsy, 534
 pharmacokinetic data of, 534t
- Ethylene diaminetetraacetic acid, for hypercalcaemia, 757t
- Etidronate
 as alternative to HRT, 816
 for osteoporosis, 164
- Etoposide
 for Hodgkin lymphoma, 898
 for non-Hodgkin's lymphoma, 895t, 898, 902t
- Etravirine, in HIV infection, 703, 707t, 718t–719t
- European League Against Rheumatism (EULAR), criteria for degree of change in DAS28, 926, 927b
- European SCORE risk charts, 426
- Evening primrose oil, 62
- Everolimus
 for Hodgkin's lymphoma, 896
 in liver transplantation, 271
- Exanthems, drug-induced, 987, 987f
- Excessive sweating, in Parkinson's disease, 553t
- Excipients, paediatric, 148
- Excitation-contraction coupling, 380
- Excretion, of drugs
 in acute kidney injury, 291
 in HIV drug-drug interactions, 708
 in pregnancy, 823–824
- Exenatide, 785
- Exercise
 for coronary heart disease, 337, 352
 and dyslipidaemia, 428
 for osteoarthritis, 942
 paediatrics and, 142
- Exfoliative dermatitis, drug-induced, 991–993
- Extended-spectrum β -lactamase (ESBL)-producing bacteria, 629
- Extensively drug-resistant tuberculosis, 673, 680
- Extracellular fluid (ECF), 87–88
 osmolality of, 88
- Extracorporeal membrane oxygenation (ECMO), 134
- Extra-corporeal photopheresis, for graft-versus-host disease, 881
- Extravasation, 919
- Extrinsic renal tract obstruction, in chronic kidney disease, 299
- Eye contact, 22
- Eye drops administration, 979
- Eye movement desensitisation and reprocessing (EMDR), 487
- Eyes
 complications of, in ulcerative colitis, 202
- Ezetimibe, for dyslipidaemia, 431
-
- F**
- Factor V Leiden
 in thrombophilia, 796
 venous thromboembolism and, 405
- Faecal calprotectin, 204
- Faecal incontinence, in Parkinson's disease, 553t
- Faecal softeners, for constipation, 234
- Familial apolipoprotein C-II deficiency, 422–423
- Familial hypercholesterolaemia, 422, 422b–423b
- Familial lipoprotein lipase deficiency, 422
- Familial type III hyperlipoproteinaemia, 422
- Famotidine, for peptic ulcer disease, 189
- Fanconi's anaemia, leukaemia and, 872
- Fats, 775
- Fatty liver, drugs associated with, 246t
- Febrile convulsions, 528–529
- Febrile neutropenia, 905
- Febuxostat, for gout, 958
- Felbamate, for epilepsy, 534
- Felodipine
 for chronic heart failure, 368
 interactions with, 61–62
 metabolism of, 58–59
 for stable angina, 341–342
- Fenofibrate, dyslipidaemia and, 423, 431
- Fentanyl
 absorption of, in children, 144
 analgesia, 584, 584t
 patches, 144
 transdermal skin patches of, 918
- Fenticonazole, for candidiasis, 730–731
- Ferritin, 101
- Ferrous sulphate, 859
 in thyroid function, 747t
- Fesoterodine fumarate, for detrusor instability, 167
- Fetal development, critical periods in, 820–821
- Fetal-placental transfer, 824
- FEV. *see* Forced expiratory volume

- Glaucoma (*Continued*)
aetiology of, 966, 966f–967f
case studies on, 981–982
chronic primary closure, 967
clinical manifestations of, 967–968, 968t
common therapeutic problems in, 981t
congenital, 966
epidemiology of, 965–966
investigations for, 968
normal tension
clinical manifestations of, 968t
epidemiology of, 965–966
treatment for, 970
pathophysiology of, 967
patient adherence to, 980–981
patient care for, 979–981
for primary angle-closure glaucoma, 979–980
for primary open-angle glaucoma, 979
primary angle-closure (PACG)
clinical manifestations of, 968t
epidemiology of, 966
pathophysiology of, 967
patient care for, 979–980
primary open-angle (POAG)
clinical manifestations of, 967, 968t
drugs contraindicated in, 980t
epidemiology of, 965
pathophysiology of, 967
patient care for, 979
treatment for, 968–969, 969t–970t
secondary
clinical manifestations of, 968, 968t
epidemiology of, 966
treatment for, 970
treatment of, 968–970
for acute primary angle closure glaucoma, 969–970
 β -blockers for, 973–975, 973t–974t
carbonic anhydrase inhibitors for, 975, 975b
combination products for, 977–978
hyperosmotic agents for, 978–979, 979t
new drugs in development for, 977
for normal tension glaucoma, 970
ocular prostanooids for, 970–973, 971t–972t
for primary open-angle glaucoma, 968–969, 969t–970t
for secondary glaucoma, 970
sympathomimetic agents for, 976, 976t
topical miotics for, 976–977, 977b
